Animal cells are like factories that run 24 hours a day. Inside the plasma membrane, the chemical reactions that sustain life produce a steady stream of wastes. Those reactions also require a steady input of raw materials. Chapter 42 analyzed how waste materials are removed from the body and excreted; Chapter 43 examined how nutrients enter the body. This chapter focuses on two major questions: (1) How are two of the most important molecules in the economy of the cell—the oxygen (O_2) required for cellular respiration and the carbon dioxide (CO_2) produced by cellular respiration—exchanged with the environment? and (2) How are these gases—along with wastes, nutrients, and other types of molecules—transported throughout the body?

Understanding gas exchange and circulation is fundamental to understanding how animals work. If either process fails, the consequences are dire. In human populations, for example, anemia, lung cancer, tuberculosis, malaria, heart disease, stroke, and other diseases caused by faulty gas exchange and circulation are leading causes of illness and death. Let's begin with an overview of animal respiratory and circulatory systems, then plunge into the details of how gases are exchanged and transported.

44.1 The Respiratory and Circulatory Systems

When the mitochondria inside animal cells are producing ATP via cellular respiration, they consume oxygen and produce carbon dioxide. To support continued ATP production, cells have to obtain oxygen and expel excess carbon dioxide continuously.

How does gas exchange occur between an animal's environment and its mitochondria? In most cases, gas exchange involves the four steps illustrated in **Figure 44.1**: (1) Ventilation occurs when air or water moves through a specialized gas-exchange organ, such as lungs or gills; (2) gas exchange takes place as O_2 and CO_2 diffuse between air or water and the blood at the ventilatory surface; (3) through circulation, the dissolved O_2 and CO_2 are transported throughout the body—along with nutrients, wastes, and other types of molecules—via the circulatory system; and (4) in tissues, where cellular respiration has led to low O_2 levels and high CO_2 levels, O_2 and CO_2 diffuse between blood and cells.

Steps 1 and 2 are accomplished by the **respiratory system**: the collection of cells, tissues, and organs responsible for gas exchange between the individual and its environment. In essence, a respiratory system consists of structures for conducting air or water to a surface where gas exchange takes place. In some animals the gas exchange surface is the skin, but in most species it is located in a specialized organ like the lungs of tetrapods, the tracheae of insects, or the gills found in molluscs, arthropods, and many types of fish. **Figure 44.2** provides an example: the respiratory system of humans. The structure and function of gills, trachaea, and lungs are analyzed in more detail in section 44.3.

An animal's **circulatory system** is responsible for moving O_2, CO_2, and other materials around the body. Not all animals have a circulatory system, however. Some animals are so small or have flattened bodies with so much surface area that materials can be exchanged directly between the interior and the environment. In most cases, however, a specialized, liquid transport tissue is propelled throughout the body by a muscular heart, through a system of vessels.

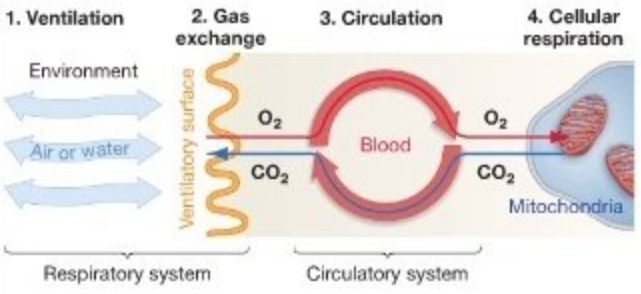

FIGURE 44.1 Gas Exchange Involves Ventilation, Circulation, and Respiration. In most animals, oxygen and carbon dioxide are exchanged across the surface of a lung, a gill, the skin, or some other gas exchange organ. These gases are transported to and from cells—where gas exchange again takes place—in blood.

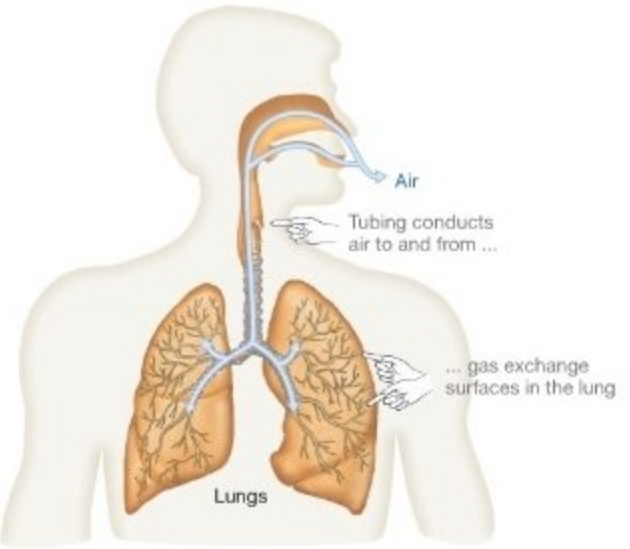

FIGURE 44.2 The Human Respiratory System. A respiratory system consists of structures that conduct air or water to a gas exchange surface.

Circulatory systems are classified as open or closed. In a **closed circulatory system**, the system of vessels is continuous (**Figure 44.3a**). In an **open circulatory system**, however, at least some vessels open into portions of the body cavity (**Figure 44.3b**). The transport tissue inside continuous systems is called **blood**; the transport tissue in open systems is called **hemolymph**. The distinction is necessary because animals with closed circulation usually have two subsystems: a system of blood vessels that carries blood, and a system of lymph vessels filled with lymph. **Lymph** consists of fluid that flows into lymph vessels from the spaces surrounding cells; it also contains specialized disease-fighting cells. The two circulatory subsystems are connected because lymph vessels eventually empty into blood vessels. Blood and lymph are not separated in open circulatory systems, so hemolymph is aptly named (the Greek root *heme* refers to blood).

Given this broad overview of gas exchange and circulatory systems, let's plunge into the details of how they work—starting with the question of how oxygen and carbon dioxide move between an animal's body and its environment.

44.2 Air and Water as Respiratory Media

Gas exchange between the environment and cells is based on diffusion. Under normal conditions, oxygen concentrations are relatively high in the environment and low in tissues, while carbon dioxide levels are relatively high in tissues and low in the

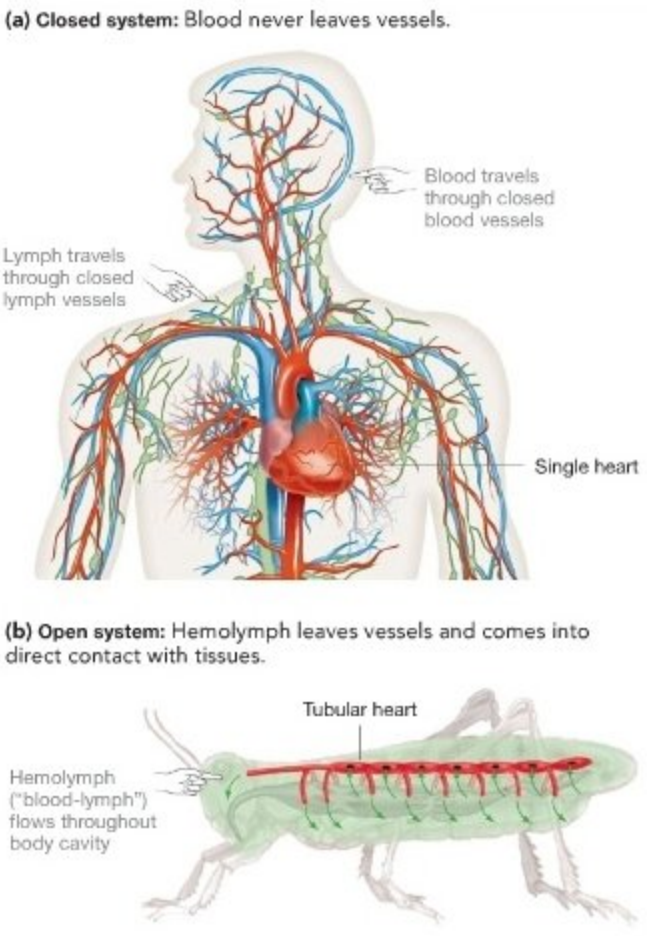

FIGURE 44.3 Closed and Open Circulatory Systems. The arrows in these figures indicate the direction of blood flow.

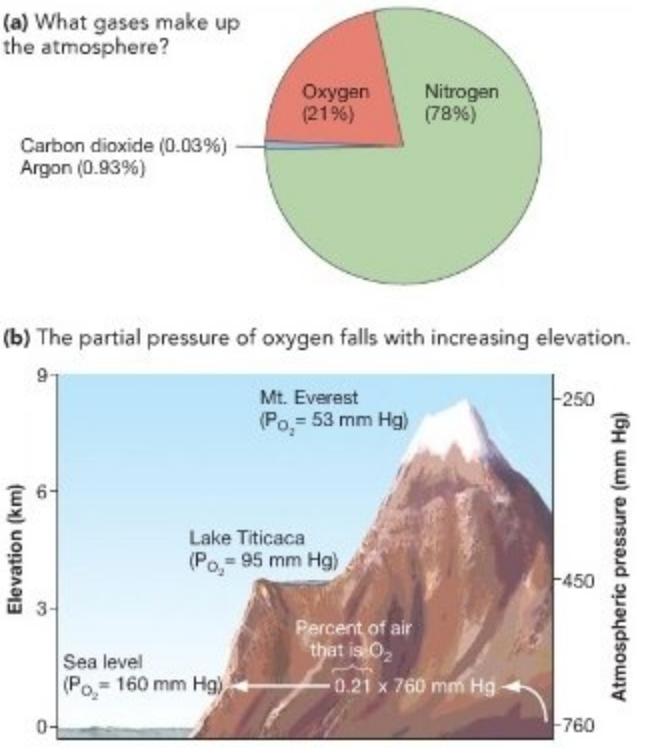

FIGURE 44.4 Oxygen Makes Up 21 Percent of the Atmosphere, but Its Partial Pressure Varies Widely. (a) Earth's atmosphere is dominated by nitrogen and oxygen. Oxygen makes up 21 percent of the atmosphere at all elevations. **(b)** Atmospheric pressure, and thus oxygen partial pressure (P_{O_2}), falls with increasing elevation.

EXERCISE Show how the partial pressure of oxygen at Lake Titicaca was calculated.

environment. Thus, oxygen tends to move from the environment into tissues, and carbon dioxide tends to move from tissues into the environment.

To get a more precise understanding of how gas exchange occurs by means of diffusion, it's important to consider some fundamental questions about how diffusion occurs in both terrestrial and aquatic environments. How much oxygen and carbon dioxide are present in the atmosphere versus in the ocean? What factors influence how quickly these gases move by diffusion?

How Do Oxygen and Carbon Dioxide Behave in Air?

As **Figure 44.4a** shows, the atmosphere is composed primarily of nitrogen (N_2) and oxygen, with trace amounts of argon and CO_2. Nitrogen and argon are not important to animals living at sea level and are usually ignored in analyses of gas exchange.

The data in Figure 44.4a are actually slightly misleading. To understand why, consider that the percentage of O_2 in the atmosphere does not vary with elevation. The atmosphere at the top of Mt. Everest is composed of 21 percent O_2, just as it is at sea level. The key difference is that far fewer molecules of oxygen and other atmospheric gases are present at high elevations than at sea level. Air at the top of Mt. Everest is much less dense than air at sea level, so much less oxygen is present.

To understand how gases move by diffusion, it is important to express their presence in terms of partial pressures instead of percentages. Pressure is a type of force. A **partial pressure** is the pressure of a particular gas in a mixture of gases. To calculate the partial pressure of a particular gas, you multiply the fractional composition of that gas by the total pressure exerted by the entire mixture.* For example, **Figure 44.4b** shows that the total atmospheric pressure at sea level is 760 mm Hg (millimeters of mercury). If you multiply this value by 0.21, which is

*This calculation is valid because the total pressure in a mixture of gases is the sum of the partial pressures of all the individual gases. This relationship is called Dalton's law.

the fraction of air that is O_2, you obtain a partial pressure of oxygen, abbreviated P_{O_2}, at sea level of 160 mm Hg. Because the atmospheric pressure is only about 250 mm Hg at the top of Mt. Everest, the P_{O_2} there is only $0.21 \times 250 = 53$ mm Hg.

Oxygen and carbon dioxide diffuse between the environment and cells along their respective partial-pressure gradients, just as solutes diffuse along their concentration gradients. In both air and water, O_2 and CO_2 move from regions of high partial pressure to regions of low partial pressure. It is hard to breathe at the top of Mt. Everest because the diffusion gradient between the atmosphere and your lung tissues is not large there.

How Do Oxygen and Carbon Dioxide Behave in Water?

To obtain oxygen, water breathers face a much more challenging environment than air breathers do. Aquatic animals live in an environment that contains much less oxygen than the environments inhabited by terrestrial animals. At 15°C, a liter of air can contain up to 209 ml of O_2, while a liter of water may contain up to a maximum of only 7 ml of O_2. To extract a given amount of oxygen, an aquatic animal has to process 30 times more water than the amount of air a terrestrial animal breathes. In addition, water is about a thousand times denser than air and flows much less easily. As a result, water breathers have to expend much more energy to ventilate their respiratory surfaces than do air breathers.

The partial pressure of oxygen varies in different types of aquatic habitats, just as it varies with altitude on land. Oxygen and carbon dioxide diffuse into water from the atmosphere, but the amount of gas that dissolves depends on several factors:

- *The solubility of the gas in water* Oxygen has very low solubility in water. Only 0.003 ml of oxygen dissolves in 100 ml of water for each 1-mm-Hg increase in oxygen partial pressure. Because of this low solubility, blood contains a molecule that binds to oxygen and delivers it to tissues. Without this carrier molecule, the rate of blood flow to tissues would have to increase dramatically in order to meet oxygen demand.
- *The temperature of the water* As the temperature of water increases, the amount of gas that dissolves in it decreases. Other things being equal, warm-water habitats have much less oxygen available than cold-water habitats do. For a fish, breathing in warm water is comparable to a land-dwelling animal breathing at high elevation.
- *The presence of other solutes* Because seawater has a much higher concentration of solutes than does freshwater, seawater can hold less dissolved gas. At 10°C, up to 8.02 ml of O_2 can be present per liter of freshwater versus only 6.35 ml of O_2 per liter of seawater. As a result, freshwater habitats tend to be more oxygen rich than marine environments are.
- *The partial pressure of the gas in contact with the water* Increasing the external partial pressure increases the rate at which a gas diffuses into a liquid. But if the partial pressure in the liquid phase exceeds that in the gas phase, the gas will "boil" out of the liquid. This is what happens when the cap is removed from a bottle of carbonated beverage. The drop in partial pressure in the gas phase that occurs when the bottle is opened allows carbon dioxide to escape the liquid phase.

Other important aspects of oxygen availability in water include the surface area of the water, the production of oxygen by photosynthesis, and the depletion of oxygen by organisms using it in cellular respiration. Surface area is important because it affects the ability of oxygen to diffuse into water. For example, shallow ponds and streams tend to be much better oxygenated than are deep bodies of water, because shallower bodies have a higher ratio of surface area to volume. Rapids, waterfalls, and other types of whitewater tend to be the most highly oxygenated of all aquatic environments, because a large surface area is exposed to the atmosphere as water splashes over rocks and logs and because air bubbles are incorporated into the water. In contrast, oxygen content tends to be extremely low in bogs and other stagnant-water habitats. The small amounts of oxygen that diffuse into stagnant water habitats are quickly used up by decomposers that use oxygen as an electron acceptor in cellular respiration.

Now let's consider how ventilatory organs are designed. How do the gills of fish, the tracheae of insects, and the lungs of mammals cope with the differences between air and water?

Check Your Understanding

If you understand that...

- O_2 and CO_2 move from regions of high partial pressure to regions of low partial pressure.
- Water breathing is much more difficult than air breathing, in part because the partial pressure of oxygen in water is much lower than its partial pressure in air.

You should be able to...

1) Describe aquatic habitats where oxygen partial pressures are relatively high and relatively low.
2) Explain whether a large, medium, or small amount of air should be bubbled into aquaria containing warm-water species, cold-water species, vigorous algal growth, highly active animals, or sedentary animals.

44.3 Organs of Gas Exchange

Many small animals do not have specialized gas exchange organs, such as gills or lungs. Instead, they obtain O_2 and eliminate CO_2 by diffusion directly across the body surface. For

these animals, diffusion across the body surface is rapid enough to fulfill their requirements for taking in O_2 and expelling CO_2. Most of these animals are restricted to living in wet environments, however. Their skin needs to be extremely thin for diffusion to take place efficiently, but thin skin is prone to water loss. Living in wet environments allows these animals to exchange gases across their outer surface while avoiding dehydration.

In contrast, animals that are large or that live in dry habitats need some sort of specialized respiratory organ. To understand why the presence of gills or lungs is associated with large size, recall from Chapter 41 that the volume of an animal's body increases much faster than does its surface area. Respiratory organs provide a greater surface area for gas exchange—enough to meet the demands of a large body filled with cells.

Biologists have long marveled at the efficiency of gills and lungs. To appreciate why, let's first examine the physical factors that control diffusion rates and then look at the structure and function of these respiratory organs.

Design Parameters: The Law of Diffusion

In 1855 Adolf Fick derived an equation regarding diffusion, based on the results of experiments he had performed on the rate at which gases diffuse. As **Figure 44.5** shows, **Fick's law of diffusion** states that the rate of diffusion of a gas depends on five parameters: the solubility of the gas in the aqueous film lining the gas-exchange surface, the temperature, the surface area available for diffusion, the difference in partial pressures of the gas across the gas-exchange surface, and the thickness of the barrier to diffusion.

Fick's law provides a compact way of identifying traits that allow animals to maximize the rate at which oxygen and carbon dioxide diffuse across the surfaces of their gills or lungs.

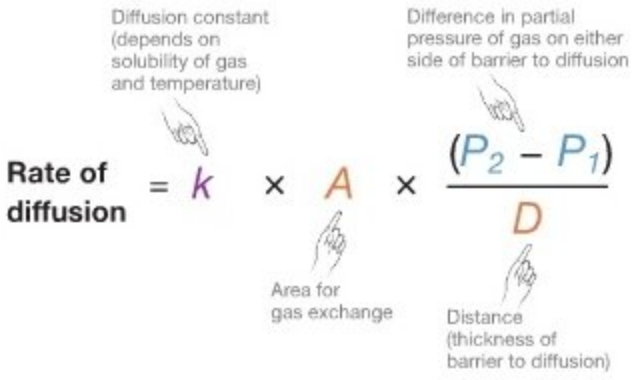

FIGURE 44.5 Fick's Law of Diffusion.

QUESTION Suppose you were going to design a system for the rapid diffusion of oxygen across a phospholipid bilayer. According to Fick's law, which aspects of the system should be maximized in order to maximize the diffusion rate? Which should be minimized?

Specifically, the law states that all gases, including O_2 and CO_2, diffuse in the largest amounts when three conditions are met:

1. A is large, meaning a large surface area is available for gas exchange. Based on Fick's law, it is not surprising that the respiratory surface in the human lungs would cover about 100 m^2—or almost a quarter of a basketball court—if the epithelium were spread flat.

2. D is small, meaning the respiratory surface is extremely thin. To appreciate just how thin the gas-exchange surface is, consider that researchers who asked bicyclists to ride up a steep hill for seven minutes observed a marked increase in blood on the respiratory surface of the athletes' lungs. To explain this observation, the researchers proposed that the cyclists' high heart rates (up to 177 beats/minute during their sprint up the hill) increased blood pressure to the point at which thin-walled vessels in the lungs ruptured and leaked blood into the structure.

3. $P_2 - P_1$ is large, meaning the partial-pressure gradient of the gas across the surface is large. High partial-pressure gradients are maintained in part by having an efficient circulatory system in close contact with the gas-exchange surface. When blood flows close to the respiratory surface, oxygen is rapidly taken away from the area where inward diffusion is occurring, and carbon dioxide is rapidly brought into the area where outward diffusion is occurring. As a result, $P_2 - P_1$ stays high.

What other aspects of gill and lung design conform to the dictates of Fick's law? What other factors affect the structure of these respiratory organs? To answer these questions, let's delve into the anatomy of gills and lungs.

How Do Gills Work?

Gills are outgrowths of the body surface or throat that are used for gas exchange in aquatic animals. To appreciate the structure and function of these organs, it is important to recognize just how challenging water is as a respiratory medium compared with air. Recall that water contains much less oxygen than air does and that water is much more difficult to move across respiratory surfaces because of its density and viscosity.

Gills are efficient solutions to the problems posed by water breathing, primarily because they present an extremely large surface area for oxygen to diffuse across an extremely thin epithelium. In some species of invertebrates, such as the nudibranch mollusc pictured in **Figure 44.6a**, gills project from the body surface and contact the surrounding water directly. In other invertebrate species, such as the crayfish in **Figure 44.6b**, gills are located inside the exoskeleton or body wall. If gills are internal, water must be driven over them by cilia, the limbs, or other specialized structures.

(a) External gills are in direct contact with water.

(b) Internal gills must have water brought to them.

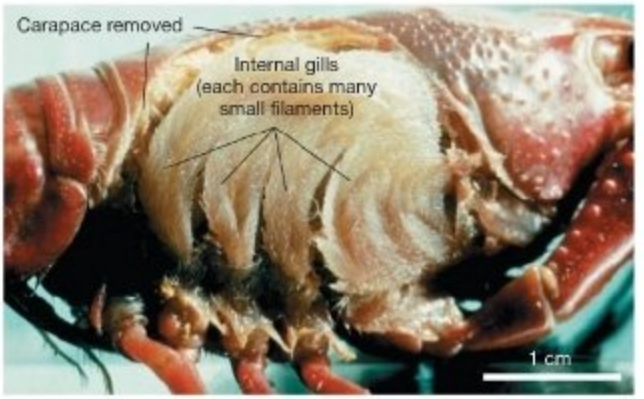

FIGURE 44.6 Gills Can Be External or Internal. (a) Nudibranchs are marine snails with gills that are outside the main body wall. **(b)** Crayfish gills are located inside the main body wall. A portion of the crayfish exoskeleton has been removed to expose the gills.

QUESTION Regarding fitness, what are the advantages and disadvantages of external versus internal gills? Why is it logical to expect that the orange-colored gills in part (a) are protected by toxins?

In contrast to the diversity of gills found in invertebrates, the gills of bony fishes are all very similar in structure. Fish gills are located on both sides of the head and in teleosts (see Chapter 34) consist of four arches, as **Figure 44.7** shows. To move water through these structures, most fish open and close their mouths and a stiff flap of tissue, called the **operculum**, that covers the gills. The pumping action of the mouth and operculum creates a pressure gradient that moves water over the gills. But tuna and other fish that are particularly fast swimmers force water through their gills by swimming with their mouths open. This process is called *ram ventilation*.

Regardless of how fish gills are ventilated, the flow of water over gills is unidirectional. To see why, note that long, thin structures called **gill filaments** extend from each gill arch. Each gill filament is composed of hundreds or thousands of **gill lamellae**. These are sheetlike structures, shown in detail at the bottom of Figure 44.7, through which a bed of small blood vessels called capillaries runs. The key point is that the flow of blood through the capillary bed is in the opposite direction to the flow of water over the gill surface. As a result, a **countercurrent exchanger** exists. Recall from Chapter 41 that countercurrent exchangers are based on two adjacent fluids flowing in opposite directions. The arrangement is important because in a co-current system, in which two adjacent fluids flowing through pipes in the same direction, oxygen transfer would stop. That is because the partial-pressure gradient driving diffusion would fall to zero partway along the length of the capillary **(Figure 44.8)**.

Countercurrent flow makes fish gills extremely efficient at extracting oxygen from water, because it ensures that the difference in the partial pressure of oxygen and carbon dioxide in water versus blood is large over the entire gas-exchange surface. If you understand this concept, you should be able to calculate how much more oxygen is extracted from water via countercurrent versus co-current exchange, using the data in Figure 44.8. Stated another way, the effect of countercurrent exchange is to maximize the $P_2 - P_1$ term in Fick's law of diffu-

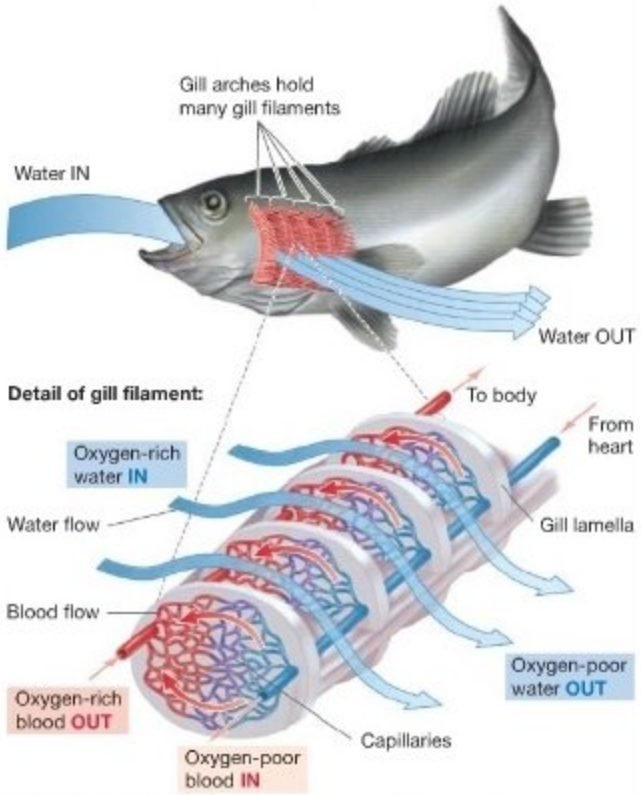

FIGURE 44.7 Fish Gills Are a Countercurrent Exchange System. In fish gills, water and blood flow in opposite directions. (Note that the operculum has been removed in the top drawing to reveal the gills.)

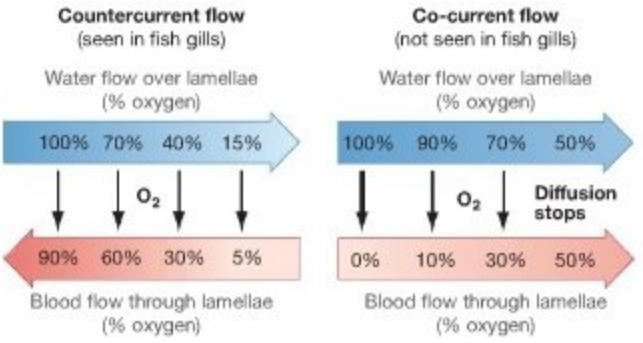

FIGURE 44.8 Countercurrent Exchange Is Much More Efficient than Co-current Exchange. In the countercurrent system of fish gills, oxygen is transferred along the entire length of the capillaries. If co-current flow occurred, oxygen transfer would stop, because the partial-pressure gradient driving diffusion would fall to zero partway along the length of the capillary.

sion over the entire gill surface. Based on this observation, biologists cite countercurrent exchange as another example of how gills are optimized for efficient gas exchange.

How Do Tracheae Work?

Air and water are dramatically different ventilatory media, because they have different densities, viscosities, and abilities to hold oxygen and carbon dioxide. In addition, the consequences of exposing the gas-exchange surface to air versus water differ. In aquatic habitats, ventilation tends to disrupt water and electrolyte balance, and homeostasis must be maintained by an active osmoregulatory system. As explained in Chapter 42, osmosis causes marine animals to lose water across their gas exchange surface and freshwater animals to gain water. Diffusion tends to cause marine animals to gain sodium, chloride, and other ions, and freshwater animals to lose them. In contrast, breathing leads to a loss of water by evaporation in terrestrial environments.

How do terrestrial animals minimize water loss while maximizing the efficiency of gas exchange? To answer this question, consider the tracheal system of insects. Recall from Chapter 42 that **tracheae** are an extensive system of tubes located well within the body. They connect to the exterior through openings called **spiracles**, which can be closed to minimize the loss of water by evaporation.

A key point about the insect tracheal system is that it consists of a series of tubes extending throughout the body. The tips of tracheae are tiny, fluid filled, and highly branched. In this way, the tracheal system transports air close enough to cells for gas exchange to take place directly across their plasma membranes. Consequently, insects do not use their circulatory system to transport gases to and from tissues, even though the insect circulatory system transports nutrients and wastes.

Recent research on the tracheal system has focused on how air moves into and out of the tubes through spiracles. Is simple diffusion efficient enough to ventilate the system, or is some type of breathing mechanism involved?

The short answer to this question is that breathing movements may play a role in at least some insects. To understand why this claim is valid, consider recent work on the sweet potato hawkmoth. A researcher set out to investigate how the amount of O_2 delivered to muscles changes during flight. To document the partial pressure of oxygen in flight muscles, he inserted a needlelike electrode into the wing muscles of a hawkmoth. The electrode was attached to an instrument that measured the partial pressure of oxygen, and the hawkmoth was tethered to a stand (**Figure 44.9**).

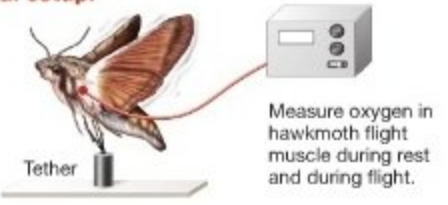
Experiment

Question: Does physical activity affect air movement through the tracheal system?

Hypothesis: Air moves through the tracheal system faster during physical activity.

Null hypothesis: Physical activity does not affect the rate of air movement.

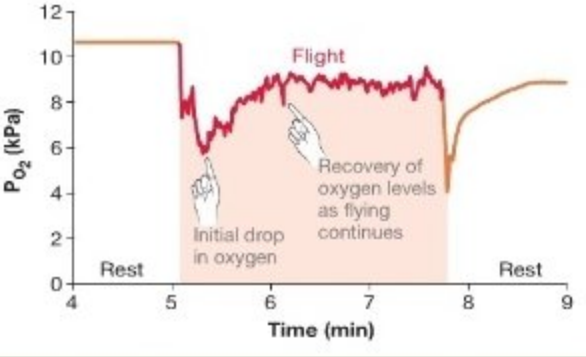
Experimental setup:



Prediction: Flying will increase ventilation of tracheal system, causing increase in P_{O_2} in wing muscle.

Prediction of null hypothesis: Flying will not increase ventilation of tracheal system; P_{O_2} in flight muscle will decline steadily during flight.

Results:



Conclusion: Muscular contractions may help ventilate the tracheal system in at least some insects.

FIGURE 44.9 Evidence That the Trachael System Is Ventilated During Movement. On the graph's y-axis, kPa stands for a unit of pressure—or force per unit area—called the kilopascal.

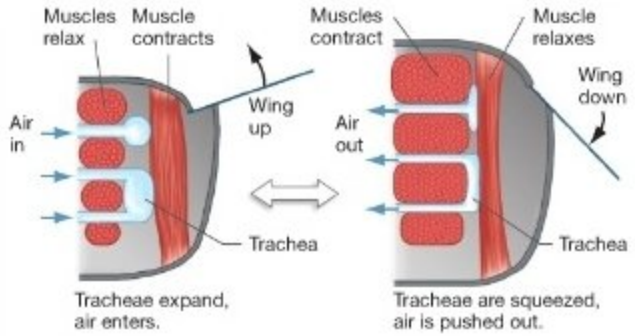


FIGURE 44.10 Muscle Activity May Ventilate Tracheae. To explain the result in Figure 44.9, biologists propose that tracheae change shape as wings beat.

When the hawkmoth recovered from the procedure and began to beat its wings normally, the biologist began recording P_{O_2} as the insect rested. Then the researcher stimulated the moth to fly by exposing it to wind. The "Results" section of Figure 44.9 shows how P_{O_2} changed during one such experiment. (The procedure was repeated on several individuals, and the same pattern was observed.) Because flight is an energetically demanding activity, it is not surprising that P_{O_2} levels in the flight muscles dropped initially. As flying continued, however, P_{O_2} levels recovered until they were nearly as high as when they were at rest.

These results can be explained by the breathing mechanism proposed in **Figure 44.10**. The key observation is that the tracheae of flying insects are sandwiched between muscles. When these muscles contract and relax, tracheae should constrict and expand in response. As a result, wing beats could force air into and out of the tracheae and lead to efficient ventilation of the respiratory surface.

How Do Lungs Work?

In most mammals, air enters the body through both the nose and mouth. A tube known as the **trachea** (not to be confused with the tracheae of insects) carries the inhaled air to narrower tubes called **bronchi** (singular: **bronchus**). The bronchi branch off into yet narrower tubes, the **bronchioles**. The organs of ventilation, the lungs, enclose the bronchioles and part of the bronchi (**Figure 44.11a**). **Lungs** are infoldings of the throat that are used for gas exchange. They occur in amphibians, reptiles (including birds), mammals, and certain fish and invertebrates. The amount of surface area available for gas exchange varies a great deal among species with lungs, however. In frogs and other amphibians, the lung is a simple sac lined with blood vessels. The lungs of mammals, in contrast, are finely divided into tiny sacs called **alveoli** (singular: **alveolus**; **Figure 44.11b**). Each human lung contains approximately 150 million of these sacs. Due to the presence of alveoli, mammalian lungs have about 40 times more surface area for gas exchange than does an equivalent volume of frog lung tissue.

As **Figure 44.11c** shows, an alveolus provides an interface between air and blood that consists of a thin aqueous film, a layer of epithelial cells, some extracellular matrix (ECM) material, and the wall of a capillary. In the human lung, this barrier to diffusion is only 0.2 μm thick—about 1/200th of the thickness of this page.

In addition to total surface area, the other major feature of lungs that varies among species is mode of ventilation. In the lungs of snails and spiders, air movement takes place by diffusion only. Vertebrates, in contrast, actively ventilate their lungs by pumping air via muscular contractions. One mechanism for pumping air is **positive pressure ventilation**, used by frogs and related animals. A frog lowers the floor of its throat to draw in air from the atmosphere, through the nasal

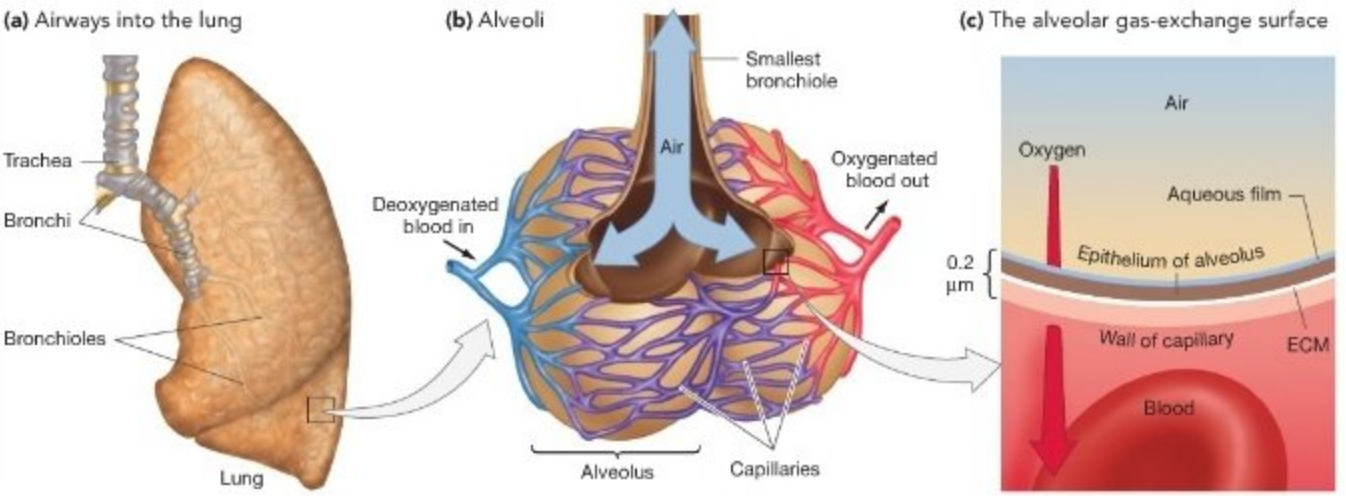

FIGURE 44.11 Lungs Offer a Large, Thin Surface Area for Gas Exchange between Air and Blood. (a) The human respiratory tract branches repeatedly from the largest airway, the trachea, to the smallest, called bronchioles. Gas exchange does not occur across these airways. The system of airways ends in clusters of tiny sacs called alveoli. **(b)** Alveoli are covered with capillary networks and **(c)** are the site of gas exchange.

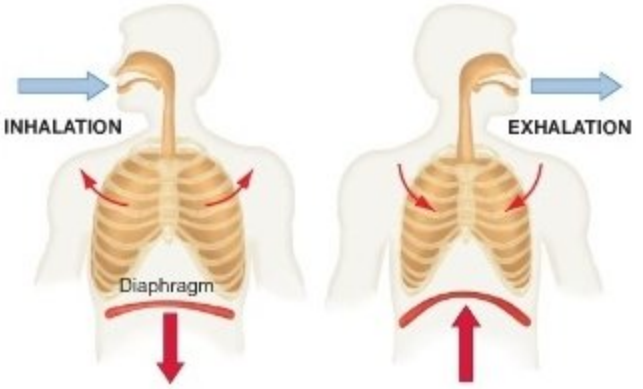
passages, and into the oral cavity. The animal then closes the nasal passages and contracts its throat muscles. These actions increase the pressure on air in the oral cavity and force it into the lungs.

In effect, frogs push air into their lungs. In contrast, humans and other mammals pull air into their lungs. How does this **negative pressure ventilation** work?

(a) Lungs expand and contract in response to changes in pressure inside the chest cavity.



(b) Ventilatory forces can be modeled by a balloon in a jar.

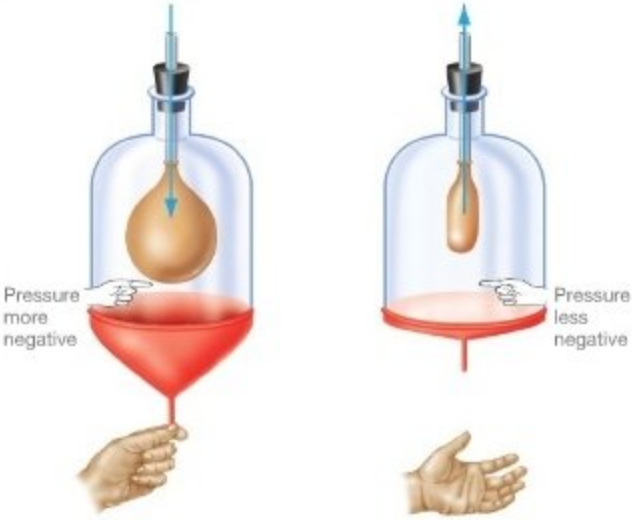


FIGURE 44.12 Changes in the Volume of the Chest Cavity Drive Negative Pressure Ventilation. (a) Inhalation: When the diaphragm and rib muscles contract, the volume of the lung cavity increases, causing internal pressure to become more negative. In response, the lungs expand and air flows in. Exhalation: When the diaphragm and rib muscles relax, the volume of the lung cavity decreases, causing internal pressure to become less negative. In response, lung volume decreases—due to elasticity of the lungs—and air flows out. **(b)** A model of negative pressure ventilation.

QUESTION What happens when a person sighs or takes a deep breath?

Ventilation of the Human Lung The pressure inside the human chest cavity is about 5 mm Hg less than atmospheric pressure. Even though the lung is **elastic**—it returns to its original, collapsed shape if it is not stretched or compressed—the negative pressure surrounding the lung is just enough to keep it expanded. If a wound results in a hole in the wall of the chest and the pressure differential between the chest cavity and the atmosphere disappears, the lung on the side of the injury will collapse like a deflated balloon.

Humans ventilate their lungs by changing the pressure within the chest cavity between about −5 mm Hg and −8 mm Hg relative to the atmosphere. As **Figure 44.12a** shows, inhalation is based on lowering the pressure in the chest cavity. The change is caused by a downward motion of the thin muscular sheet called the **diaphragm** and an outward motion of the ribs. These movements increase the volume of the chest cavity and thus lower its internal pressure. As the pressure surrounding the lungs drops, air flows into the airways along a pressure gradient. Exhalation, in contrast, is a passive process driven by the elastic recoil of the lungs and chest wall as the diaphragm and rib muscles relax. (This is true at rest—exhalation is an energy-demanding, active process during exercise.) The changes in pressure that occur during negative pressure ventilation are analogous to changing the volume of a jar, as shown in **Figure 44.12b**.

About 450 ml of air moves into and out of the lungs in an average breath. Only about two-thirds of this volume actually participates in gas exchange, however, because 150 ml of the air occupies **dead space**—portions of the air passages that do not have a respiratory surface. The trachea and bronchi shown in Figure 44.11a, for example, represent dead space. Breathing is much more efficient during exercise, when the chest cavity undergoes larger changes in volume. When a person is breathing hard, over 2500 ml of air can move with each inhalation-exhalation cycle, but the 150 ml in dead space stays the same.

The volume and pressure changes that occur during a ventilatory cycle are fairly straightforward. But what accounts for the elasticity of the human lung? Stated another way, what force is responsible for returning lung tissue to its former shape? An early hypothesis was inspired by the thin aqueous film that exists on the surface of alveoli. The idea was that hydrogen bonding between water molecules in the film would create a high degree of surface tension and thus create a pull or tension on the alveolar wall (**Figure 44.13**). Once an alveolus finished expanding during inhalation, the contractile force created by surface tension would return the structure to its original size, imparting elasticity to the entire lung.

To test this hypothesis, a biologist realized that he could quantify the elasticity of a lung by measuring the pressure required to force a known volume of air into the structure. If the surface tension hypothesis is correct, then much less pressure should be required to force the same volume of saline solution, rather than air, into the same lung. This prediction is logical, because the presence of the solution would eliminate the air-water

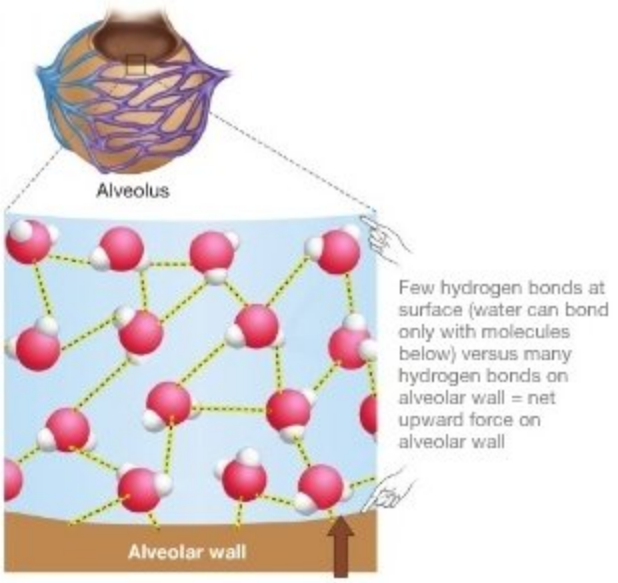

FIGURE 44.13 Surface Tension Creates a Pull on the Surface of the Lung.

interface inside the alveolus and thus eliminate surface tension. The biologist tested this prediction on lungs from a cadaver and showed that it was correct. Much less pressure was required to inflate the lungs with saline solution than with air. When other researchers repeated the experiment and got similar results, biologists accepted the hypothesis that most of the lung's elasticity is due to surface tension. Follow-up work has shown that surface tension within alveoli is so strong that it must actually be diminished somewhat for breathing to occur at all (see **Box 44.1**).

Ventilation of the Bird Lung Flight is one of the most energy-demanding activities performed by animals. Nevertheless, birds may fly tens of thousands of miles during annual migrations. Even more impressive is the observation that geese regularly fly over the top of Mount Everest. At this elevation, the partial pressure of oxygen is so low that most humans would immediately black out if they were flown there and dropped off. How are birds able to extract enough oxygen from the atmosphere to support long flights and flights at high elevations?

Biologists began working on this question by analyzing the anatomy of the avian respiratory system. As **Figure 44.14a** shows, a bird's trachea bypasses the lungs almost entirely and enters two large air sacs posterior to the lungs. These sacs are connected to the posterior portion of the lung by a series of tubes. The tubes branch into tiny airways, called **parabronchi**, within the lung. The parabronchi pass straight through the lung and terminate in another system of air sacs. These sacs link up with the trachea near the anterior portion of the lung. Gas exchange occurs in millions of spongelike air tubes, which extend laterally along the length of the parabronchi.

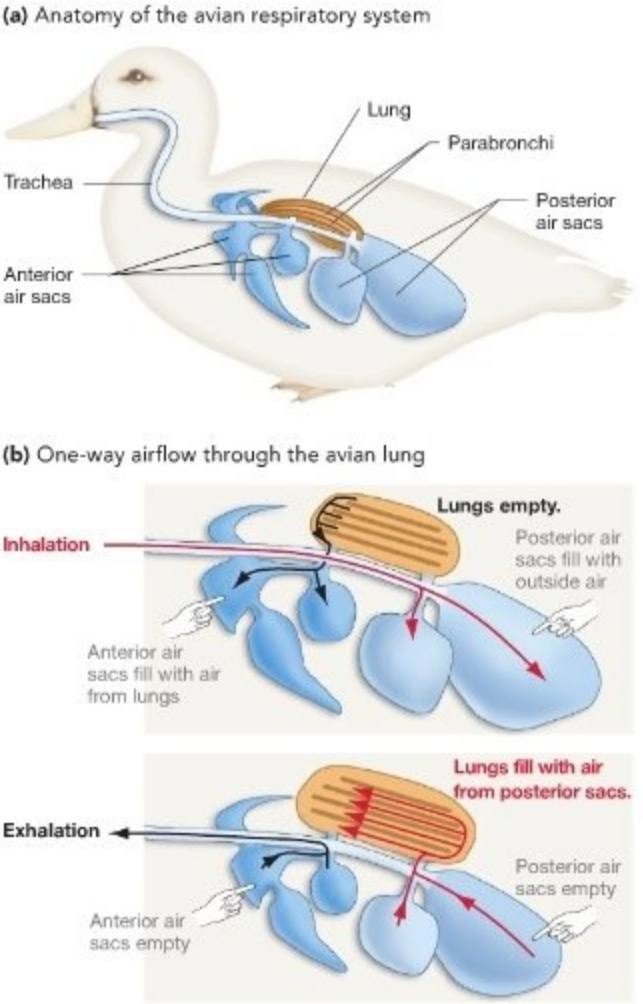

FIGURE 44.14 Air Flows in One Direction through the Bird Lung.

To explore how this respiratory system functions, Knut Schmidt-Nielsen and co-workers used a variation on the pulse-chase technique introduced in Chapter 7. In this case, the pulse was a single breath of pure oxygen, followed by a "chase" that consisted of a breath of normal air. To the researchers' surprise, the oxygen-enriched air was not detected at the bird's mouth until the *second* exhalation following the pulse. Follow-up experiments showed that air moves through a bird's respiratory system as diagrammed in **Figure 44.14b**. The key conclusion was that airflow through the avian lung is unidirectional.

To drive home how birds breathe, biologists make an analogy with how the Scottish bagpipe is played. Air is introduced intermittently into a large reservoir, such as the bag of a bagpipe or the posterior air sacs of a bird. Then the air is expelled continuously through air passages, such as the drone pipes of the instrument or the parabronchi of the bird lung. In birds, the air expelled from the parabronchi is collected in the anterior

BOX 44.1 Respiratory Distress Syndrome in Premature Infants

Because alveoli have a large amount of surface area in contact with gas, the watery film that covers them generates a large amount of surface tension. If water were the only molecule present, the pulling force on the alveolar wall would be so great that the structure would not inflate readily during inhalation. Fortunately, cells within each alveolus produce a mixture of soap-like phospholipids and proteins that act as a **surfactant**—that is, they disrupt the aqueous film lining the wall and greatly reduce its surface tension. The presence of the surfactant decreases lung stiffness enough to reduce the amount of work that has to be done by the diaphragm and rib muscles during inhalation.

Human infants acquire the ability to produce adequate amounts of surfactant at between 32 and 34 weeks of gestation, and birth normally occurs at 36 weeks. If born prior to 32 weeks of gestation, an infant may have such stiff lungs that it quickly fatigues from the effort of breathing and suffocates. This condition is called **respiratory distress syndrome**. Fortunately, it can be treated by administering a synthetic surfactant mixture directly into the lungs, through a tube placed in the trachea. This relatively simple technology has made it possible for infants to survive even if they are born after as little as 24 weeks of gestation.

air sacs and ultimately exhaled into the trachea through an opening that prevents the mixing of inhaled and exhaled air. One-way airflow is possible because the chest and air sacs do not compress at the same time, but alternately.

Three features make the avian respiratory system efficient:

1. Dead space in birds is restricted to the short stretch of trachea between the mouth and the opening of the anterior air sacs. As a result, inhaled air is used much more efficiently in birds than in mammals.
2. Birds exchange gases during both inhalation and exhalation. In contrast, no gas exchange occurs during the exhalation half of the respiratory cycle in mammals. Bird ventilation resembles the continuous ventilation of fish gills in this respect.
3. Blood circulates through the bird lung in capillaries that cross the parabronchi perpendicularly. This crosscurrent pattern is not as efficient as the countercurrent circulation of fish gills, but it is far more efficient than the weblike arrangement of capillaries that surrounds mammalian alveoli.

Homeostatic Control of Ventilation

An animal is in trouble if homeostasis with respect to blood oxygenation or the elimination of carbon dioxide fails. To ensure adequate ATP production, the partial pressures of oxygen and carbon dioxide must be maintained within a narrow range, both at rest and during vigorous exercise. How is ventilation controlled to achieve this critical homeostasis?

When mammals are resting, the rate of breathing is established by the medullary respiratory center, an area at the base of the brain, just above the spinal cord. This center stimulates the rib and diaphragm muscles to contract about 12–14 times per minute in humans. But during exercise, things change. Active muscle tissue takes up more oxygen from the blood. As a result, the partial pressure of oxygen (P_{O_2}) in blood drops. Those same muscles release quantities of carbon dioxide to the blood, tending to raise its partial pressure (P_{CO_2}) in blood. When it reaches the brain, carbon dioxide rapidly diffuses from the blood into the cerebrospinal fluid that bathes the brain. In both blood and cerebrospinal fluid, CO_2 reacts with water to form carbonic acid (H_2CO_3), which then dissociates to release a hydrogen ion (H^+) and a bicarbonate ion (HCO_3^-):

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

The result is a slight drop in the pH of blood and cerebrospinal fluid. The change is sensed by specialized nerves located near the large arteries that travel from the heart into the neck and to the base of the brain itself. Signals from these nerves or from pH detectors in the medullary respiratory center cause the breathing rate to increase. The resulting rise in ventilation rate increases the rate of oxygen delivery to the tissues and the rate at which carbon dioxide is eliminated from the body, restoring P_{O_2} and P_{CO_2} to their resting levels.

This control system is so effective that it can maintain stable levels of oxygen and carbon dioxide in the blood even in the face of intense exercise. In addition, it allows the body to regulate blood pH carefully. To see why this is so, it's important to recognize that carbon dioxide is transported in the blood in the form of bicarbonate ions. When CO_2-rich blood reaches the lungs, the bicarbonate ions have to react with hydrogen ions to regenerate carbon dioxide, which then diffuses across the walls of alveoli and is exhaled. When breathing rate increases, then, excess hydrogen ions that are produced during rapid metabolism are eliminated along with the excess CO_2 that is generated, and blood pH is stabilized.

Now let's look in greater depth at blood itself. What is this substance, and how does it transport oxygen and carbon dioxide between the gas-exchange surface and an animal's tissues?

Check Your Understanding

If you understand that...

Most large-bodied animals exchange gases via gills, tracheae, or lungs.

You should be able to ...

1) Identify at least three features that are common to all three of these types of organs as well as one trait that is unique to each.
2) Explain the contrast between airflow in the mammalian lung and in the bird lung.
3) Make a diagram summarizing the sensor, integrator, and effector(s) involved in homeostatic control of the ventilation rate.

44.4 How Are Oxygen and Carbon Dioxide Transported in Blood?

Blood is a tissue—a collection of cells that functions as an integrated unit. More specifically, **blood** is a connective tissue that consists of cells in a watery extracellular matrix. In an average human, 50–60 percent of the blood volume is composed of an extracellular matrix called **plasma**. The remainder of the volume comprises a variety of cells and cell fragments that are collectively called formed elements.

Given the wide variety of functions that blood serves, it is not surprising that this tissue is complex. Besides carrying oxygen and carbon dioxide between cells and the lungs, blood transports nutrients from the digestive tract to other tissues in the body, moves waste products to the kidney and liver for processing, conveys hormones from glands to target tissues, delivers immune system cells to sites of infection, and distributes heat from deeper organs to the surface.

The formed elements in blood include platelets, several types of white blood cells, and red blood cells. **Platelets** are cell fragments that minimize blood loss from ruptured blood vessels by releasing material that assists in the formation of blockages known as clots. **White blood cells** are part of the immune system. As Chapter 49 will explain in detail, white blood cells are responsible for fighting infections. Although both platelets and white blood cells play an essential role in the body, they are vastly outnumbered by red blood cells. In humans, red blood cells make up 99.9 percent of the formed elements. **Red blood cells** transport oxygen from the lungs to tissues throughout the body. They also play a critical role in transporting carbon dioxide from tissues to the lungs.

In humans, new red blood cells are synthesized at the rate of 2.5 million per second to replace old red blood cells, which are dying at the same rate. These red blood cells live about 120 days. They develop along with white blood cells and platelets from stem cells located in the tissue inside bone (bone marrow). Vertebrates other than mammals transport oxygen in red blood cells that retain their nuclei. But in most mammals, red blood cells lose their nuclei as they mature, along with their mitochondria and most other organelles. Mammalian red blood cells are essentially bags filled with some 280 million copies of the oxygen-carrying molecule **hemoglobin**. (**Box 44.2** on page 993 analyzes some of the membrane proteins found on human red blood cells and their importance in managing blood transfusions.)

Structure and Function of Hemoglobin

Even though oxygen is not very soluble in water, it is often found in high concentrations in blood. Blood has a high oxygen-carrying capacity because O_2 readily binds to the hemoglobin molecules found in red blood cells. The evolution of hemoglobin was a key event in the diversification of animals. By increasing the oxygen-carrying capacity of blood, hemoglobin made it possible for cellular respiration rates to increase. High rates of ATP production, in turn, support high rates of growth, movement, digestion, and other activities.

Hemoglobin is a tetramer, meaning that it consists of four polypeptide chains (**Figure 44.15**). Each of the four polypeptide

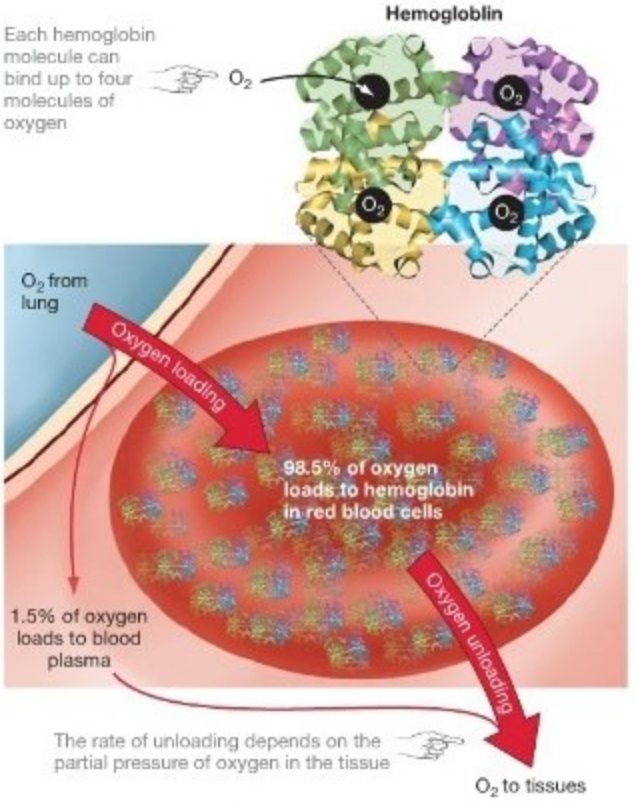

FIGURE 44.15 Hemoglobin Transports Oxygen to Tissues.

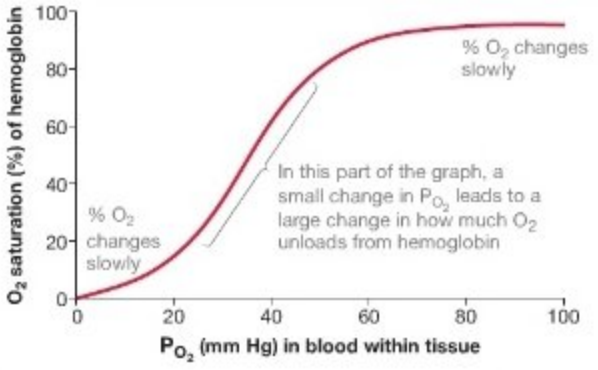

FIGURE 44.16 The Oxygen-Hemoglobin Equilibrium Curve. Partial pressure of oxygen in blood and tissues versus the percentage of binding sites on hemoglobin that hold oxygen molecules. The sigmoidal curve has three distinct regions.

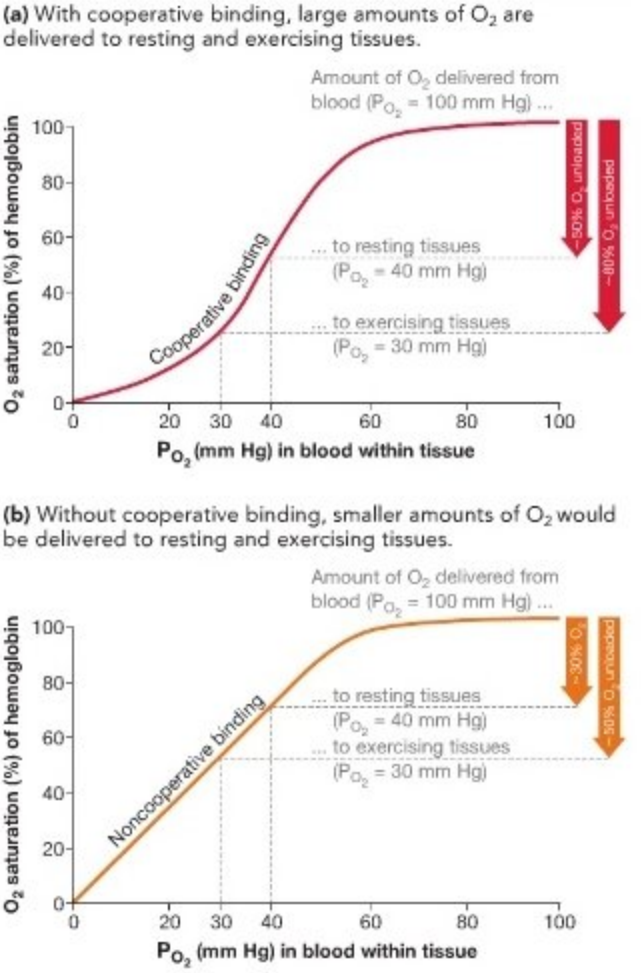

FIGURE 44.17 Cooperative Binding of O_2 by Hemoglobin Results in Greater O_2 Delivery than Noncooperative Binding. (a) Effect of cooperative versus (**b**) noncooperative oxgyen binding. As blood moves from a P_{O_2} of 100 mm Hg in the lungs to 30 mm Hg in exercising tissue, cooperative binding results in much more oxygen being transferred to tissues.

chains binds to a nonprotein group called **heme**. Each heme molecule, in turn, contains an iron ion (Fe^{2+}) that can bind to an oxygen molecule. As a result, each hemoglobin molecule can bind up to four oxygen molecules. In blood, 98.5 percent of the oxygen is bound to hemoglobin; only 1.5 percent is dissolved in plasma.

What happens when red blood cells carrying oxygen-rich hemoglobin reach cells that contain little oxygen?

Cooperative Binding Blood leaving the human lungs has a P_{O_2} of about 100 mm Hg, while muscles and other tissues have P_{O_2} levels of about 40 mm Hg at rest. This partial-pressure difference creates a diffusion gradient that results in the unloading of O_2 from hemoglobin to the tissues.

Researchers who studied the dynamics of O_2 unloading in tissues found the pattern shown in **Figure 44.16**. This graph, which plots the percentage saturation of hemoglobin in red blood cells versus the P_{O_2} levels in the blood within tissues, is called the **oxygen-hemoglobin equilibrium curve**. Each 25 percent change in saturation corresponds to an average of one additional oxygen molecule bound per hemoglobin molecule or one oxygen molecule delivered to tissues.

The most remarkable feature of the oxygen-hemoglobin equilibrium curve is that it is sigmoidal, or S-shaped. The pattern occurs because the binding of each successive oxygen molecule to a subunit of the hemoglobin molecule causes a conformational change in the protein that makes the remaining subunits much more likely to bind oxygen. This phenomenon is called **cooperative binding**. Conversely, the loss of a bound oxygen molecule changes hemoglobin's conformation in a way that makes the loss of additional oxygen molecules more likely.

Cooperative binding is important because it makes hemoglobin exquisitely sensitive to changes in the P_{O_2} of tissues. Consider what happens to hemoglobin saturation when tissue P_{O_2} changes from its resting level of about 40 mm Hg to 30 mm Hg, as might be seen during exercise (**Figure 44.17a**). In response to this small change in tissue P_{O_2}, there is an enormous change in the percentage saturation of hemoglobin—from about 52 percent to about 22 percent. This means that when blood encounters tissues at rest, hemoglobin gives up about 50 percent of the oxygen it is carrying (from almost 100 percent saturation to about 50 percent). But when blood encounters tissues during exercise, it gives up about 80 percent of its oxygen (from almost 100 percent saturation to

about 20 percent). Because of cooperative binding, the loss of one oxygen molecule to the surrounding tissues means that others are more likely to follow. Stated another way, the sigmoidal shape of the oxygen equilibrium curve means that a small change in tissue P_{O_2} produces a large change in how much oxygen stays attached to hemoglobin. ● If you understand this concept, you should be able to explain the consequences of an oxygen-hemoglobin equilibrium curve with a middle section that is even steeper than the one shown in Figure 44.17a.

If cooperative binding did not occur, all four subunits of hemoglobin would load or unload oxygen independently of each other. They would lose or gain oxygen in direct proportion to the partial pressure of oxygen in the blood, until the molecule was either completely saturated or unsaturated with oxygen. The relationship shown in **Figure 44.17b** would result. As the dotted lines in that figure indicate, much less oxygen would be delivered when tissue P_{O_2} changes from its resting level of about 40 mm Hg to 30 mm Hg—specifically, the percentage of O_2 saturation would drop from about 68 percent to about 52 percent. The total amount of oxygen delivered would only increase from about 30 percent to about 50 percent, instead of the 50 percent to 80 percent change observed with cooperative binding.

How Do Temperature and pH Affect Hemoglobin?

Cooperative binding is only part of the story behind oxygen delivery. Hemoglobin—like other proteins—is sensitive to changes in pH and temperature. During exercise, the temperature and partial pressure of CO_2 in active muscle tissue rise. The CO_2 produced by exercising muscle reacts with the water in blood to form carbonic acid, which dissociates and releases a hydrogen ion. As a result, the pH of the blood in exercising muscle drops.

Decreases in pH and increases in temperature alter hemoglobin's conformation. As the graph in **Figure 44.18** shows, these shape changes make hemoglobin more likely to release O_2 at any given value of tissue P_{O_2}. This phenomenon is known as the **Bohr shift**. The name honors Christian Bohr, who published on the phenomenon in 1904, and highlights the rightward shift of the oxygen-hemoglobin equilibrium curve with decreasing pH. The Bohr shift is important because it makes hemoglobin more likely to release oxygen during exercise or other conditions in which P_{CO_2} is high, pH is low, and tissues are under oxygen stress. ● If you understand the Bohr shift and cooperative binding, you should be able to add notes to Figure 44.15 indicating (1) what happens to the other three oxygen molecules that are bound to heme groups once one O_2 molecule leaves, and (2) what happens to bound O_2 molecules in tissues that are acidic.

To appreciate the effect of cooperative binding and the Bohr shift in action, consider a recent experiment on how the oxygen

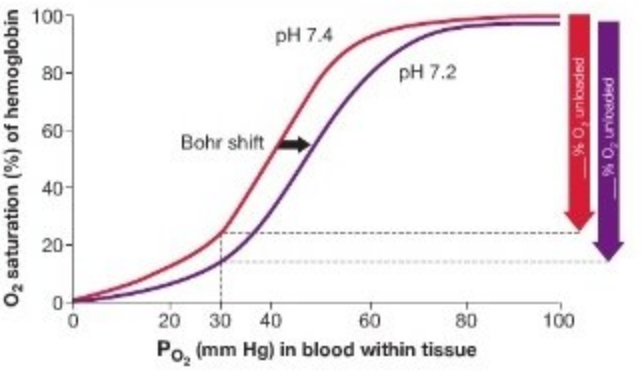

FIGURE 44.18 The Bohr Shift Makes Hemoglobin More Likely to Release Oxygen to Tissues with Low pH. As pH drops, oxygen becomes less likely to stay bound to hemoglobin at all values of tissue P_{O_2}. Exercising tissues have lower pH than resting tissues have and thus receive more oxygen from hemoglobin.

● **EXERCISE** Estimate how much more oxygen is released from hemoglobin at pH 7.2 than at pH 7.4 when the tissue has a P_{O_2} of 30 mm Hg.

transport system in rainbow trout responds to sustained exercise. To explore changes in blood O_2 content during exercise, biologists had fish swim continuously against a current in a water tunnel. As the researchers increased the speed of the current and thus the swimming speed of the fish, they periodically sampled the O_2 content of both the arterial and venous blood of experimental individuals. Arterial blood is freshly oxygenated and moving away from the gills; venous blood is returning to the gills from the rest of the body. Not surprisingly, the biologists found that arterial O_2 levels remained fairly constant as swimming speed increased—meaning the gills continued to work efficiently enough to saturate hemoglobin with oxygen. In contrast, the O_2 content of venous blood, which had undergone gas exchange with the tissues, dropped steadily as swimming speed increased. When the fish had reached their maximum sustainable speed, virtually all the oxygen available in hemoglobin in the venous blood had been extracted. The data show that in hard-working tissues, the combination of increased temperature, lower pH, and lower P_{O_2} caused hemoglobin to become almost completely deoxygenated. Oxygen-delivery systems based on hemoglobin are extremely efficient.

Comparing Hemoglobins In addition to recognizing that individual hemoglobin molecules can change in structure and function depending on conditions in the body, it's important to appreciate that hemoglobin molecules from different individuals or species may vary in ways that affect fitness—the ability to survive and produce offspring. For example, consider the oxygen-hemoglobin equilibrium curves in **Figure**

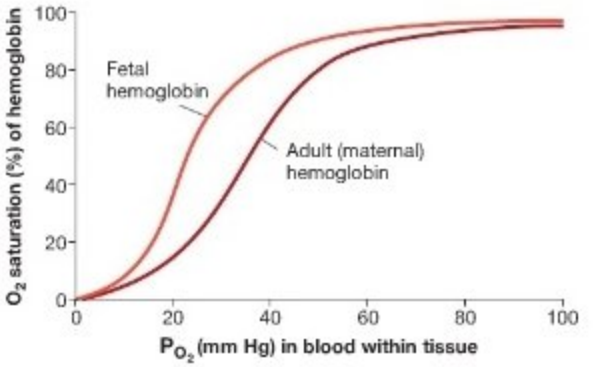

FIGURE 44.19 Some Types of Hemoglobin Bind Oxygen More Tightly than Others.

QUESTION Suppose you compare oxygen-hemoglobin equilibrium curves for hemoglobins found in closely related animal species that live at high elevation versus low elevation. Would the two curves differ? If so, how and why? If not, why not?

44.19. The curve in dark red is from a pregnant human; the curve in light red is from a fetus she is carrying. The hemoglobin found in fetuses is encoded by different genes than adult hemoglobin and has a distinctive structure and function. Specifically, the oxygen-hemoglobin equilibrium curve for fetal hemoglobin is shifted to the left with respect to the curve for adult hemoglobin. This means that at every P_{O_2}, fetal hemoglobin has a higher affinity for oxygen than adult hemoglobin. As a result, oxygen is transferred from the mother's blood to the fetus's blood. This difference in hemoglobin structure and function between mother and fetus ensures an adequate supply of oxygen as the fetus develops.

Now let's consider the other side of gas exchange: What happens as CO_2 is released from tissues to the blood? How does the body cope with the decline in pH that results? After all, if hemoglobin's conformation and activity are affected so dramatically by pH changes, it is likely that many other proteins will be altered as well. If these proteins function less well at low pH, then carbon dioxide buildup should result in illness.

CO_2 Transport and the Buffering of Blood pH

The carbon dioxide that is produced by cellular respiration in the tissues enters the blood, where it reacts with water to form carbonic acid. Recall that the resulting drop in blood pH stimulates an increase in breathing rate. Rapid exhalation of CO_2 then counteracts the drop in blood pH.

Changes in blood pH are also diminished by an elegant series of reactions that takes place inside red blood cells. Biologists were able to work out what was happening when they discovered large amounts of the enzyme **carbonic anhydrase** in red blood cells. Recall from Chapter 43 that carbonic anhydrase catalyzes the formation of carbonic acid from carbon dioxide in water. Consequently, CO_2 that diffuses into red blood cells is quickly converted to bicarbonate ions and protons. This is the mechanism responsible for the observation, made in Section 44.3, that most CO_2 is transported in blood (specifically in plasma) in the form of HCO_3^-—the bicarbonate ion. The same reaction occurs in the plasma surrounding red blood cells, but much more slowly in the absence of the enzyme.

Why is the carbonic anhydrase activity in red blood cells so important? The answer has two parts. First, the protons produced by the enzyme-catalyzed reaction induce the Bohr shift, which makes hemoglobin more likely to release oxygen. Second, the partial pressure of CO_2 in blood drops when carbon dioxide is converted to soluble bicarbonate ion, maintaining a strong partial-pressure gradient favoring the entry of CO_2 into red blood cells. Thus, carbonic anhydrase activity makes CO_2 uptake from tissues more efficient (**Figure 44.20**).

Once bicarbonate ions form in the red blood cell, they diffuse into the blood plasma along a concentration gradient. Bicarbonate ions move via an antiporter that exchanges bicarbonate with chloride ions. (Antiporters were introduced in Chapter 37.) In contrast, the protons produced by the reaction stay inside red blood cells. Relatively small amounts of H^+ build up in the plasma.

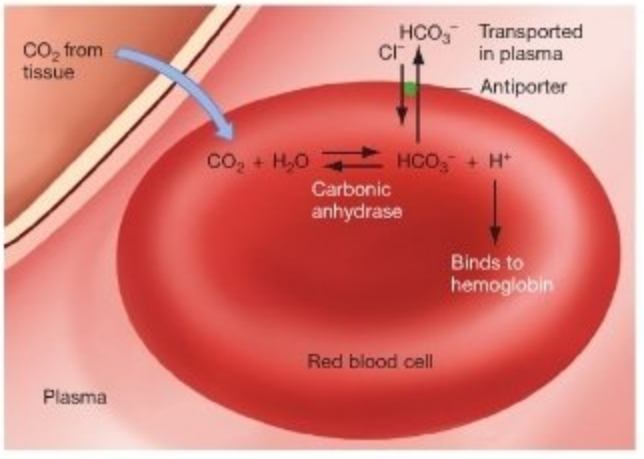

FIGURE 44.20 How Is Carbon Dioxide Transported in Blood? When CO_2 diffuses into red blood cells, carbonic anhydrase quickly converts it to carbonic acid, which dissociates into bicarbonate ion (HCO_3^-) and a proton (H^+). This reaction maintains the partial-pressure gradient favoring the entry of CO_2 into red blood cells. The protons produced by the reaction bind to deoxygenated hemoglobin. Most CO_2 in blood is transported to the lungs in the form of HCO_3^-.

QUESTION This diagram shows the sequence of events in tissues. Explain what happens when the red blood cell in the diagram reaches the lungs.

What happens to the protons inside red blood cells? The answer to this question emerged when researchers studied the composition of deoxygenated hemoglobin. These analyses showed that when hemoglobin is not carrying oxygen molecules, it has a high affinity for protons. As a result, much of the H^+ that is produced by the dissociation of carbonic acid is taken up by hemoglobin. In this way, hemoglobin acts as a **buffer**—a compound that minimizes changes in pH. In addition, analyses of hemoglobin in deoxygenated blood revealed that the CO_2 that is not transported as HCO_3^- binds to amino

BOX 44.2 ABO and Rh Blood Types

As red blood cells are maturing in bone marrow, their plasma membranes gain glycolipids that function like the security badges worn by hospital staff—they help identify the cells as legitimate components of the body. Their presence prevents red blood cells from being attacked by immune system cells, which are responsible for detecting and eliminating viruses, bacteria, and other types of dangerous invaders.

Some of the key glycolipids on human red blood cells are encoded by a single gene. Three alleles of this gene, symbolized i, I^A, and I^B, are common in most human populations and are responsible for the **ABO blood types.** The allele i is a loss-of-function allele that leads to a lack of glycoprotein on the cell surface; I^A encodes the A glycolipid; and I^B encodes the B glycolipid. Individuals with the genotype ii have blood type O; I^AI^A and I^Ai individuals have blood type A; I^BI^B and I^Bi individuals have blood type B; and I^AI^B individuals, who produce both types of glycolipid, have blood type AB.

The ABO blood types are well studied because they are critical to the success of the most common type of tissue transplant: blood transfusions. If blood from an individual with blood type A is introduced to a person with blood type O or B, the recipient's immune system produces proteins called antibodies that bind to the A glycolipids and cause the red blood cells to clump together. The clumping reaction inhibits blood flow and can endanger the recipient's life.

A similar issue occurs in response to a protein on the surface of red blood cells called the rhesus or Rh factor—so called because it was discovered in the rhesus macaque. Individuals with the **Rh factor** are said to be Rh positive (Rh^+); those without the Rh factor are typed Rh negative (Rh^-). Rh^- individuals produce antibodies to the Rh factor. If Rh^+ blood is introduced to an Rh^- individual, clumping may occur.

To prevent these problems, agencies that collect and distribute blood for transfusions do simple tests to determine the blood type of the donor, so it can be matched to the recipient. **Table 44.1** summarizes which ABO and Rh blood types can be successfully transferred from donor to recipient.

TABLE 44.1 **Blood Transfusions and the ABO/Rh Blood Types**

An "OK" indicates a successful transfusion; an "X" indicates a transfusion that causes red blood cells to clump.

Recipient Blood Type (antibodies present)	Donor Blood Type							
	A^+	A^-	B^+	B^-	AB^+	AB^-	O^+	O^-
A^+ (anti-B)	OK	OK	X	X	X	X	OK	OK
A^- (anti-B, anti-Rh)	X	OK	X	X	X	X	X	OK
B^+ (anti-A)	X	X	OK	OK	X	X	OK	OK
B^- (anti-A, anti-Rh)	X	X	X	OK	X	X	X	OK
AB^+ (none)	OK	OK	OK	OK	OK	OK	OK	OK
AB^- (anti-Rh)	X	OK	X	OK	X	OK	X	OK
O^+ (anti-A, anti-B)	X	X	X	X	X	X	OK	OK
O^- (anti-A, anti-B, anti-Rh)	X	X	X	X	X	X	X	OK

QUESTION Why is type O^- called the "universal donor" and type AB^+ considered the universal recipient?

groups on the protein portion of the molecule. The overall effect of these events is efficient transport of CO_2, with a minimal effect on blood pH.

When deoxygenated blood reaches the alveoli, however, the environment changes dramatically. In the alveoli, a partial-pressure gradient favors the diffusion of CO_2 from plasma and red blood cells to the atmosphere. As CO_2 diffuses from the blood into the alveoli, P_{CO_2} in blood declines. The drop promotes the reversal of the chemical reactions that occurred in tissues: Hydrogen ions leave their binding sites on hemoglobin and combine with bicarbonate to form CO_2, which then diffuses into the alveoli and is exhaled from the lungs.

In the meantime, hemoglobin has picked up O_2. Oxygen transfer from air to blood is efficient. Hemoglobin's affinity for oxygen is high in alveoli because blood pH rises as P_{CO_2} declines.

When blood leaves the lungs, it has unloaded carbon dioxide and hemoglobin is saturated with oxygen. The cycle begins anew.

Check Your Understanding

If you understand that...

- In blood, oxygen is bound to hemoglobin and transported inside red blood cells. Carbon dioxide is converted to bicarbonate ions and transported in plasma.
- Hemoglobin has several properties that make it an effective transport protein, including cooperative binding of oxygen, the Bohr shift response to low pH, and the ability to bind the protons that are generated when carbon dioxide is converted to bicarbonate ions.

You should be able to...

Draw an oxygen-hemoglobin equilibrium curve and explain how it increases the efficiency of oxygen delivery to tissues, relative to an equilibrium curve in which cooperative binding does not occur.

Gas Exchange in the Lungs and Tissues

44.5 The Circulatory System

Recall from Chapter 41 that large animals have a much smaller amount of surface area relative to their volume than do small animals. In most animals that are more than a few millimeters in size, the available surface area is too small for gases, nutrients, and wastes to diffuse efficiently between the animal's surface and its interior. As a result, diffusion across the individual's exterior surface is not rapid enough to support metabolism. In large animals, this problem is solved by a circulatory system.

The function of a circulatory system is to carry blood or hemolymph into close contact with every cell in the body. In this case, "close contact" is a distance of about 0.1 mm between the smallest blood vessels and cells within tissues. Diffusion is efficient at this scale. But an enormous amount of tubing is required to distribute blood this close to cells throughout the body. If all the blood vessels in a human body were laid end to end, they would stretch about 100,000 km (over 60,000 miles).

The most sophisticated circulatory systems consist of one or more pumps called **hearts**; tough, thick-walled **arteries**, which are vessels that take blood away from the heart under high pressure; vessels called **capillaries**, whose walls are just one cell thick, allowing gases and other molecules to exchange with tissues in networks called **capillary beds**; and **veins**, which are vessels that return blood to the heart under low pressure. It's important to recognize that animals may lack some or all of these components or may have no circulatory system at all. In jellyfish and corals, for example, a large, internal gastrovascular cavity offers enough surface area that adequate exchange of molecules with the environment occurs via diffusion. Circulatory systems are also lacking in flatworms and tapeworms, whose bodies are flattened enough that their surface area/volume ratio is high. In these animals, molecules are exchanged with the environment directly across the outer body surface. Roundworms lack hearts but facilitate exchange between their fluid-filled body cavity and the environment through muscular contractions in their body wall. In effect, roundworms circulate fluids by sloshing them back and forth.

To explore how more sophisticated circulatory systems work, let's start by distinguishing the two most general types of systems—open and closed.

What Is an Open Circulatory System?

In an open circulatory system, hemolymph is actively pumped throughout the body but is not confined exclusively to blood vessels. The key observation about hemolymph is that it comes into direct contact with the tissues—meaning the molecules being exchanged between hemolymph and tissues do not have to diffuse across the wall of a blood vessel. **Hemolymph** transports wastes and nutrients and may also contain oxygen-carrying pigments, some cells, and clotting agents.

Figure 44.21 illustrates the open circulatory system in a clam. Note that the heart pumps hemolymph into blood vessels that empty into an open, fluid-filled space. Hemolymph is returned to the heart when the heart relaxes and its internal pressure drops below that in the body cavity. General body movements also move hemolymph to and from the heart(s).

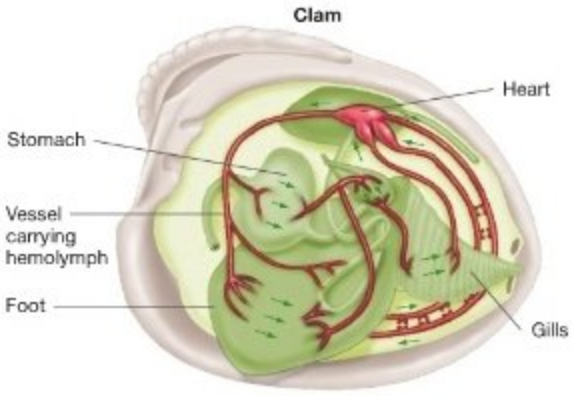

FIGURE 44.21 Open Circulatory Systems in Clams.

EXERCISE Circle the locations where hemolymph is in direct contact with tissues.

QUESTION What is "open" about an open circulatory system?

One salient characteristic of an open circulatory system is that hemolymph is under relatively low pressure. As a result, hemolymph flow rates may also be low. This feature makes open systems most suitable for relatively sedentary organisms, which do not have high oxygen demands. Insects, with their rapid movements and more active lifestyles, are an obvious exception to this rule. Insects overcome the limitations imposed by low hemolymph pressure via their tracheal respiratory system, which delivers oxygen directly to the tissues.

Another characteristic of open circulatory systems is that without discrete, continuous vessels, the flow of hemolymph cannot be directed toward tissues that have a high oxygen demand and CO_2 buildup. An open circulatory system moves hemolymph throughout an animal's body in much the same way that a ceiling fan moves air throughout a room in a house.

What Is a Closed Circulatory System?

In a closed circulatory system, blood flows in a continuous circuit through the body under pressure generated by the heart. Because blood is confined to vessels, a closed system can generate enough pressure to maintain a high flow rate. Blood flow can also be directed in a precise way. Regulatory systems can direct blood to specific vessels and thus to specific locations, such as muscles during exercise, the intestines after a meal, or regions of the brain engaged in particular mental tasks.

Closed circulatory systems are found in vertebrates and a few other lineages where individuals tend to be active. Earthworms and other annelids, for example, have closed circulatory systems. Annelids exchange gases with the environment across their thin, moist skin, which has a dense supply of capillaries. With this ventilatory surface and closed circulatory system, annelids are able to obtain and circulate enough oxygen to support intense muscular activity. Based on these observations, it is logical to find that most annelids live as active burrowers and hunters. A similar situation occurs in squid, octopuses, and other cephalopods that hunt down prey. The closed circulatory system of these animals generates high rates of blood flow, which oxygenates their muscles well enough to support rapid movements and a predatory lifestyle. And even though the circulatory system of crustaceans is classified as open, crustaceans have a fine network of vessels that can preferentially send blood to tissues with the highest oxygen demands.

Closed circulatory systems contain an array of blood vessel types, each of which has a distinct structure and function. Let's review some of these major types and then consider how the vessels of a closed circulatory system interact with the lymphatic system.

Types of Blood Vessels In a closed circulatory system, the heart ejects blood into a large artery, usually called the **aorta**. Although all arteries have both muscle fibers and elastic fibers in their walls, the walls of the aorta are dominated by elastic fibers. As a result, the aorta can expand when blood enters it under high pressure from the heart. When contraction of the heart ends, the diameter of the aorta returns to its resting state. This elastic response propels blood away from the heart and augments the force generated by heart contraction. Similar types of secondary pumping action occur to some extent in other large and medium-sized arteries as well and help maintain forward blood flow in the period between cardiac contractions.

In the walls of smaller blood vessels called **arterioles**, a continuous sheet of smooth muscle fibers is broken up by distinct bands of fibers that wrap around the circumference of the vessel. These muscle fibers are called **sphincters** and allow the diameter of the vessel to be carefully regulated in response to signals from the nervous system. When the muscle fibers are relaxed, the arteriole diameter increases, resistance to flow in the arteriole is reduced, and blood flow increases in the tissues served by the vessel. But when these arteriolar sphincters constrict, they increase resistance to flow, slow blood passage, and thus divert blood flow for use by other tissues.

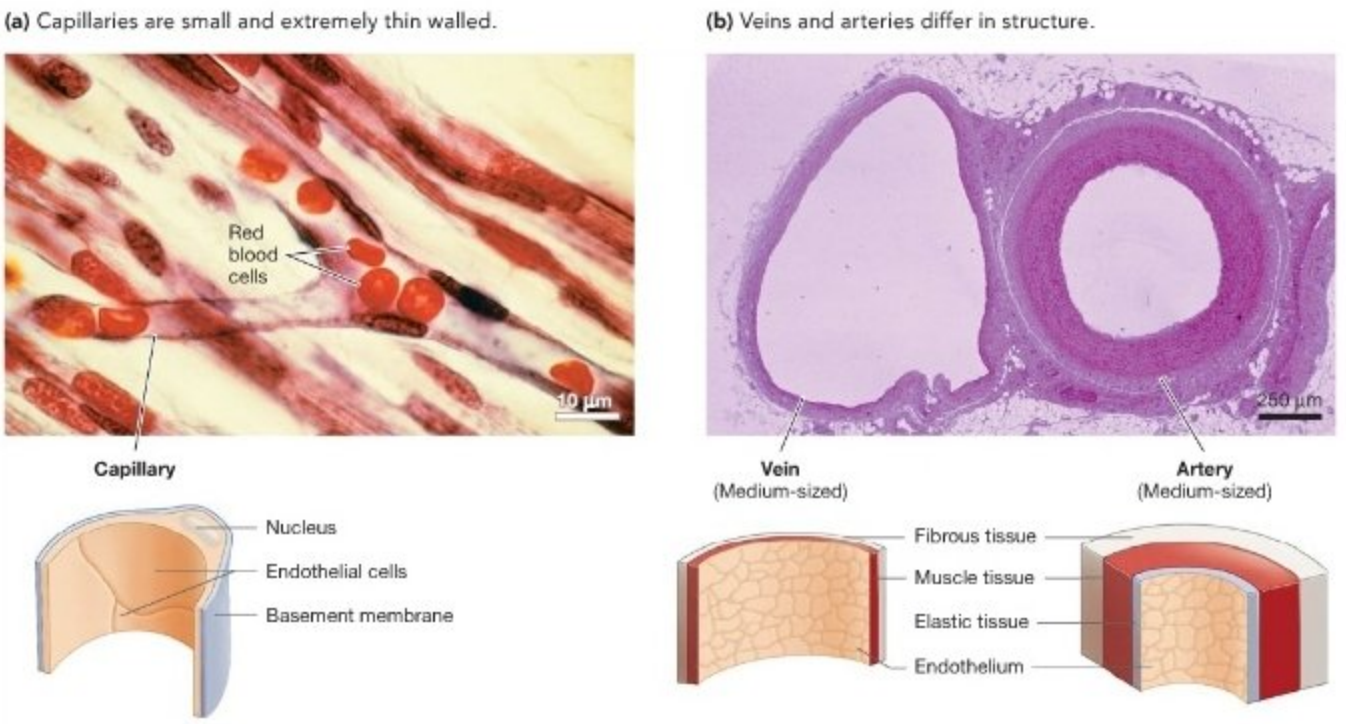

FIGURE 44.22 Capillaries, Veins, and Arteries. Micrographs of **(a)** a capillary and **(b)** a cross section through a vein and an artery. Notice the difference in relative wall thickness and overall size of the vein and artery.

Capillaries are the smallest blood vessels. They have walls that are only one cell layer thick, and they are just wide enough to let red blood cells through one at a time (**Figure 44.22a**). Because capillaries are extremely thin and because they form an extremely dense network throughout the body, they are the structure where gases, nutrients, and wastes are exchanged between the blood and other tissues. In some organs, such as the liver, the walls of capillaries contain numerous small openings, which further diminish the barrier to diffusion between blood and the tissues. Despite their thinness, it is rare for capillaries to rupture, because blood pressure drops dramatically as blood passes through arterioles on its way to capillary beds.

Veins carry blood back to the heart after the blood passes through capillaries. Because blood is under relatively low pressure by the time it exits the tissues, veins have thinner walls and larger interior diameters than arteries do (**Figure 44.22b**). Large veins are compressed by muscle activity in the extremities (say, the hands and feet), which helps speed the return of blood to the heart. Larger veins also contain one-way **valves**, which are thin flaps of tissue that prevent any backflow of blood. All veins contain some muscle fibers, which contract in response to signals from the nervous system, decreasing the diameter and overall volume of the vessels. Blood pressure in a closed circulatory system is regulated, in part, by active adjustment of the volume of blood contained within the veins.

Blood, Interstitial Fluid, and the Lymphatic System The relatively high operating pressure of closed circulatory systems, combined with the thinness of capillaries, produces a small but steady leakage of fluid from the blood vessels into the surrounding space. The area between cells is called interstitial space, and the fluid that fills it is called **interstitial fluid**. Because blood cells are retained within capillaries, the interstitial fluid resembles plasma in its electrolyte composition.

In 1896 Ernest Starling proposed that two forces affect fluid flow across capillaries (**Figure 44.23**). The first is the outward-directed hydrostatic force created by the pressure on blood generated by the heart. This force is analogous to the pressure that drives water through the wall of a leaky garden hose. The second is an inward-directed osmotic force, created by the higher concentration of solutes in the blood plasma than in the interstitial space.

Starling reasoned that at the end of the capillary nearest to an arteriole, the hydrostatic force would exceed the osmotic force and fluid would move out of the capillary into the interstitial space. But because blood pressure drops as fluid passes through a long, thin tube, he proposed that the osmotic force would exceed the hydrostatic force at the venous end of the capillary. Thus, the fluid lost at the arteriolar end of the capillary would be largely reclaimed at the venous end.

Starling also proposed that any interstitial fluid that was not reclaimed in the capillary would be collected in the **lym-**

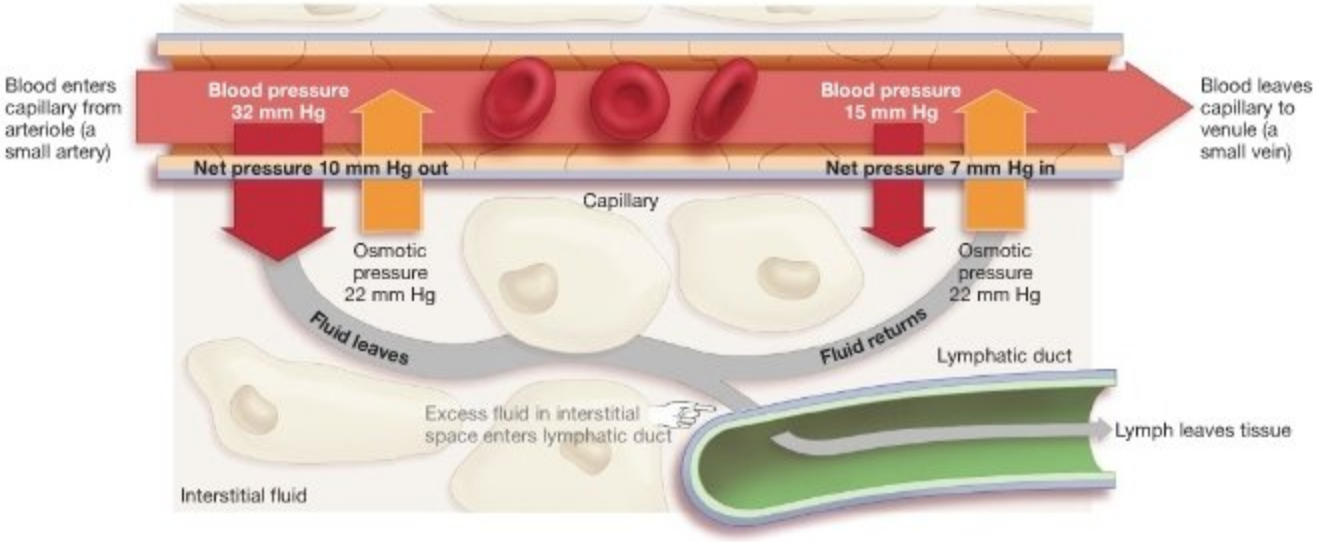

FIGURE 44.23 Pressure Differences in Capillaries Create Interstitial Fluid and Lymph. The balance of blood pressure and osmotic forces favors fluid loss from the beginning (inflow end) of capillaries and fluid recovery at the other (outflow) end. Fluid that is not recovered by the capillaries is transported out of the tissue as lymph.

phatic system, consisting of thin-walled, branching tubules called lymphatic ducts or vessels. It had been known for many years that these tiny ducts permeate all tissues and that they eventually join with one another like the tributaries of a river, to form larger vessels. The largest lymphatic vessels return excess interstitial fluid, in the form of **lymph**, to the major veins entering the heart. Starling's model was a comprehensive proposal for how blood, lymph, and the lymphatic ducts interact.

This model rested on a key assumption, however: For Starling's hypothesis to work, the total solute concentrations in plasma and interstitial fluid must be different enough to bring fluid into capillaries via osmosis. For this to be true, capillaries would have to act as filters. Specifically, large protein molecules or other solutes would have to be retained inside capillaries as fluid leaked out. To test this assumption, a group of biologists placed small tubes in the lymphatic ducts of animals so that they could collect lymph. Then the team introduced radioactively labeled proteins of various sizes into the blood inside veins. They found that even though small proteins crossed readily from the blood to the lymph, larger proteins did not. Enough large proteins were retained in the capillaries to set up the osmotic gradient required by Starling's model.

Follow-up work has shown that the most important of these large proteins is **albumin**. Albumin's large size and net negative charge effectively excludes it from interstitial fluid. The presence of albumin in blood keeps solute concentrations high, maintaining a strong osmotic gradient that brings fluid into capillaries. As a result, the total daily formation of lymph is limited to just 2–5 percent of plasma volume. This amount is easily taken up by lymph vessels and returned to the blood. To summarize, the lymphatic system consists of thin-walled vessels that take up excess fluid from throughout the body and return it to the veins of the circulatory system.

How Does the Heart Work?

In animals with closed circulatory systems, the heart contains at least two chambers. There is at least one thin-walled **atrium** (plural: **atria**), which is a chamber that receives blood, and at least one thick-walled chamber called a **ventricle**, which generates the force required to propel blood out of the heart and through the system. Atria are separated from ventricles by atrioventricular valves.

When studies of vertebrate hearts and circulatory systems had advanced enough to make comparisons among groups possible, biologists noticed several important patterns. To understand these, study **Figure 44.24**. This phylogenetic tree shows the evolutionary relationships among some major vertebrate groups. The sketches for each group offer a simplified version of the heart and circulatory system found in each lineage. Two points are particularly important to note:

1. The number of distinct chambers in the heart increased as vertebrates diversified. Fish hearts have two chambers; amphibians have three; turtles and lizards have five (if the partially divided ventricle is counted as three chambers); crocodiles, birds, and mammals have four.

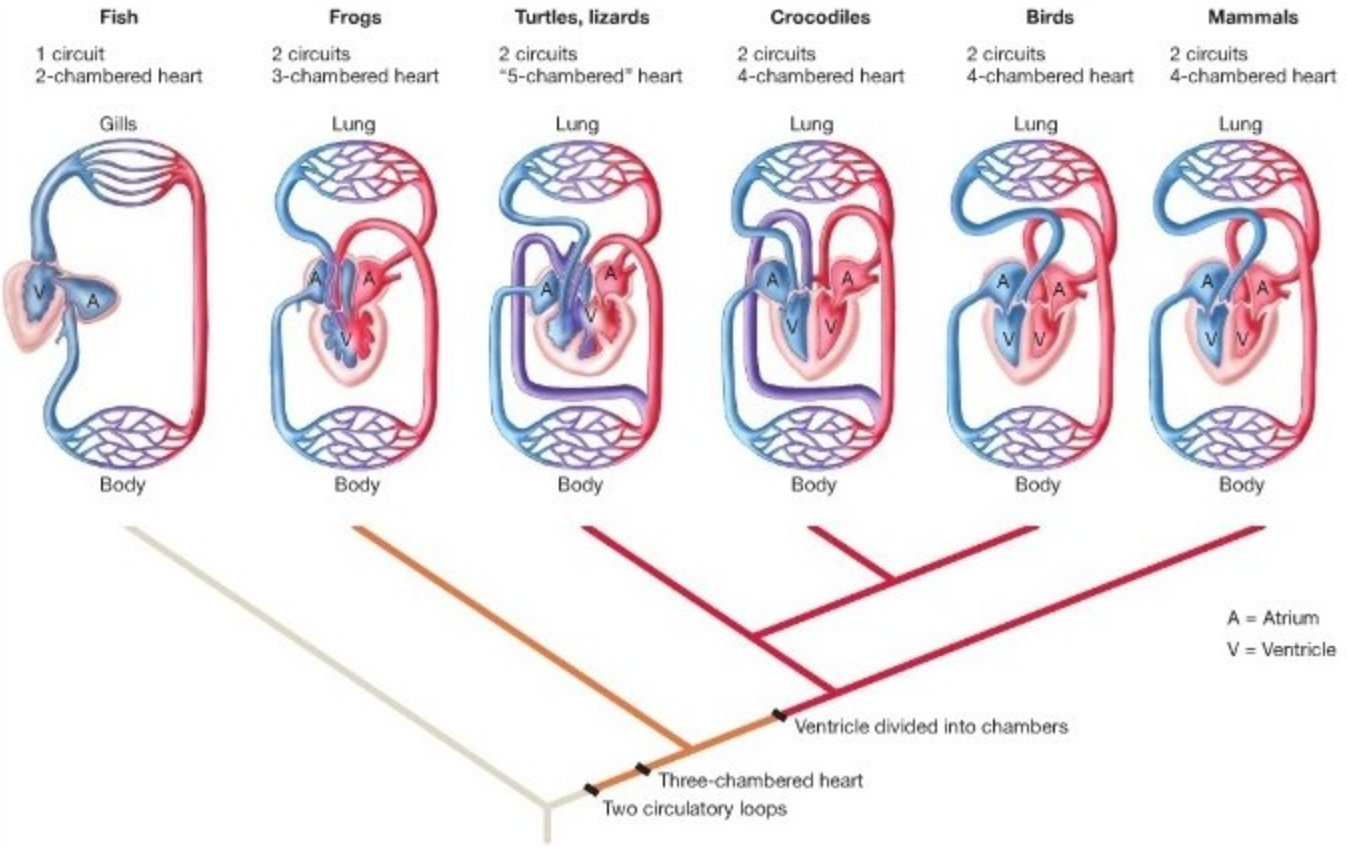

FIGURE 44.24 The Evolution of the Vertebrate Circulatory System. "A" denotes the atria—chambers that receive blood coming into the heart from the body and the lungs; "V" denotes the ventricles—chambers that pump blood out to the lungs and the body.

EXERCISE Turtles (and relatives) and crocodiles have a blood vessel that shunts blood between their two circuits, as needed. Label these shunts on the diagram.

EXERCISE Add arrows to major blood vessels, showing the direction of blood flow.

2. In fish, the circulatory system forms a single circuit—one loop services the gills and the body. In other groups, there are separate circuits to the lungs and to the body.

To understand these evolutionary patterns, let's first consider the relatively simple heart and circulatory system found in fish. A two-chambered heart and single circuit are adequate in fish. Even though blood pressure drops as blood passes through the gills—due to the mechanical resistance to flow that occurs in the gills' capillary beds—blood pressure stays high enough to move blood throughout the body. This is largely because fish live in the neutrally buoyant environment of water, where gravity does not have a large impact on blood flow.

In contrast, circulation in land-dwelling vertebrates is much more affected by the force of gravity. Gravity is particularly important in opposing blood flow to elevated portions of the body. To overcome gravity in terrestrial environments, blood must be pumped at high pressure. But high pressure blood flow presents a problem, because the capillaries and alveoli of the lungs are too thin to withstand high pressures.

The successful solution used by land-dwelling vertebrates was the evolution of two separate pumping circuits. The **pulmonary circulation** is a lower-pressure circuit to and from the lung, while the **systemic circulation** is a higher-pressure circuit to and from the rest of the body. The pulmonary and systemic circulations are completely separated in the four-chambered hearts of birds and mammals, which are essentially two fish hearts side by side.

The pulmonary and systemic circulations are only partially separated in the three-chambered hearts of amphibians and the "five-chambered" hearts of turtles and lizards, however. In addition, some of these animals have a bypass vessel running from the right side of the ventricle directly into the systemic circulation. This trait is also observed in the unusual four-chambered hearts of crocodiles. The bypass vessel has an important function: It allows blood to be shunted from the pulmonary to the systemic circulation when the animal is underwater. As a result,

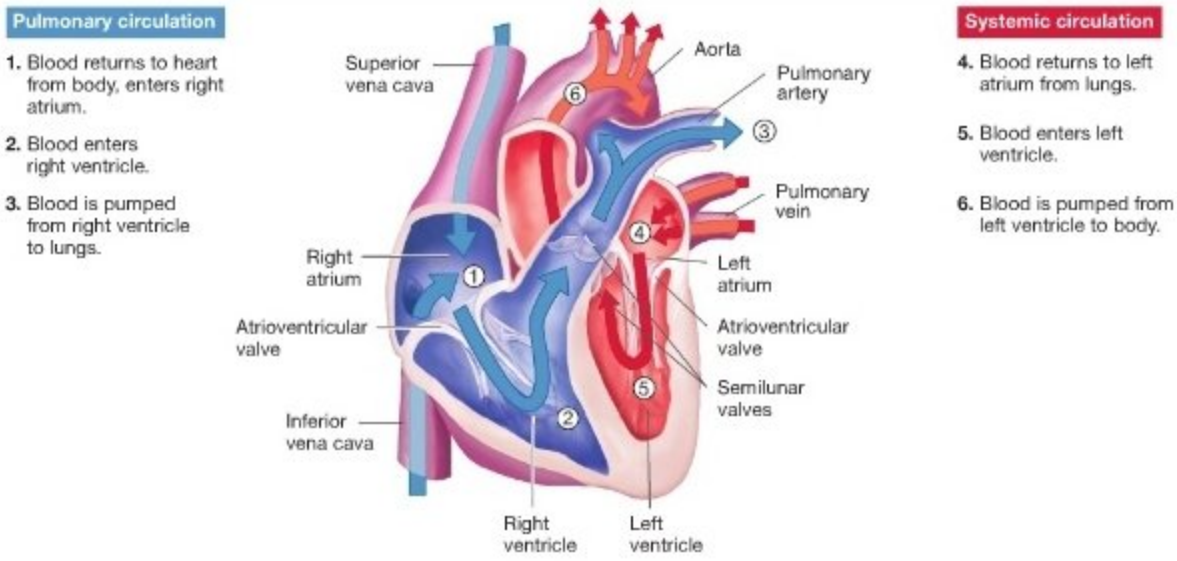

FIGURE 44.25 The Human Heart. Blood flows through a four-chambered heart in the sequence shown.

EXERCISE Circle the valves that separate the atria and ventricles, and the valves that separate the ventricles from the pulmonary artery (to lungs) and aorta (to body).

the individual greatly reduces blood flow to the lungs when it is not breathing.

The Human Heart Your heart is located in the chest cavity between your lungs and is roughly the size of your fist. As **Figure 44.25** shows, the circulatory system returns blood from the body to the right atrium of the human heart through two large veins called the inferior (lower) and superior (upper) **venae cavae** (singular: **vena cava**). This blood is low in oxygen. When the muscles that line the right atrium contract, this deoxygenated blood is sent to the right ventricle. The right ventricle, in turn, contracts and sends blood out to the lungs, via the **pulmonary artery**. In this way, the right ventricle powers the movement of blood through the pulmonary circulation. Blood that returns to the heart from the body is sent to the lungs.

Blood flows from atrium to ventricle to artery only one way, because one-way valves separate the heart's chambers from each other and from the adjacent blood vessels. As Figure 44.25 indicates, the valves are flaps, oriented in a way that ensures a one-way flow of blood with little or no backflow. If heart valves are damaged or defective, the resulting backflow can be heard through a stethoscope. The backflow reduces the organ's efficiency and is called a **heart murmur**.

After blood has circulated through the capillary beds in the lung's alveoli and becomes oxygenated, it returns to the heart through the **pulmonary veins**. The oxygenated blood enters the left atrium. When this chamber contracts, blood is pushed into the left ventricle. The walls of the left ventricle are so thick with muscle cells that their contraction sends oxygenated blood at high pressure out the aorta and into the arteries and capillaries that form the systemic circulation.

Figure 44.26 summarizes the flow pattern through the human circulatory system and the blood gas concentrations at various points in the pulmonary and systemic circulations. Notice that blood vessels are called arteries or veins according to the direction of blood flow relative to the heart, not because of the oxygen content of the blood in them. Thus, the pulmonary artery is called an artery because it takes blood away from the heart, even though this blood is low in oxygen content.

The data on gas partial pressures in Figure 44.26 make another important point: In healthy individuals, gas exchange in the lungs and tissues is rapid relative to the rate at which blood flows through capillaries. This situation ensures that the maximum amount of oxygen is taken up and the maximum amount of carbon dioxide is released. Thus, the partial pressures of oxygen and carbon dioxide in the alveoli and the pulmonary veins are equal. Similarly, the maximum amount of oxygen is released from blood to tissues and the maximum amount of carbon dioxide is taken up—resulting in partial pressures for oxygen and carbon dioxide in the tissues and the systemic veins that are equal.

The Cardiac Cycle Although the preceding discussion suggests that each chamber in the heart acts independently, this is not the case. The contraction phase of the atria and the ventricles, called **systole**, is closely coordinated with their relaxation phases, or **diastole**. For example, both atria contract simultaneously about 0.1 second ahead of ventricular con-

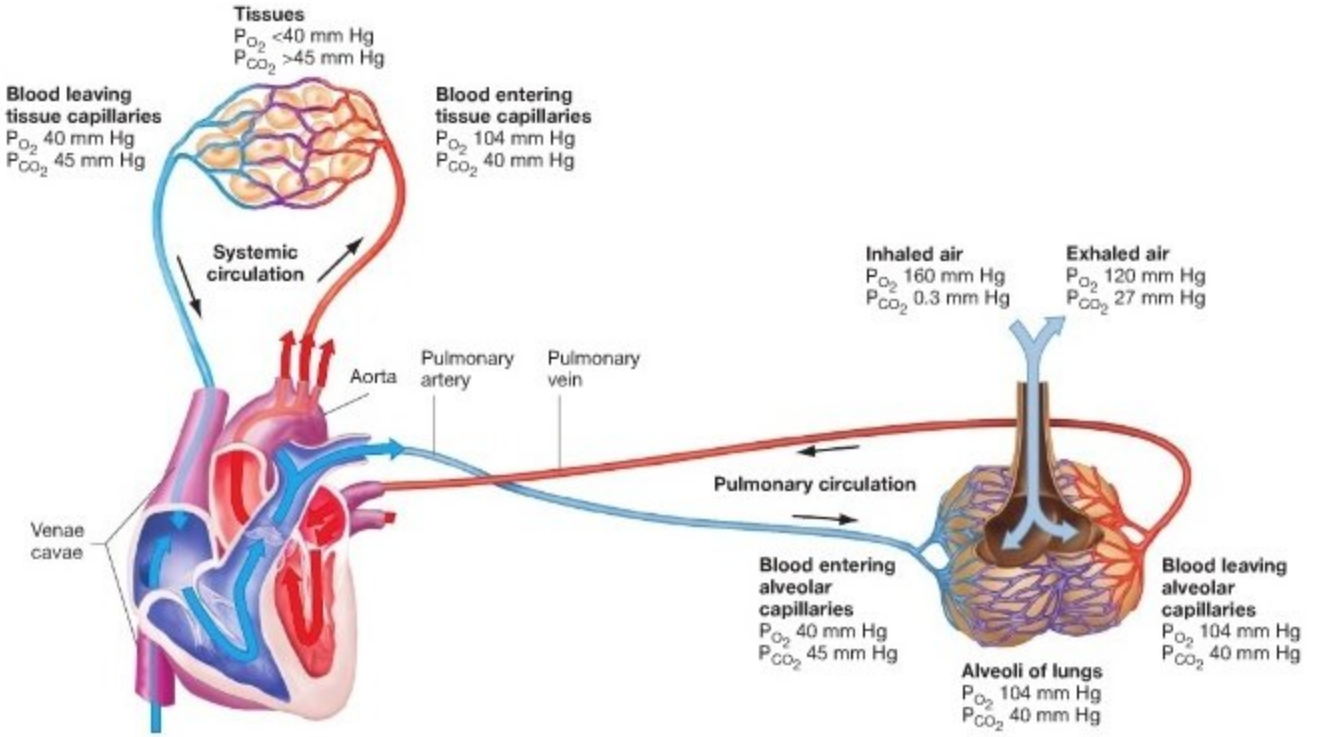

FIGURE 44.26 Partial Pressures of Gases Vary throughout the Human Circulatory System. Partial pressures of oxygen and carbon dioxide at various points in the human circulatory system.

QUESTION Why are the partial pressures of oxygen and carbon dioxide in exhaled air intermediate in magnitude between the partial pressures in inhaled and alveolar air?

traction. Because both ventricles are still in diastole and relaxed when the atria contract, the ventricles fill with blood from the atria just before they enter systole and contract. This sequence of contraction and relaxation is called the **cardiac cycle**. It consists of one diastole and one systole for both atria and ventricles.

Ventricular contraction (ventricular systole) leads to a rapid increase in pressure within both ventricles (**Figure 44.27**). Blood is ejected into the pulmonary artery and the aorta when ventricular pressure equals the pressure within each respective artery. Blood pressure measured in the systemic arterial circulation at the peak of ventricular ejection into the aorta is called the **systolic blood pressure**. Blood pressure measured just prior to ventricular ejection is called the **diastolic blood pressure**. Clinicians report blood pressure measurements in fractional notation, with systolic pressure as the numerator and diastolic pressure as the denominator. For the example shown in Figure 44.27, blood pressure is 120/80 mm Hg. People with blood pressures in excess of 150/90 mm Hg are considered to have high blood pressure, or **hypertension**. The measurement of blood pressure and some of the health consequences of hypertension are discussed further in **Box 44.3**.

The Human Heart

Electrical Activation of the Heart How is the activity of each chamber of the heart coordinated? Cardiac muscle cells, like other muscle cells, contract in response to electrical signals. In invertebrates, the electrical impulses that trigger contraction come directly from the nervous system. But in vertebrates, a group of cells in the heart itself is responsible for generating the initial signal. The cells that initiate contraction, known as **pacemaker cells**, are located in a region of the right atrium called the **sinoatrial (SA) node** (**Figure 44.28**). The SA node and the muscle cells of the heart receive input from the nervous system and from chemical messengers carried in the blood. These inputs are important for regulating both the heart rate and the strength of ventricular contraction. However, a vertebrate heart will beat even if all nerves supplying it are severed.

The electrical impulse generated by the SA node is rapidly conducted throughout the right and left atria. The signal spreads quickly from cell to cell because of a striking property of cardiac muscle cells: They form physical and electrical connections with each other. More specifically, all cardiac muscle

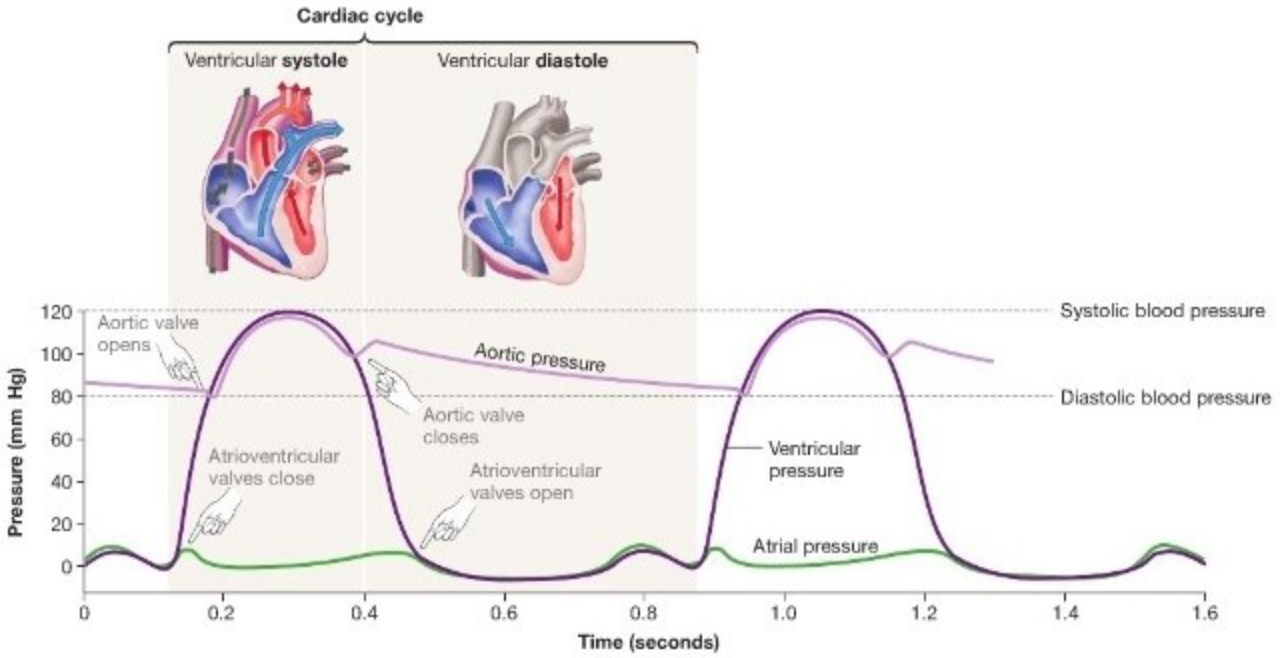

FIGURE 44.27 Blood Pressure Changes during the Cardiac Cycle. Pressures created by the left ventricle and aorta in the cardiac cycle. In this case, the blood pressure measured in the upper arm would be 120/80 mm Hg. The right ventricle and pulmonary artery pressures follow a similar pattern, but the blood pressure measured in the pulmonary artery would be closer to 25/8 mm Hg.

● **QUESTION** Why does the left aortic valve open shortly after the beginning of ventricular systole and close slightly before the end of systole?

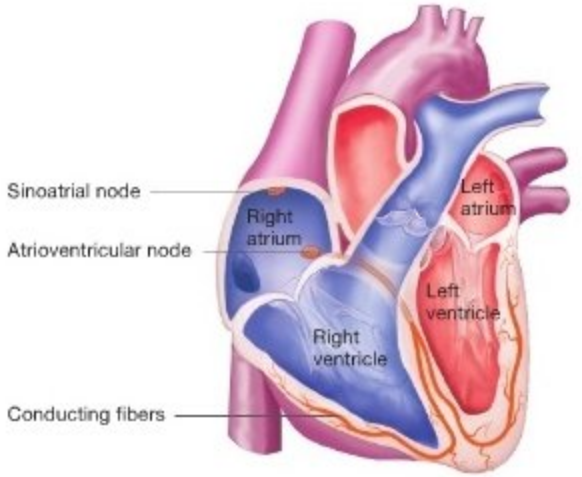

FIGURE 44.28 Sequential Electrical Activation Leads to Coordinated Contraction of the Heart. Electrical activation of the heart begins with the pacemaker cells in the sinoatrial node, spreads through the electrically connected muscle cells of the atria, and converges on the atrioventricular node, where it is delayed long enough to allow the atria to eject blood into the ventricles. The ventricles are then activated rapidly by the spread of electricity through specialized conducting fibers in the ventricular walls.

● **EXERCISE** In this diagram, the heart is sectioned through the pulmonary artery. Circle the conducting fibers just dorsal to this artery.

cells branch to contact several other cells, are joined end to end with these neighboring cells, and are connected by specialized structures called **intercalated discs**. Because these discs contain numerous gap junctions—cell-to-cell connections described in Chapter 8—electrical signals pass directly from one cardiac muscle cell to the next. (In Chapter 45, we'll explore how electrical signals in animals are initiated and propagated.) As a result, the atria contract simultaneously and fill the ventricles.

Once the electrical signal has swept over the atria, however, it is conducted to an area of the heart called the **atrioventricular (AV) node**, which delays the signal slightly before passing it to the ventricles. This delay allows the ventricles to fill completely before they contract. After the delay, the electrical impulse is rapidly transmitted through specialized conducting fibers lying within the muscular wall that separates the ventricles. The impulse spreads through both ventricles, causing them to contract as the atria relax. The ventricles empty efficiently because the signal and the resulting muscular contraction move up to the top of each ventricle and then move forward to the arteries that allow blood to exit.

The electrical events responsible for the synchronized contraction of the atria and ventricles are summarized in

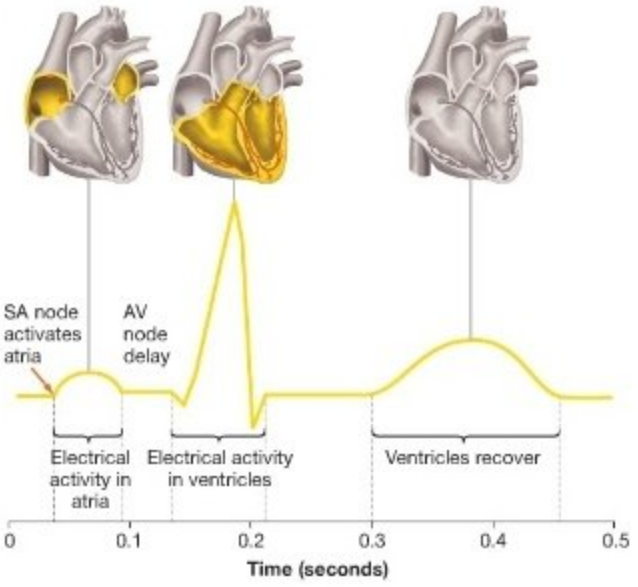

FIGURE 44.29 EKGs Record Electrical Events Associated with Cardiac Muscle Contraction.

QUESTION The electrical activity generated by ventricular contraction is much larger and more compressed than the electrical activity generated by atrial contraction. Why?

Figure 44.29. This figure also shows the recording known as an **electrocardiogram**, or **EKG**, which corresponds to the electrical activity associated with cardiac muscle contraction. The EKG recording is generated by amplifying the overall electrical signal conducted from the heart to the chest wall through the tissues of the body. By inspecting the waves generated by the EKG, physicians can diagnose disturbances of heart rhythm and detect damage to the heart muscle.

Patterns in Blood Pressure and Blood Flow

As blood moves through capillaries, blood pressure drops dramatically. **Figure 44.30** shows why. The key point is that as arteries branch, rebranch, and eventually form networks of capillaries, the total cross-sectional area of blood vessels in the circulatory system increases—even though the size of individual blood vessels decreases as blood moves away from the heart. Because the amount of mechanical resistance to flow is a function of total cross-sectional area of the vessels, friction losses are high in capillary beds and blood pressure drops dramatically. The pulsing nature of the pressure noted in the larger arteries diminishes as a result of this pressure drop.

The velocity of blood flow also decreases significantly in capillary beds relative to arteries and veins, because the same amount of fluid is passing through a much larger area. The slow rate of blood flow through capillaries is important: It provides sufficient time for gases, nutrients, and wastes to diffuse between tissues and blood.

These general patterns of blood pressure and blood flow don't tell the entire story, however, because blood movement throughout the body is also carefully regulated. Recall that arterioles have muscular sphincters in their walls, and that changes in the size of these sphincters can constrict or allow blood flow. This means that the nervous system, along with certain chemical messengers in the circulation, can accurately control blood flow to various tissues by contracting or relaxing the arteriolar sphincters. For example, arterioles in the skin may dilate during exercise. When they do, they divert blood flow to the skin for the purpose of eliminating excess heat. This accounts for the flushed facial appearance often induced by vigorous exercise.

As another example of how blood pressure and blood flow are regulated, consider what happens if you sit long enough for blood to pool in your lower extremities, under the influence of

BOX 44.3 Hypertension and the Measurement of Blood Pressure

Hypertension is a serious concern to physicians because it can lead to a variety of defects in the heart and circulatory system. Abnormally high blood pressure puts mechanical stress on arteries. If the walls of an artery fail, the individual may experience heart attack, stroke, kidney failure, and burst or dilated blood vessels.

Physicians often rely on blood pressure measurements to diagnose hypertension. A blood pressure reading—especially when combined with a measurement of resting pulse rate and cholesterol counts, gives clinicians relatively quick, accurate, and inexpensive data on the health risk to a patient's heart and circulatory system.

To measure a person's blood pressure, a clinician wraps an inflatable cuff attached to a pressure gauge around the upper arm. When the cuff is fully inflated, the pressure it exerts is transmitted evenly throughout the arm and closes down the main artery in this part of the body. The clinician then uses a stethoscope to listen for the sounds of blood flow downstream from the cuff.

At first, the clinician hears no pulse sounds through the stethoscope, because no blood is flowing downstream of the cuff. As the clinician slowly releases air from the cuff, however, the pressure in the cuff begins to fall until it is just below the systolic pressure in the artery. At this point, blood begins to spurt through the artery with each systolic peak. The flow is turbulent, so the clinician can detect a thumping pulse sound in the stethoscope. The cuff pressure when sound is first detected is equal to the systolic pressure. As more air is released from the cuff, its pressure falls below the diastolic pressure in the artery. At this point, blood flow in the artery is smooth and the sound of turbulent flow fades away. The cuff pressure when the sound becomes muffled or disappears represents the diastolic pressure.

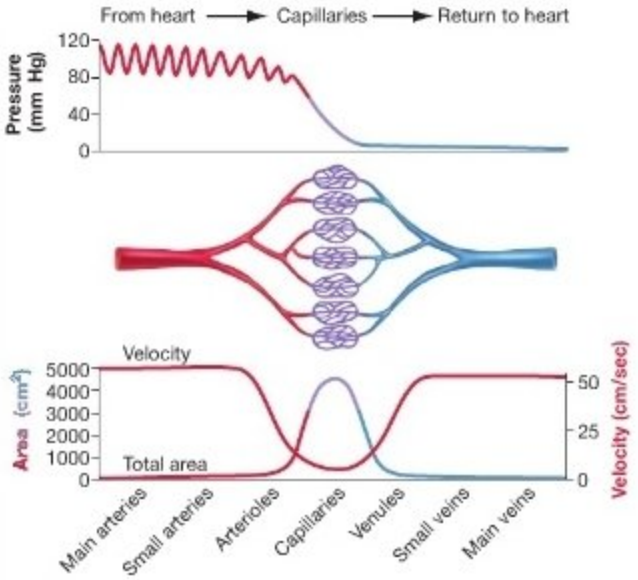

FIGURE 44.30 Blood Pressure Drops Dramatically in the Circulatory System. The top graph shows how blood pressure changes as blood leaves the heart and travels through arteries, capillaries, and veins, as in the branching pattern of the middle diagram. In arteries near the heart, each heartbeat causes fluctuations in blood pressure. These pressure pulses disappear in the capillaries, so blood flows there at a steady speed. The bottom graph plots the total area of blood vessels shown in the diagram, as well as the velocity of blood flow through the vessels.

EXERCISE Label the systolic and diastolic blood pressures in the top graph.

gravity. If you stand up rapidly, your blood pressure can drop enough to limit blood flow to the brain and cause dizziness, lightheadedness, or even a blackout. More serious drops in blood pressure, due to severe dehydration or blood loss following an injury, can lead to death. Fortunately, decreases in blood pressure elicit a powerful homeostatic response.

Recall from Chapter 41 that all homeostatic responses involve (1) sensors that detect the change in condition, (2) an integrator that processes information about the change, and (3) effectors that diminish the impact of the change. In the case of the circulatory system, falling blood pressure is detected by specialized pressure-sensing nerve cells called **baroreceptors**. Baroreceptors are found in the walls of the heart and the major arteries, both as they leave the heart and as they enter the neck. This distribution is logical, because the head tends to be the most elevated part of land-dwelling animals and because the preservation of blood flow to the brain is the highest priority.

When baroreceptors transmit signals to the brain indicating a serious fall in blood pressure, a rapid, three-component effector response ensues:

1. An increase in cardiac output, meaning the volume of blood leaving the left ventricle, is brought about by both an increase in heart rate and an increase in stroke volume—the amount of blood ejected from the ventricles during each cardiac cycle. (Cardiac output = heart rate × stroke volume.)
2. The constriction of arterioles serving the capillaries of tissues such as the skin and intestines, which can endure short-term restrictions in their blood supply. This arteriolar constriction diverts blood to more critical organs.
3. A generalized constriction of the veins, resulting in a decrease in their overall volume. Because more than half of the blood in the circulatory system is contained within the veins, constriction of these vessels shifts blood volume toward the heart and arteries to maintain blood pressure and flow to vital organs.

This coordinated response is mediated both by a portion of the nervous system called the sympathetic nervous system (Chapter 45) and by hormones (Chapter 47) produced by the adrenal glands. Sympathetic nerves and the hormones involved in blood pressure regulation deliver their messages directly to the SA node to increase heart rate, the ventricles of the heart to increase stroke volume, the sphincters of the arterioles to modify their resistance, and the muscular walls of the veins to modify their total volume.

The homeostatic response to falling blood pressure resembles the **fight-or-flight response**, which is triggered by a threatening stimulus (see Chapter 47). During the fight-or-flight response, an organism prepares to defend itself or rapidly escape from danger. Part of this response involves directing blood to the brain and muscles in preparation for quick action. The side effects include the "cold sweat" and nausea often induced by a fearful situation. These feelings occur because blood flow is directed away from the skin and intestines.

Check Your Understanding

If you understand that...

- Animal circulatory systems may be open or closed, but both types of systems circulate blood or hemolymph via pressure generated by one or more hearts.
- In closed systems, regulated changes in the diameter of blood vessels can direct blood to specific regions, and overall blood pressure is carefully regulated through changes in cardiac output.

You should be able to...

1) Explain how the mammalian lymphatic system and circulatory system interact.
2) Make a labeled diagram showing how blood circulates through the mammalian heart.
3) Explain why blood pressure drops dramatically as blood moves from arterioles through capillary beds.

Chapter Review

SUMMARY OF KEY CONCEPTS

Animals have to take in oxygen and expel carbon dioxide to sustain cellular respiration and stay alive. Terrestrial animals and aquatic animals face different challenges in performing gas exchange.

As media for exchanging oxygen and carbon dioxide, air and water are dramatically different. Compared with water, air contains much more oxygen and is much less dense and viscous. As a result, terrestrial animals have to process a much smaller volume of air to extract the same amount of O_2 and don't have to work as hard to do so.

Both aquatic and terrestrial animals pay a price for exchanging gases. Land-dwellers lose water to evaporation during ventilation. Freshwater animals lose ions through diffusion and gain excess water by osmosis. Marine animals gain sodium and chloride through diffusion and lose water by osmosis.

You should be able to explain why no water breathers have the extremely high rates of metabolism required for endothermy.

The organs responsible for gas exchange maximize the rate of oxygen and carbon dioxide diffusion by presenting a large, thin surface area to the environment. These organs also function in a way that maintains a steep partial-pressure gradient that favors entry of oxygen and elimination of carbon dioxide.

Natural selection has resulted in the evolution of gills, tracheae, lungs, and other gas-exchange organs that minimize the cost of ventilation while maximizing the rate at which O_2 and CO_2 diffuse. Consistent with predictions made by Fick's law of diffusion, respiratory epithelia tend to be extremely thin and folded to increase surface area. In fish gills, countercurrent exchange ensures that the partial-pressure differences between O_2 and CO_2 in water and blood are high over the entire length of the ventilatory surface. In bird lungs, structural adaptations lead to a much greater ratio of useful ventilatory space to dead space than is observed in the lungs of mammals. The rate of breathing is regulated by an area in the brain to keep the carbon dioxide content of the blood stable during both rest and exercise.

You should be able to explain why no large animals have gas exchange occurring only across the skin.

Blood is a specialized tissue that transports gases, along with nutrients and wastes, in some animals. Hemoglobin is an oxygen-carrying protein with characteristics that make it extremely efficient at taking up oxygen in the lungs and delivering it to tissues.

About half the blood volume in a typical human consists of red blood cells that are specialized for gas exchange. Red blood cells lack most organelles but contain hundreds of millions of hemoglobin molecules. Each hemoglobin molecule can carry up to four oxygen molecules. The tendency of hemoglobin to give up these oxygen molecules varies as a function of the P_{O_2} in surrounding tissue in a sigmoidal fashion. As a result, a relatively small change in tissue P_{O_2} causes a large change in the amount of oxygen released from hemoglobin. In addition, oxygen binds less tightly to hemoglobin when pH is low. Because CO_2 tends to react with water to form carbonic acid, the existence of high CO_2 partial pressures in exercising muscle tissues lowers their pH and makes oxygen less likely to stay bound to hemoglobin and more likely to be released into tissues.

The CO_2 that diffuses into red blood cells from tissues is rapidly converted to carbonic acid by the enzyme carbonic anhydrase. The protons that are released as carbonic acid dissociates bind to deoxygenated hemoglobin. In this way, hemoglobin acts as a buffer that takes protons out of solution and prevents large fluctuations in blood pH.

You should be able to explain how oxygen and carbon dioxide are transported in blood in the icefish native to the Antarctic, since these fish lack hemoglobin.

Gas Exchange in the Lungs and Tissues

Circulatory systems use the pressure generated by one or more hearts to transport blood and other substances throughout the body.

In many animals, blood or hemolymph moves through the body via a circulatory system consisting of a pump (heart) and vessels. In open circulatory systems, overall pressure is low and tissues are bathed directly in hemolymph. In closed circulatory systems, blood is contained in vessels that form a continuous circuit. Containment of blood allows higher pressures and flow rates, as well as the ability to direct blood flow accurately to tissues that need it the most. In organisms with a closed circulatory system, a lymphatic system returns excess fluid that leaks from the capillaries back to the circulation.

In mammals and birds, a four-chambered heart pumps blood into two circuits, which separately serve the lungs and the rest of the body. Although the heart rate is controlled by electrical signals that originate in the heart itself, heart rate, cardiac output, and contraction of both arterioles and veins are constantly modified by signals from the sympathetic nervous system and the adrenal glands. These signals act to preserve blood flow to vital organs in response to falling blood pressure or situations that are perceived as threatening.

You should be able to describe the circulatory systems expected to be found in terrestrial animals with high versus low activity rates, and in terrestrial versus aquatic animals.

QUESTIONS

Test Your Knowledge

1. O_2 will diffuse from blood to tissue faster in response to which of the following conditions?
   a. an increase in the P_{O_2} of the tissue
   b. a decrease in the P_{O_2} of the tissue
   c. an increase in the thickness of the capillary wall
   d. a decrease in the surface area of the capillary
2. Which of the following does blood *not* do?
   a. transport O_2 and CO_2
   b. distribute body heat
   c. produce red blood cells and other formed elements
   d. buffer against pH changes
3. How is most carbon dioxide transported in the blood?
   a. as a gas in the plasma
   b. bound to amino groups on hemoglobin
   c. bound to the heme group of hemoglobin
   d. as bicarbonate ions (HCO_3^-) in plasma
4. Which of the following is *not* an advantage of breathing air over breathing water?
   a. Air is less dense than water, so it takes less energy to move during ventilation.
   b. Oxygen diffuses faster through air than it does through water.
   c. The oxygen content of air is greater than that of an equal volume of water.
   d. Air breathing leads to high evaporation rates from the respiratory surface.
5. Which of the following promotes oxygen release from hemoglobin?
   a. a decrease in temperature
   b. a decrease in CO_2 levels
   c. a decrease in pH
   d. a decrease in carbonic anhydrase
6. An open circulatory system is less efficient than a closed circulatory system in what respect?
   a. It is harder to deliver O_2 to specific tissues based on need.
   b. Hemolymph does not contain oxygen-binding molecules.
   c. There is no heart to pump the blood.
   d. In closed systems, body movements cannot help circulate the blood.

Test Your Knowledge answers: 1. b; 2. c; 3. d; 4. d; 5. c; 6. a

Test Your Understanding

Answers are available at www.masteringbio.com

1. Compare and contrast the respiratory and circulatory systems of an insect and a human. What are some advantages and disadvantages of each system?
2. Why is the sigmoidal shape of the oxygen-hemoglobin equilibrium curve significant? Describe the changes in oxygen delivery that occur as a person changes from a resting state to intense exercise. How does the Bohr shift affect O_2 delivery to tissues?
3. Explain how carbon dioxide is transported in the blood. In humans, why doesn't intense exercise and rapid production of CO_2 lead to a rapid reduction in blood pH?
4. Draw a diagram summarizing how bird lungs are ventilated. Why is this pattern of ventilation considered much more efficient than the respiratory system of humans and other mammals?
5. Review Fick's law of diffusion. Explain how each parameter in the equation is reflected in the structure of ventilatory organs.
6. Explain why surface tension helps make the lungs of mammals elastic. Why does the large surface area in alveoli increase elasticity?

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Researchers who compared the total amount of ventilatory surface area in the gills of various species of fish found that species that do a lot of high-speed swimming have a larger total surface area than do slow-moving species of the same size. Interpret this pattern in light of the theory of evolution by natural selection.
2. At high elevations, certain cells in humans increase the production of 2,3-diphosphoglycerate (DPG). In blood, DPG shifts the oxygen-hemoglobin equilibrium curve to the right. How does this shift affect O_2 unloading and loading?
3. Carp are fish that thrive in stagnant-water habitats with low-oxygen partial pressures. Compared with the hemoglobin of many other fish species, carp hemoglobin has an extremely high affinity for O_2. Is this trait adaptive? If so, why?
4. The carbon monoxide (CO) found in furnace and engine exhaust and in cigarette smoke binds to the heme groups in hemoglobin 210 times more tightly than does O_2. Explain why exposure to large doses of CO can lead to suffocation.

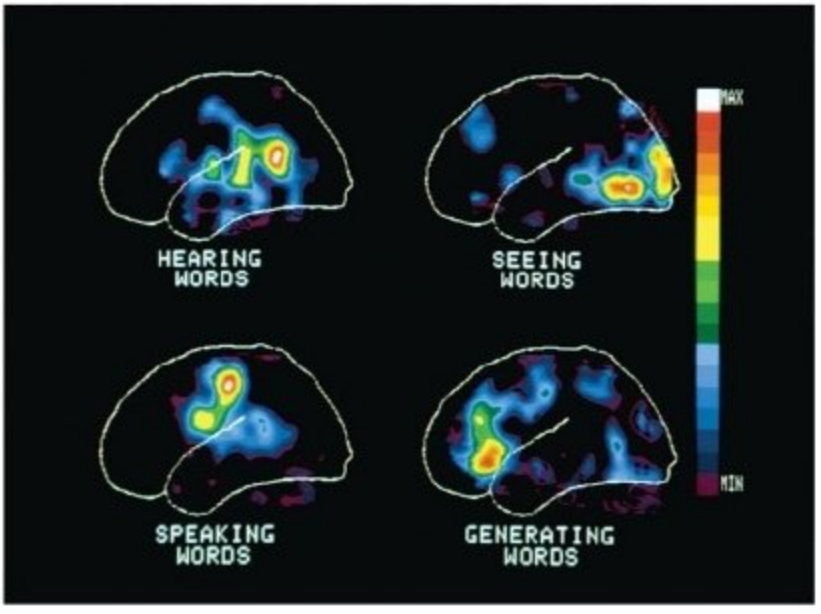
45 Electrical Signals in Animals

KEY CONCEPTS

- Neurons are cells that transmit electrical signals used in communication. Neurons have a membrane potential, which is an electric potential difference, or voltage, across the plasma membrane. A voltage exists due to differences in the concentrations of ions on the two sides of the plasma membrane.
- Electrical signals are transmitted as graded or all-or-none changes in membrane voltage. All-or-none changes are called action potentials. During an action potential, an inflow of sodium ions is followed by an outflow of potassium ions.
- At synapses, an electrical signal from one neuron is converted to a chemical signal in the form of a neurotransmitter. When it arrives at an adjacent neuron, the neurotransmitter causes a change in that cell's membrane potential.
- Animals have a central nervous system (CNS) and a peripheral nervous system (PNS). PNS neurons receive sensory information and transmit it to the CNS for processing. The CNS then sends signals to muscles, glands, or other target tissues via other PNS neurons.



Positron-emission tomography (PET) scans showing changes in the activity of brain cells during different tasks, such as remembering words and speaking them aloud. Different brain areas are specialized for performing different tasks.

If you are unfortunate enough to touch a hot stove burner, your hand will jerk away before your brain perceives pain. When a trout is about to be attacked by an osprey, the trout's tail thrashes so rapidly that the movement is a blur. These and other animal movements are triggered by electrical impulses. Sensory cells in your finger and in the trout's eye send information to the brain and spinal cord, which send electrical signals to muscles in your arm and the trout's tail. Electrical signals are fast and precise. They are conducted from point to point by nerve cells, called **neurons**, at speeds of up to 200 m/sec (450 mph). The result is movement that saves your finger from extensive tissue damage—or saves the trout's life.

The goal of this chapter is to explore how electrical signaling occurs. Section 45.1 introduces the general anatomy of a nerve cell, discusses why a voltage exists across the cell's plasma membrane, and investigates how electrical currents are produced in cells. The next three sections focus on how neurons generate and propagate electrical signals, how information is transferred from cell to cell, and how neurons work in groups to integrate information from different sources. One of this chapter's most fundamental messages is that complex processes such as seeing, moving, and thinking are based on seemingly simple events: flows of ions across plasma membranes.

45.1 Principles of Electrical Signaling

Nerve cells, or neurons, transmit information. In many cases, the information they carry originates in sensory cells that are located on the periphery of the body. Sensory receptors inside the skin, eyes, ears, and nose transmit streams of data about the external environment in the form of electrical signals. Similarly, sensory cells inside the body monitor conditions that are important in homeostasis, such as blood pH and oxygen levels. In this way, sensory cells monitor conditions both outside and inside the body.

As **Figure 45.1a** shows, a sensory receptor cell transmits the information it receives by means of a nerve cell known as a **sensory neuron**. (In many cases, the receptor cell itself also acts as a sensory neuron.) In vertebrates, the sensory neuron sends the information to neurons in the brain or spinal cord via nerves; in other animals nerves send the information to the brain. **Nerves** are long, tough strands of nervous tissue. They contain thousands of projections from neurons and carry information to and from the brain and spinal cord. Together, the brain and spinal cord form the **central nervous system**, or **CNS**. One function of the CNS is to integrate information from many sensory neurons. Cells in the CNS called **interneurons** (literally, "between-neurons") perform this integration. Interneurons make connections between sensory neurons and **motor neurons**, which are nerve cells that send signals to effector cells in glands or muscles. Recall from Chapter 41 that effectors are structures that respond to stimuli. All neurons and other components of the nervous system that are outside the CNS are considered part of the **peripheral nervous system**, or **PNS**. (Section 45.4 describes the structure and function of the PNS in more detail.)

Typically, sensory information from receptors in the PNS is sent to the CNS, where it is processed. Then a response is transmitted back to appropriate parts of the body. When you stub your toe, pain receptors in your toe relay sensory information rapidly to the brain, which then modifies your movements to avoid further injury. You might limp to avoid further contact with that toe. In some cases, however, information from a sensory neuron never reaches the brain. This is what happens when you touch a hot burner and jerk your hand back (**Figure 45.1b**). When pain receptors are stimulated, sensory neurons activate interneurons in the spinal cord that directly activate motor neurons serving muscles in the arm. The signals from these motor neurons stimulate muscles that pull the lower part of your arm toward the body and inhibit muscles that extend the lower arm. The movement is a **reflex**—a direct response to a signal without integration by the brain. It is fast and automatic. Later, when your brain integrates information from pain receptors in your hand and from light receptors as you look at the burn, other motor neurons might direct your hand as it plunges into cold water. What do the cells that carry and process this information look like?

The Anatomy of a Neuron

Compared with studying cells in the kidney, digestive system, or lungs, documenting the anatomy of neurons was difficult. Neurons are small, transparent, and morphologically complex. So

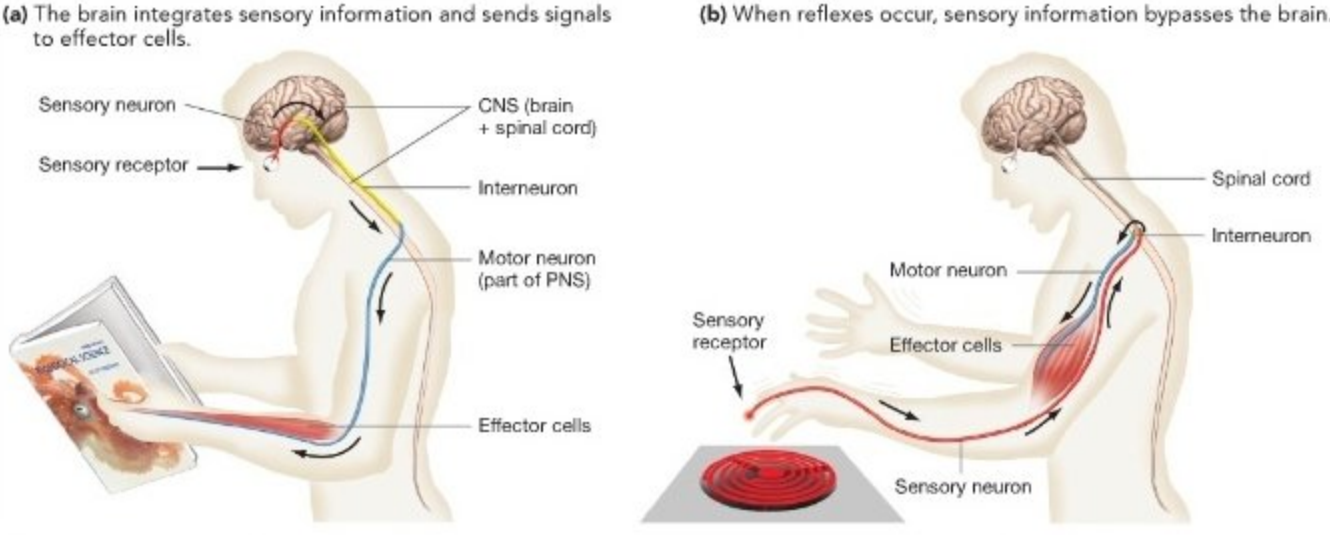


FIGURE 45.1 How Does Information Flow through the Nervous System? (a) In most cases, sensory neurons send information to the brain. There, the electrical signals are integrated with information from other sources. Once integration is complete, a response is sent to effector cells through motor neurons. **(b)** In a spinal reflex, sensory information triggers a direct response by effector cells—without integration by the brain.

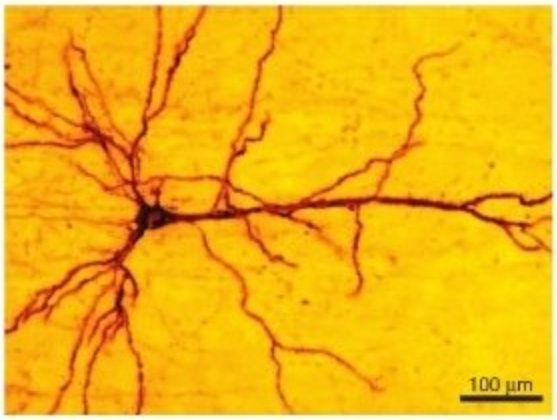

FIGURE 45.2 Early Methods for Visualizing Neurons. The discovery of stains that made transparent neurons visible launched the study of electrical signaling in animals.

when Camillo Golgi discovered that some neurons became visible when samples of preserved tissue were treated with a solution containing silver nitrate, his finding was a major advance (**Figure 45.2**).

Golgi published his initial observations in 1898. Through the early decades of the twentieth century, his work and that of Santiago Ramón y Cajal revealed several important points about the anatomy of neurons. Most neurons have the same three parts, shown in **Figure 45.3a**: (1) a cell body, (2) a highly branched group of short projections called dendrites, and (3) one or more long projections called axons. Dendrites are rarely more than 2 mm long, but axons can be over a meter in length. The number of dendrites and their arrangement vary greatly from cell to cell. Further, many brain cells have only dendrites and lack axons.

What do dendrites and axons do? Long before the anatomists began their work, it had been established that neurons carry electrical signals. Based on observations of stained cells, researchers suggested that a **dendrite** receives an electrical signal from the axons of adjacent cells and that a neuron's **axon** then sends the signal to the dendrites and cell bodies of other neurons (**Figure 45.3b**). Dendrites collect electrical signals; axons pass them on. The **cell body**, or **soma**, which includes the nucleus, also receives signals from axons. The cell body is where incoming signals are integrated and an outgoing signal is sent to the axon.

Ramón y Cajal maintained that the plasma membrane of each neuron is distinct and that the membranes of axons and dendrites meet at junctions called synapses. This hypothesis was confirmed in the 1950s, when images from electron microscopes showed that only a small subset of neurons make direct, cytoplasm-to-cytoplasm connections; most interactions occur where the plasma membranes of two neurons meet at synapses.

The basic message of early anatomical studies was that neurons are highly branched and that each neuron makes many connections with other neurons. The focus of research shifted to a new question: If these cells transmit electrical signals, how do they create these signals?

(a) Information flow through neurons

An Introduction to Membrane Potentials

Ions carry an electric charge. In virtually all cells, the cytoplasm and extracellular fluids adjacent to the plasma membrane contain unequal distributions of ions. As a result, cells are inherently electrical in nature. A difference of electrical charge between any two points creates a difference in **electrical potential**, or a **voltage**. If the positive and negative charges on ions that exist on the two sides of a plasma membrane do not balance each other, the membrane will have an electrical potential. When an electrical potential exists on either side of a plasma membrane, the separation of charges is called a **membrane potential**. If there is a large separation of charges across the membrane, then the membrane potential is large. It is important to remember that membrane potentials refer only to a separation of charge immediately adjacent to the plasma membrane, on either side of the membrane. Even if there is a large membrane potential, there may be no charge separation slightly farther from the membrane.

Membrane potentials are measured in units called millivolts. A **millivolt** (**mV**) is 1/1000 of a volt; a **volt** is the standard unit of electrical potential. To help you get a better understanding of how large a millivolt is, an AA battery that you buy in the store has an electrical potential of 1500 mV between its + and − terminals. In neurons, membrane potentials are typically about 70–80 mV.

Membrane potentials are a form of potential energy. When a membrane potential exists, the ions on both sides of the membrane have potential energy. To convince yourself that this is true, consider that if the membrane were removed, ions would spontaneously move from the area of like charge to the area of unlike charge—causing a flow of charge. A flow of charge is called an **electric current**. This movement would occur because like charges repel and unlike charges attract.

As Chapter 6 emphasized, however, ions move across membranes in response to concentration gradients as well as charge gradients. Therefore, a membrane potential also includes energy stored as the concentration gradient of charged ions on the two sides of the membrane. Recall that the combination of an electric gradient and a concentration gradient is called an **electrochemical gradient**. What do all of these facts have to do with neurons?

How Is the Resting Potential Maintained?

When a neuron is not transmitting an electrical signal but is merely sitting in extracellular fluid at rest, the membrane potential across its membrane is called the **resting potential**. To understand why the resting potential exists, consider the distribution of the various ions and other charged molecules on the two sides of the neuron's plasma membrane. Most of the large molecules inside cells are acids, which tend to release a proton. Proteins, for example, are made up of amino acids. When acids release a proton, they acquire a negative charge. Intracellular proteins that tend to be negatively charged are referred to as *organic anions*. Because of their large size and charge, organic anions do not move across membranes. The interior of a neuron also contains low concentrations of Na^+ and Cl^-. Inside a neuron, the dominant positively charged ion is the potassium ion (K^+). In the extracellular fluid, however, the sodium ion (Na^+) and chloride ion (Cl^-) predominate. K^+, Na^+, and Cl^- can cross the membrane if appropriate channels are present.

Figure 45.4 shows the relative concentrations of organic anions, K^+, Na^+, and Cl^- inside and outside a resting neuron. If each type of ion diffused across the membrane in accordance with its concentration gradient, organic anions and K^+ would leave the cell while Na^+ and Cl^- would enter. But ions cannot cross phospholipid bilayers readily. They cross plasma membranes efficiently in only three ways: (1) flowing along their electrochemical gradient through an ion channel; (2) carried, via a membrane cotransporter, with an ion that experiences a strong electrochemical gradient; or (3) pumped against an electrochemical gradient by a membrane protein that hydrolyzes ATP.

In each case of ion movement across the plasma membrane, a membrane channel or pump is involved. Recall from Chapter 6 that **ion channels** are pores in the membrane that allow only specific ions to pass through. When a neuron is not actively involved in transmitting an electrical signal, the most common

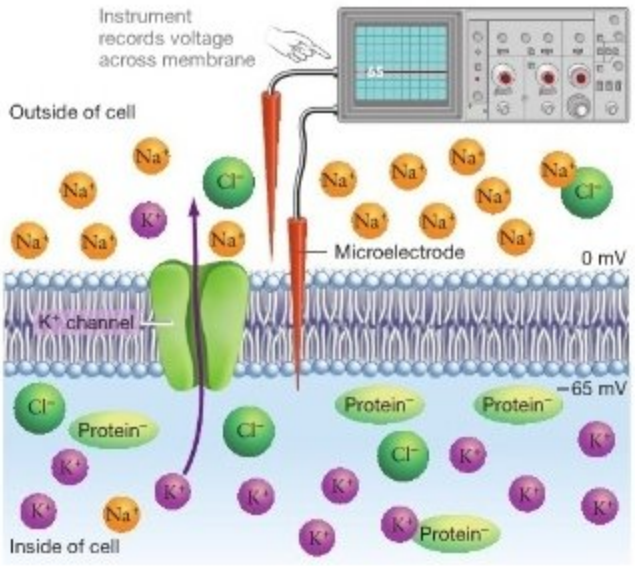

FIGURE 45.4 Neurons Have a Resting Potential. In resting neurons, the membrane is selectively permeable to K^+. As K^+ leaves the cell along its concentration gradient, the inside of the membrane becomes negatively charged relative to the outside. To measure a neuron's membrane potential, researchers insert a microelectrode into the cell and compare that reading with the reading outside the cell.

QUESTION Will K^+ continue to leave indefinitely? Explain why or why not.

type of channel that is open is one that admits potassium ions. Therefore, resting neurons are most permeable to K^+ ions, which cross the membrane easily along their concentration gradient. To capture this point, biologists say that the membrane is **selectively permeable**—it permits a much greater flow of K^+ ions compared with Cl^- or Na^+ ions. The potassium channels involved are sometimes called **leak channels**, because they allow K^+ to leak out of the cell.

As K^+ moves from the interior of the cell to the exterior through potassium channels, the inside of the cell becomes more and more negatively charged relative to the outside. This buildup of negative charge inside the cell begins to attract K^+ and counteract the concentration gradient that had favored the movement of K^+ out. As a result, the membrane reaches a voltage at which there is an equilibrium between the concentration gradient that moves K^+ out and the electrical gradient that moves K^+ in. At this voltage, there is no longer a net movement of K^+. This voltage is called the **equilibrium potential** for K^+. Although Cl^- and Na^+ cross the plasma membrane much less readily than does K^+, some movement of these ions also occurs through a small number of open ion channels that are selective for each ion. As a result, each type of ion has an equilibrium potential. The membrane as a whole has a membrane potential that combines the effects of the individual ions.

Besides the passive movement of ions that takes place when neurons are at rest, Na^+/K^+-ATPase actively pumps Na^+ out of the cell and K^+ into the cell. More specifically, the sodium-potassium pump uses the energy released from the breakdown of ATP to remove three Na^+ ions that had leaked into the cell and simultaneously recover two K^+ ions that had leaked out of the cell (**Figure 45.5**). In this way, active transport via Na^+/K^+-ATPase ensures that eventually the concentration of K^+ is much higher inside the cell than outside, while the concentration of Na^+ is lower inside than outside.

As a result of these concentration differences on the two sides of the membrane, Na^+ ions would readily enter the cell and K^+ ions would rapidly exit the cell if they could cross the plasma membrane easily. In addition, the inside of the neuron is negatively charged with respect to the extracellular environment. Thus, the neuron has a negative resting membrane potential. The resting potential represents energy stored as concentration gradients in a series of ions. ● If you understand this concept, you should be able to add an Na^+/K^+-ATPase to Figure 45.4 and explain why the Na^+/K^+-ATPase and the K^+ "leak" channels are vital to establishing the resting potential.

Box 45.1 discusses how equilibrium potentials for individual ions are calculated, and how data on the relative concentrations and permeabilities of several ions are used to predict the resting potential. How do researchers actually go about measuring the size of this voltage in actual cells?

Membrane Potentials

Using Microelectrodes to Measure Membrane Potentials

During the 1930s and 1940s, A. L. Hodgkin and Andrew Huxley helped pioneer the study of electrical signaling in animals. Their work focused on what has become a classic model

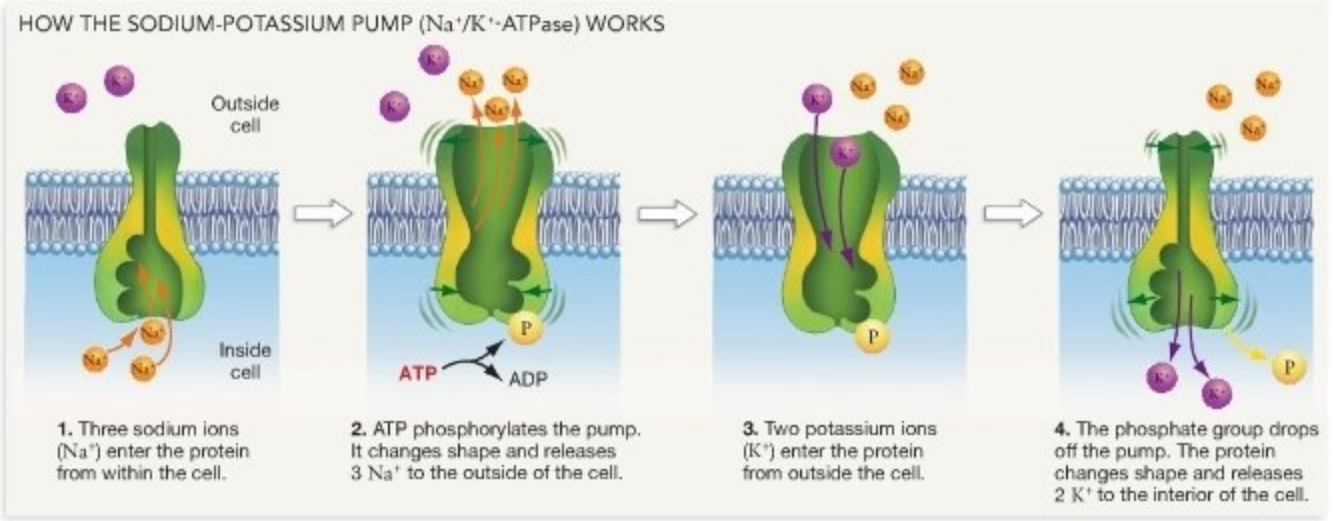

FIGURE 45.5 In Neurons, Na^+/K^+-ATPase Imports Potassium Ions and Exports Sodium Ions. A model of how the pump works. By following radioactive Na^+ and K^+, biologists found that the pump transports 3 Na^+ out of the cell for every 2 K^+ brought in. Notice that this pump operates via a conformational change.

BOX 45.1 Using the Nernst and Goldman Equations

To calculate a membrane voltage created by several ions, biologists begin by calculating the equilibrium potential for each ion involved.

The equilibrium potential for an ion is the voltage that develops across the membrane when the rate at which an ion moves across the membrane down its concentration gradient is equal to the rate at which it moves across the membrane, in the opposite direction, down its electrical gradient. Stated another way, the equilibrium potential is the voltage at which the concentration and electrical gradients acting on an ion balance out. An equilibrium potential exists if there is a concentration gradient for an ion and if the membrane is permeable to that ion.

The ion concentration gradients that contribute to equilibrium potentials are due to the action of Na^+/K^+-ATPase. In this way, chemical energy in the form of ATP is converted to electrical energy in the form of a membrane potential.

To calculate the amount of energy involved, biologists use the Nernst equation—a formula that converts the energy stored in a concentration gradient to the energy stored as an electrical potential. The concentration gradient is symbolized $[ion]_o/[ion]_i$, where $[ion]_o$ and $[ion]_i$ are the concentrations of the ion outside and inside the cell, respectively. The electrical potential for that ion is symbolized E_{ion}. The Nernst equation specifies the equilibrium potential for a type of ion as

$$E_{ion} = 2.3\frac{RT}{zF}\log\frac{[ion]_o}{[ion]_i}$$

In this expression, z is the valence of the ion (for instance, +1 for potassium) and the expression RT/F is known as the thermodynamic potential. The three terms in the thermodynamic potential are the gas constant (R), which acts as a constant of proportionality; the absolute temperature (T), measured in kelvins; and the Faraday constant (F), which specifies the amount of charge carried by one mole of an ion with a valence of +1 or −1. Note that the Nernst equation is based the base-10 logarithm of the ion concentration ratio, $[ion]_o/[ion]_i$. Thus, the thermodynamic potential specifies the voltage required to balance a tenfold concentration ratio across the membrane. (For more on using logarithms, see **BioSkills 5**.)

It is important to remember that the Nernst equation applies to only a single ion. For example, suppose that the potassium concentration inside the axon of a squid neuron has been measured as 400 mM, yet the outside concentration for this ion is only 20 mM (**Table 45.1**). Potassium has a charge of +1, so at 20°C the RT/zF part of the equation yields +25 mV. In this case, the equilibrium potential for potassium becomes

$$E_K = 2.3 \times 25\text{ mV} \times \log\frac{20\text{ mM}}{400\text{ mM}}$$

$$E_K = 58\text{ mV} \times \log 0.05 = -75\text{ mV}$$

The minus sign indicates that the interior of the axon is negatively charged with respect to the exterior. Repeating this process for Na^+ ions and Cl^- ions yields the following results for the squid axon:

$$E_{Na} = 58\text{ mV} \times \log\frac{440\text{ mM}}{50\text{ mM}} = +54.8\text{ mV}$$

$$E_{Cl} = -58\text{ mV} \times \log\frac{560\text{ mM}}{51\text{ mM}} = -60\text{ mV}$$

Again, notice that the equilibrium potential given by the Nernst equation is calculated independently for each ion.

How do individual equilibrium potentials relate to the overall resting membrane potential? The Nernst equation cannot be used to calculate resting membrane potentials, because no cell is permeable to only a single ion. David Goldman described a way to calculate the membrane potential when K^+, Na^+, and Cl^- are able to cross the membrane. The Goldman equation calculates a membrane potential by combining the effects of key individual ions. If the permeabilities to these ions are symbolized as P_K, P_{Na}, and P_{Cl}, respectively, then the membrane potential is given by the following expression:

$$V_m = 58\text{ mV} \times \log\frac{[K^+]_o + \frac{P_{Na}}{P_K}[Na^+]_o + \frac{P_{Cl}}{P_K}[Cl^-]_i}{[K^+]_i + \frac{P_{Na}}{P_K}[Na^+]_i + \frac{P_{Cl}}{P_K}[Cl^-]_o}$$

In a squid's neuron, the relative permeabilities for K^+, Na^+, and Cl^- are described by the ratio 1.0 : 0.03 : 0.1. Given these ratios and the observed concentration of each ion inside and outside the axon, the resting potential of the neuron can be calculated as follows:

$$V_m = 58\text{ mV} \times \log\frac{20 + (0.03)440 + (0.1)51}{400 + (0.03)50 + (0.1)560} = -62.5\text{ mV}$$

This is close to the observed value. The Nernst and Goldman equations are remarkably efficient ways to capture the dyamics of equilibrium potentials and membrane potentials.

TABLE 45.1 **Concentration of Important Ions across a Squid Neuron's Plasma Membrane at Rest**

Ion	Cytoplasm Concentration	Extracellular Concentration	Equilibrium Potential
Na^+	50 mM	440 mM	+54.8 mV
K^+	400 mM	20 mM	−75 mV
Cl^-	51 mM	560 mM	−60 mV
Organic ions$^-$	385 mM	—	—

QUESTION Why isn't there an equilibrium potential for organic ions?

system in the study of electrical signaling: the axons of squid. Squid live in the ocean and are preyed on by fish and whales. When a squid is threatened, electrical signals travel down the axon to muscle cells. When these muscles contract, water is expelled from a cavity in the squid's body. As a result, the squid lurches away from danger by jet propulsion (see Chapter 31). The extremely rapid electrical signal is an adaptation that helps squid avoid predation.

Hodgkin and Huxley decided to study the squid's axon simply because it is so large. Many of the axons found in humans are a mere 2 μm in diameter, but the squid axon is about 500 μm in diameter. The squid axon was large enough that the researchers could record membrane potentials by inserting a wire down its length. That was the best approach available at the time for measuring voltages in cells and required an axon with an exceptionally large diameter.

By measuring the voltage difference between the wire in the interior of the cell and an electrode on the outside of the cell, Hodgkin and Huxley could estimate the voltage that existed across the neuron's plasma membrane and observe how it changed through time. Later, other researchers developed glass microelectrodes that were small enough to be inserted into smaller nerve cells to record membrane voltage.

With their relatively simple early equipment, Hodgkin and Huxley were able to record the axon's resting potential and document that it can be disrupted by an event called the action potential.

What Is an Action Potential?

An **action potential** is a rapid, temporary change in a membrane potential. **Figure 45.6** shows the form of the action potential that Hodgkin and Huxley recorded from the squid's giant axon—the signal that allows these animals to jet away from predators. The action potential has three distinct phases:

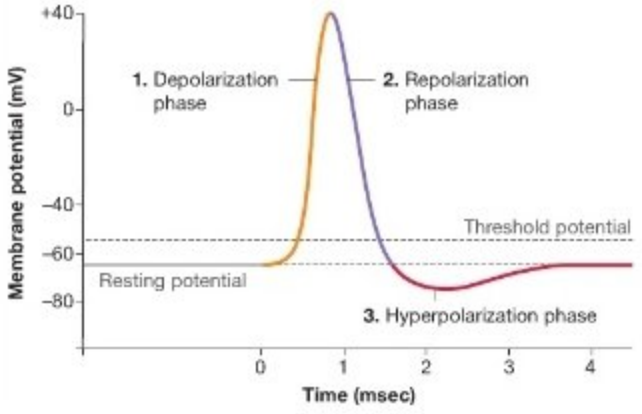

FIGURE 45.6 The Action Potential Is a Stereotyped Change in Membrane Potential. Most action potentials have the general shape shown here.

1. The initial event is a rapid **depolarization** of the membrane. (A membrane is said to be polarized if the charges on the two sides are different. Depolarization means that the membrane becomes less polarized than before.) For an action potential to begin, the membrane potential must shift from its resting potential of −65 mV to about −55 mV. If the membrane depolarizes less than that, an action potential does not occur. But if this **threshold potential** is reached, certain channels in the axon membrane open and ions rush into the axon, following their electrochemical gradients. The current flow causes further depolarization. More specifically, the inside of the membrane becomes less negative and then positive with respect to the outside.
2. When the membrane potential reaches about +40 mV, an abrupt change occurs. This change is triggered by the closing of certain ion channels and the opening of other ion channels in the membrane. During this second phase of the action potential, the membrane experiences a rapid **repolarization** as ions flow out of the axon.
3. The repolarization event actually results in the membrane briefly becoming more negative than the resting potential, a state called **hyperpolarization**. For this reason, biologists call the final part of the action potential the hyperpolarization phase.

Taken together, all three phases of an action potential occur in a few milliseconds.

Hodgkin and Huxley made other important observations about the action potential. In addition to being fast, it is an all-or-none event. There is no such thing as a partial action potential, and all action potentials for a given neuron are identical in magnitude and duration. The biologists also found that action potentials could be triggered by artificially depolarizing the membrane with an injection of electrical current through a microelectrode. Finally, action potentials are propagated down the length of the axon. When an impulse was recorded at a particular point on a squid axon, an action potential that was identical in shape and size would be observed farther down the same axon soon afterward. Neurons are said to have **excitable membranes**, because they are capable of generating action potentials that propagate rapidly along the length of their axons.

Taken together, these observations suggested a mechanism for electrical signaling. In the nervous system, information is coded in the form of action potentials that travel along axons. The frequency of action potentials—not their size—is the meaningful signal. In the squid's giant axon, action potentials signal muscles to contract. As a result, the animal escapes from danger.

Check Your Understanding

If you understand that...

The plasma membranes of neurons carry a resting potential because Na^+/K^+-ATPase pumps Na^+ out of the cell and K^+ into the cell and because the membrane is selectively permeable to K^+ ions, which leak out.

You should be able to...

1) Explain in words what the Nernst equation and Goldman equation do.
2) Predict what would happen to the resting potential of a squid axon if potassium channels were blocked.

45.2 Dissecting the Action Potential

Once it became possible to record rapid changes in membrane potential accurately, an entirely new field of research opened up. The most urgent question was to understand which ions are involved in the currents that form the action potential. Is Na^+, Cl^-, or K^+ responsible for the depolarization and repolarization phases of the event? One early hypothesis was that the action potential resulted from a temporary breakdown in the membrane's selective permeability. The idea was that all channels opened and allowed a free flow of Na^+ and Cl^- as well as K^+. But the all-channels-open hypothesis ran into trouble when researchers were able to measure the concentrations of each ion on the two sides of the squid's axon membrane. Given the observed concentrations of ions when the neuron was at rest, the all-channels-open hypothesis predicted that the peak of the action potential should occur at about 0 mV, not the +40 mV observed.

In contrast, Hodgkin noted that +40mV was close to the equilibrium potential for Na^+. This insight led to the hypothesis that the action potential's depolarization phase resulted from an influx of sodium ions. How could this idea be tested?

Distinct Ion Currents Are Responsible for Depolarization and Repolarization

To understand the currents responsible for the action potential, Hodgkin and Huxley recorded electrical activity in a squid axon bathed in seawater. Then they replaced the seawater with an isotonic solution containing an uncharged and metabolically inert sugar called dextrose. **Figure 45.7** shows the result of this experiment. Washing Na^+ out of the solution surrounding the axon abolished action potentials. But when the biologists replaced the dextrose solution with seawater, action potentials were restored. Further, when they used solutions with various concentrations of Na^+ instead of seawater, Hodgkin and Huxley found that the peak of the action potential tracked the equilibrium potential of Na^+ as it varied with Na^+ concentration outside the cell. Taken together, the data furnished strong support for the hypothesis

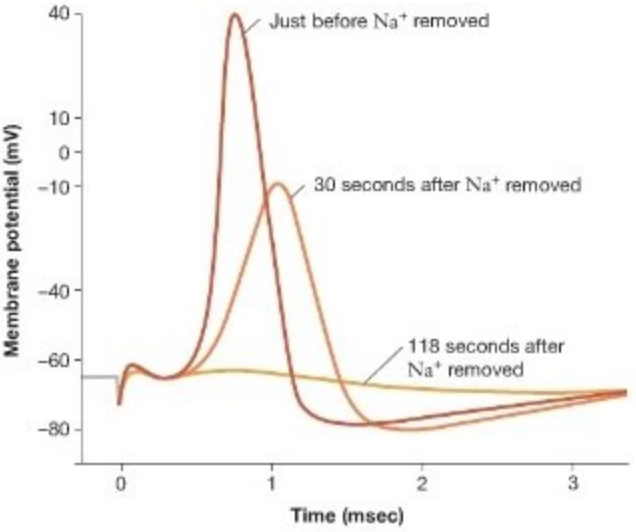

FIGURE 45.7 Action Potentials Diminish when Na^+ Is Removed from the Solution Surrounding a Neuron. Action potentials recorded at intervals after a solution containing Na^+ was flushed away from a squid axon with a solution containing isotonic dextrose.

QUESTION Why was it important that the researchers used an isotonic solution of dextrose?

that the action potential begins when Na^+ flows into the neuron. Sodium ions are responsible for the depolarization phase.

What flow of ions is responsible for the repolarization phase of an action potential? Using radioactive K^+, Hodgkin and Huxley showed that there was a strong flow of potassium ions out of the cell during the repolarization phase. Thus, the action potential consists of a strong inward flow of sodium ions followed by a strong outward flow of potassium ions. If you understand this concept, you should be able to add labels that read, "Sodium channels open—Na^+ enters" and "Potassium channels open—K^+ leaves" to Figure 45.6. Which ion channels are responsible for these currents, and how do they work?

How Do Voltage-Gated Channels Work?

When ion channels were introduced in Chapter 6, they were presented as simple, static proteins that facilitate a constant stream of ions. But research on the action potential suggests that certain ion channels open and close in response to changes in membrane voltage. These types of proteins are called **voltage-gated channels**. The conformation of voltage-gated channels changes in response to the charges present at the membrane surface. These conformational changes lead to the opening or closing of the channels.

To study the relationship between membrane voltage and channel activity, Hodgkin and Huxley used a technique called voltage clamping. **Voltage clamping** allows researchers to hold an axon at any voltage and record the electrical currents generated by flows of Na^+ and K^+ across the membrane.

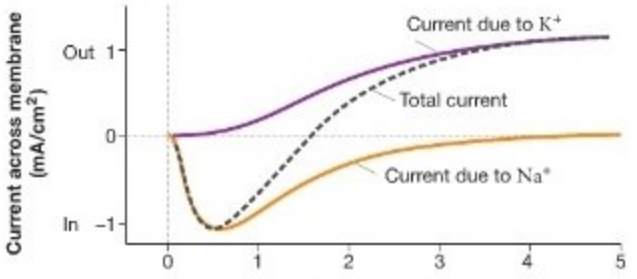

FIGURE 45.8 Voltage Clamping Allows Researchers to Record Current Flows across Membranes. When Hodgkin and Huxley voltage-clamped a squid axon at −9 mV, they recorded the flow of current shown in the dashed record. Current initially flowed into the axon and then back out. As the orange and purple records show, this overall current is due to a rapid flow of Na^+ into the cell and a slower flow of K^+ out of the cell.

Figure 45.8 shows the currents that Hodgkin and Huxley recorded when they voltage-clamped a squid axon at −9 mV. The dashed record shows the current that resulted from the depolarization. Notice that this record indicates a rapid inward-directed current followed by a slower outward-directed current. The orange and purple records break this overall current down into the components due to an inward flow of Na^+ and outward flow of K^+, respectively.

This experiment, and others like it, confirmed that Na^+ and K^+ channels open in response to changes in voltage. When the plasma membrane in the region of the axon is depolarized, voltage-gated Na^+ channels open for less than a millisecond. Sodium ions rush into the cell through these open channels, because the Na^+ concentration is much higher outside the cell and because Na^+ ions are attracted to the negatively charged interior. The result is that the inside of the membrane becomes more positively charged—it goes from a resting potential of −70 mV to −50 mV. This change in electrical potential triggers many additional Na^+ channels to open. As a result, Na^+ ions flood the interior, generating an action potential. Shortly after the action potential is under way, the voltage-gated Na^+ channels close and voltage-gated K^+ channels open.

Hodgkin and Huxley's data also answered an important question: If Na^+ flows in and K^+ flows out, why don't the two currents cancel each other out? The key observation is that the potassium current is delayed. The Na^+ channels close as the membrane potential approaches +54 mV and as the voltage-gated K^+ channels open. At this point, the interior of the membrane contains excess positive charge and favors the outward flow of K^+ through the open K^+ channels. As K^+exits the cell, the membrane potential drops back toward resting levels.

To summarize, early work on electrical signaling showed that action potentials result from the staggered activity of voltage-gated Na^+ and K^+ channels. ● If you understand this concept, you should be able to explain (1) why the opening of Na^+ channels depolarizes a membrane, and (2) why flows of K^+ repolarize the membrane. Once this sequence of events was worked out, attention turned to the channels themselves. How do these voltage-gated proteins work?

Patch Clamping and Studies of Single Channels Studying individual ion channels became possible when Erwin Neher and Bert Sakmann perfected a technique known as **patch clamping**. As **Figure 45.9a** shows, the researchers touched a membrane with a fine-tipped microelectrode and then applied suction to capture a single ion channel within the tip of the microelectrode. The suction seals the membrane against the glass so that no current leaks out. Using this technique, the researchers documented the currents that flowed through individual channels. The recordings shown in **Figure 45.9b** are typical, and they make several important points about the nature of voltage-gated channels:

- *Voltage-gated channels are either open or closed.* There is no gradation in channel behavior. This conclusion is based on the shape of the current records.
- *Sodium channels open quickly after depolarization.* They stay open for about a millisecond and then close. As Na^+ rushes into the axon, the inside becomes electrically positive. Shortly after the initial depolarization, the sodium channels close and remain inactive for 1 to 2 milliseconds. That explains why the cell can repolarize: Once the sodium channels close, they have a lag before they can open again. **Figure 45.9c** shows a simplified model of how voltage-gated sodium channels open.
- *Potassium channels open with a delay after depolarization.* They continue to flip open and closed until the membrane repolarizes. Once the membrane returns to the resting potential, these channels remain closed.

Observations of the behavior of Na^+ channels also helped explain why the action potential is an all-or-none event. The key observation is that Na^+ channels are more likely to open as a membrane depolarizes. An initial depolarization thus leads to the opening of more Na^+ channels, which depolarizes the membrane further and leads to the opening of additional Na^+ channels. In this way, the opening of Na^+ channels exhibits **positive feedback**. This type of control mechanism takes place when the occurrence of an event makes the same event more likely to recur. When a fuse is lit, for example, the heat generated by the oxidation reaction accelerates the reaction itself, which generates still more heat and leads to additional oxidation reactions and keeps the fuse burning. Positive feedback is rare in organisms because it often leads to uncontrolled events. The opening of Na^+ channels during an action potential is one of the few examples known.

● If you understand how sodium and potassium channels work, you should be able to explain (1) why positive feedback occurs in the opening of Na^+ channels, (2) why Na^+ stops flowing across a membrane during an action potential, and (3) why K^+ channels start opening.

Voltage clamping and patch clamping were not the only technical advances that helped researchers explore the dynamics of

voltage-gated channels. The discovery of poisons that target neurons, from sources as diverse as venomous snakes and foxglove plants, also provided important experimental tools.

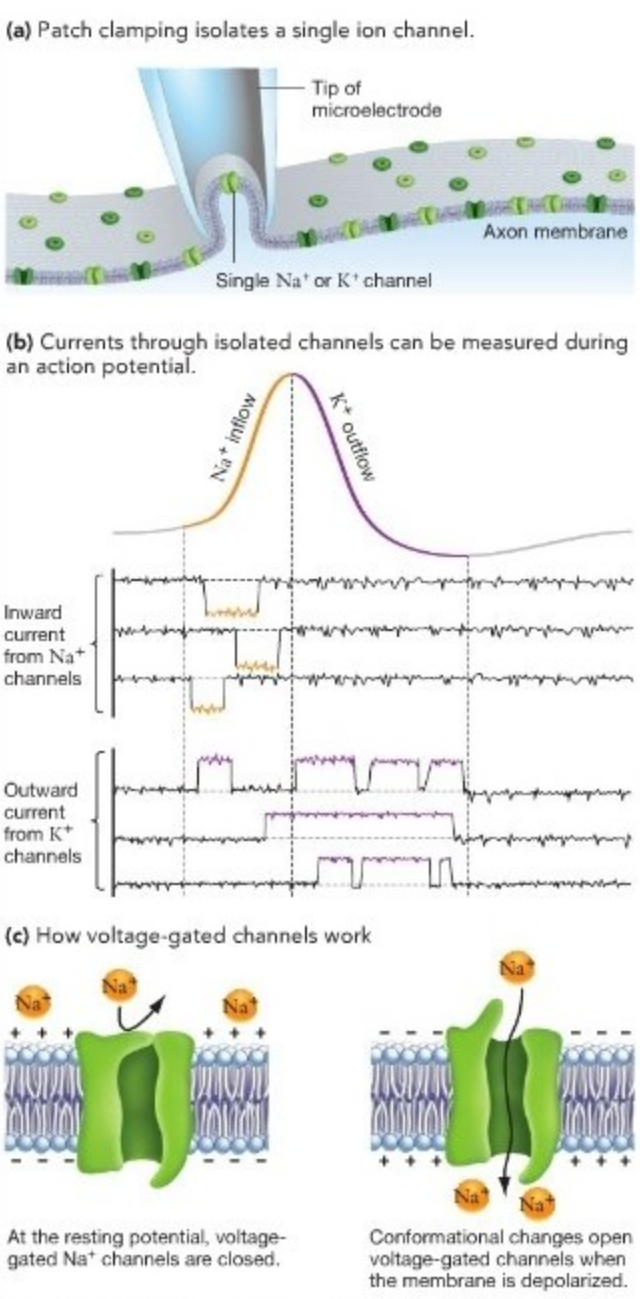

FIGURE 45.9 Patch Clamping Allows Researchers to Record from Individual Channels. **(a)** Patch clamping depends on the use of extremely fine-tipped microelectrodes. The goal is to isolate one channel and record from it. **(b)** Current records from three voltage-gated sodium channels and three voltage-gated potassium channels. No current flows through either type of channel at the resting potential. **(c)** Changes in the conformation of voltage-gated channels are responsible for changes in a neuron's permeability to Na^+ and K^+.

Using Neurotoxins to Identify Channels and Dissect Currents Many of the toxins produced by poisonous animals and plants cause convulsions, paralysis, or unconsciousness when they are ingested. Based on these symptoms, physicians and researchers suspected that at least some poisons affect neuron function; such poisons are known as **neurotoxins**. This hypothesis was supported when biologists used the tetrodotoxin found in puffer fish to treat giant axons from lobsters. Although the resting potential in treated neurons was normal, action potentials were abolished. More specifically, the outward-directed K^+ current was normal but the inward-directed Na^+ flow was wiped out. Based on this result, researchers concluded that puffer-fish toxin specifically blocks the voltage-gated Na^+ channel. The hypothesis is that the toxin binds to a specific site on the channel protein, preventing the channel from functioning. Thus, researchers can use neurotoxins to block only certain channels.

In contrast, when researchers treated neurons with the venom of black mamba snakes, preliminary data hinted that K^+ channels were blocked. To test this finding more rigorously, researchers bathed neurons in a solution containing black-mamba poison and studied the K^+ currents that resulted. As predicted, the poison had a dramatic effect on membrane permeability to K^+. However, the venom did not stop the current completely. Instead, the data suggest that a specific K^+ channel was poisoned but that other K^+ channels still allowed an outflow of current (**Figure 45.10**). The existence of multiple K^+ channels in axons was confirmed by patch-clamping studies that documented K^+ flowing through several types of K^+ channels, each of which had distinct properties. Experiments with neurotoxins helped establish that most neurons contain just one type of sodium channel but several types of potassium channels.

The experiments reviewed thus far haven't considered a fundamental question about electrical signaling, however: How do action potentials move down the axon?

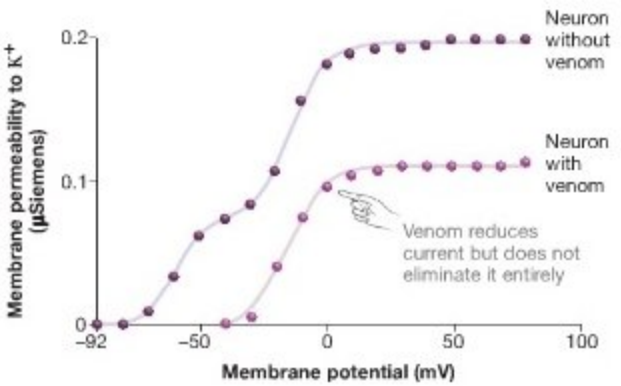

FIGURE 45.10 Experiments with Poisons Showed that There Is More than One Potassium Channel. Neuron permeability to K^+ as a function of membrane voltage (μSiemens are a unit of conductance). Each data point was generated by measuring membrane permeability while the membrane was voltage-clamped at a particular potential.

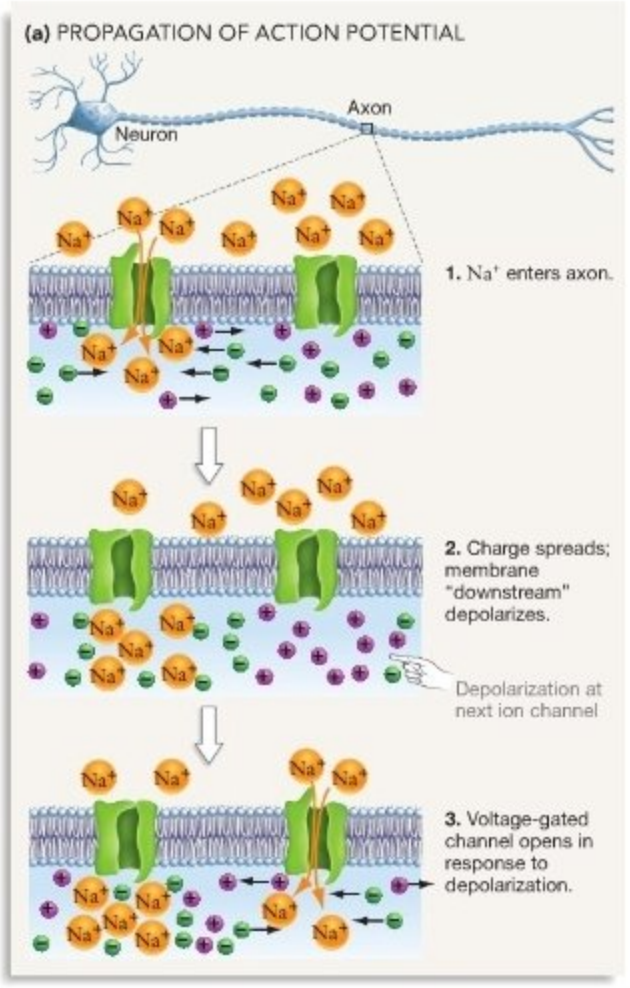
How Is the Action Potential Propagated?

To explain how action potentials propagate down an axon, Hodgkin and Huxley hypothesized that the influx of Na^+ causes charge to spread away from sodium channels. As **Figure 45.11a** shows, positive charges inside the cell are repulsed by the influx of Na^+, and negative charges are attracted to the Na^+. As these positive charges are pushed farther from the initial sodium channel, they create a local current that causes new sections of the membrane, close to the initial site of an action potential, to become depolarized. Voltage-gated Na^+ channels that are nearby pop open in response, positive feedback occurs, and a full-fledged action potential results. In this way, an action potential is continuously regenerated as it moves down the axon (**Figure 45.11b**). The signal does not diminish as it moves, because the response is all or none.

Why don't action potentials propagate back up the axon? The answer is that Na^+ channels are **refractory**—that is, once they have opened and closed, they are less likely to open again for a short period. Action potentials are propagated in one direction only, because sodium channels "downstream" of the site are not in the refractory state. The hyperpolarization phase, in which the membrane is more negative than the resting potential—also keeps the charge that spreads "upstream" from triggering an action potential in that direction.

Understanding how the action potential propagates helped researchers explain why the squid's axons are so large. The same amount of charge spreads farther in an axon with a large diameter versus a small diameter, because proportionally less charge spreads to the side and is "lost" in terms of conducting the signal. As a result, the squid's giant axon and other large neurons transmit action potentials much faster than small axons can. The squid axon's large size is an adaptation that makes particularly rapid signaling possible.

Analyzing charge spread also helped biologists explain the phenomenon called myelination. Relatively few vertebrates have giant axons. Instead, in vertebrates—and some invertebrates—the membranes of specialized accessory cells wrap around the axons of neurons. In the central nervous system, these cells are **oligodendrocytes**. In the peripheral nervous system, described in Section 45.4, the cells are **Schwann cells** (**Figure 45.12a**). Oligodendrocytes and Schwann cells are two of several types of nervous system cells that support neurons. Collectively, these accessory cells are called **glia**. When oligodendrocytes or Schwann cells wrap around an axon, they form a **myelin sheath**, which acts as a type of electrical



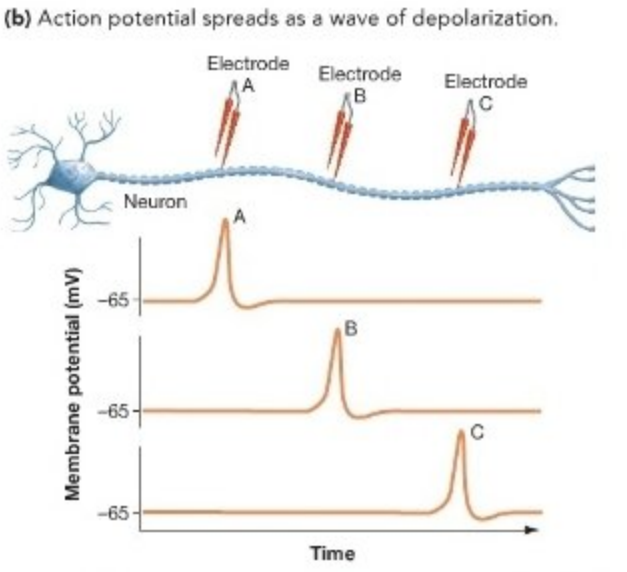


FIGURE 45.11 Action Potentials Propagate because Charge Spreads down the Membrane. (a) An action potential starts with an inflow of Na^+. The influx of positive charge attracts negative charges inside the cell and repels positive charges. As a result, positive charge spreads away from the channel where the Na^+ enters, and depolarizes nearby regions of the neuron. Voltage-gated Na^+ channels open in response. **(b)** The action potential spreads down the axon as a wave of depolarization, but there is no loss of signal because the all-or-none action potential regenerates itself as it travels.

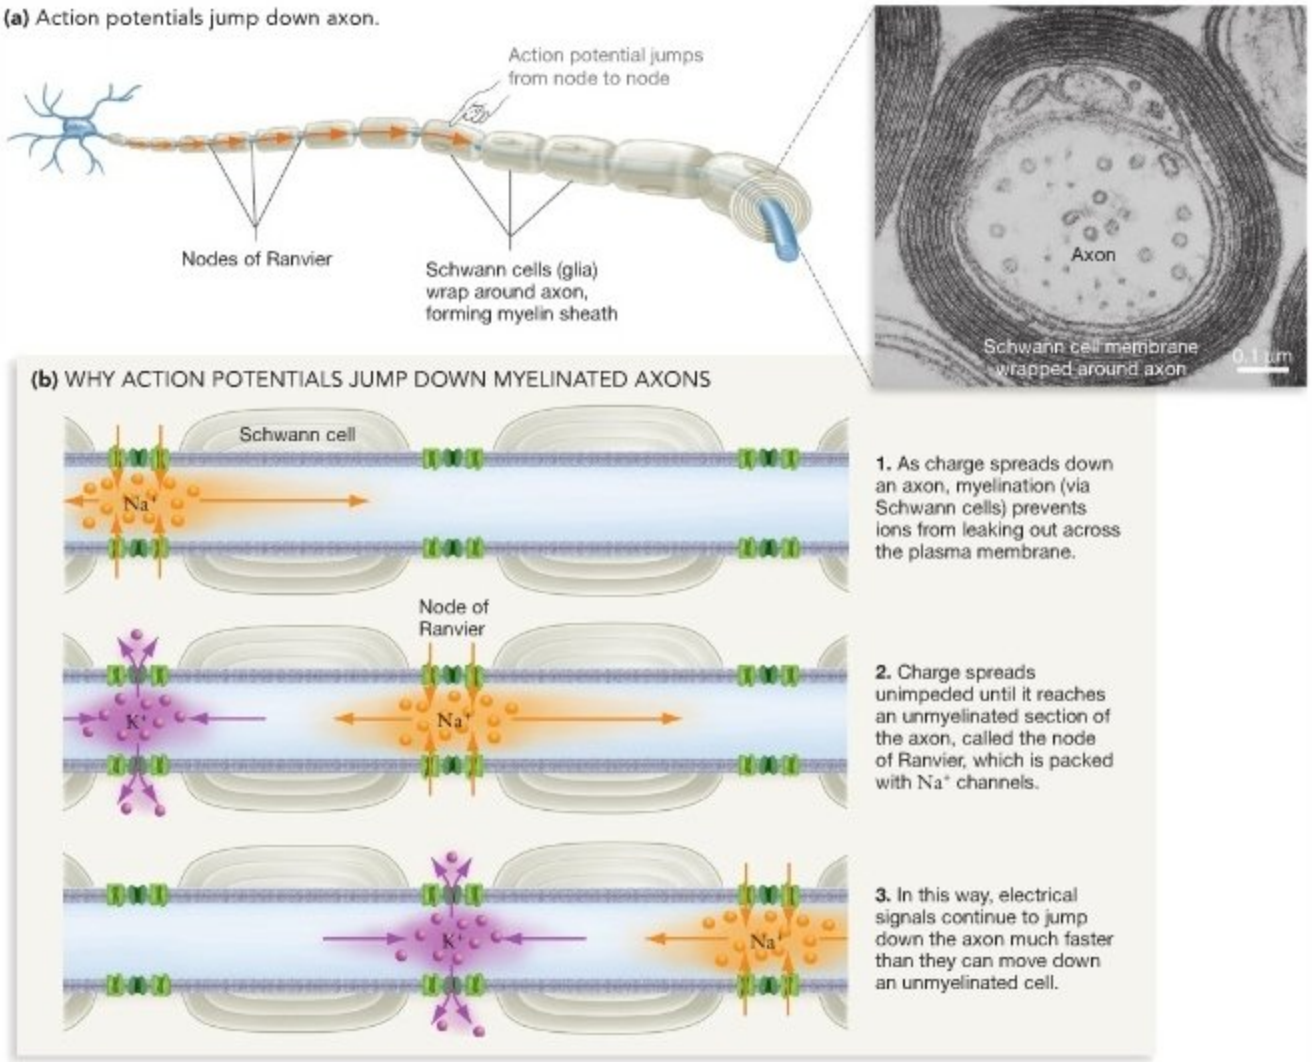

FIGURE 45.12 Action Potentials Propagate Quickly in Myelinated Axons.

insulation. As charge spreads down an axon, the presence of the myelin sheath prevents charge in the form of ions from leaking out across the plasma membrane of the neuron. Consequently, the influx of charge that results from an action potential is able to spread unimpeded until it hits an unmyelinated section of the axon, called a **node of Ranvier** (**Figure 45.12b**). The node has a dense concentration of voltage-gated Na^+ channels, so action potentials can occur. In this way, electrical signals jump down the myelinated axon much faster than they can move down an unmyelinated axon. In an unmyelinated axon, sodium and potassium channels are found in all locations and action potentials occur continuously down its length. ● If you understand this concept, you should be able to draw a diagram like Figure 45.12, showing how action potentials are slowly propagated down the length of unmyelinated axons. (Hint: Consult Figure 45.11a.) Myelination is interpreted as an adaptation that makes rapid transmission of electrical signals possible in axons that have a small diameter.

To drive the importance of myelination home, consider what happens when it is decreased. If myelin degenerates, the transmission of electrical signals slows considerably. The disease **multiple sclerosis** (**MS**) develops as damage to myelin increases and electrical signaling is impaired, causing the muscles to weaken and coordination to lessen. The symptoms of MS are highly variable; in severe cases the disease progresses and can be crippling.

What happens once an action potential has traveled the length of the axon? Ramón y Cajal proposed, and electron microscopy confirmed, that in most neurons the membrane at the end of the axon approaches the membrane of another neuron's dendrite. The surfaces of the two membranes are separated by a tiny gap. What happens when an action potential arrives at this interface between cells?

Check Your Understanding

If you understand that...

- During an action potential, membrane voltage undergoes rapid changes due to an influx of sodium ions, followed by an outflow of potassium ions.
- Action potentials propagate down an axon because inrushing sodium ions depolarize adjacent portions of the membrane.

You should be able to...

1) Diagram the changes in membrane voltage that occur during the action potential, and add notes explaining why —at the molecular level—each step in the signal occurs.
2) Make a labeled diagram that explains why an action potential spreads down an axon.
3) Explain how voltage gating works, why the action potential is an all-or-none phenomenon, why the refractory nature of sodium channels is important, and why myelination increases the speed of electrical signals.
4) Predict what would happen if sodium channels continued to open once membrane depolarization was complete.

45.3 The Synapse

The cytoplasm of most neurons is not directly connected to the cytoplasm of other neurons. Based on this observation, there must be some indirect mechanism that transmits electrical signals from cell to cell, across their plasma membranes. In the 1920s Otto Loewi showed that the indirect mechanism involves molecules called neurotransmitters. **Neurotransmitters** are molecules that transmit information from one neuron to another neuron or from a neuron to a target cell in a muscle or gland.

Loewi was interested in how the nervous system affects the heart rate, and he knew that signals from the vagus nerve—a nerve that originates in the brain stem and extends into the abdomen—slow the heart. He performed the experiment diagrammed in **Figure 45.13** to test his hypothesis that the signal from nerve to muscle is delivered by a chemical. First, he isolated the vagus nerve and heart of a frog. As predicted, the heart rate slowed when he stimulated the nerve electrically. But when he took the solution that bathed the first heart and applied it to another, isolated heart, the second heart rate slowed as well. This result provided strong evidence for the chemical transmission of electrical signals. The vagus nerve had released a neurotransmitter into the bath.

How are neurotransmitters delivered? When transmission electron microscopy became available in the 1950s, biologists finally understood the physical nature of the interface between neurons. This interface is called a **synapse**. As **Figure 45.14** shows, the membranes of axons and dendrites juxtapose closely. The figure also shows that the ends of axons contain numerous

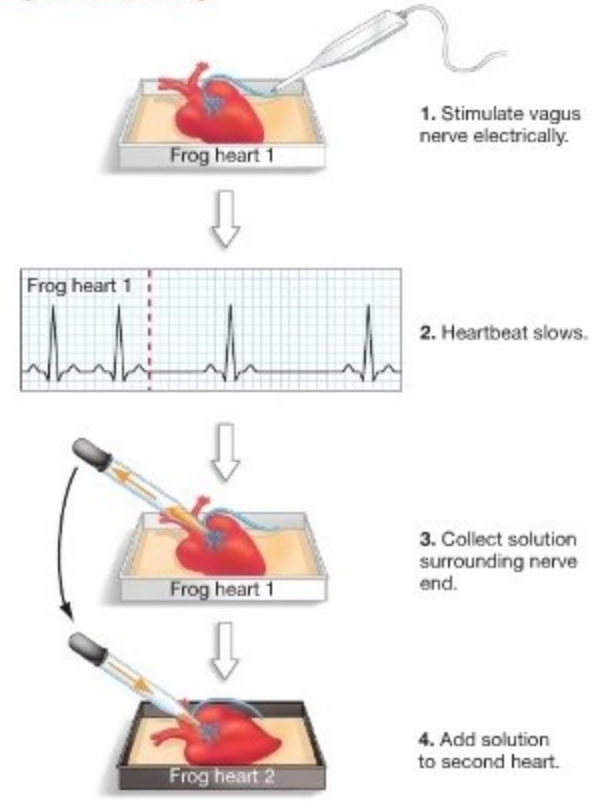
Experiment

Question: How is information transferred from one neuron to another?

Hypothesis: Molecules called neurotransmitters carry information from one neuron to the next.

Null hypothesis: Information is not transferred between neurons in the form of molecules.

Experimental setup:



Prediction: The heartbeat will slow.

Prediction of null hypothesis: There will be no change in heartbeat.

Results:

Conclusion: The vagus nerve releases molecules that slow heartbeat. Neurotransmitters carry information.

FIGURE 45.13 Experimental Evidence for the Existence of Neurotransmitters.

QUESTION Prior to this experiment, some researchers contended that most neurons communicated with each other or target cells electrically, not chemically. Why does this experiment fail to support the hypothesis of electrical transmission? (Note: It turns out that a few neurons do make electrical connections with one another.)

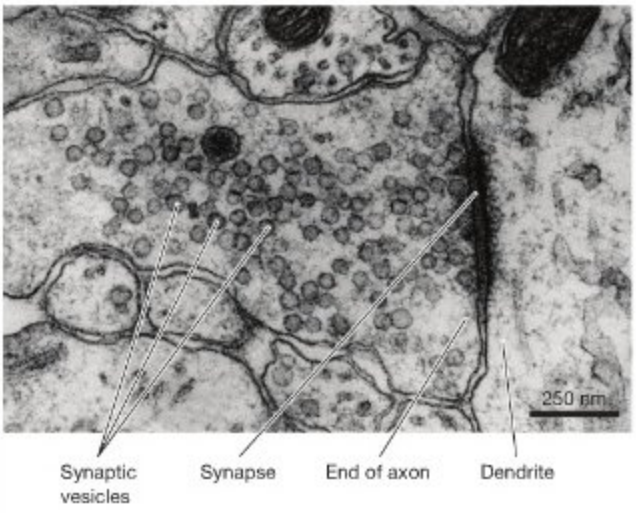


FIGURE 45.14 Synaptic Vesicles Cluster Near Synapses. A cross section of the site where an axon meets a dendrite.

sac-like structures called **synaptic vesicles**. These structures were hypothesized to be storage sites for neurotransmitters.

Anatomical observations such as these, combined with chemical studies of the synapse, led to the model of synaptic transmission illustrated in **Figure 45.15**. Notice that the "sending" cell is called the **presynaptic neuron** and the "receiving" cell is called the **postsynaptic neuron**. The sequence of events begins when the depolarization created by an action potential opens voltage-gated calcium channels located near the synapse, in the presynaptic membrane. The electrochemical gradient for Ca^{2+} results in the inflow of calcium ions through the open channels. In response to the increase in calcium concentration inside the axon, synaptic vesicles fuse with the membrane and release a neurotransmitter into the gap between the cells. This gap is called the **synaptic cleft**. The delivery of neurotransmitters into the cleft is an example of exocytosis, a process introduced in Chapter 7.

What happens next? Biologists hypothesized that neurotransmitters bind to receptors in the membrane of the next cell in the circuit. As step 3 in Figure 45.15 shows, the idea was that interactions between neurotransmitters and receptors on the postsynaptic cell would cause a change in the membrane potential of the postsynaptic cell and possibly trigger the start of an action potential there. Is this part of the model correct?

What Do Neurotransmitters Do?

Once Loewi had established that neurotransmitters exist, investigators were able to isolate and purify them from a variety of neurons. They accomplished this by stimulating a neuron, collecting the neurotransmitter that was released, and analyzing it chemically. To find the receptor for a particular neurotransmitter, researchers could add a radioactive label to the neurotransmitter and add the labeled transmitter to neurons. Once the labeled transmitter had bound to its receptor, the receptor protein could be identified, isolated, and analyzed.

Using techniques such as these, biologists have discovered and characterized a wide array of neurotransmitters and receptors, some of which are listed in **Table 45.2**. To establish that a molecule functions as a neurotransmitter, researchers have to provide evidence for the following three criteria: (1) The neurotransmitter is present at the synapse and released in response to an action potential, (2) it binds to a receptor on a postsynaptic cell, and (3) it is taken up or degraded.

By patch-clamping receptors, biologists confirmed that many neurotransmitters function as ligands. A **ligand** is a molecule

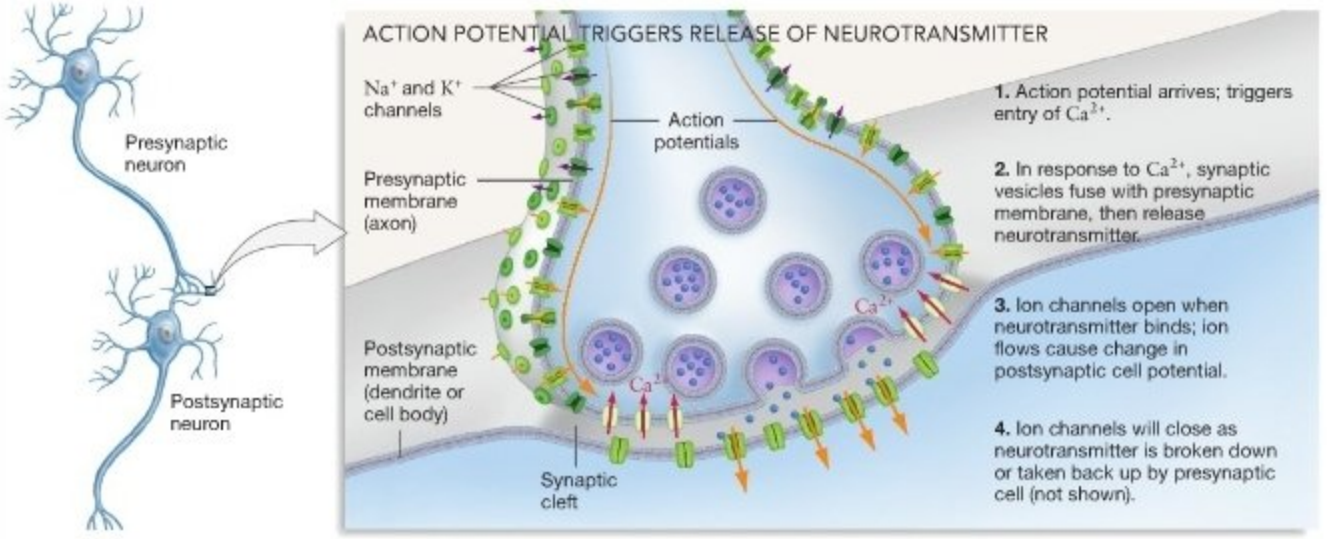

FIGURE 45.15 Neurons Meet and Transfer Information at Synapses. The sequence of events that occurs when an action potential arrives at a synapse.

TABLE 45.2 **Categories of Neurotransmitters**

Excitatory neurotransmitters make action potentials more likely in postsynaptic cells. Inhibitory neurotransmitters make them less likely; modulatory neurotransmitters modify the response at other synapses. Drugs that prevent re-uptake of neurotransmitters increase their activity.

Neurotransmitter	Site of Action	Action	Drugs That Interfere
Acetylcholine	Neuromuscular junction, some CNS pathways	Excitatory (inhibitory in some parasympathetic neurons)	• Botulism toxin blocks release • Black widow spider venom increases, then eliminates, release • α-bungarotoxin (in some snake venoms) binds to receptor
Monoamines			
Norepinephrine	Sympathetic neurons, some CNS pathways	Excitatory or inhibitory	• Ritalin (used for ADHD) increases release • Some antidepressants prevent re-uptake
Dopamine	Many CNS pathways	Primarily excitatory	• Cocaine prevents re-uptake • Amphetamines prevent re-uptake
Serotonin	Many CNS pathways	Inhibitory or modulatory	• MDMA (ecstasy) causes increased release • Prozac, Paxil, Zoloft prevent re-uptake
Amino Acids			
Glutamate	Many CNS pathways	Excitatory	• PCP blocks receptor
Gamma-aminobutyric acid (GABA)	Some CNS pathways	Inhibitory	• Ethanol mimics response
Peptides			
Endorphins, enkephalins, substance P	Used in sensory pathways (pain)	Inhibitory	

that binds to a specific site on a receptor molecule. Many neurotransmitters are ligands that bind to receptors called **ligand-gated channels**. These are channel proteins that open in response to binding by a specific ligand. When a neurotransmitter binds to a ligand-gated ion channel in the postsynaptic membrane, the channel opens and admits a flow of ions. In this way, the neurotransmitter's chemical signal is transduced to an electrical signal—a change in the membrane potential of the postsynaptic cell. If you understand this concept, you should be able to draw a membrane with a resting potential of −65 mV and explain what happens when a ligand-gated ion channel opens and allows chloride ions to leave the cell.

Not all the receptors to which neurotransmitters bind are ion channels, however. Some receptors activate enzymes that lead to the production of a second messenger molecule in the postsynaptic cell. Recall from Chapter 8 that **second messengers** are chemical signals produced inside a cell in response to a chemical signal that arrives at the cell surface. The second messengers induced by neurotransmitters may trigger changes in enzyme activity, gene transcription, or membrane potential. The role of second messengers in cells is explored in detail in Chapter 47.

Postsynaptic Potentials and Summation

What happens when a neurotransmitter binds to a receptor and opens an ion channel? As the scanning electron micrograph in **Figure 45.16a** indicates, numerous synapses can be found in the same region of a dendrite or cell body. And as **Figure 45.16b** illustrates, these synapses can be one of two general types. If the receptors at the synapse admit sodium ions in response to the arrival of the neurotransmitter, then the postsynaptic membrane depolarizes in response to an action potential in the presynaptic cell. In most cases, depolarization makes an action potential in the postsynaptic cell more likely. Changes in the postsynaptic cell that make action potentials more likely are called **excitatory postsynaptic potentials** (**EPSPs**). Other receptors, in contrast, lead to an outflow of potassium ions or an inflow of chloride ions in the postsynaptic cell. These events hyperpolarize the membrane and make action potentials less likely to occur in the postsynaptic cell. Changes in the postsynaptic cell that make action potentials less likely are called **inhibitory postsynaptic potentials** (**IPSPs**). Synapses can be excitatory, inhibitory, or modulatory—meaning that they modify a neuron's response to other EPSPs or IPSPs.

It is critical to realize that, unlike action potentials, EPSPs and IPSPs are not all-or-none events. Instead, they are graded in size. The size of an EPSP or IPSP depends on the amount of neurotransmitter that is released at the synapse. Both types of signal are short lived because neurotransmitters do not bind irreversibly to channels in the postsynaptic cell. Instead, they are quickly inactivated or taken up by the presynaptic cell and recycled. If either the amount or life span of neurotransmitters is altered, the normal functioning of neurons is altered. The street drugs cocaine and amphetamine, for example, exert their effects by inhibiting the uptake and recycling of particular neurotransmitters. (see Table 45.2)

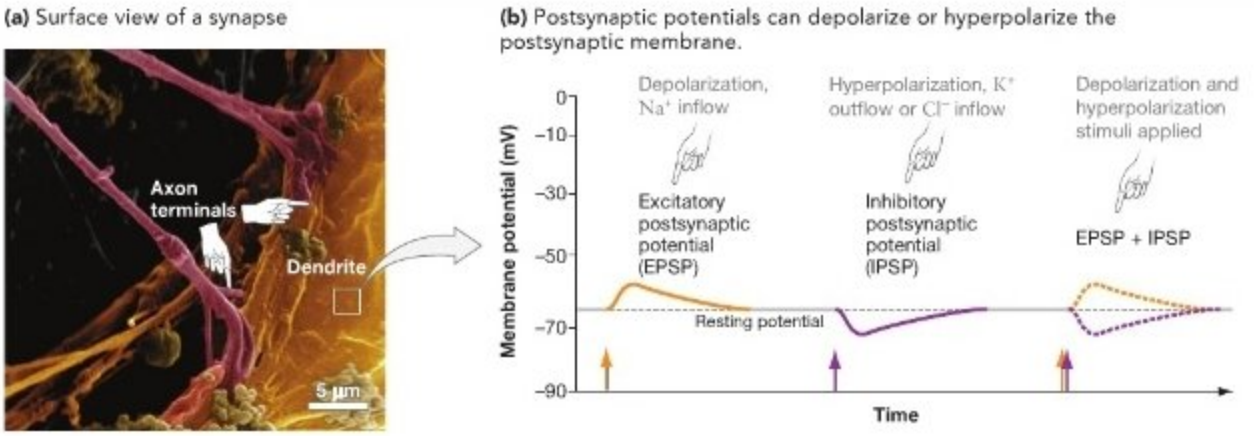

FIGURE 45.16 There Are Two Major Types of Synapses, Distinguished by Whether They Lead to Depolarization or Hyperpolarization of the Membrane. **(a)** Scanning electron micrograph showing axons from one neuron synapsing with the dendrite of a second neuron. **(b)** Records showing that the arrival of an action potential causes a short-lived depolarization or hyperpolarization of the postsynaptic plasma membrane. The change in postsynaptic potential can be excitatory or inhibitory, depending on whether it makes action potentials more or less likely. If both excitatory and inhibitory signals arrive at the same time, they cancel one another and the cell remains at resting level.

What effect do EPSPs and IPSPs have on the postsynaptic cell? As **Figure 45.17a** shows, the many dendrites and the cell body of a neuron typically make hundreds or thousands of synapses with other cells. At any instant, the EPSPs and IPSPs that occur at each of these synapses lead to short-lived surges of charge in the dendrites and cell body of the postsynaptic cell. If an IPSP and EPSP occur close together in space or time, the changes in membrane potential tend to cancel each other out (see Figure 45.16b). But if several EPSPs occur close together in space or time, they sum and make the neuron likely to fire an action potential (**Figure 45.17b**). The additive nature of postsynaptic potentials is termed **summation.**

The sodium channels that trigger action potentials in the postsynaptic cell are located near the start of the axon at a site called the **axon hillock** (see Figure 45.17a). As IPSPs and EPSPs are received and interact throughout the dendrites and cell body, charge spreads to the axon hillock. If the membrane at the axon hillock depolarizes past the threshold potential, enough sodium channels open to trigger positive feedback and an action potential. Once an action potential starts at the axon hillock, it propagates down the axon to the next synapse.

The summation that occurs prior to the axon hillock is a crucial phenomenon, because it determines whether an action potential begins in the postsynaptic cell. It also explains why the chemical transmission of electrical signals and synapses exists in the first place. If the plasma membranes and cytoplasm of adjacent neurons were continuous, then action potentials would

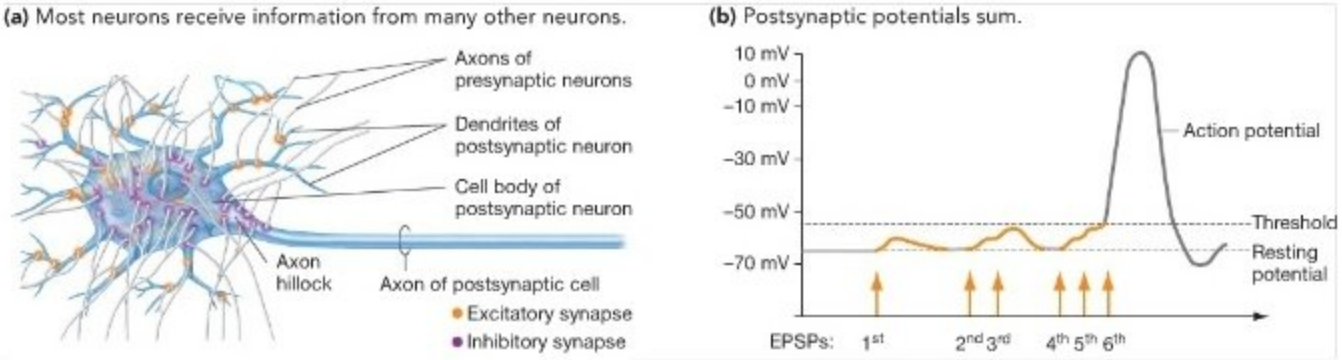

FIGURE 45.17 Neurons Integrate Information from Many Synapses. **(a)** The dendrites and cell body of a neuron typically receive signals from hundreds or thousands of other neurons. **(b)** When action potentials arrive close together in time from the same axon or from different axons with synapses close to one another, the postsynaptic potentials sum. In this example, the first excitatory signal is insufficient to generate an action potential. Two excitatory signals arriving close together cause summation but do not reach the threshold for generating an action potential. Three excitatory signals arriving closely spaced sum to exceed the threshold. If excitatory postsynaptic potentials depolarize the axon hillock past threshold, enough Na^+ channels open to trigger an action potential.

simply propagate from one cell to another without changing. But because neurons receive input from many synapses and because IPSPs and EPSPs sum, information in the form of electrical signals is modified at the synapse before being passed along. In addition, it turns out that synapses are dynamic—their behavior can change through time in response to events. This "plasticity" in the structure and function of synapses underlies many types of processes, including learning and memory.

The general message is that the postsynaptic cell integrates information from hundreds or thousands of other neurons. The information arrives in the form of action potentials that produce EPSPs and IPSPs. If the combination of postsynaptic potentials depolarizes the membrane at the axon hillock sufficiently, the postsynaptic cell fires an action potential in response. But if the events lead to a depolarization that is below threshold, the rate of firing decreases.

Check Your Understanding

If you understand that...

- At a synapse, electrical information in the form of changes in membrane voltage is transduced to chemical information in the form of the release of neurotransmitter.
- Binding of a neurotransmitter to its receptor causes a change in the membrane potential of the postsynaptic cell.

You should be able to...

Explain why the presence of synapses is important to a neuron's ability to integrate and process information from many different neurons.

Action Potentials; How Neurons Work

45.4 The Vertebrate Nervous System

The first three sections of this chapter examined electrical signaling at the level of molecules, membranes, and individual cells. The goal of this section is to discuss electrical signaling at the level of tissues, organs, and systems.

To begin, let's consider the overall anatomy of the vertebrate nervous system. Then we can ask how researchers explore the function of the most complex organ known: the human brain. The chapter concludes by returning to the molecular level and introducing recent work on learning and memory.

What Does the Peripheral Nervous System Do?

Biologists routinely distinguish the central nervous system, or CNS, from the peripheral nervous system, or PNS. Recall from Section 45.1 that the CNS is made up of the brain and spinal cord and is concerned primarily with integrating information, and that the PNS is made up of neurons outside the CNS.

What specific functions do the cells of the PNS control? Anatomical and functional studies indicate that the PNS consists of two systems with distinct functions: (1) an **afferent division**, which transmits sensory information to the CNS, and (2) an **efferent division**, which carries commands from the CNS to the body. Neurons in the afferent division monitor conditions inside and outside the body. Once information from afferent neurons has been processed in the CNS, neurons in the efferent division carry signals that allow the body to respond to changed conditions in an appropriate way. The afferent and efferent divisions carry out sensory and motor functions, respectively.

As **Figure 45.18** shows, the afferent and efferent divisions are part of a larger hierarchy of PNS functions. The efferent division is further divided into a **somatic nervous system**, which controls the skeletal muscles, and an **autonomic nervous system**, which controls internal processes such as digestion and heart rate. In effect, the somatic system responds to external stimuli and results in movement, while the autonomic system responds to internal stimuli and controls the activity of internal organs and glands. Many organs and glands are served by two functionally distinct types of autonomic nerves. Those in the **parasympathetic nervous system** promote functions that conserve or restore energy. For example, the parasympathetic nerves that innervate the heart slow it down, while those that serve the digestive tract stimulate its activity. Nerves in the **sympathetic nervous system**, in contrast, typically prepare organs for stressful situations. Sympathetic nerves speed up the heart rate, stimulate the release of glucose from the liver, and inhibit action by digestive organs. **Figure 45.19** summarizes the effects of signals from parasympathetic and sympathetic nerves.

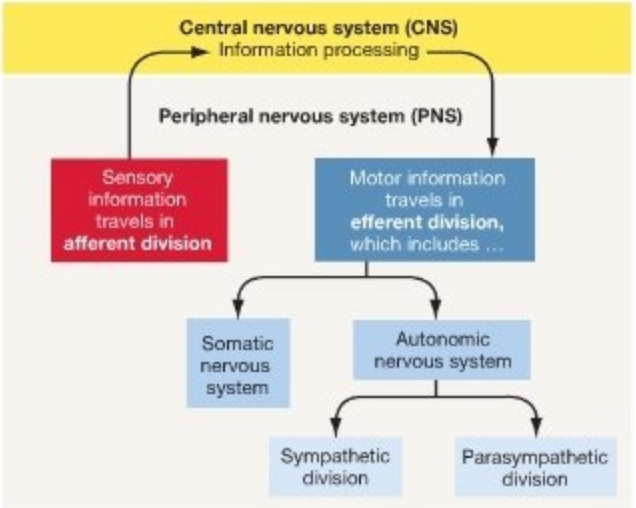

FIGURE 45.18 The Functions of the PNS Form a Hierarchy.

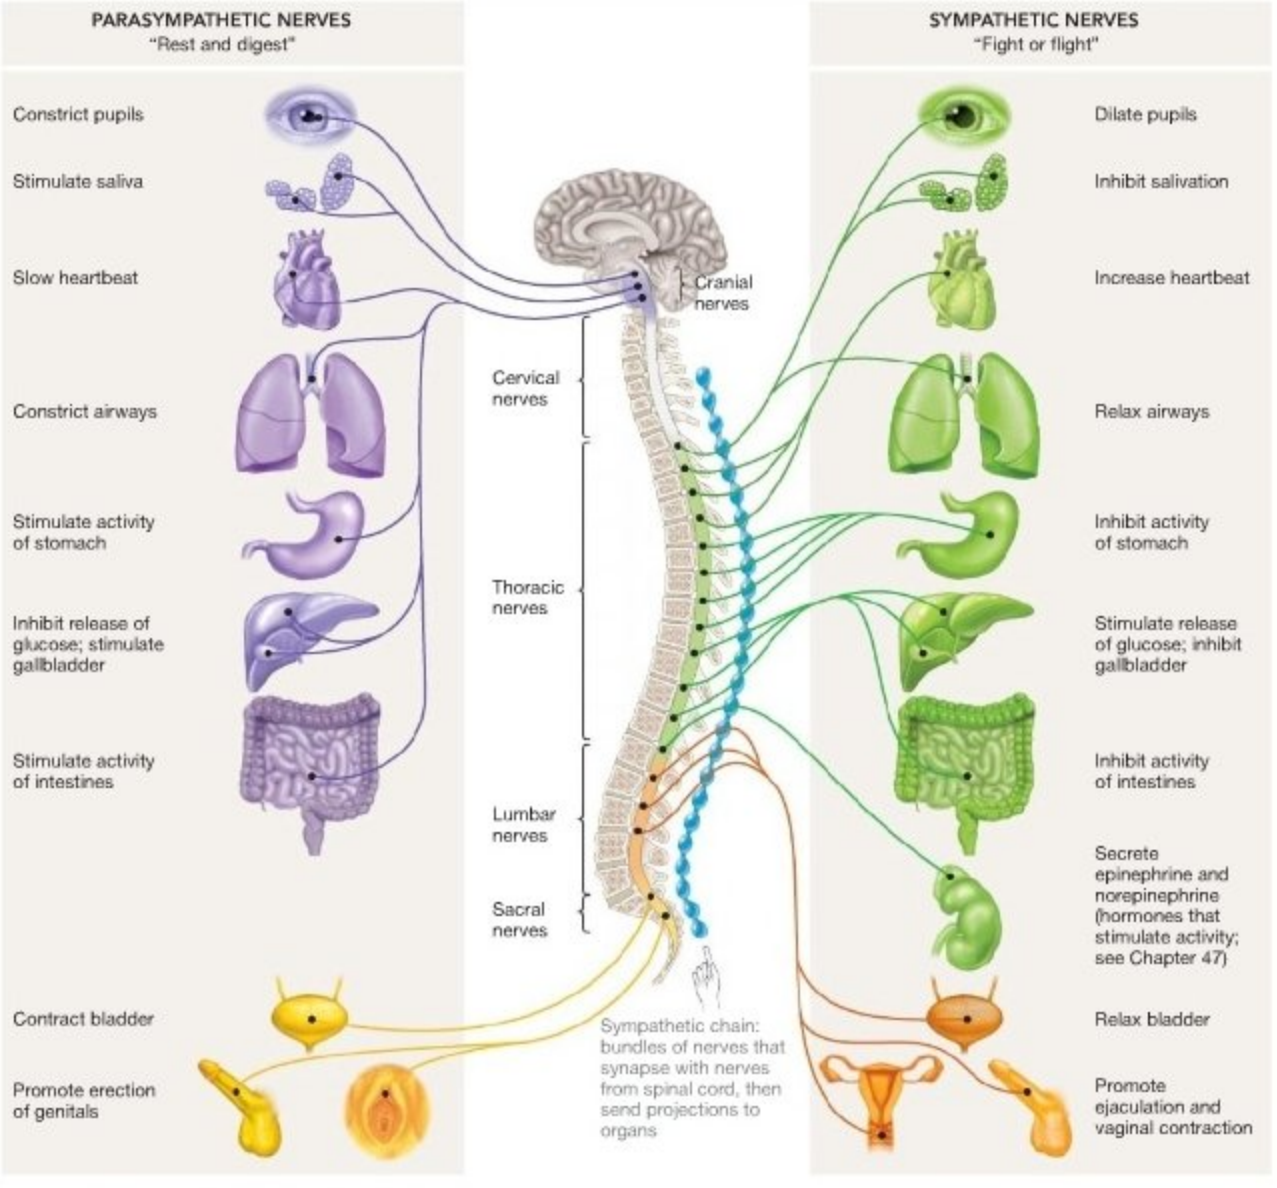

FIGURE 45.19 The Autonomic Nervous System Controls Internal Processes.

QUESTION Many parasympathetic nerves promote digestion and lack of movement; many sympathetic nerves support energy use and muscle activity. How do each of the responses listed here support these functions?

Functional Anatomy of the CNS

Parasympathetic nerves originate at the base of the brain or the base of the spinal cord. Most sympathetic nerves also originate in the spinal cord, but they emerge along the middle of its length. Similarly, most sensory and motor neurons in the somatic nervous system project to or from the spinal cord. In effect, then, the spinal cord serves as an information conduit. It collects and transmits information from throughout the body. With a few exceptions, such as the spinal reflexes illustrated in Figure 45.1, virtually all the information that travels to or from the spinal cord is sent to the brain for processing.

The brain is far and away the most complex organ found in animals. Researchers estimate that the human brain has 100 billion neurons, each making thousands of synaptic connections with other neurons. How do biologists even begin to study how

such a fantastically complex structure functions? Researchers begin with general anatomy.

Nineteenth-century anatomists established that the brain is made up of the four structures labeled in **Figure 45.20a**: the cerebrum, the cerebellum, the diencephalon, and the brain stem. The largest of these areas, the **cerebrum**, makes up the bulk of the brain. The cerebrum is divided into left and right hemispheres and is involved in conscious thought and memory. The **cerebellum** coordinates complex motor patterns. The **diencephalon** relays sensory information to the cerebellum and controls homeostasis. The **brain stem**, which connects the brain to the spinal cord, is the autonomic center for regulating the heart, lungs, and digestive system.

Each cerebral hemisphere has four major areas, or lobes: the frontal lobe, the parietal lobe, the occipital lobe, and the temporal lobe (**Figure 45.20b**). The two hemispheres are connected by a thick band of axons called the **corpus callosum**. What tools do researchers use to explore the function of each area within the cerebrum?

Mapping Functional Areas: Lesion Studies Early work on brain function focused on studying people with specific mental deficits caused by areas of brain damage, or lesions. Paul Broca, for example, studied an individual who could understand language but could not speak. After the individual's death in 1861, Broca examined the patient's brain and discovered a damaged area in the left frontal lobe of the cerebrum. Based on this observation, Broca hypothesized that this region is responsible for speech. More generally, he formulated the hypothesis that specific regions of the brain are specialized for coordinating particular functions.

Broca's claim that functions are localized to specific brain areas has been verified through extensive efforts to map the cerebrum. In some cases, advances were made by studying people who had to have portions of their brains removed. In 1953, for example, surgeons treated a 27-year-old man for life-threatening seizures by removing a small portion of his temporal lobe. The man recovered (he is still alive, in fact), has normal intelligence, and vividly remembers his childhood, but he has no short-term memory. Brenda Milner, who studied this individual for over 40 years, had to introduce herself to him every time they met; he cannot recognize a recent picture of himself. Based on case histories and data from studies of memory in laboratory animals, a consensus has emerged that several aspects of memory localize to interior sections of the temporal lobe.

Electrical Stimulation of Conscious Patients Studying the mental abilities of people who have suffered accidental or surgical brain damage has been extraordinarily fruitful. A different approach to studying brain function, however, was pioneered by Wilder Penfield, who worked with severe

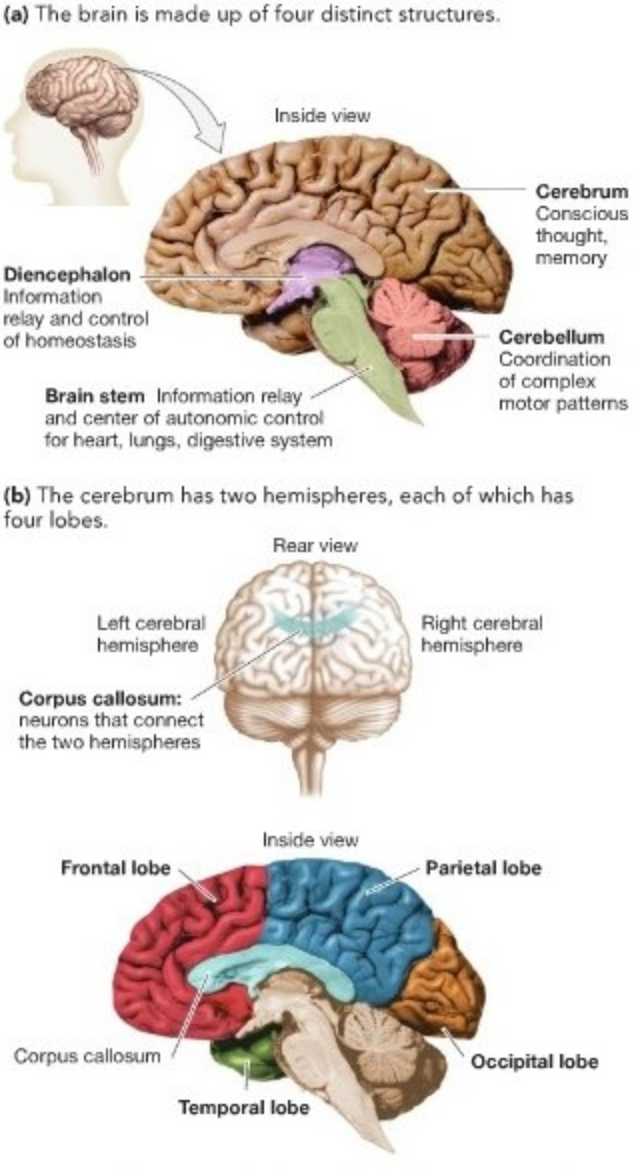

FIGURE 45.20 The Human Brain Has Four Major Lobes and Two Hemispheres.

EXERCISE On your own head, point to each of the labeled areas.

epileptics—people suffering from seizures. These individuals were scheduled to have seizure-prone areas of their brains surgically removed. While the patients were awake and under a local anesthetic, Penfield electrically stimulated portions of their cerebrums. His goal was to map areas that are essential and should be spared from removal if possible. When he stimulated specific areas, patients reported sensations or movement in particular regions of the body. Penfield was able to map the sensory regions of the cerebrum shown in **Figure 45.21**, as well as the adjacent motor regions. The technique is

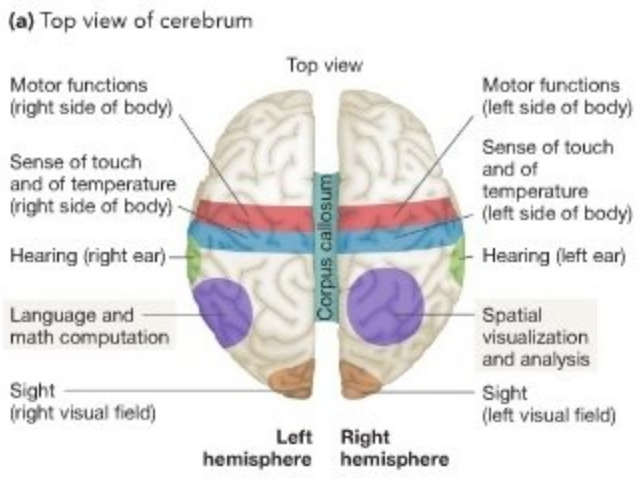

FIGURE 45.21 Specific Brain Areas Have Specific Functions. (a) Map of the brain, in top view (as if the person is looking at the top of the page), showing the functions of some major regions. The map was compiled from studies of people with damaged brain areas or with brain regions that were removed surgically. **(b)** Researchers mapped the area responsible for the sense of touch and of temperature by stimulating neurons in the brains of patients who were awake.

QUESTION Is there a correlation between the size of the brain area devoted to sensing a particular body part and that body part's size? Explain.

still used by brain surgeons to map critical areas near tumors and seizure-prone areas.

Perhaps the most striking of Penfield's findings was that, on occasion, patients would respond to stimulation of their temporal lobe by having what appeared to be flashbacks. After one region was stimulated, a woman said, "I hear voices. It is late at night around the carnival somewhere—some sort of traveling circus. . . . I just saw lots of big wagons that they used to haul animals in."

Was this a memory, stored in a small set of neurons that Penfield happened to simulate? The hypothesis that memories are stored in specialized cells is intensely controversial. As critics have pointed out, Penfield's results are difficult to interpret, because he was working with people who suffered from severe brain dysfunction. In addition, Penfield's patients sometimes described the same memory when other cells were stimulated after the original area had been surgically removed. Have other approaches to studying memory been productive?

How Does Memory Work?

Learning is an enduring, usually adaptive change in behavior that results from a specific experience in an individual's life. **Memory** is the retention of learned information. Learning and memory are thus closely related and are often studied in tandem. Research on these phenomena has been extensive, and progress has been particularly rapid recently. As an introduction to how researchers explore learning and memory, let's first explore work that is focused at the level of whole neurons and then review research at the molecular level.

Recording from Single Neurons during Memory Tasks

One approach to studying learning and memory is to record a sequence of action potentials from individual neurons during learning and memory tasks. How do the action potentials generated by a cell change as learning and memory take place? Researchers have attempted to answer this question by recording from individual neurons in the temporal lobes of humans. Before operating on patients who were still awake and about to undergo surgery to remove seizure-prone areas of their brains, physicians have projected words or names of objects on a screen and asked the individuals to read them silently, read them aloud, and/or remember them and repeat them later. The data shown in **Figure 45.22** are informative. In this case, the neuron being recorded was relatively quiet while the patient first identified objects but extremely active when the individual was remembering the objects and repeating their names aloud.

What do such data mean? Neurons in the temporal lobe are most active during memory tasks. So how could action potentials from particular cells make memory possible?

Documenting Changes in Synapses Research on the molecular basis of memory is based on two fundamental ideas. First, learning and memory must involve some type of short-term or long-term change in the neurons responsible for these processes. This change could be structural or chemical in nature. Structural changes might include modifications in the number of synapses that a particular neuron makes. Chemical (molecular) changes might involve alterations in the amount of neurotransmitter released at certain synapses and changes in

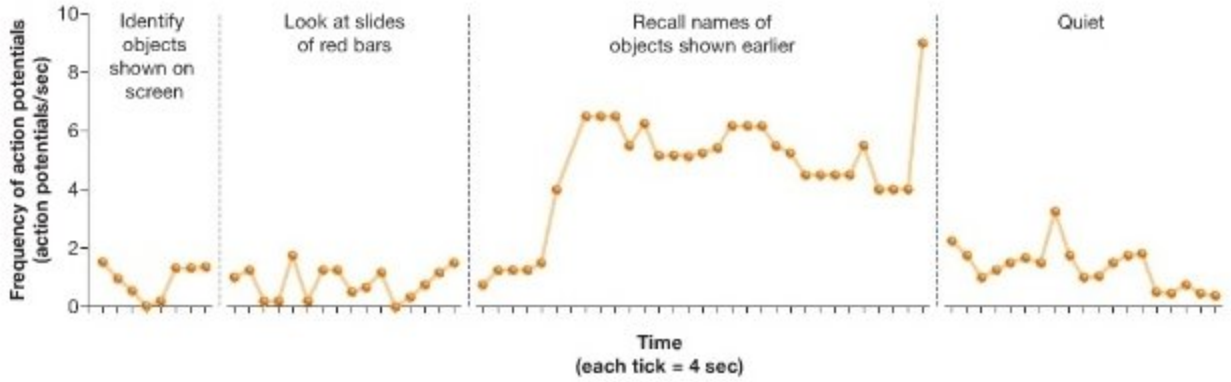

FIGURE 45.22 The Frequency of Action Potentials from Brain Neurons Varies with Activity. Data showing the frequency of action potentials from a single brain neuron from the temporal lobe as a patient identified a series of objects shown on slides, looked at a series of red bars shown on slides, recalled the names of the objects shown previously, and looked at a blank screen while doing nothing.

QUESTION Are the data here consistent or inconsistent with the data from PET scans shown in the chapter opening photo? Explain your answer.

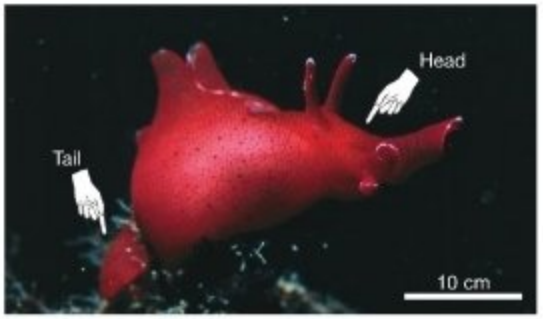
the number of receptors present in postsynaptic cells. Second, it will be much easier to understand what these changes are if an extremely simple system of neurons can be studied.

To explore the molecular basis of learning and memory, Eric Kandel's group has focused on the sea slug *Aplysia californica* (**Figure 45.23a**). Much of their work has explored the reflex diagrammed in **Figure 45.23b**. When a structure in *Aplysia* called the siphon is touched, the individual responds by withdrawing its gill. The reflex involves a sensory neuron that is activated by touch and a motor neuron that projects to a gill muscle. Retracting the gill protects it from predators.

Early work established that this simple reflex is modified by learning. For example, *Aplysia* also withdraw their siphons when their tails are given an electrical shock. If shocks to the tail are combined with a very light touch to the siphon—too light to normally get a response on its own—an *Aplysia* will learn to withdraw its gills in response to a light siphon touch alone.

Follow-up studies on this reflex showed that the neurons involved in learning release the neurotransmitter **serotonin** and that serotonin causes an EPSP in the motor neuron to the gill. Repeated application of serotonin mimics what happens at the synapse during learning and changes the serotonin-secreting cell (**Figure 45.24a**). After learning or increased serotonin application, EPSPs are higher and the motor neuron is more likely to generate action potentials. These results implied that in

(a) Sea slug *Aplysia californica*



(b) Gill-withdrawal reflex protects the gills during an attack.

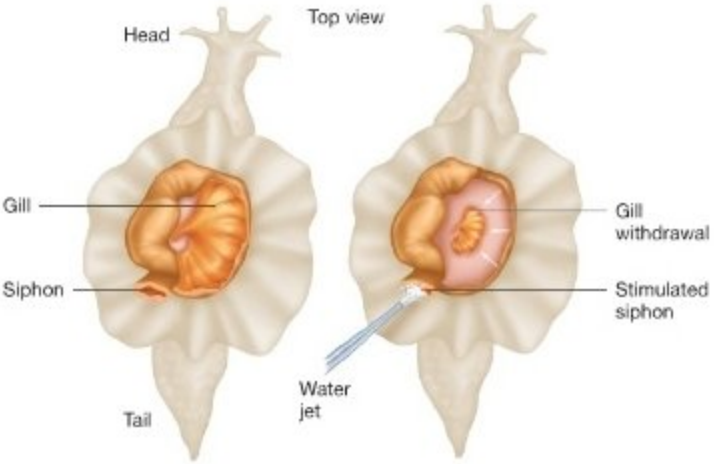


FIGURE 45.23 The Gill-Withdrawal Reflex in *Aplysia* Is a Model System in Learning and Memory.

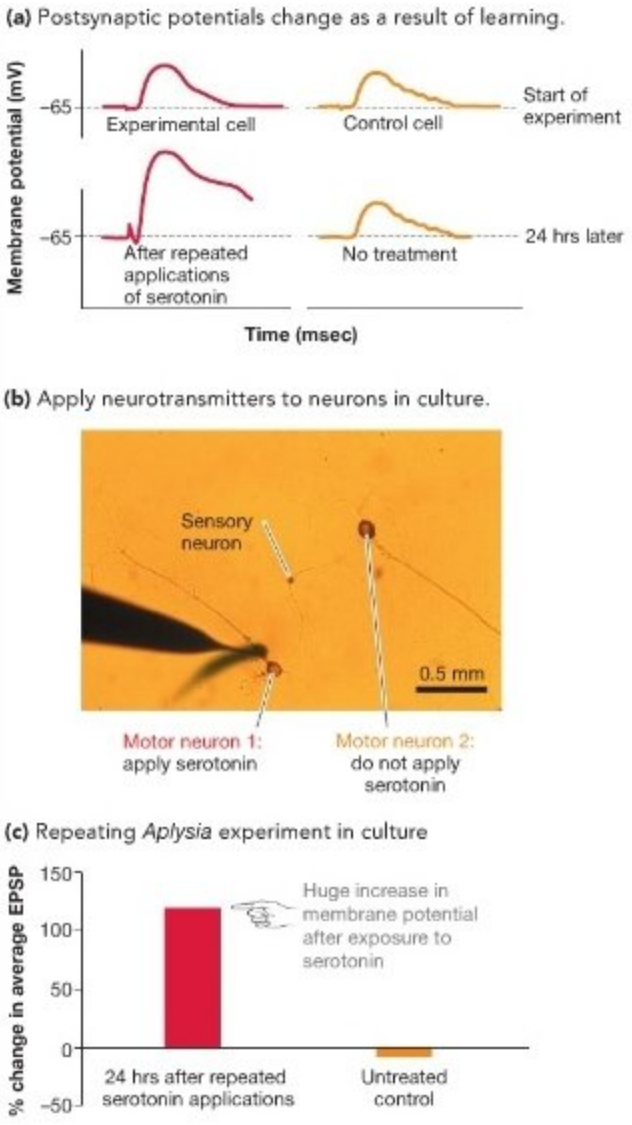

FIGURE 45.24 Learning and Memory Involve Changes in Synapses. **(a)** Experiment showing that repeated application of serotonin changes the behavior of postsynaptic neurons. **(b)** An in-culture study of interactions between *Aplysia* motor neurons and sensory neurons. **(c)** Histograms documenting the percentage increase in postsynaptic potentials that occurs after repeated application of serotonin, as in part (a).

Aplysia, changes in the nature of the synapse form the molecular basis of learning and memory. This process is termed **synaptic plasticity.**

Kandel's team was recently able to replicate these results with sensory and motor neurons growing in culture. **Figure 45.24b** shows two *Aplysia* motor neurons on a culture plate. Each motor neuron is receiving synapses from a sensory neuron. To mimic the learning process, the investigators applied serotonin to one synapse five times over a short period. When they stimulated the sensory neuron a day later, they found a huge increase in EPSPs (**Figure 45.24c**). The cells had also established additional synapses. Neurons that had not received the repeated stimulation with serotonin had normal postsynaptic responses and numbers of synapses.

Results like these reinforce a growing consensus that learning and memory involve both molecular and structural changes in synapses. Further, most researchers now agree that at least some aspects of long-term memory involve changes in gene expression. Chapter 47 explores how the chemical messengers called hormones cause changes in gene expression in target cells. But before investigating how hormones work, let's focus on the electrical signals involved in vision, hearing, taste, and movement—the subject of Chapter 46.

Check Your Understanding

If you understand that...

The CNS and PNS work together to gather information about the external and internal environments, process that information, and signal muscles, glands, and other tissues to make appropriate responses to the information.

You should be able to...

1) Diagram the hierarchical structure of the PNS.
2) Describe the types of research strategies that allowed biologists to localize particular functions to specific regions in the brain.
3) Predict whether the degree of synaptic plasticity is greater in the sensory neurons of sea slugs or in the brain neurons of humans, and why.

Chapter Review

SUMMARY OF KEY CONCEPTS

Neurons are cells that transmit electrical signals used in communication. Neurons have a membrane potential, which is an electric potential difference, or voltage, across the plasma membrane. A voltage exists due to differences in the concentrations of ions on the two sides of the plasma membrane.

Although neurons are highly variable in size and shape, all have a cell body and multiple short dendrites that receive electrical signals from other cells. Most neurons have axons that transmit electrical signals to other neurons or to effector cells in glands or muscles.

Studies of the squid giant axon neurons established that neurons have a resting potential due to differences in the concentrations of ions on the two sides of the membrane and the selective permeability of the membrane to ions. The difference in concentration of ions is created, in part, by the sodium-potassium pump. When Na^+/K^+-ATPase hydrolyzes ATP, it transports 3 Na^+ out of the cell and 2 K^+ in.

You should be able to diagram the plasma membrane of a neuron. Add symbols to show the relative concentrations of Na^+, K^+, and Cl^-. Add labels indicating the role of K^+ leak channels and the Na^+/K^+-ATPase.

MB Web Animation at www.masteringbio.com
Membrane Potentials

Electrical signals are transmitted as graded or all-or-none changes in membrane voltage. All-or-none changes are called action potentials. During an action potential, an inflow of sodium ions is followed by an outflow of potassium ions.

Studies of the squid axon established that the action potential is a rapid, all-or-none change in membrane potential. An action potential begins with an inflow of Na^+ that depolarizes the membrane. An outflow of K^+ follows and repolarizes the membrane. As charge spreads from the site of an action potential, the nearby membrane is depolarized enough to trigger additional Na^+ inflows and propagate the signal. Both Na^+ and K^+ flow through voltage-gated channels. Propagation takes place most rapidly in large axons or myelinated axons.

You should be able to explain why the action potential never stops once a membrane potential depolarizes past threshold, and why every action potential in a neuron is identical.

MB Web Animation BioFlix at www.masteringbio.com
Action Potentials; How Neurons Work

At synapses, an electrical signal from one neuron is converted to a chemical signal in the form of a neurotransmitter. When it arrives at an adjacent neuron, the neurotransmitter causes a change in that cell's membrane potential.

When action potentials arrive at a synapse, synaptic vesicles fuse with the axon's membrane and deliver neurotransmitters that bind to receptors on the membrane of a postsynaptic cell. One class of receptors functions as ligand-gated channels. In response to binding by a neurotransmitter, the channels open and admit ions that depolarize or hyperpolarize the postsynaptic cell's membrane. Postsynaptic potentials from nearby synapses sum. If the membrane at the axon hillock depolarizes to a threshold value, then an action potential is triggered.

You should be able to predict the effect of a drug that binds to K^+ channels in the postsynaptic membranes of certain brain neurons.

Animals have a central nervous system (CNS) and a peripheral nervous system (PNS). PNS neurons receive sensory information and transmit it to the CNS for processing. The CNS then sends signals to muscles, glands, or other target tissues via other PNS neurons.

The CNS consists of the brain and spinal cord (in vertebrates); the PNS consists of all nervous system components outside the CNS. In vertebrates, the PNS contains somatic and autonomic components. The somatic PNS is responsible for sensing external stimuli and effecting movement; the autonomic system monitors internal conditions and effects changes in the activity of organs.

Although the CNS is enormously complex, researchers have succeeded in mapping the functions of brain structures. Early mapping studies depended on analyzing deficits in individuals with brain lesions or on the direct stimulation of certain regions of the cerebral cortex. Efforts to understand higher brain functions such as learning and memory form the current focus of research on the CNS. To date, research has established that learning and memory are based on modifications in synapses. After learning takes place, certain neurons release more or less neurotransmitter, or make additional synapses, in response to stimulation.

You should be able to describe what an animal would be like if synapses were "fixed" early in development and unchangeable.

QUESTIONS

Test Your Knowledge

1. Why does the resting potential exist?
   a. because cells contain several types of ions
   b. because ion concentrations differ on the two sides of the membrane and because the membrane is selectively permeable to K^+
   c. because ion concentrations differ on the two sides of the membrane and because the membrane is selectively permeable to Na^+
   d. because ion concentrations differ on the two sides of the membrane and because the membrane is selectively permeable to Cl^-
2. Why did the squid axon become a model system for studying electrical signaling in animals?
   a. Its action potentials are particularly large and frequent.
   b. It is the tissue from which researchers initially isolated Na^+/K^+-ATPase.
   c. Squids are abundant and easy to obtain.
   d. It was large enough to support intracellular recording by the first microelectrodes.
3. How does myelination affect the propagation of an action potential?
   a. It speeds propagation by increasing the density of voltage-gated channels.
   b. It speeds propagation by increasing electrochemical gradients favoring Na^+ entry.
   c. It speeds propagation because charge does not leak out of the membrane as it spreads down the axon.
   d. It slows down propagation because Na^+ channels exist only at unmyelinated nodes (nodes of Ranvier).
4. In a neuron, what creates the electrochemical gradient favoring the outflow of K^+?
   a. Na^+/K^+-ATPase
   b. voltage-gated K^+ channels
   c. voltage-gated Na^+ channels
   d. ligand-gated Na^+/K^+ channels

5. Why do biologists say that positive feedback occurs during an action potential?
   a. The action potential is an all-or-none event, meaning that once it starts, it goes to completion.
   b. The opening of potassium channels repolarizes the membrane, making it less likely that sodium channels will open and depolarize the membrane.
   c. Once sodium channels open and begin to depolarize the membrane, they become more likely to open and cause further depolarization.
   d. Sodium channels are refractory—once they have opened, they are less likely to open again for a few milliseconds.
6. Why is memory thought to involve changes in particular synapses?
   a. In some systems, an increased release of neurotransmitters occurs after learning takes place.
   b. In some systems, the type of neurotransmitter released at the synapse changes after learning takes place.
   c. When researchers stimulated certain neurons electrically, individuals replayed memories.
   d. People who lack short-term memory have specific deficits in synapses within the brain regions responsible for memory.

Test Your Knowledge answers: 1. b; 2. d; 3. c; 4. a; 5. c; 6. a

Test Your Understanding

Answers are available at www.masteringbio.com

1. Explain why the resting potential exists. Be sure to differentiate between the roles of K^+ channels and that of Na^+/K^+-ATPase in the membrane's selective permeability and ion concentration gradients.
2. Draw a graph of an action potential and label the axes. Label the parts of the graph and explain which ion flow or flows are responsible for each part.
3. Draw a diagram of a synapse. Label the parts. Then make a series of diagrams showing what happens when an action potential arrives at a synapse. Explain the events that occur at both the presynaptic cell and the postsynaptic cell.
4. Why do summation and integration occur in postsynaptic cells? Why is it important that synapses exist, instead of neurons having a continuous plasma membrane and direct cytoplasmic connections?
5. Compare and contrast the somatic and autonomic components of the PNS.
6. Compare and contrast the sympathetic and parasympathetic components of the autonomic nervous system.

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Study the circuitry in the nervous system diagrammed in Figure 45.1 and the roles of the parasympathetic nerves described in Figure 45.19. Discuss how the nervous system functions as a mechanism for achieving homeostasis.
2. Discuss the pros and cons of lesion studies and electrical stimulation of conscious patients in determining the functions of particular brain structures.
3. During an epileptic seizure, muscles convulse spasmodically and the person, although awake, is unable to think, see, or hear. The cause of epilepsy is unknown. Speculate on what is happening at the level of the synapse in seizure-prone areas of the brain. How would you test your hypothesis?
4. In some species, researchers are able to identify individual neurons in the brain and record the action potentials they produce. Using these data, how can they infer the function of particular neurons?

www.masteringbio.com is also your resource for • Answers to text, table, and figure caption questions and exercises • Answers to *Check Your Understanding* boxes • Online study guides and quizzes • Additional study tools including the *E-Book for Biological Science* 3rd ed., textbook art, animations, and videos.

46 Animal Sensory Systems and Movement

KEY CONCEPTS

- Sensory receptor cells transduce sound, light, or other stimuli to a change in membrane potential. Receptor cells or sensory neurons send action potentials to the brain, where the signals are processed and integrated.
- Hearing is based on sensory receptor cells that move in response to sound waves of a particular frequency. The movement opens ion channels in the sensory cells and results in a change in membrane potential.
- Vision is based on sensory receptor cells that contain a light-absorbing pigment bound to a protein. The pigment changes conformation when it absorbs light and triggers a series of events that changes the cell's membrane potential.
- Taste and smell sensations are registered by membrane proteins that act as receptors or channels for particular molecules and that trigger changes in membrane potential.
- In many cases, animals respond to sensory stimuli by moving. Movement is based on antagonistic muscle groups that act on a stiff skeleton containing joints that flex or extend in response to electrical signals.

In many species of moth, males have much larger antennae than females do. Receptor cells on the males' feathery antennae detect airborne chemical signals that are produced by sexually mature females. As a result, males can locate females in total darkness.

Adult moths are active at night when it is difficult or impossible to see. It is logical, then, to observe that sexually mature female and male moths do not go looking for each other. Instead, females release a chemical attractant called a pheromone into the air. A **pheromone** is a small molecule that acts as a signal between individuals and that usually causes a change in physiology or behavior. Male moths of the same species that are flying in the area can detect even a single molecule of the pheromone, due to the receptor cells located on their large, feathery antennae. In response to an airborne gradient of pheromone molecules, males fly toward a female.

As they patrol in search of these airborne pheromones, however, male moths are hunted by bats. Like moths, bats are active almost exclusively at night. Instead of hunting by sight, like a falcon or a cheetah, bats hunt with the aid of sonar. Bats emit a train of high-pitched sounds as they fly and then listen for echoes that indicate the direction and shape of objects in their path. If the object is a moth, the bat flies toward it, catches the individual in its mouth, and eats it. Some moth species can hear bat calls, however. When moths detect sounds from an onrushing bat, they tumble out of the sky in chaotic escape flights (see Chapter 50).

If you were out at night as these dramas unfolded, at best you might be dimly aware that bats and moths were flying about. Humans cannot smell moth pheromones or hear the sounds that bats emit when flying. It took decades of careful experimentation for biologists to understand how moths and bats sense the world around them and how they move in response to the information they receive.

Sensing changes in the environment and moving in response to this information is fundamental to how animals work. To explore the mechanisms involved, Section 46.1 introduces how animals receive information from the external or internal environment and respond to it. The next three sections delve into the molecular processes involved in hearing, vision, and taste and smell. The chapter concludes by investigating the cellular and molecular mechanisms responsible for movement.

46.1 How Do Sensory Organs Convey Information to the Brain?

As a moth flies through the night, its brain receives streams of signals from an array of sensory organs. Antennae provide information about the concentration of pheromones; ears located on various parts of the body send data on the presence of high-pitched sounds; detectors for balance and gravity transmit signals about the body's orientation in space. Each type of sensory information is detected by a sensory neuron or by a specialized receptor cell that makes a synapse with a sensory neuron. As **Figure 46.1** shows, the moth's nervous system integrates the sensory input—information from sensory neurons—and responds with motor output, via electrical signals, to specific muscle groups (effectors).

The ability to sense a change in the environment depends on four processes: (1) **transduction**, or the conversion of an external stimulus to an internal signal in the form of an action potential; (2) amplification of the signal; (3) transmission to the central nervous system (CNS); and (4) **integration**, or processing with other incoming signals.

The first step in the sequence requires a sensory receptor cell to convert light, sound, touch, or some other signal into an electrical signal. Sensory receptors are located throughout the body and are categorized by the type of stimulus: **Nociceptors** sense harmful stimuli; **thermoreceptors** detect changes in temperature; **mechanoreceptors** respond to distortion caused by touch or pressure; **chemoreceptors** perceive specific molecules or classes of molecules; **photoreceptors** respond to particular wavelengths of light; and **electroreceptors**, if present, detect electric fields. With such a broad range of sensory detectors available, it is no wonder that animals can monitor and respond to a wide array of changes in their environments (see **Box 46.1** on page 1034).

Now, how do all these sensory cells receive information from the environment and report it to the brain, so an appropriate response can occur?

Sensory Transduction

Chapter 45 analyzed how electrical signals are generated and propagated in nerve cells. Electrical signaling is based on changes in membrane voltage. Recall that an **electrical potential**, or voltage, is created whenever a plasma membrane separates charges in the form of different concentrations of ions. When most sensory cells are in the resting state, the inside of the plasma membrane is more negative than the exterior.

Researchers can record changes in a cell's membrane potential with the aid of microelectrodes. If ion flows cause the interior to become more positive (less negative), the membrane is said to be **depolarized**. If changes in ion channels cause the cell interior to become more negative than the resting potential, the membrane is said to be **hyperpolarized**.

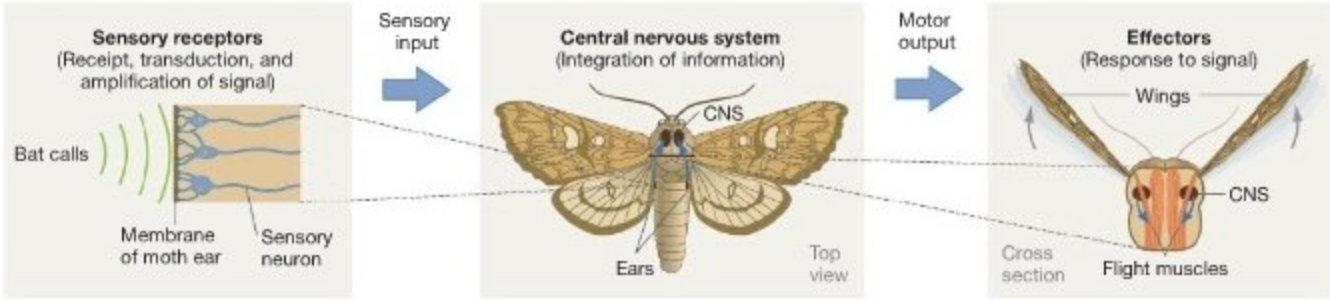

FIGURE 46.1 Sensory Systems, the CNS, and Effectors Such as Muscles Are Linked. Sensory neurons relay information about conditions inside and outside an animal to the central nervous system. After integrating information from many sensory neurons, the CNS sends signals to muscles.

QUESTION Why is it appropriate to call these moth organs "ears"? Why is it inaccurate or misleading? (Hint: Insects and vertebrates made the water-to-land transition independently—see Chapters 33 and 34.)

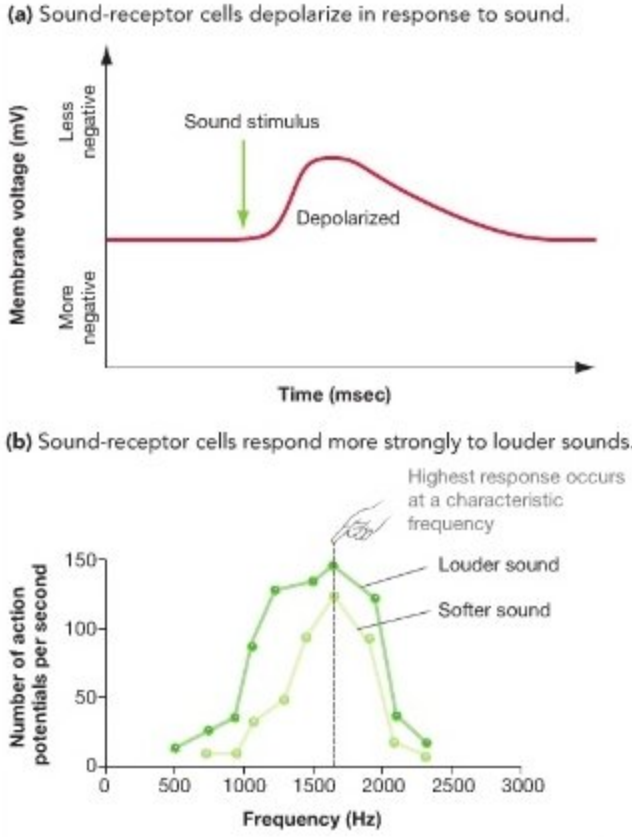

FIGURE 46.2 Sensory Inputs Change the Membrane Potential of Receptor Cells. (a) In response to sensory stimuli, ions flow across the membranes of receptor cells and either depolarize or hyperpolarize the membrane. **(b)** The frequency of action potentials from a receptor transmits information about the nature and intensity of the sensory stimulus.

What do these principles have to do with sensory systems? To answer this question, examine the voltage recording from a sound-receptor cell in **Figure 46.2a**. Notice that when the experimenter played a sound, the sound-receptor cell depolarized in response.

Other sensory cells work in a similar way. Although animals have sensory receptors that detect a remarkable variety of stimuli, they all transduce sensory input—including light, sounds, touch, and odors—to a change in membrane potential. In this way, different types of information are transduced to a common type of signal.

If a sensory stimulus induces a large change in a sensory receptor's membrane potential, there is a change in the firing rate of action potentials sent to the brain. For example, the amount of depolarization that occurs in a sound-receptor cell is proportional to the loudness of the sound. If the depolarization passes threshold, enough voltage-gated sodium channels open to trigger action potentials that are sent to the brain. Recall from Chapter 45 that all action potentials are identical in size and shape. As **Figure 46.2b** shows, however, louder sounds induce a higher frequency of action potentials than do softer sounds. In this way, receptor cells provide information about the intensity of a stimulus.

The universal nature of sensory transduction raises an important question: If all types of external stimuli are converted to electrical signals in the form of action potentials, and if all action potentials are alike, then how is it possible for the brain to interpret the information properly?

Transmitting Information to the Brain

There are two keys to understanding how the brain interprets sensory information. First, receptor cells tend to be highly specific. For example, each receptor cell in a human ear responds best to certain frequencies of sound. Some receptors are more sensitive to low-pitched sounds at a frequency of 1000 Hz (hertz, or cycles per second); others respond best to high-pitched sounds at 8000 Hz. The receptor-cell response depicted in Figure 46.2b is strongest for sounds at about 1650 Hz. At this frequency, the maximum number of action potentials per second emerge from the receptor. In this way, the pattern of action potentials from a cell contains information about the frequency of sound that is being received, its intensity, and how long the stimulus lasts.

Second, each type of sensory neuron sends its signal to a specific portion of the brain. Axons from sensory neurons in the human ear project to a particular area at the side of the brain, but axons from sensory receptors in the eye deliver action potentials to a specific area at the back of the brain. Different regions of the brain are specialized for interpreting different types of stimuli.

Now that the basic principles of sensory reception and transduction have been introduced, let's delve into the details of four sensory systems that are particularly well understood: hearing, vision, taste, and smell.

46.2 Hearing

Hearing is the ability to sense the wavelike changes in air pressure called sound. A sound consists of waves of pressure in air or in water. The number of pressure waves that occur in one second is called the **frequency** of the sound. We perceive different sound frequencies as different **pitches**.

Animals actually have a wide variety of mechanisms for sensing changes in pressure in addition to hearing airborne or waterborne sound waves. Crabs, for example, have a fluid-filled organ that helps them sense the pressure created by gravity. The organ, known as a **statocyst**, is lined with pressure-receptor cells and contains a small calcium-rich structure. The calcium-rich particle normally rests on the bottom of the organ. But if the crab is tipped or flipped over, this structure

presses against receptors that are *not* on the bottom of the organ. When the brain receives action potentials from these cells, it responds by activating muscles that restore the animal to its normal posture. It's also common for animals to have cells that are responsible for detecting direct physical pressure on skin, as well as pressure-receptor cells that monitor how far muscles or blood vessels are stretched.

Virtually all the pressure-sensing systems found in animals are based on the same mechanism, however. Let's briefly examine the general nature of a mechanoreceptor cell that responds to pressure, then investigate the specific structures involved in vertebrate hearing.

How Do Sensory Cells Respond to Sound Waves and Other Forms of Pressure?

The mechanoreceptors responsible for sensing sound and vibrations in the environment are relatively simple in design. In every case, direct physical pressure on a plasma membrane or distortion by bending changes the conformation of ion channels in the membrane and causes the channels to open or close. In response to a change in ion flow, the membrane depolarizes or hyperpolarizes. The result is a new pattern of action potentials from a sensory neuron.

In the pressure-sensing organs found in vertebrates, ion channels that respond to pressure are found in hair cells similar to the one shown in **Figure 46.3a**. **Hair cells** are pressure-receptor cells named for their appearance, which they owe to a set of stiff outgrowths called **stereocilia** (singular: **stereocilium**). The "hairy-looking" stereocilia are microvilli that are reinforced by actin filaments. Many hair cells also have a single **kinocilium**; the kinocilium is a true cilium that contains a 9+2 arrangement of microtubules introduced in Chapter 7. Hair cells are found in the ears of land-dwelling vertebrates and the lateral line system observed in many species of fish.

As Figure 46.3a shows, the stereocilia in hair cells are arranged in order of increasing height; if a kinocilium is present, it is the tallest of all the projections. All these structures extend into a fluid-filled chamber. If the stereocilia are bent in the direction of the kinocilium in response to pressure (as illustrated in **Figure 46.3b**), the membranes of the structure are distorted. The distortion causes potassium ion (K^+) channels in the stereocilia to open. This is the common theme in pressure-sensing cells: Bending opens ion channels.

Recall from Chapter 45 that the opening of K^+ channels causes an outflow of K^+ that hyperpolarizes neurons. Hair-cell plasma membranes respond differently, because they are bathed by extracellular fluid with an extraordinarily high K^+ concentration. As a result, the equilibrium potential for K^+ in hair cells is 0 mV instead of the −85 mV in a typical neuron. The resting potential of the hair-cell plasma membrane is −70 mV, so K^+ rushes in and causes a depolarization of approximately 20 mV.

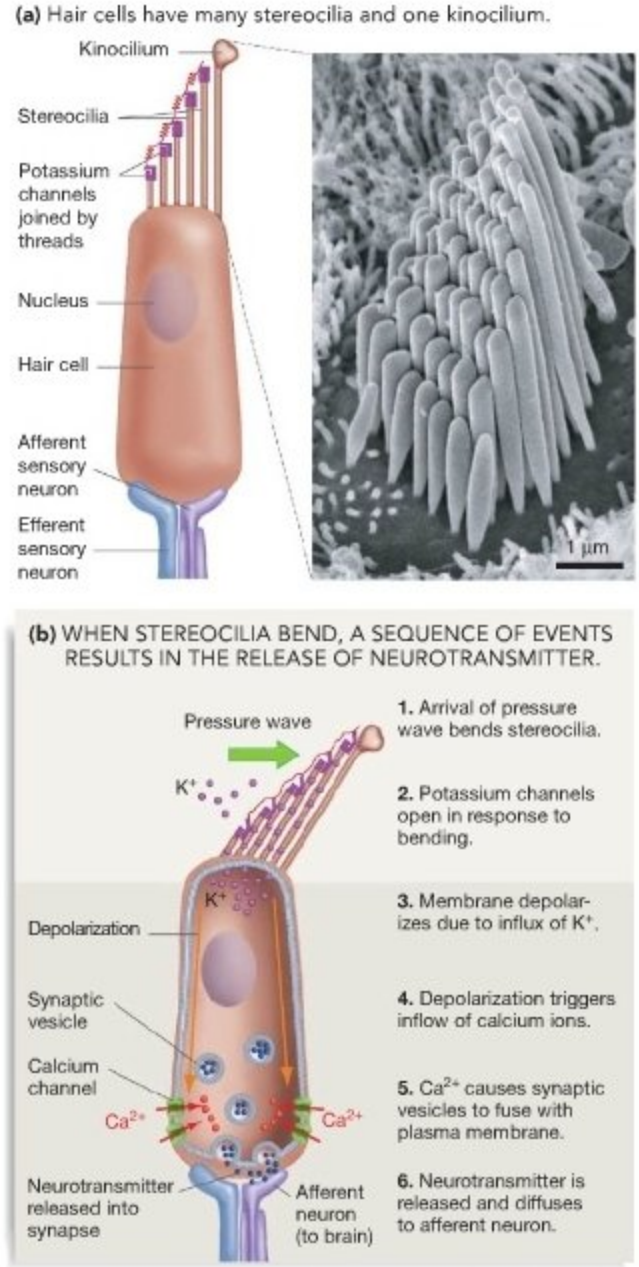

FIGURE 46.3 Hair Cells Transduce Sound Waves to Electrical Signals. **(a)** Hair cells are named for the hairlike stereocilia that project from one end. **(b)** If potassium channels open when stereocilia bend, then the hair cell's membrane depolarizes—resulting in an influx of calcium ions and the release of neurotransmitter to an afferent neuron.

In hair cells, depolarization causes an inflow of calcium ions, which triggers an increase in the amount of neurotransmitter released at the synapse between the hair cell and a sensory neuron. The end result is excitation of the postsynaptic cell, meaning that it becomes more likely to fire an action potential to the brain, via an afferent sensory neuron.

BOX 46.1 Senses That Humans Don't Have

This chapter introduces animals that can sense wavelengths of light, frequencies of sound, and odors that humans cannot perceive. But in addition to having eyes, ears, noses, and taste buds that are more acute than ours, many species have completely different sensory capabilities. Some aquatic predators are so sensitive to electric fields that they can detect electrical activity in the muscles of passing prey. Sharks become badly disoriented in captivity by electric fields generated by water pumps near their tanks. Similarly, many birds, sea turtles, and other animals can detect magnetic fields and use Earth's magnetic field as an aid in navigation. Homing pigeons tend to become disoriented if small magnets are glued to their heads. Some species of birds can also sense changes in barometric pressure. Biologists who work on species such as these are faced with the challenge of studying stimuli that they themselves cannot sense. In addition, it is possible that animals have senses that are yet to be discovered.

If sound pressure waves bend stereocilia the other way, however, then the K^+ channels close and the cell hyperpolarizes by 5 mV. Hyperpolarization of the hair cell results in a decrease in neurotransmitter released at the synapse and the inhibition of the sensory neuron, meaning that the neuron becomes less likely to trigger action potentials. Pressure that is perpendicular to the stereocilia does not change the activity of the ion channels.

How can bending affect ion channels? Electron micrographs show that tiny threads connect the tips of stereocilia to each other. One hypothesis contends that when the stereocilia are bent, the threads somehow pull open ion channels in the wall of the next tallest stereocilium—like tiny trapdoors (see Figure 46.3b, step 2). This hypothesis remains to be confirmed, however. Researchers still do not fully understand how the ion channels involved in pressure reception work.

The Mammalian Ear

To understand how changes in the membrane potential of hair cells result in hearing, let's focus on the human ear as a case study. The upper part of **Figure 46.4** shows that the structure has three general sections: the **outer ear**, **middle ear**, and **inner ear**. Each of these three sections is separated from the others by a membrane.

To trace the path of sound through the three sections of the ear, study the lower part of Figure 46.4, beginning with sound waves that are just reaching your head. Pressure waves are collected by the outer ear, which projects from the head, and are funneled into a tube known as the ear canal. At the end of the ear canal, the waves strike the **tympanic membrane**, or eardrum, which separates the outer ear from the middle ear. The repeated cycles of air compression cause the tympanic membrane to vibrate back and forth with the same frequency as the sound wave. The vibrations are passed to three tiny bones called the **ear ossicles**. In response, these bones vibrate against one another. The last ossicle, called the **stapes** (pronounced *STAY-peez*), vibrates against a membrane. That membrane, called the **oval window**, separates the middle ear from

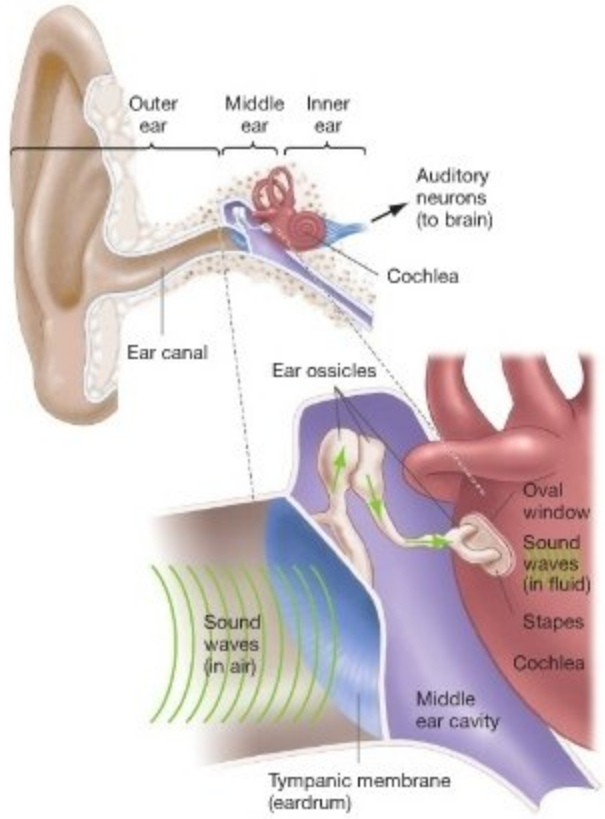

FIGURE 46.4 Mammals Have an Outer Ear, a Middle Ear, and an Inner Ear. The middle ear starts with the tympanic membrane and ends in the oval window of the cochlea.

the inner ear. The oval window oscillates in response. It generates waves in the fluid inside a chamber known as the **cochlea** (pronounced *KOK-lee-ah*). These pressure waves are sensed by hair cells in the cochlea.

In effect, the ear translates airborne waves to waterborne waves. The system seems extraordinarily complex, though, for such a simple result. Why doesn't the outer ear canal lead directly to the oval window? Why have a middle ear at all?

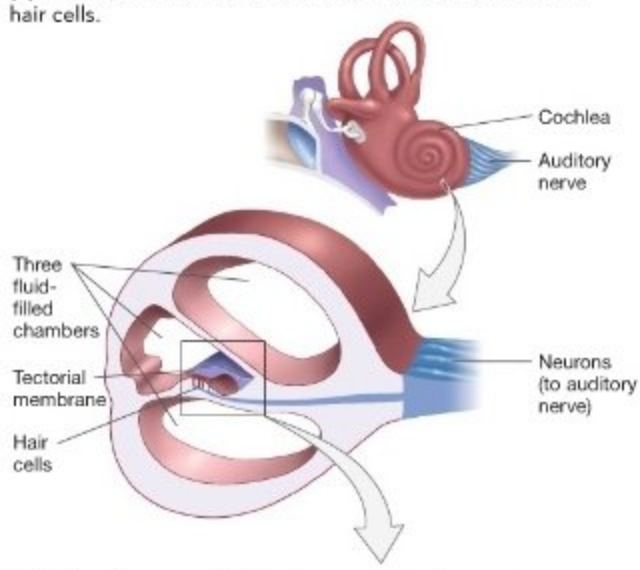
The Middle Ear Amplifies Sounds Biologists began to understand the function of the middle ear when they recognized two key aspects of its structure. First, the size difference between the tympanic membrane and the oval window is important. Because the tympanic membrane is about 15 times larger than the oval window, the amount of vibration induced by sound waves is increased by a factor of 15 by the time it reaches the oval window. This phenomenon is similar to using the same amount of force to bang on a very large door versus a very small door. In addition, the three ossicles act as levers that further amplify the vibrations at the tympanic membrane. In reptiles and birds, there is just one ear ossicle instead of three, and this levering action is not possible. The overall effect in the mammalian middle ear is to amplify sound by a factor of 22. This is important because it means that soft sounds are amplified enough that the hair cells lining the cochlea are stimulated. Biologists interpret the mammalian middle ear as an adaptation for increasing sensitivity to sound.

To summarize, the mammalian outer ear transmits sound waves from the environment to the middle ear; the middle ear amplifies these waves enough to stimulate the hair cells within the cochlea of the inner ear. How can hair cells distinguish different frequencies of sound? If all hair cells responded equally to all frequencies of sound, we would be able to perceive only one pitch. Everyone's voice—indeed, every sound—would sound the same.

The Cochlea Detects the Frequency of Sounds Careful anatomical studies and experimental work have revealed why different hair cells respond to specific frequencies of sound. As the cross section in **Figure 46.5a** shows, the cochlea has a set of internal membranes that divide it into three chambers. Hair cells form rows in the middle chamber. As **Figure 46.5b** indicates, the bottom of each hair cell connects to a structure called the **basilar membrane**. In addition, the hair cells' stereocilia touch yet another, smaller surface called the **tectorial membrane**. (The kinocilium is not present in a mature cochlear hair cell.) In effect, hair cells are sandwiched between membranes.

Researchers struggled for decades to understand how these membranes affect hair-cell function. It is virtually impossible to study cochleas in living organisms, because the cochleas are tiny, complex, coiled, and buried deep inside the skull. During the 1920s and 1930s, however, Georg von Békésy was able to perform experiments on cochleas that he had dissected from human cadavers. Once a cochlea was isolated, von Békésy was able to vibrate the oval window and record how the cochlea's internal membranes moved in response. He found that when a pressure wave traveled down the fluid in the upper and lower chambers, the basilar membrane vibrated in response. His key finding, though, was that sounds of different frequencies caused the basilar membrane to vibrate maximally at specific

(a) The middle chamber of the fluid-filled cochlea contains hair cells.



(b) Hair cells are sandwiched between membranes.

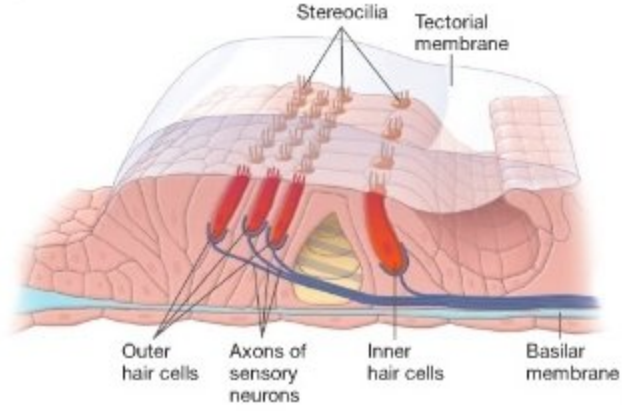


FIGURE 46.5 In the Human Cochlea, Hair Cells Are Sandwiched between Membranes. (a) The cochlea contains fluid-filled chambers separated by membranes. Hair cells are located in the middle chamber and **(b)** are sandwiched between the basilar membrane and the tectorial membrane.

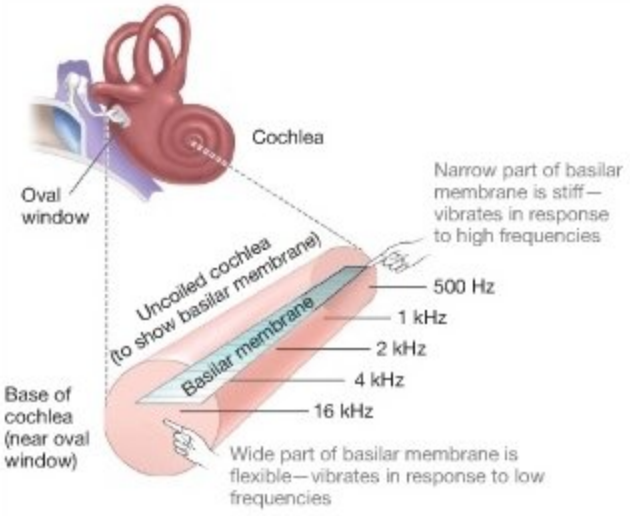

FIGURE 46.6 The Basilar Membrane Varies in Stiffness.
High-frequency sounds are detected at the narrow, stiff end of the cochlea; low-frequency sounds are detected at the wider end near the oval window.

spots along its length (**Figure 46.6**). When the basilar membrane vibrated in a particular location, the stereocilia of the hair cells there were bent one way and then the other by the tectorial membrane.

Another observation allowed von Békésy to understand cochlea function: He noted that the basilar membrane varies in stiffness. It is very stiff near the oval window and very flexible at the other end. Thus, each segment of the membrane vibrates in response to a different frequency of sound. Just as a stiff drumhead produces a high-pitched sound and a loose drumhead yields a low-pitched sound, high-frequency sounds cause the stiff part of the basilar membrane to vibrate, and low-frequency sounds cause the more flexible part to vibrate.

To summarize, certain portions of the basilar membrane vibrate in response to specific frequencies and result in the bending of hair-cell stereocilia. In this way, hair cells in a particular place on the membrane respond to sounds of a certain frequency. The brain, in turn, receives action potentials from the neurons associated with each hair cell and interprets them as a particular pitch—meaning a specific frequency of sound. Complex sounds contain a wide variety of frequencies and trigger particular combinations of hair cells. Through experience, the brain learns which combinations of frequencies represent music, a fire alarm, or a parent's voice.

Sensory Worlds: What Do Other Animals Hear?

Compared with the hearing of many mammals, human hearing is not particularly acute. This point was driven home to Katherine Payne as she was observing elephants at a zoo in the mid-1980s. She noticed a throbbing sensation in the air, coming from the elephants. Payne knew that infrasound, or sound frequencies that are too low for humans to hear, can produce such sensations. To test the hypothesis that the elephants were producing infrasonic vocalizations, she returned to the zoo with microphones that were capable of picking up sounds at extremely low frequency. At normal speed, the tape Payne made was silent. But when she raised the pitch of the sounds by speeding up the tape, she heard a chorus of cow-like noises. The elephants were calling to each other, using low-frequency sounds.

According to follow-up research, elephants have the best infrasonic hearing of any land mammal. Biologists note that infrasound can travel exceptionally long distances, and they hypothesize that infrasonic calls allow wild elephants to coordinate their movements when they are miles apart. Recent research suggests that in addition to detecting infrasound via their large ears, elephants use their feet to detect a by-product of infrasound: seismic vibrations traveling in the ground.

The bats introduced at the start of the chapter furnish another example of an animal perceiving sounds that humans cannot. But in this case, the sounds are ultrasonic—that is, they have frequencies *above* the range of human hearing. Humans can hear sounds between 20 Hz and 20,000 Hz (20,000 Hz is equal to 20 kHz, or kilohertz). Ultrasonic hearing in bats was discovered in the late 1930s, when Donald Griffin borrowed the only ultrasonic apparatus then in existence from Robert Galambos, a fellow graduate student. Griffin used the machine to demonstrate that flying bats constantly emit ultrasounds. In follow-up experiments, he documented that a bat with cotton in its ears, or with its mouth taped shut, crashed into walls when released in a room. Blindfolded bats, in contrast, never crashed.

Griffin and Galambos concluded that bats use sound echoes (sonar) to navigate. This concept, termed **echolocation**, was an outlandish idea at the time. When Galambos described the use of sonar by bats at a meeting in 1940, another scientist shook him by the shoulders and said, "You can't really mean that!" But continued research showed that dolphins, shrews, and certain other animals besides bats use sonar. In fact, it is likely that at least some of these species perceive shapes with their ears better than they do with their eyes.

Although the use of sonar is much more extensive than originally believed, most animals rely on vision to detect the size, shape, and location of the objects around them. In fact, it turned out that Griffin and Galambos were fortunate to have started out studying echolocation in the lineage of bats called Microchiroptera—also known as whispering bats. Virtually all members of the other major bat lineage, the Megachiroptera, or Old World flying foxes, do not echolocate. Instead of hunting insects at night by echolocation, flying foxes feed on fruit or nectar and rely on vision to find food. How do megachiropterans and other animals see the world?

Check Your Understanding

If you understand that...

Hearing is a type of pressure detection that begins when the stereocilia on hair cells bend in response to changes in pressure. The bending movement opens ion channels and results in a change in membrane potential.

You should be able to...

1) Make a labeled diagram of the mammalian ear and describe the function of each part.
2) Predict the type of hearing loss that results from each of the following: a punctured eardrum, a severe mutation in a gene affecting stereocilium length, and an age-related loss of flexibility in the basilar membrane.

46.3 Vision

Most animals have a way to sense light. The organs involved range from simple light-sensitive eyespots in flatworms to the sophisticated, image-forming eyes of vertebrates, cephalopod mollusks, and arthropods. Insects, for example, have a **compound eye**, which is composed of hundreds or thousands of light-sensing columns called **ommatidia** (**Figure 46.7**). Each ommatidium contributes information about one small piece of the visual field, not unlike a single pixel on a computer monitor. Thus, the more ommatidia in a compound eye, the better the resolution—meaning the resolving power, or ability to distinguish objects. In addition, the presence of many light-sensing columns makes species with compound eyes particularly good at detecting movement. Vertebrates and cephalopods, in contrast, have a **camera eye**. This is a structure that focuses incoming light onto a layer of receptor cells. Let's examine this structure more closely.

The Vertebrate Eye

Figure 46.8a shows a typical vertebrate eye. The outermost layer of the structure is a tough rind of white tissue called the sclera. This is the "white of the eye." The front of the sclera forms the **cornea**, a transparent sheet of connective tissue. Just inside the cornea is a colored, round muscle called the **iris**. The iris can contract or expand to control the amount of light entering the eye. The hole in the center of the iris is the **pupil**. Light enters the eye through the cornea and passes through the pupil and then through a curved, clear **lens**. Together, the cornea and lens focus incoming light onto the retina in the back of the eye. The **retina** contains a thin layer of light-sensitive cells and several layers of neurons.

Figure 46.8b provides a closer look at the retina. The structure is attached to the rest of the eye by a single layer of pigmented epithelial cells. The sensory cells that respond to light, the photoreceptors, are held in place by the pigmented epithelium and form a layer at the back of the retina. Photoreceptors synapse with an intermediate layer of connecting neurons. Cells in the intermediate neuron layer connect with one another and with the neurons called **ganglion cells**, which form the innermost layer of the retina. The axons of the ganglion cells project to the brain via the **optic nerve**. This is an unusual arrangement of neurons; **Box 46.2** discusses the consequences. Here, though, let's explore how photoreceptors work.

What Do Photoreceptor Cells Do? Early anatomists established that the photoreceptors in vertebrate eyes are small rod-shaped or cone-shaped cells called **rods** and **cones**

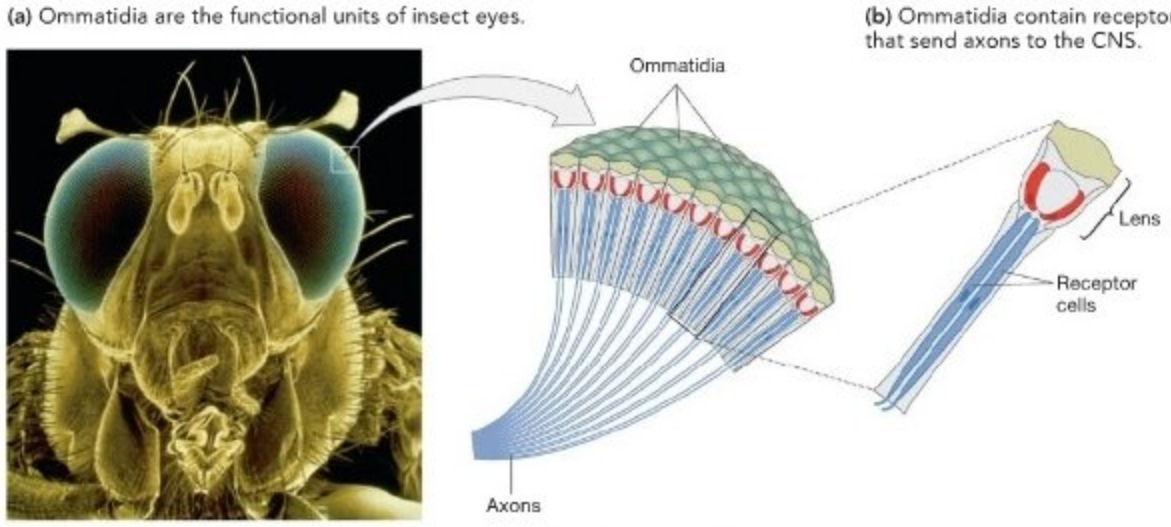

FIGURE 46.7 In the Compound Eyes of Insects, Each Ommatidium Sees Part of the World.

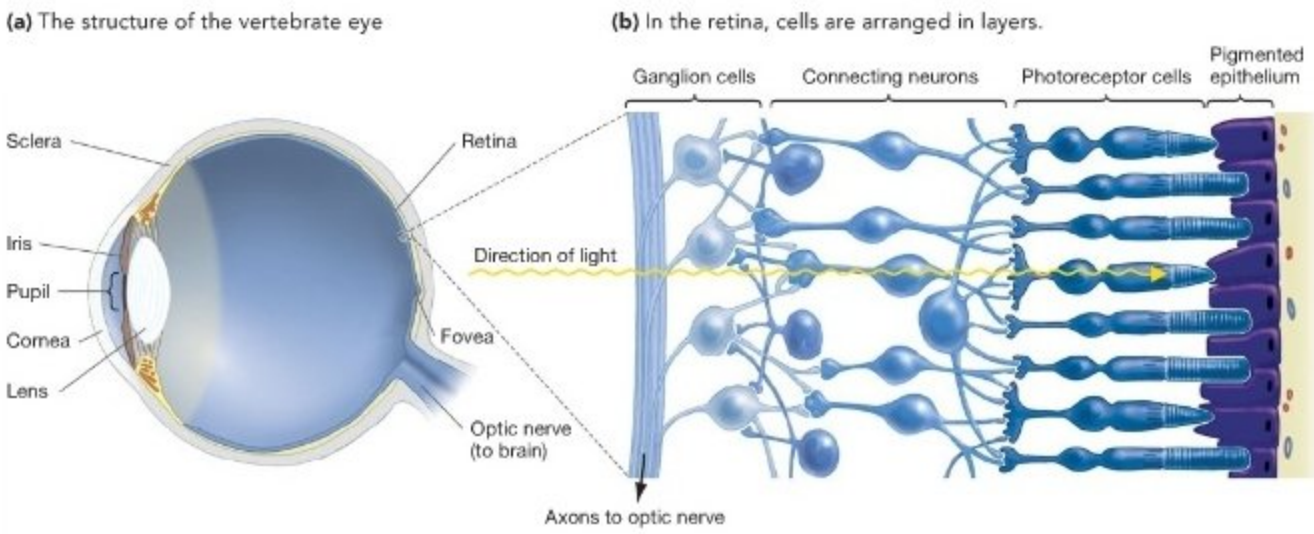

FIGURE 46.8 Camera Eyes Have a Single Lens That Focuses Incoming Light on Receptor Cells.
(a) Light passes through the pupil of the eye and is focused onto the retina by the cornea and lens. **(b)** The photoreceptor cells that respond to light are in the "outermost" layer of the retina, furthest from the light source.

● **QUESTION** Are any photoreceptor cells located in the spot where the optic nerve leaves the retina?

● **EXERCISE** In part (b), add an arrow indicating the path of an electrical signal from one of the photoreceptor cells to the optic nerve.

BOX 46.2 Vertebrate versus Cephalopod Eyes

The photoreceptor cells in the vertebrate eye are located in the outermost layer of the retina—farthest from the incoming light. As a result, light must pass through several layers of neurons before reaching the photoreceptors. This arrangement has an important consequence: The axons of the ganglion cells in the inner layer must block the photoreceptor cells in the outermost layer in order to exit the eye at the optic nerve. This disruption creates a blind spot—that is, a portion of the retina where there are no photoreceptors.

To convince yourself that this blind spot exists, point a finger up and hold it out at arm's length. Close your left eye, and focus your right eye on a location just beyond the tip of your finger. Now slowly move your pointed finger to the right, while continuing to focus on the original spot. Can you find a place where the tip of your finger seems to vanish? Light from this region is falling on the blind spot of your right eye. If an arrow or other projectile approached from this direction, you would not detect the danger.

Squid, octopus, and other cephalopods have camera eyes analogous to those found in vertebrates, but their photoreceptors are located in the innermost layer of the retina (**Figure 46.9**). As a result, light strikes the photoreceptors directly, and the eye has no blind spot. Why do vertebrates have what appears to be an inferior eye design? Recall from Chapter 24 that adaptations are not perfect. To explain the existence of blind spots, biologists hypothesize that the ancestor of vertebrates had an eyelike organ with photoreceptors located in the outermost cell layer. As a camera eye evolved in the descendants of this species, the ancestral arrangement was retained. If this hypothesis is correct, our blind spots furnish another example of historical constraints on adaptation.

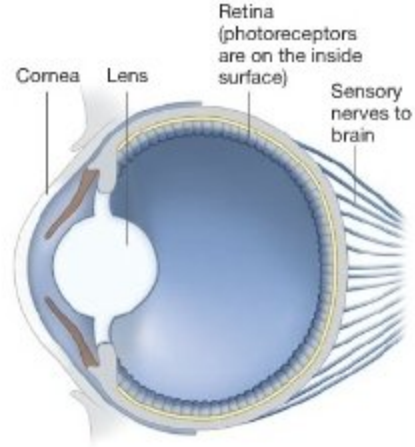

FIGURE 46.9 Cephalopods Have a Camera Eye, but No Blind Spot.

● **EXERCISE** In Figure 46.8a, circle the structure that creates the blind spot in the vertebrate eye.

(**Figure 46.10a**). When technical advances allowed changes in the membrane potentials of these cells to be recorded, it became clear that rods and cones differ in function as well as structure. Rods are sensitive to dim light but not to color. Cones, in contrast, are much less sensitive to faint light but are stimulated by different wavelengths (that is, colors). These discoveries explained why night vision is largely black and white—at night, the rods do most of the work.

Early descriptions of the human retina also established that rods dominate most of the structure. There is one small spot in the center of the retina, however, that has only cones. This is the **fovea** (see Figure 46.8a). Researchers noticed that when people focus on an object, their eyes move so that the image falls on the fovea of each eye. Based on these observations, biologists concluded that the high density of cones in the fovea maximizes the resolution of the image.

How Do Rods and Cones Detect Light? The effort to understand how rods and cones work required a combination of careful anatomical and biochemical studies. As Figure 46.10a shows, rods and cones have segments that are packed with membrane-rich disks. The membranes of these disks contain large quantities of a transmembrane protein called **opsin**. Each opsin molecule is associated with one much smaller molecule, the pigment **retinal**. In rod cells, the two-molecule complex is called rhodopsin (**Figure 46.10b**).

Experiments with isolated retinal, opsin, and rhodopsin molecules confirmed that retinal changes shape when it absorbs light. More specifically, the number-11 carbon in the retinal molecule changes from the *cis* conformation to the *trans* conformation (**Figure 46.10c**). Documenting this conformational change helped confirm that rhodopsin is the light receptor.

The shape change that occurs in retinal triggers a series of events that culminate in a different stream of action potentials being sent to the brain. The sequence of events is unusual, though, because the receipt of a light stimulus does not open ion channels or trigger the release of a neurotransmitter to a

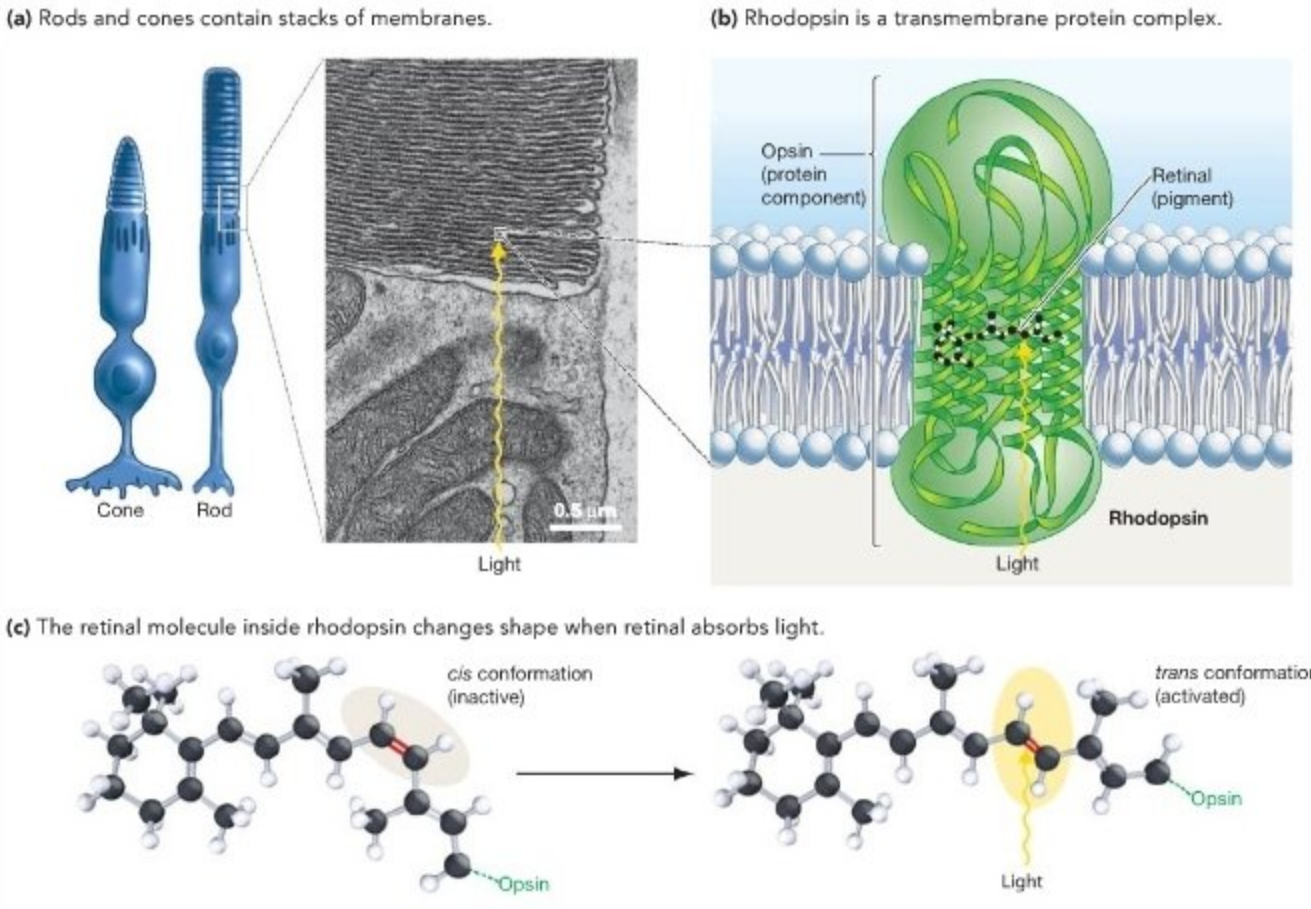

FIGURE 46.10 Rods and Cones Are Packed with Transmembrane Proteins That Contain the Pigment Retinal.
(a) Rods and cones have membranous disks containing thousands of opsin molecules. **(b)** Each opsin holds one retinal molecule. **(c)** Retinal changes conformation when it absorbs light. In response, opsin also changes shape.

QUESTION Explain why the change from *cis* to *trans* shown in part (c) would affect opsin's shape.

sensory neuron. In vertebrates, the molecular basis of vision is a shape change in retinal that shuts down an existing ion channel and causes a decrease in the amount of neurotransmitter being released to the sensory neuron. In rod cells, electrical activity across the membrane, as well as neurotransmitter release, are maximized in the dark. Exposure to light transmits information by shutting down both processes.

As **Figure 46.11** shows, the sequence of events begins when light causes retinal to change shape from the *cis* to *trans* conformation, activating rhodopsin. Rhodopsin activation causes a membrane-bound molecule called transducin to activate the enzyme phosphodiesterase (PDE). PDE breaks down an important nucleotide called cyclic guanosine monophosphate (cGMP), to guanosine monophosphates (GMP). As cGMP levels decline, cGMP-gated sodium channels in the plasma membrane of the rod cell close. This is a critical event, because it causes Na^+ entry to decrease. As a result, the membrane hyperpolarizes. If you understand this sequence of events, you should be able to explain why cGMP acts as both a second messenger and a ligand in this system, and how transducin compares to the G proteins introduced in Chapter 8. You should also be able to explain why shutting Na^+ channels results in a hyperpolarization.

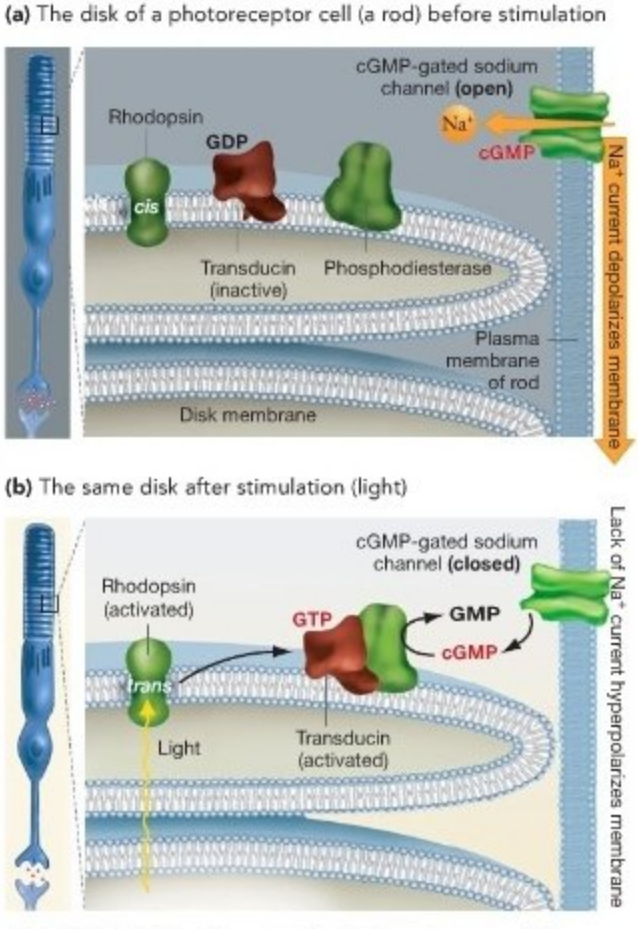

FIGURE 46.11 A Signal Transduction Pathway Connects Light Absorption with Changes in Membrane Potential. (a) An unstimulated photoreceptor. Notice that sodium ions flow into the cell when light is *not* being received. **(b)** A stimulated photoreceptor. When rhodopsin is activated, it leads to a reduction in cGMP concentration in the photoreceptor. With less cGMP available, cGMP-gated sodium channels close and the membrane hyperpolarizes.

QUESTION The inflow of sodium ions into a photoreceptor cell is called "the dark current." Why?

EXERCISE Circle the synapses in the rod cell drawings on the left of each part. Is the rod cell releasing more neurotransmitters into the synapse in the dark or in the light?

In response to the ensuing change in membrane potential, smaller quantities of the neurotransmitter glutamate are discharged at the synapse. The decrease in neurotransmitter indicates to the postsynaptic cell, called a **bipolar cell**, that the rod absorbed light. As a result, a new pattern of action potentials is sent to the brain. This system is exquisitely sensitive: Biologists have recorded a measurable change in the membrane potentials of rod cells in response to a single photon of light.

Color Vision: The Puzzle of Dalton's Eye Studies of rhodopsin revealed the molecular mechanism responsible for light perception. But it remained to be determined how humans and other animals can respond to specific wavelengths of light. How do we perceive color?

To answer this question, consider the research program initiated by John Dalton[1] in the late eighteenth century. At the age of 26, Dalton realized that he and his brother saw colors differently than did other people. To them, red sealing wax and green laurel leaves appeared to be the same color, and a rainbow exhibited only two hues. Dalton and his brother could not differentiate the colors red and green. This condition is called red-green color deficiency (**Figure 46.12**).

In a lecture delivered in 1794, Dalton explained his perceptions by hypothesizing that red wavelengths failed to reach his retinas. Further, he hypothesized that because a normal eyeball is filled with clear fluid, and because blue fluids absorb red light, his defective vision resulted from the presence of bluish fluid rather than clear fluid in his eyes. To test this hypothesis, Dalton left explicit instructions that his eyes should be removed after his death and examined to see if the fluid inside was blue. When he died 50 years later, an assistant dutifully removed the eyes from Dalton's corpse and examined them. The fluid inside the eye was not blue at all, however, but slightly yellow—the normal color for an older person. Further, when

[1] Dalton was an accomplished physicist. He was the first proponent of the atomic theory and formulated Dalton's law on the partial pressures of gases (introduced in Chapter 44). Red-green color blindness is sometimes called Daltonism in his honor.

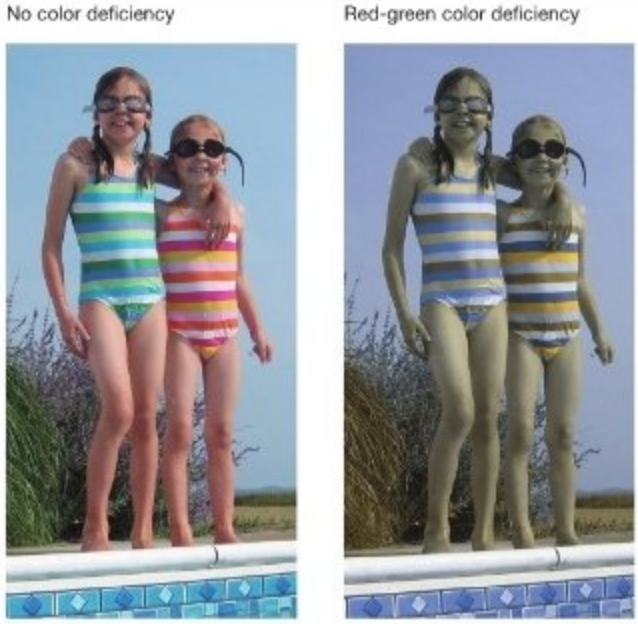

FIGURE 46.12 People with Color Deficiencies See Colors Differently than Do People without Deficiencies. These images show what a person with red-green color deficiency would see, as compared to a person with intact color receptors.

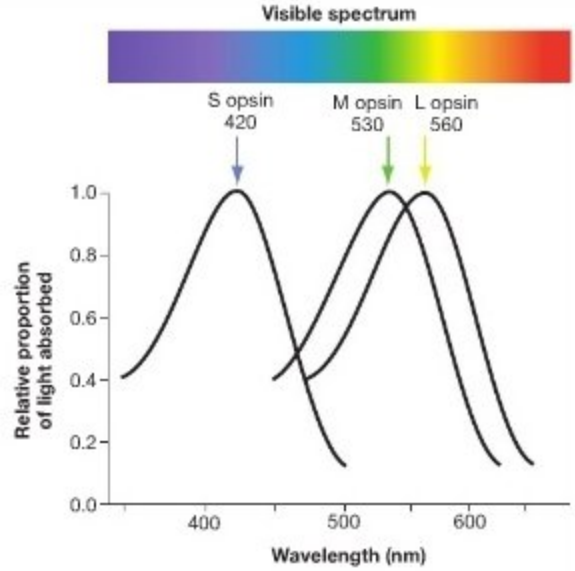

FIGURE 46.13 Color Vision Is Possible because Different Opsins Absorb Different Wavelengths of Light. Each human cone cell contains one of three different types of opsin. Each of the opsins has a different range of absorbed wavelengths.

QUESTION The retinal molecules in S, M, and L opsins are identical. How is it possible that they respond to different wavelengths of light?

the back was cut off of one eye and colored objects were viewed through the lens, the objects looked perfectly normal. Dalton's hypothesis was incorrect.

What caused Dalton's color blindness? The key to answering this question was the hypothesis that the human retina contains just three types of color-sensitive photoreceptors: blue, green, and red cones, named for the colors that they best perceive. Researchers who analyzed the activity of these three types of cone cells found that each absorbed short, medium, or long wavelengths of light, respectively. To follow up on this result, biologists analyzed opsin molecules from the three cell types and found that each had a distinct amino acid sequence. The three proteins are called the blue, green, and red opsins (or S, M, and L, for short, medium, and long wavelengths, respectively). Although retinal is the light-absorbing molecule in all photoreceptor cells, various types of opsins respond only to distinct wavelengths of light.

Based on these results, biologists hypothesized that the brain distinguishes colors by combining signals initiated by the three classes of opsins. For example, notice in **Figure 46.13** that a wavelength of 560 nm stimulates L cones strongly, M cones to an intermediate degree, and S cones hardly at all. In response to the corresponding signals from these cells, the brain perceives the color yellow.

Does this hypothesis explain Dalton's color blindness? According to the data in Figure 46.13, wavelengths from green to red do not stimulate S opsin at all. It is thus unlikely that S opsin is involved in red-green color blindness. Did Dalton fail to distinguish red and green because his M or his L cones were defective? Research has shown that color-blind people lack either functional M or L cones, or both. Was the same true of Dalton? Answering this question became possible in the 1990s, when the genes for the M and L opsins were identified and sequenced. Researchers realized that if they could get a sample of Dalton's DNA, they could analyze his M opsin genes and L opsin genes directly. Remarkably, Dalton's eyes had been preserved. The research group managed to extract DNA from the 150-year-old tissue and found that Dalton had a normal *L* allele but lacked a functional *M* allele. As a result, he did not have green-sensitive cones. The puzzle of Dalton's color vision was solved.

The Vertebrate Eye

Sensory Worlds: Do Other Animals See Color?

What about other animals—do they see color the way humans do? The short answer to this question is probably not. Animals that are active at night have relatively few cone cells and many rods, giving them high sensitivity to light but poor color vision. And recent research has shown that different species with good color vision have opsins with different peak light sensitivities. A marine fish called the coelacanth (pronounced *SEE-luh-kanth*), which lives in water 200 meters

Recently, Buck determined that each olfactory neuron has only one type of receptor and that neurons with the same type of receptor are linked to distinct regions in the olfactory bulb of the brain. These regions are called **glomeruli** (meaning "little balls"). Follow-up work from Axel's lab indicated that particular smells in mice are associated with the activation of a certain subset of the 2000 glomeruli in the brain. For example, the activation of clumps 130, 256, and 1502 might be perceived as the smell "cinnamon." In essence, then, the sense of smell is similar to the visual system's use of three cones to perceive many colors, but on a much larger scale. Research on this complex and impressive sense continues at a furious pace.

Check Your Understanding

If you understand that...

In most cases, chemoreception occurs when a specific molecule in air or food binds to a specific receptor in the nose or mouth and the binding event is transduced to a change in membrane voltage.

You should be able to...

1) Why a loss in chemosensory ability occurs when you burn your tongue with extremely hot food.
2) Why dogs have a better sense of smell than people do.
3) Why some people cannot taste the compound PTC.

46.5 Movement

The first four sections of this chapter focused on how animals sense different aspects of their environment. Acquiring information is only a first step, however. Information about changes in the environment is useless to an animal unless the individual can respond to it in an appropriate way—usually by moving. Bats and moths not only hear ultrasonic frequencies but also alter their flight paths and activities in response—in a way that allows them to catch food or avoid being eaten. Flight and other types of motion are based on muscle contractions in conjunction with a skeleton.

Recall from Chapters 32–34 that diversification in methods of moving has been extremely important during the evolution of animals. But it's also important to remember that **locomotion**, or the movement of an entire animal, is only one type of movement. Sessile organisms, such as barnacles and sea anemones, may not undergo locomotion, but they rely on movement of the heart muscle or gills to accomplish circulation and respiration.

To explore locomotion in detail, let's briefly examine the skeleton's role as a scaffold for muscle attachment. The analysis of animal skeletons is followed by a description of the diversity of muscle cells and tissues found in vertebrates and how they work.

Skeletons

Skeletons provide attachment sites for muscles and a support system for the body's soft tissues. As Chapters 32–34 indicated, three types of skeletons are found in animals. **Exoskeletons** are hard, hollow structures that envelop the body; **hydrostatic skeletons** use the pressure of enclosed body fluids to support the body; and **endoskeletons** are hard structures inside the body. Because those chapters introduced the design of exoskeletons and hydrostatic skeletons in some detail, our focus here is on the structure and function of endoskeletons.

Endoskeletons are composed of connective tissues called cartilage and bone. You might recall from Figure 41.3b that **cartilage** is made up of cells scattered in a gelatinous matrix of polysaccharides and protein fibers. In the skeletal system, cartilage provides padding between bones. **Bone** is made up of cells in a hard extracellular matrix of calcium phosphate ($CaPO_4$) with small amounts of calcium carbonate ($CaCO_3$) and protein fibers. Bones meet and interact at locations called **articulations**, or **joints**. Bones articulate in ways that allow limbs to swivel, hinge, or pivot (**Figure 46.17**).

How do skeletal muscles attach to and move elements of an endoskeleton? In vertebrates, most skeletal muscles have ends that are attached to different bones by tendons. **Tendons** are bands of tough, fibrous connective tissue. Muscles can exert force only by contracting, so pairs of muscles must work together to move a bone back and forth. In the case of a limb, one muscle pulls the limb in one direction; the other muscle pulls it in the opposite direction. This pairing of muscles is called an antagonistic muscle group. The muscle that swings

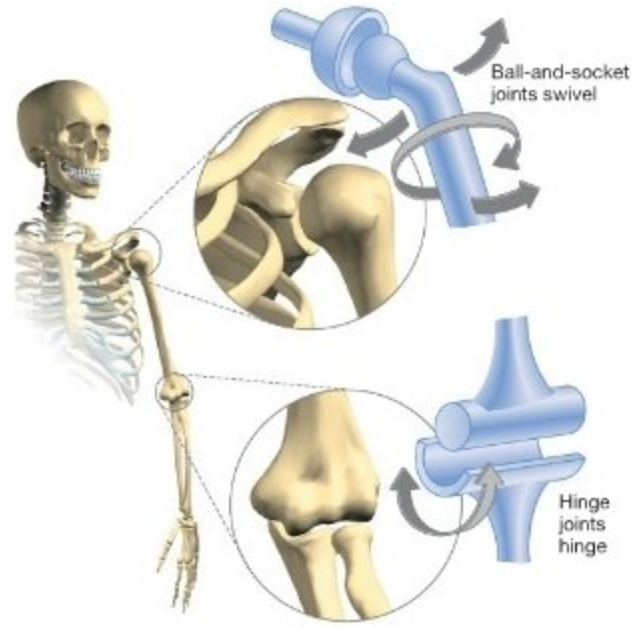

FIGURE 46.17 Bones Articulate at Joints. Bones articulate in ways that make specific types of movement possible.

techniques became available for identifying how particular molecules bind to certain receptors. But in the past 15 years, research on the chemosenses has exploded.

Understanding taste and smell is important because animals use these senses to find food, assess mates, and avoid danger. For researchers in the food and cosmetic industries, understanding particular aspects of chemoreception, such as the sensation of sweetness and the activity of perfumes, is critical to developing new products.

Taste: Detecting Molecules in the Mouth

The chemoreceptor cells that sense taste are clustered in structures known as **taste buds**. Although humans have taste buds scattered around the mouth and throat, most taste buds are located on the tongue (**Figure 46.15**). A taste bud contains about 100 spindle-shaped taste cells, which are taste receptors that synapse onto sensory neurons. How do these receptors work on a molecular level, and how do they produce the sensation of taste?

Early taste research focused almost exclusively on the hypothesis that four "basic tastes" existed: salty, sour, sweet, and bitter. Researchers who analyzed the membrane proteins in taste cells found strong evidence that salt and sour sensations result from the activity of ion channels. Specifically, the sensation of saltiness is due primarily to sodium ions (Na^+) dissolved in food. These ions flow into certain taste cells through open Na^+ channels and depolarize the cells' membranes. Similarly, sourness is due to the presence of protons (H^+), which flow directly into certain taste cells through H^+ channels. The sour taste of grapefruit and other citrus fruits, for example, results from the release of protons by citric acid. In general, the lower the pH of a food, the more it depolarizes a taste cell's plasma membrane and the more sour the food tastes.

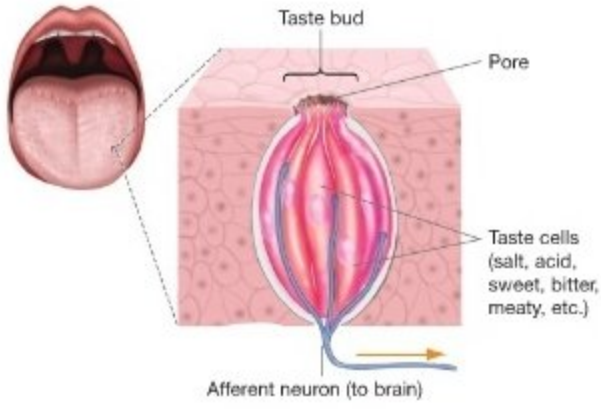

FIGURE 46.15 Taste Buds Contain Many Types of Receptor Cells. The human tongue has a high density of taste cells located in structures called taste buds.

The molecular mechanisms responsible for the sensations of bitterness and sweetness have been much more difficult to identify, however. Researchers have only recently been able to document that certain food molecules actually bind to specific receptors on taste cells to cause bitter and sweet tastes.

Why Do Many Different Foods Taste Bitter? Bitterness has been a particularly difficult taste to understand. The problem is that molecules with very different structures are perceived as bitter. How is this possible? An answer began to emerge after researchers confirmed that some humans genetically lack the ability to taste certain bitter substances. This phenomenon came to light in 1931, when Arthur Fox was synthesizing phenylthiocarbamide (PTC) and accidentally blew some of it into the air. A nearby colleague complained of a bitter taste in his mouth. Fox could not taste anything, however. Follow-up research confirmed that the ability to taste PTC is inherited and polymorphic. About 25 percent of United States citizens cannot sense the molecule. To find the gene responsible for this trait, biologists compared the distribution of genetic markers observed in "tasters" and "nontasters." The mapping effort recently narrowed down this gene's location to several candidate chromosomal segments. (Chapter 19 introduced how this type of gene hunt is done.)

At about the same time, researchers who were working on taste reception in mice found that some individuals are better than others at perceiving bitter substances and avoiding them. Gene mapping narrowed down the location of the bitter receptor gene to a specific region of a mouse chromosome.

These independent lines of research converged when different research teams searched a database of known genes to look for sequences similar to those from the candidate regions of the human and mouse chromosomes. Independently, the two teams identified a family of 40 to 80 genes that encode transmembrane receptor proteins. Follow-up work documented that each protein in the family binds to just one particular type of bitter molecule. A taste cell, however, can have many different receptor proteins from this family. As a result, many different kinds of molecules can depolarize the same cell and cause the taste of bitterness. These results explained why so many different molecules give rise to the same sensation.

Why do animals have such extensive molecular machinery to detect bitterness? To answer this question, biologists note that many of the molecules that bind to bitter receptors are found in toxic plants. Also, most animals react to bitter foods by spitting them out and avoiding them in the future. Based on these observations, researchers hypothesize that bitter receptors evolved in response to selection for avoiding toxic molecules. In essence, bitterness indicates "this food might be dangerous; don't swallow it." The proliferation of genes responsible for detecting bitterness hints that the trait is

extremely important—meaning that individuals with the capacity to detect a wide array of bitter compounds produce more offspring than do individuals that lack this ability.

What Is the Molecular Basis of Sweetness and Other Tastes? Inspired by the rapid recent progress on bitter receptors, research teams are using the same techniques to search for sweetness and other types of receptors. Several proteins have been identified as possible sweetness detectors, some of which are closely related to recently discovered membrane receptors for glutamate and other amino acids. The glutamate receptor is responsible for the sensation called **umami**, which is the meaty taste of the molecule monosodium glutamate (MSG). Researchers are still struggling to understand how the sweetness receptors work, however, and exactly how many different membrane proteins might be involved in detecting the presence of sugars in food.

In addition to searching for other types of taste receptors, several teams are studying how the different taste sensations are conveyed to the brain and interpreted. Although taste is beginning to reveal its secrets, the complete story will probably not be known for many more years.

Olfaction: Detecting Molecules in the Air

Taste allows animals to assess the quality of their food before swallowing it. Smell, in contrast, allows animals to monitor airborne molecules that convey information. Wolves and domestic dogs, for example, can distinguish millions of different odors at vanishingly small concentrations. The molecules that cause odor contain information about the movements and activities of prey and other members of their own species.

How does the sense of smell work? When odor molecules, or odorants, reach the nose, they diffuse into a mucus layer in the roof of the nose (**Figure 46.16**). There, they activate olfactory receptor neurons via membrane-bound receptor proteins. Axons from these neurons project up to the olfactory bulb. The **olfactory bulb** is the part of the brain where olfactory signals are processed and interpreted.

Understanding the anatomy of the odor recognition system was a relatively simple task. Understanding how receptor neurons distinguish one molecule from another turned out to be much more difficult. Initially, investigators hypothesized that receptors respond to a small set of "basic odors," such as musky, floral, minty, and so on. The idea was that each basic odor would be detected by its own type of receptor.

In 1991, however, Linda Buck and Richard Axel demolished the basic-odor hypothesis with an astonishing result: Their studies of odor recognition in mice culminated in the discovery of a gene family—containing hundreds of distinct coding regions—that encodes receptor proteins on the surface of odor-receptor neurons. Follow-up experiments confirmed that each receptor protein binds to a small set of molecules. Further work established that most, if not all, vertebrates have this family of genes. Mammals typically have between 500 and 1000 of these genes, meaning mammals can produce 500 to 1000 different odor-receptor proteins. In humans, however, about half of these genes have mutations that probably render them nonfunctional. This observation may explain why the sense of smell is so poor in humans compared with that of other mammals.

Buck and Axel's announcement inspired a series of questions. How many different receptors occur in the membrane of each neuron involved in odor reception? How does the brain make sense of the input from so many different receptors?

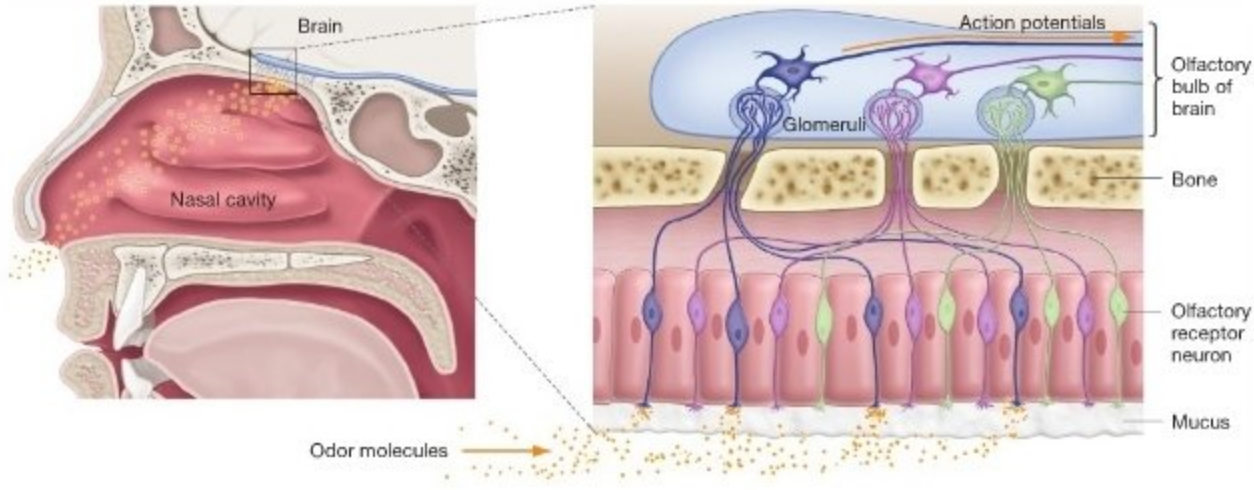

FIGURE 46.16 In Mammals, Receptor Cells in the Nose Respond to Specific Odorants. Odor molecules are detected in the nose by chemoreceptor cells. Each of these sensory neurons carries one type of odor-receptor protein on its dendrites. Sensory neurons with the same receptor project to the same glomerulus, or section within the olfactory bulb of the brain.

Recently, Buck determined that each olfactory neuron has only one type of receptor and that neurons with the same type of receptor are linked to distinct regions in the olfactory bulb of the brain. These regions are called **glomeruli** (meaning "little balls"). Follow-up work from Axel's lab indicated that particular smells in mice are associated with the activation of a certain subset of the 2000 glomeruli in the brain. For example, the activation of clumps 130, 256, and 1502 might be perceived as the smell "cinnamon." In essence, then, the sense of smell is similar to the visual system's use of three cones to perceive many colors, but on a much larger scale. Research on this complex and impressive sense continues at a furious pace.

46.5 Movement

The first four sections of this chapter focused on how animals sense different aspects of their environment. Acquiring information is only a first step, however. Information about changes in the environment is useless to an animal unless the individual can respond to it in an appropriate way—usually by moving. Bats and moths not only hear ultrasonic frequencies but also alter their flight paths and activities in response—in a way that allows them to catch food or avoid being eaten. Flight and other types of motion are based on muscle contractions in conjunction with a skeleton.

Recall from Chapters 32–34 that diversification in methods of moving has been extremely important during the evolution of animals. But it's also important to remember that **locomotion**, or the movement of an entire animal, is only one type of movement. Sessile organisms, such as barnacles and sea anemones, may not undergo locomotion, but they rely on movement of the heart muscle or gills to accomplish circulation and respiration.

To explore locomotion in detail, let's briefly examine the skeleton's role as a scaffold for muscle attachment. The analysis of animal skeletons is followed by a description of the diversity of muscle cells and tissues found in vertebrates and how they work.

Skeletons

Skeletons provide attachment sites for muscles and a support system for the body's soft tissues. As Chapters 32–34 indicated, three types of skeletons are found in animals. **Exoskeletons** are hard, hollow structures that envelop the body; **hydrostatic skeletons** use the pressure of enclosed body fluids to support the body; and **endoskeletons** are hard structures inside the body. Because those chapters introduced the design of exoskeletons and hydrostatic skeletons in some detail, our focus here is on the structure and function of endoskeletons.

Endoskeletons are composed of connective tissues called cartilage and bone. You might recall from Figure 41.3b that **cartilage** is made up of cells scattered in a gelatinous matrix of polysaccharides and protein fibers. In the skeletal system, cartilage provides padding between bones. **Bone** is made up of cells in a hard extracellular matrix of calcium phosphate ($CaPO_4$) with small amounts of calcium carbonate ($CaCO_3$) and protein fibers. Bones meet and interact at locations called **articulations**, or **joints**. Bones articulate in ways that allow limbs to swivel, hinge, or pivot (**Figure 46.17**).

How do skeletal muscles attach to and move elements of an endoskeleton? In vertebrates, most skeletal muscles have ends that are attached to different bones by tendons. **Tendons** are bands of tough, fibrous connective tissue. Muscles can exert force only by contracting, so pairs of muscles must work together to move a bone back and forth. In the case of a limb, one muscle pulls the limb in one direction; the other muscle pulls it in the opposite direction. This pairing of muscles is called an antagonistic muscle group. The muscle that swings

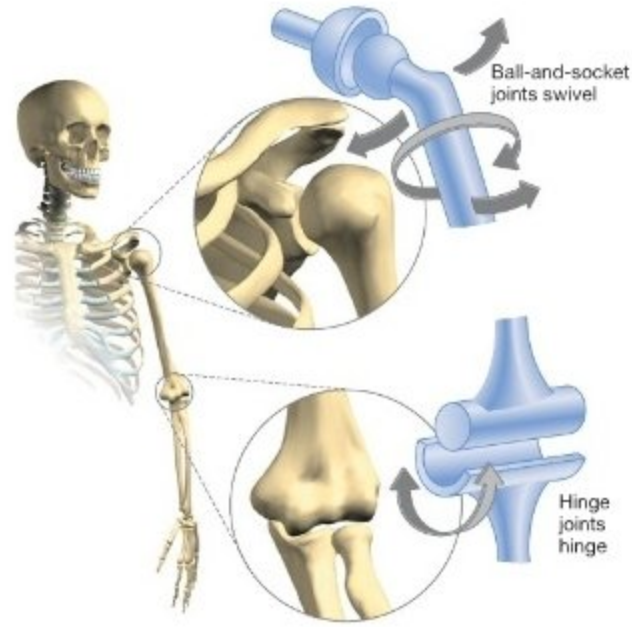

FIGURE 46.17 Bones Articulate at Joints. Bones articulate in ways that make specific types of movement possible.

two long bones in an arc toward each other is called a **flexor**; the muscle that straightens them out is called an **extensor** (**Figure 46.18a**). For example, the hamstring muscle in the back of your thigh flexes your lower leg; the quadriceps muscle in the front of your thigh extends it. When the hamstring contracts, the quadriceps relaxes; when the quadriceps contracts, the hamstring relaxes. The hamstring and quadriceps together make up an antagonistic muscle group.

Locomotion in animals with exoskeletons and hydrostatic skeletons is also based on antagonistic muscle groups. Animals with exoskeletons have paired flexor-extensor muscles inside their leg joints (**Figure 46.18b**). Many animals with hydrostatic skeletons have both circumferential muscles and longitudinal muscles, and these muscles work in concert to shorten and lengthen parts of the body (**Figure 46.18c**).

In all vertebrate animals, the movements of paired muscles are coordinated by motor neurons that originate in the brain or spinal cord. These motor neurons project from processing centers that receive input from sensory systems. Motor neuron activity changes in response to information about balance, smells, sights, and sounds. In this way, an animal's movements are directly tied to the functioning of its sensory systems. The interplay of sensory input and motor output results in the coordinated behaviors we call running, eating, swimming, and flying.

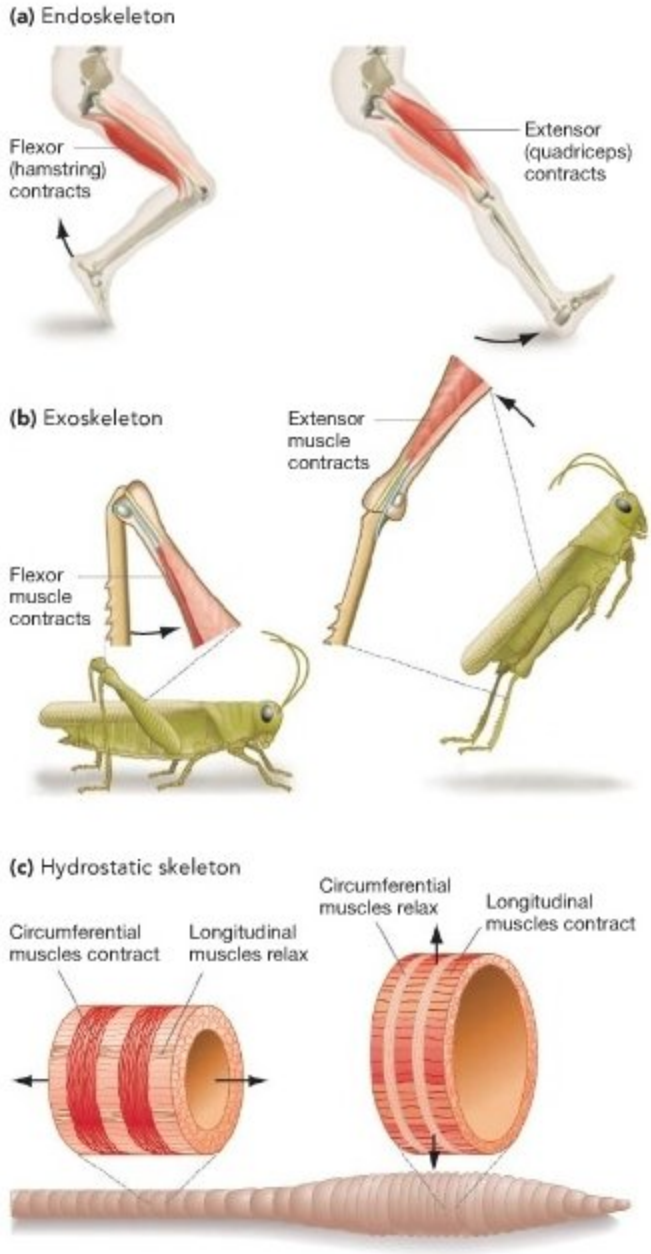

FIGURE 46.18 Antagonistic Muscle Groups Flex or Extend Skeletal Elements.

How Do Muscles Contract?

Early microscopists established that the muscle tissue found in vertebrate limbs and hearts is composed of slender fibers. A **muscle fiber** is a long, thin muscle cell. Within each of the muscle cells from limbs are many small strands called **myofibrils**. How do these strands work?

The Sliding-Filament Model As **Figure 46.19** shows, the myofibrils inside skeletal muscle cells look striped when viewed with the electron microscope. The pattern is caused by alternating light-dark units called **sarcomeres**, which repeat down the length of a myofibril. The sarcomeres in a myofibril shorten as the cell contracts. They lengthen when the cell is relaxed and an external force—exerted by the antagonistic muscle of the pair—stretches the muscle.

Based on these observations, it became clear that the question of how muscles contract simplifies to the question of how sarcomeres contract. Hugh Huxley and Jean Hanson proposed an answer to this question in 1954. These biologists had noticed that the relationship between different parts of the sarcomere—specifically, the points labeled A–D in the photographs in Figure 46.19—change during contraction. Points A and B move closer to each other during contraction, as do points C and D. But the distance from point A to point C does not change, and the distance from point B to point D does not change.

To explain these observations, Huxley and Hanson hypothesized that the banding patterns in the sarcomere are actually caused by two types of long filaments—**thick filaments** and **thin filaments**—and that these filaments slide past one another during contraction. **Figure 46.20** illustrates the model. Notice that thin filaments extend from A to C and thick filaments extend from B to D. According to Huxley and Hanson, the thick and thin filaments slide past one another during a contraction. This explanation became known as the **sliding-filament model**.

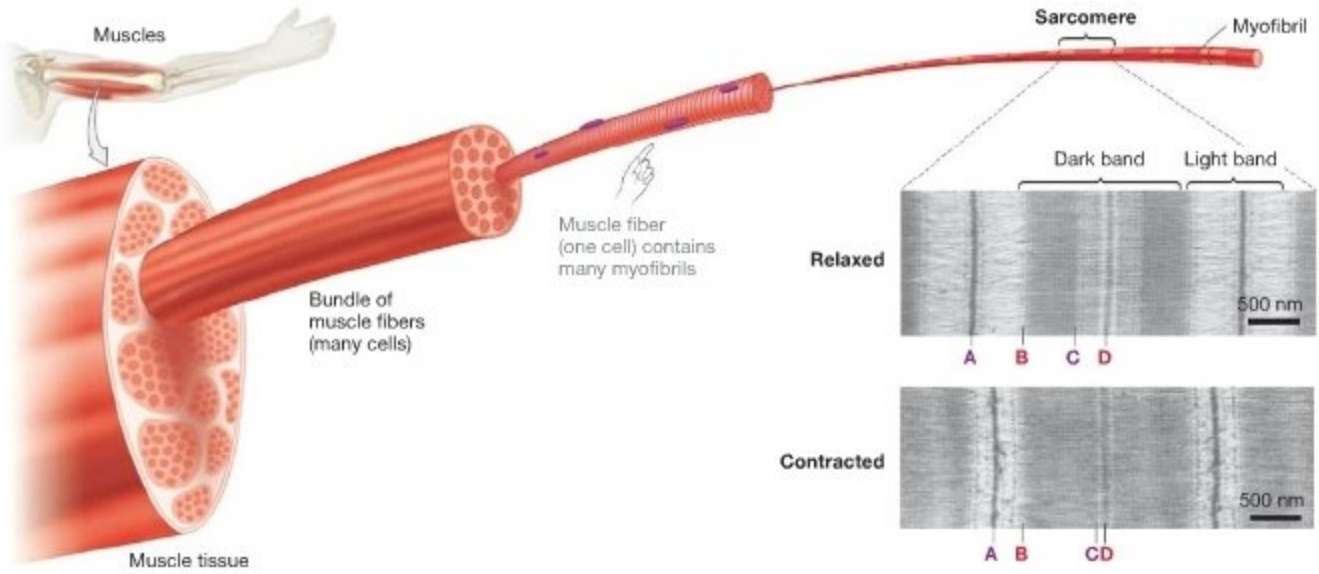

FIGURE 46.19 Muscle Cells Contain Many Myofibrils, Which Contain Many Sarcomeres. Skeletal muscle cells (fibers) have a striped appearance due to repeating sarcomeres, which are units of alternating light-dark bands. When a sarcomere contracts, the distances between the points labeled A, B, C, and D change.

● **QUESTION** Measure the distance from A to B, A to C, A to D, B to C, B to D, and C to D. Which points get closer together during contraction? Which points stay the same distance from each other?

Follow-up research has shown that the Huxley-Hanson model is correct in almost every detail. Thin filaments are composed of two coiled chains of the globular protein **actin**. (Recall from Chapter 7 that actin is the building block of the microfilaments found in the cytoskeleton. The structure of microfilaments is similar to the structure of thin filaments.) One end of each thin filament is bound to a structure called the **Z disk**, which forms the wall of the sarcomere. Z disks contain a protein that binds tightly to actin, anchoring the thin filament. The other end of a thin filament is free to interact with thick filaments. Thick filaments are composed of multiple strands of a long protein called **myosin** and are anchored to the middle of the sarcomere; at both ends they are free to interact with thin filaments. Indeed, researchers who

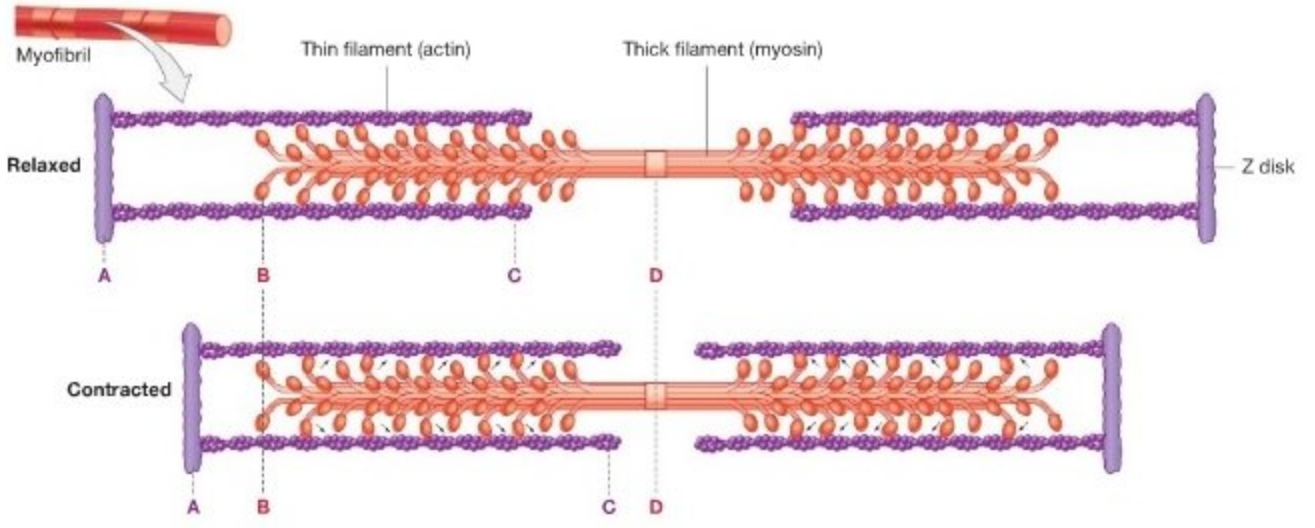

FIGURE 46.20 The Sliding-Filament Model of Sarcomere Contraction. Points A, B, C, and D are the same as those labeled on the sarcomere photographs in Figure 46.19.

● **EXERCISE** Label the Z disks in Figure 46.19. Label the "Dark band" and "Light band" regions in Figure 46.20.

● **QUESTION** Does this model explain the changes in distances that you observed in Figure 46.19? Explain.

isolated actin filaments and myosin molecules and mixed them together on a glass slide in the presence of ATP then observed actin sliding past myosin. As predicted, thick and thin filaments interact in a way that allows them to slide past one another.

To appreciate how the sliding-filament model works, consider the following analogy: Two large trucks are parked 50 m apart, facing each other. Each has a long rope attached to the front bumper. Teams of burly weightlifters grab onto each rope and pull, hand over hand, so that the two trucks roll toward one another. ● If you understand the model, you should be able to explain which elements in the analogy represent the Z disks, the thick filaments, and the thin filaments.

How Do Actin and Myosin Interact? Once the sliding-filament model was confirmed, researchers focused on the question of how the sliding action occurs at the molecular level. Early work on the three-dimensional structure of myosin revealed that each molecule has a head region that projects from the main body of the thick filament. Follow-up experiments established that the myosin head can bind to actin and that the head region can catalyze the hydrolysis of ATP into ADP and a phosphate ion. These results suggested that myosin—not actin—was the site of active movement.

In addition, electron microscopy revealed that myosin and actin are locked together shortly after an animal dies and its muscles enter the stiff state known as rigor mortis. Because ATP is unavailable in dead tissue, the data suggested that ATP is involved in getting myosin to release from actin once the two molecules have bound to each other.

The next major advance in understanding how actin and myosin interact to produce movement was achieved when Ivan Rayment and colleagues solved the detailed three-dimensional structure of the myosin head (**Figure 46.21**), using the X-ray crystallographic techniques introduced in **BioSkills 8**. Rayment's group determined the location of the actin binding site, and they examined how the protein's structure changed when ATP or ADP was bound to it. Because phosphorylation or dephosphorylation can lead to dramatic changes in the shape of a protein, the investigators were not surprised to find significant changes in the protein's conformation when bound to ATP versus ADP.

Based on these data, Rayment and co-workers proposed the model for actin-myosin interaction illustrated in **Figure 46.22**. The cycle of interactions begins at step 1, when the myosin head of a thick filament is attached to ATP but not to actin in a thin filament. (This is the conformation that occurs when a muscle is relaxed.) When ATP is subsequently hydrolyzed to ADP and inorganic phosphate in step 2, the conformation of the protein changes. Specifically, the neck of the myosin straightens out, and the head pivots. The myosin head then

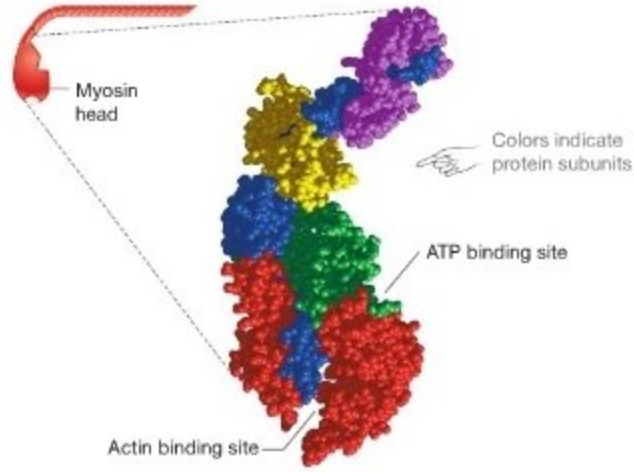

FIGURE 46.21 Myosin's "Head" Binds ATP and Actin. The head region of the myosin protein contains both an ATP binding site and an actin-binding site.

● **EXERCISE** Label the myosin heads in Figure 46.20.

binds to a new actin subunit farther down the thin filament. The third step occurs when inorganic phosphate is released and the protein's conformation changes again. Specifically, the neck bends back into its original position. This bending is called the power stroke, because it moves the entire thin filament. In step 4, ADP is released. A new ATP molecule then binds to the myosin, causing myosin to release from actin. The cycle can then start anew. (The transition from step 4 to step 1 cannot occur after death. Rigor mortis sets in as the ATP supplies run out.)

As ATP binding, hydrolysis, and release continue, the two ends of the sarcomere are pulled closer together. The same basic mechanism is observed in cardiac and smooth muscle cells. Most animal movement, in fact, is powered by similar interactions between actin and myosin. These two proteins are also responsible for the amoeboid movement observed in amoebae and slime molds (see Chapter 29) and the streaming of cytoplasm observed in algae and land plants. The message of these observations is that actin and myosin are evolutionarily ancient proteins. Because they make movement possible in the absence of cilia and flagella, they have played a critical role in the diversification of eukaryotes.

How Does Relaxation Occur? The results summarized in Figures 46.20 and 46.22 were obtained by studying myosin and actin in isolation. Although elegant and powerful, experiments on isolated fibers indicate only what is happening in individual fibers. In vitro, thick filaments from muscle continue to crawl along thin filaments as long as ATP and a length of

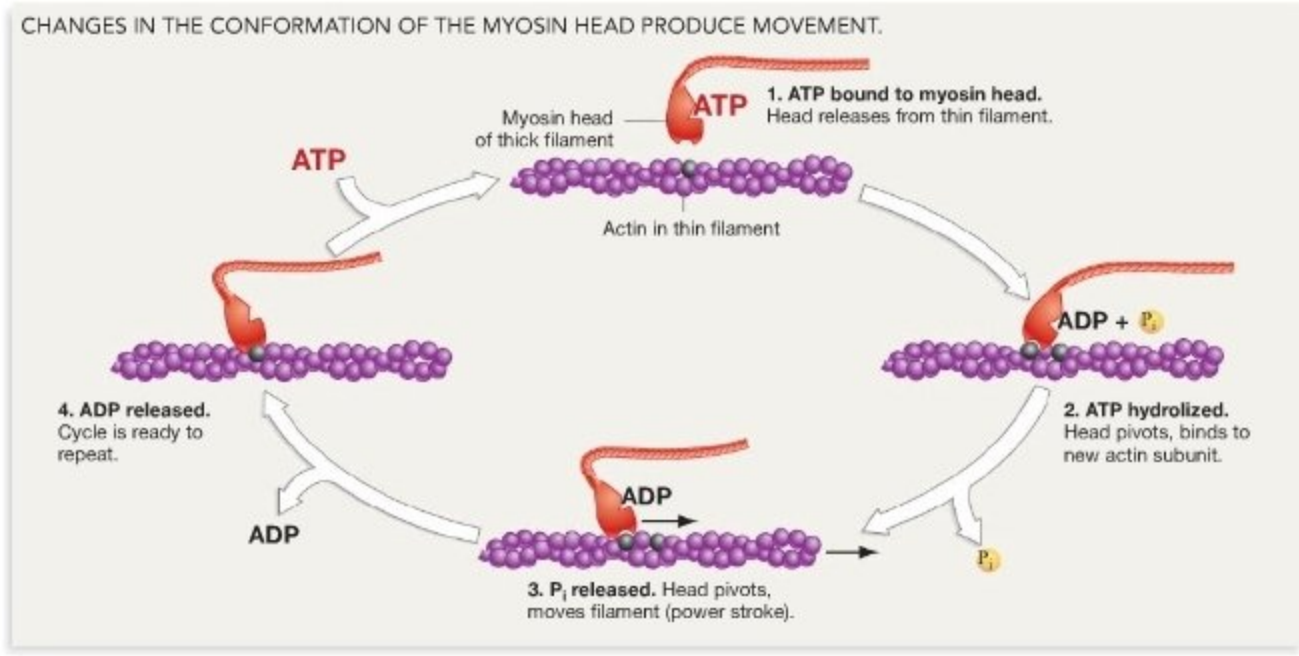

FIGURE 46.22 Myosin and Actin Interact during Muscle Contraction. Summary of the current model of how myosin and actin interact as a sarcomere contracts. The four steps repeat rapidly.

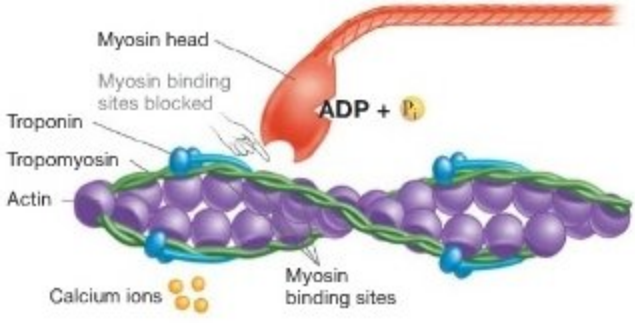
(a) Tropomyosin and troponin work together to block the myosin binding sites on actin.



(b) When a calcium ion binds to troponin, the troponin-tropomyosin complex moves, exposing myosin binding sites.

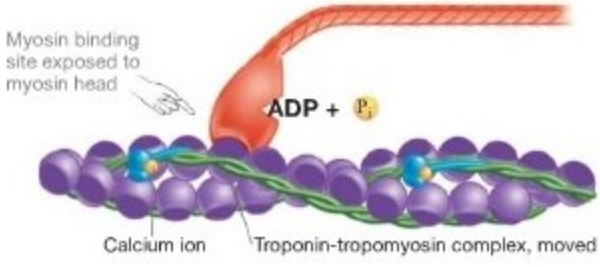


FIGURE 46.23 Troponin and Tropomyosin Regulate Muscle Activity.

thin filament are available. ATP is almost always available in living muscles. How do our muscles ever stop contracting and relax?

Researchers were able to answer this question when they confirmed that, in addition to containing actin, thin filaments contain two key proteins called **tropomyosin** and **troponin** (**Figure 46.23a**). Tropomyosin and troponin work together to block the myosin binding sites on actin. When tropomyosin and troponin are in the conformation shown at the top in **Figure 46.23b**, the myosin-actin interaction cannot occur, and thick and thin filaments cannot slide past each other. But when calcium ions bind to troponin, the troponin-tropomyosin complex moves in a way that exposes the myosin binding sites on actin.

In vivo, how are calcium ions released so that contraction can begin? The answer turned out to have several steps, beginning with the arrival of an electrical signal from a motor neuron.

An Overview of Events at the Neuromuscular Junction

Figure 46.24 summarizes what happens when an action potential from a motor neuron arrives at a muscle cell and initiates contraction:

1. Action potentials trigger the release of the neurotransmitter called **acetylcholine** (**ACh**) from the motor neuron into the synaptic cleft between the motor neuron and the muscle cell.

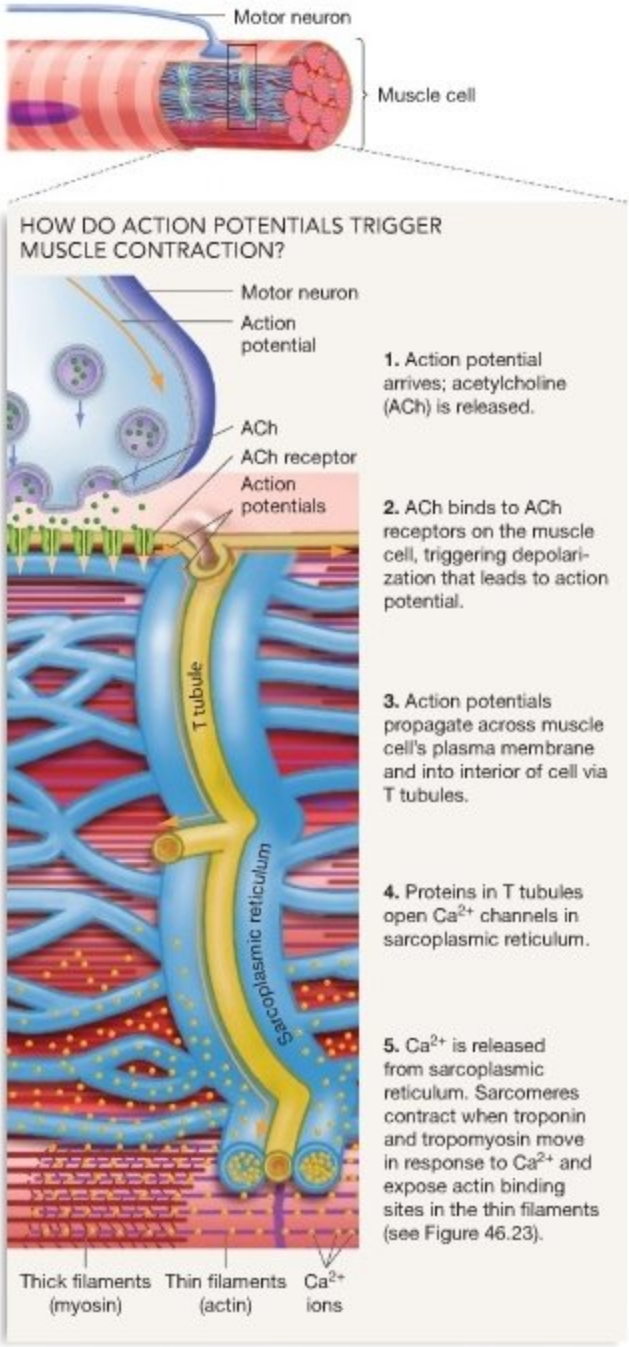

FIGURE 46.24 Action Potentials at the Neuromuscular Junction Trigger the Release of Ca^{2+}, Which Binds to Troponin-Tropomyosin and Allows Myosin to Form a Cross-Bridge with Actin. The arrival of action potentials from a motor neuron triggers a series of events in a muscle cell. The sequence ends with changes in troponin-tropomyosin proteins that allow contraction to begin.

2. Acetylcholine diffuses across the synaptic cleft and binds to ACh receptors on the plasma membrane of the muscle cell. By recording voltage changes in muscle cells, biologists showed that a membrane depolarization occurs in response to ACh release. If enough ACh is applied to a muscle cell, depolarization triggers an action potential in the fiber itself.

3. The action potentials propagate along the length of the muscle fiber and spread into the interior of the fiber via invaginations of the muscle cell membrane called **T tubules**. (The *T* stands for *transverse*, meaning "extending across.")

4. T tubules intersect with extensive sheets of smooth endoplasmic reticulum called the **sarcoplasmic reticulum**. When an action potential passes down a T tubule and reaches one of these intersections, a protein in the T tubule membrane changes conformation and opens calcium channels in the sarcoplasmic reticulum.

5. Calcium ions (Ca^{2+}) are released from the sarcoplasmic reticulum into the cytoplasm. The outward flow occurs because a tremendous concentration gradient exists—the concentration of calcium ions inside the sarcoplasmic reticulum is about 40,000 times that of the cytosol. Contact with Ca^{2+} causes a conformational change in troponin. The conformational change in troponin moves tropomyosin away from the myosin binding sites on actin. Myosin binds to actin.

To summarize, the arrival of an action potential causes a release of calcium ions that bind to troponin, causing tropomyosin to move and allowing contraction to begin. In the absence of an action potential, calcium is not released and the troponin-tropomyosin complex blocks further contraction. The grand result is that an arm or a leg or a wing moves; an animal grabs or runs or flies; and a piece of ripe fruit is picked, a sprinter breaks the tape, or a moth ducks under the gaping jaws of a bat.

Muscle Contraction

Muscle Types

Early anatomical studies confirmed that vertebrates have three distinct types of muscle tissue: (1) skeletal muscle, (2) cardiac muscle, and (3) smooth muscle. These muscle types were introduced briefly in Chapter 41; **Table 46.1** provides a more detailed comparison. Although all three cell types contract in response to electrical stimulation and actin-myosin interactions, they differ in overall morphology as follows:

SUMMARY TABLE **46.1 Types of Muscle in Vertebrates**

	Skeletal Muscle	Cardiac Muscle	Smooth Muscle
			Location	Attached to bones	Heart	Intestines, arteries, other
Function	Move skeleton	Pump blood	Move food, help regulate blood pressure, etc.
Cell characteristics	Multinucleate Unbranched Contains myofibrils Activity is "voluntary," meaning that signal from motor neuron is required	1 or 2 nuclei Branched; intercalated discs form direct cytoplasmic connection end to end Contains myofibrils Activity is "nonvoluntary," meaning that signal from motor neuron is not required	Single nucleus Unbranched No myofibrils Activity is "nonvoluntary," meaning that signal from motor neuron is not required

1. **Skeletal muscle** consists of unbranched multinucleate cells—they contain multiple nuclei. This tissue is also known as striated muscle, because it appears to be striated, or striped.
2. **Cardiac muscle** contains branched cells whose ends are connected via specialized regions called intercalated discs. In an **intercalated disc**, protein-lined openings called gap junctions provide a direct cytoplasmic connection between adjacent muscle cells. As Chapter 45 noted, intercalated discs are critical to the flow of electrical signals from cell to cell and to the coordination of the heartbeat.
3. **Smooth muscle** is unbranched, lacks myofibrils, and is often organized into thin sheets. It is essential to the function of the lungs, blood vessels, digestive system, urinary bladder, and reproductive system.

In combination, the three muscle types keep your blood flowing, the food you've eaten moving through your digestive system, and your body moving where you want it to go. Understanding movement is fundamental to understanding how animals work.

Check Your Understanding

If you understand that...

- Antagonistic muscle groups work in conjunction with skeletons to produce movement.
- Many types of movement are based on interactions between actin and myosin.

You should be able to...

1) Make a labeled diagram of a skeletal muscle fiber, showing the relationship between the multinucleate cell, myofibrils, and sarcomeres.
2) Describe the sliding-filament model.
3) Explain how binding by ATP and hydrolysis of ATP affect the interaction between actin and myosin.
4) Predict the effect on muscle function of drugs that have the following actions: increase ACh release at the neuromuscular junction, prevent conformational changes in troponin, and block uptake of calcium ions into the sarcoplasmic reticulum.

Chapter Review

SUMMARY OF KEY CONCEPTS

Sensory receptor cells transduce sound, light, or other stimuli to a change in membrane potential. Receptor cells or sensory neurons send action potentials to the brain, where the signals are processed and integrated.

If the membrane potential of a sensory cell is altered substantially enough in response to a stimulus, the pattern of action potentials that it sends to the brain changes. In this way, sensory stimuli as different as sound and light are transduced to electrical signals. The brain is able to distinguish different types of stimuli because axons from different types of sensory neurons project to different regions of the brain.

You should be able to suggest a hypothesis to explain why people who have had limbs amputated experience "phantom pain"—the perception that their missing tissue hurts.

Hearing is based on sensory receptor cells that move in response to sound waves of a particular frequency. The movement opens ion channels in the sensory cells and results in a change in membrane potential.

Pressure receptors detect direct physical stimulation, including stimulation from sound. Hair cells, the major sensory detectors in the vertebrate ear, undergo a change in membrane potential in response to bending of their stereocilia. Hair cells contact a basilar membrane, and experiments with isolated cochleas showed that sound waves of a certain frequency cause a certain part of the basilar membrane to vibrate. Because of this specificity in hair-cell response, mammals can discriminate different pitches.

You should be able to predict how a hair-cell–like receptor could be involved in gravity sensing in plants, in response to pressure exerted by the dense, starch-filled organelles called amyloplasts.

Vision is based on sensory receptor cells that contain a light-absorbing pigment bound to a protein. The pigment changes conformation when it absorbs light and triggers a series of events that change the cell's membrane potential.

In the vertebrate eye, photoreceptors are located in rods and cones. Although these two cell types differ in structure and function, both contain rhodopsin molecules that consist of retinal paired with opsin. The rhodopsin found in rods is stimulated by even the faintest light. Color vision is possible because cones contain opsins that respond to specific wavelengths of light absorbed by retinal. Humans distinguish colors based on the pattern of stimulation of three types of opsins found in cones. People who lack one of these cone opsins are color blind, meaning they cannot distinguish as many colors as people with all three opsins can.

You should be able to explain why different animal species are able to see different colors.

MB Web Animation at www.masteringbio.com
The Vertebrate Eye

Taste and smell are based on membrane proteins that act as receptors or channels for particular molecules and that trigger changes in membrane potential.

Chemoreceptors detect the presence of certain foodborne or airborne molecules. Taste buds, for example, contain taste cells with membrane proteins that respond to toxins, salt, acid, and other types of molecules in food. Sodium ions and protons enter taste cells via channels and depolarize the membrane directly. Toxic compounds bind to membrane receptors and trigger action potentials that are interpreted by the brain as bitterness. Smell, or olfaction, is used to scan molecules from the outside environment. Airborne chemicals are detected by hundreds of different odor-receptor proteins located in the membranes of receptor cells in the nose.

You should be able to explain why the brain can perceive so many different flavors based on inputs from just four or five basic types of taste receptors, and why people with nasal congestion complain that food tastes bland.

In many cases, animals respond to sensory stimuli by moving. Movement is based on antagonistic muscle groups that act on a stiff skeleton containing joints that flex or extend in response to electrical signals.

All animal muscles use the same basic mechanism for contraction. Muscles shorten when thick filaments comprised of myosin slide past thin filaments comprised of actin, in a series of binding events mediated by the hydrolysis of ATP. Calcium ions play an essential role in muscle contraction, by making the actin in thin filaments available for binding by myosin. In animals with exoskeletons or endoskeletons, muscles are usually arranged in opposing pairs of flexors and extensors. Many animals with hydrostatic skeletons have muscles arranged in opposing pairs of circular and longitudinal bands. In all cases, muscles work in concert with skeletons.

You should be able to predict the primary symptom of botulism, which occurs when a toxin prevents release of ACh from the neuromuscular junction.

Muscle Contraction

QUESTIONS

Test Your Knowledge

1. What is the major function of the mammalian middle ear?
   a. It amplifies the sound energy transmitted to the cochlea.
   b. It transmits sound vibrations to the tympanic membrane.
   c. It circulates fluid through the cochlea.
   d. It contains hair cells that detect specific frequencies of sound.

2. In the human ear, why do different hair cells respond to different frequencies of sound?
   a. Waves of pressure move through the fluid in the cochlea.
   b. Hair cells are "sandwiched" between membranes.
   c. Receptors in the stereocilia of each hair cell are different; each receptor protein responds to a certain range of frequencies.
   d. Because the basilar membrane varies in stiffness, it vibrates in certain places in response to certain frequencies.
3. Which of the following comparisons of rods and cones is *false*?
   a. The eyes of most humans have one type of rod and three types of cones.
   b. Rods are more sensitive to dim light than cones are.
   c. There are more rods than cones in the fovea.
   d. Both rods and cones use retinal and opsins to detect light.
4. Which of the following statements about taste is *true*?
   a. Sweetness is a measure of the concentration of hydrogen ions in food.
   b. Sodium ions from foods can directly depolarize certain taste cells.
   c. All bitter-tasting compounds have a similar chemical structure.
   d. Membrane receptors are involved in detecting acids.
5. In muscle cells, myosin molecules continue moving along actin molecules as long as
   a. ATP is present and troponin is not bound to Ca^{2+}.
   b. ADP is present and tropomyosin is released from intracellular stores.
   c. ADP is present and intracellular ACh is high.
   d. ATP is present and intracellular Ca^{2+} is high.
6. Which of the following is critical to the function of exoskeletons, endoskeletons, and hydrostatic skeletons?
   a. Muscles interact with the skeleton in antagonistic groups.
   b. Muscles attach to each of these types of skeleton via tendons.
   c. Muscles extend joints by pushing them.
   d. Segments of the body or limbs are extended when paired muscles relax in unison.

Test Your Knowledge answers: 1. a; 2. d; 3. c; 4. b; 5. d; 6. a

Test Your Understanding

Answers are available at www.masteringbio.com

1. Describe how a sound, a light, and an odor are transduced into a change in the pattern of action potentials from a sensory cell. How does the brain know which sense is which when the action potentials reach the brain?
2. Give three examples of how the sensory abilities of an animal correlate with its habitat or method of finding food and mates.
3. How did the discovery of odor-receptor genes affect our understanding of how the sense of smell works?
4. Draw a hair cell and explain how bending of stereocilia results in a change in membrane potential.
5. Scientists generally think that a "good hypothesis" is one that is reasonable, is testable, and inspires further research into the field. Using these criteria, was Dalton's hypothesis about color vision a good hypothesis? Was it correct?
6. How did observations of sarcomere structure inspire the sliding-filament model of muscle contraction? Explain why the observation that muscle cells contain a large number of mitochondria and extensive smooth endoplasmic reticulum turned out to be logical once the molecular mechanism of muscular contraction was understood.

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Myasthenia gravis is a disease that develops in humans when the immune system produces proteins that bind to the acetylcholine (ACh) receptors in muscles. The primary symptom of myasthenia gravis is muscle weakness. Why?
2. Houseflies have about 800 ommatidia in each of their compound eyes. Dragonflies, in contrast, have up to 10,000 ommatidia per eye. Houseflies feed by lapping up watery material from piles of excrement or rotting carcasses, which they locate by scent. Dragonflies are aerial predators and hunt by sight. Suggest a hypothesis to explain the difference in the structure of their eyes. How would you test your hypothesis?
3. Skeletal muscles contain two general types of cells. "Slow-twitch fibers" produce ATP via cellular respiration. They are reddish because they have a high concentration of myoglobin—a protein that delivers oxygen to electron transport chains during cellular respiration. Slow-twitch fibers support endurance exercise. Fast-twitch fibers, in contrast, produce ATP primarily via fermentation. They do not have large quantities of myoglobin and are light in color. They support extremely fast contraction but tire easily. Chickens, turkeys, and other ground-dwelling birds can run long distances but escape from predators by flying in short, extremely fast bursts. Based on these observations, explain the distribution of "dark meat" and "white meat" in these birds. Most other birds do not have white meat. Why?
4. When looking at faint stars through a telescope, astronomers will focus their eyes just to the side of the object. Instead of landing on the fovea, then, the star's image falls next to the fovea. With this technique, faint objects pop into view. They vanish if looked at directly, however. Explain what is going on.

47 Chemical Signals in Animals

KEY CONCEPTS

- Animals use at least six major types of chemical signals. Hormones are those chemical signals that are present in tiny concentrations and travel throughout the body to affect target cells.
- The information in hormonal signals helps animals respond to environmental change, develop as embryos, undergo sexual maturation, and achieve homeostasis.
- The production of a hormone is tightly regulated by input from the nervous system and by other hormones.
- Some hormones bind to receptors inside target cells and change gene expression. Other hormones bind to receptors at the cell surface and lead to changes in protein activation.

The spectacular transformation that occurs during insect metamorphosis is triggered by the chemical signals called hormones.

In response to sights, sounds, and other sensory stimuli, an animal's nervous system sends rapid messages to precise locations in the body. In many cases, these messages result in muscle contractions and movement.

As conditions inside and outside an animal change, however, cells in the central nervous system (CNS) or cells in specialized organs that make up the **endocrine system** may trigger the release of molecules that produce longer-term responses in a broad range of tissues and organs. A chemical signal that circulates through body fluids and affects distant target cells is called a **hormone**. As you read this, a large suite of hormones is coursing through your circulatory system. These molecules are regulating the maturation of sperm or eggs by your reproductive system, changing the composition of the urine forming in your kidneys, and controlling the release of digestive enzymes in your gastrointestinal tract. Earlier in your life, changes in hormone concentrations led to the dramatic physical changes associated with puberty.

Animal hormones are present in extremely low concentrations but have enormous effects on their target cells. Unlike action potentials, which are electrical impulses that have a short-term effect on a single cell or on a small population of adjacent cells, the messages that hormones carry are received by many different cells and have a relatively long-lasting effect. In combination, electrical and chemical signals allow animals to coordinate the activities of cells throughout the body. They are the mechanism responsible for maintaining trillions of cells as the integrated unit we call an individual.

The goal of this chapter is to explore how hormones and other types of chemical signals work in animals. Let's begin with an overview of their chemical signaling systems, and then plunge into analyzing how hormones regulate the activity of target cells.

47.1 Cell-to-Cell Signaling: An Overview

For over a century, biologists have been exploring how chemical messengers function in animals. One of the most basic conclusions from this work is that the chemical signals found in animals have diverse structures and functions. **Figure 47.1** summarizes how biologists go about organizing the diversity of chemical signals, based on where the molecules originate and where they act. Notice that the names for most of the categories use the Greek word root *crin*, meaning "separated." Its use captures something essential about how chemical signals act: They are released from cells and thus are separated from them. There are six major categories of chemical signals:

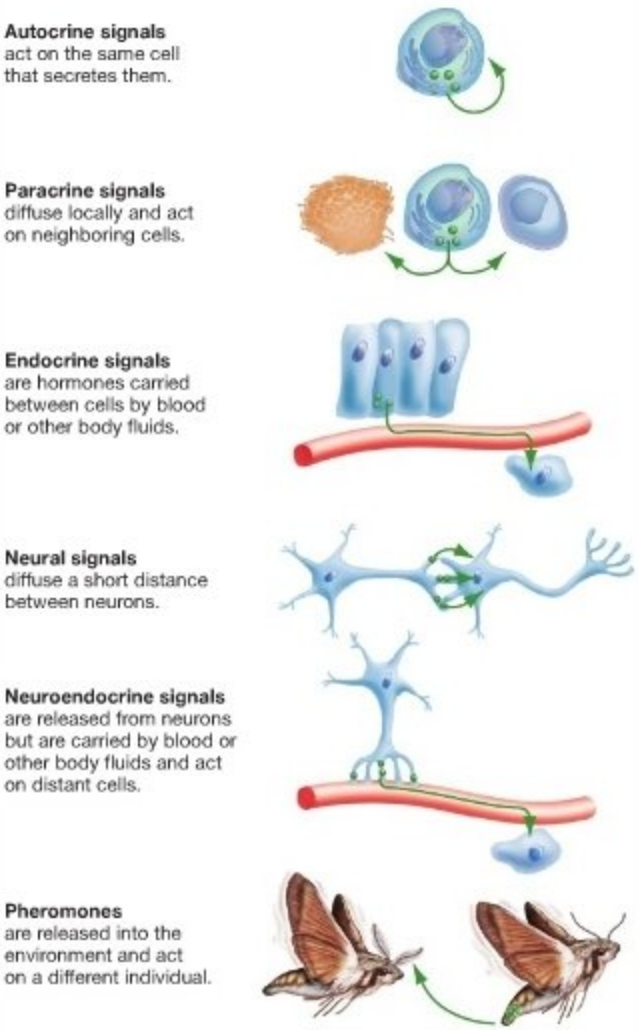

FIGURE 47.1 There Are Six Categories of Chemical Signals in Animals. Chemical signals can be categorized by how they move from the cells that produce them to the target cells that respond to them.

1. **Autocrine** (literally, "same-separated") signals act on the same cell that secretes them. Perhaps the best-studied autocrine signals are **cytokines** ("cell-movers"). The function of most cytokines is to amplify the response of a cell to a stimulus. An example is interleukin 2, which is synthesized and released by a type of white blood cell called a T cell in the course of fighting an infection. Interleukin 2 activates T cells to help eliminate the infection. It also causes the cells to divide repeatedly, producing more activated T cells for host defense.

2. **Paracrine** ("beside-separated") signals diffuse locally and act on neighboring cells. Cytokines may act as paracrine signals as well as autocrine signals, because they can trigger responses by other cells of the immune system. It is common, in fact, to observe that a single chemical messenger acts in a variety of ways. As an example, consider molecules that are produced by three distinct populations of cells within a region of the pancreas called the islets of Langerhans. The molecules named **insulin**, **glucagon**, and **somatostatin** act on nearby pancreatic cells as paracrine signals and ensure a smooth, steady response to changing blood-glucose levels. But they also act as hormones—meaning they target distant cells—in controlling the concentration of glucose in the blood.

3. **Endocrine** ("inside-separated") signals are hormones—molecules that are carried between distant cells by blood or other body fluids. The cells that produce endocrine signals may be organized into discrete organs called **glands** or may be interspersed among the cells of other organs.

4. **Neural** signals, introduced in Chapter 45, are the chemical messengers called **neurotransmitters**. Neural signaling can be very fast, because neurotransmitters have to diffuse only a short distance—the tiny gap between two neurons, called the synaptic cleft.

5. **Neuroendocrine** ("nerve-inside-separated") signals are considered hormones because they act on distant cells after being released from neurons, instead of acting at the adjacent synapse. Antidiuretic hormone (ADH; also called vasopressin), introduced in Chapter 42, is a good example. ADH is produced by neurons that originate in the hypothalamus of the brain, but the molecule acts on cells in the collecting duct of the kidney to help regulate water excretion.

6. **Pheromones** are signals that are released into the environment and act on a different individual. In sea urchins, insects, and many other species, pheromones help coordinate reproduction in males and females or function in attracting mates.

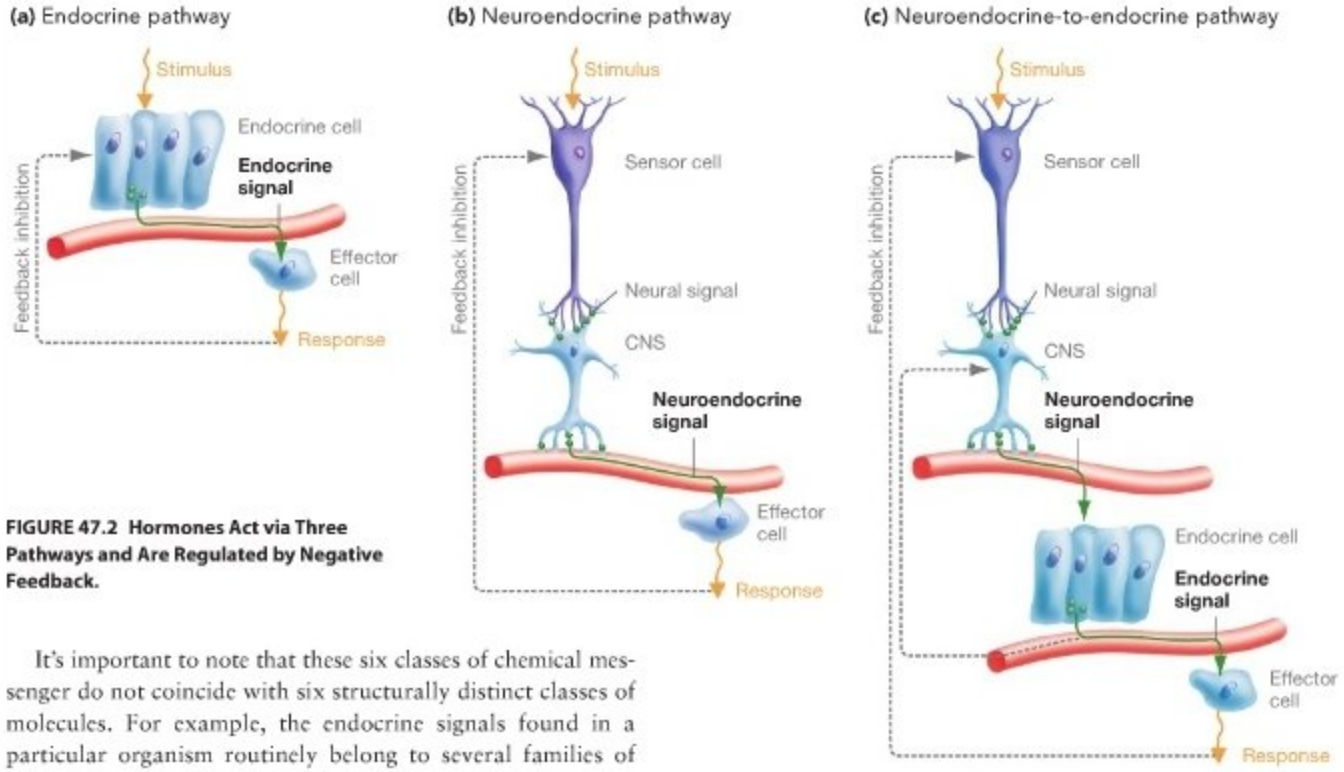

FIGURE 47.2 Hormones Act via Three Pathways and Are Regulated by Negative Feedback.

It's important to note that these six classes of chemical messenger do not coincide with six structurally distinct classes of molecules. For example, the endocrine signals found in a particular organism routinely belong to several families of chemical compounds, ranging from amino acid derivatives to glycoproteins. And a particular family of molecules—say, peptides or the lipids called steroids—may function as endocrine, autocrine, and paracrine signals in the same individual.

The diversity of chemical signal types observed in animals is impressive. This chapter focuses primarily on hormones, however, because they are well studied and because they are particularly important to understanding how animals work. Let's begin with an introduction to how these long-distance signals are produced and received.

Hormone Signaling Pathways

In plants, sensory cells perceive changes in the environment and broadcast a hormonal signal that triggers an appropriate response from effector cells. Some animal hormones are also sent directly from endocrine cells to effector cells, in response to a stimulus (**Figure 47.2a**). But more frequently, hormonal signaling in animals involves additional steps.

In many or most cases, information about external or internal conditions is gathered by receptors and then integrated by neurons in the central nervous system (CNS) prior to the production of a hormonal signal. Neurons in the CNS respond by synthesizing and releasing neuroendocrine signals that either act on effector cells directly (**Figure 47.2b**) or—more commonly—stimulate cells in the endocrine system. The endocrine cells then respond by producing a hormone: an endocrine signal that acts on effector cells and triggers an appropriate response (**Figure 47.2c**).

All three types of signaling pathway—direct from an endocrine cell, direct from CNS, or CNS-to-endocrine system—are regulated by **negative feedback,** or **feedback inhibition.** When feedback inhibition occurs, the product of a process inhibits its production. In the case of the endocrine pathway, the response by the effector cells feeds back on endocrine cells, lowering production of the hormone and down-regulating the response (Figure 47.2a). An effector's response also feeds back to cells that initiate the neuroendocrine and neuroendocrine-to-endocrine pathways. A change in input from these cells then lowers production of the signal and reduces the response (see Figures 47.2b and 47.2c). Neuroendocrine-to-endocrine signaling pathways have an additional layer of regulation, because the endocrine signal usually inhibits production of the neuroendocrine signal (Figure 47.2c).

Feedback inhibition in the endocrine system is analogous to temperature control by a heat-sensitive thermostat. If the temperature is too high, the thermostat sends a signal that turns the furnace off; if the temperature is too low, the thermostat sends a signal that turns the furnace on. The result is a constant air temperature. With hormonal signals, feedback inhibition reduces production of the hormone. ● If you understand this concept, you should be able to explain which parts of the thermostat analogy correspond to the sensory input, CNS, cell-to-cell signal, and effector in a hormone signaling pathway. You should also be able to predict what happens when feedback inhibition fails in a hormone signaling pathway.

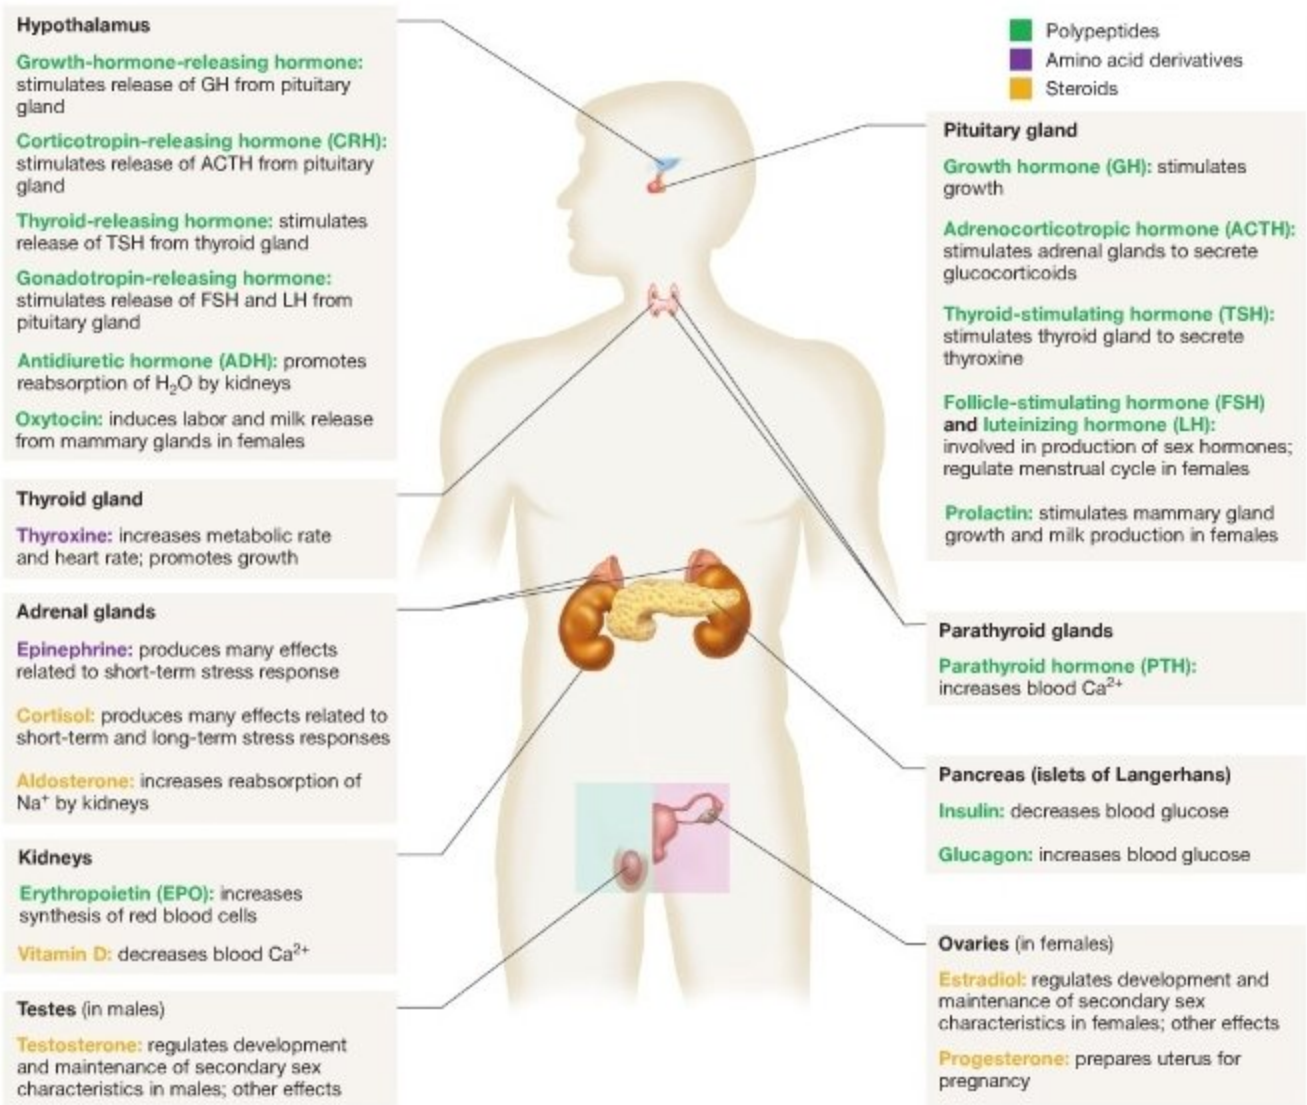

FIGURE 47.3 An Overview of the Human Endocrine System. A partial list of the endocrine glands and hormones found in humans. The heart, gastrointestinal tract, adipose tissue, and many other hormone-producing organs and cells could also be added to this list.

EXERCISE Write the meanings of the following word roots next to the appropriate hormone: *tocus* ("birth"), *insula* ("island"), *pro* ("before"), *lacto* ("milk"), *epi* ("above"), *nephro* ("kidney"), *cortic* ("outer shell," or "cortex"), *erythryo* ("red"), *poiesis* ("make"), *luti* ("yellowing").

What Are the Components of the Endocrine System?

The endocrine system is the collection of cells, tissues, and organs responsible for hormone production and secretion. Organs that secrete a hormone into the bloodstream are called **endocrine glands**.

The tissues and organs that make up the endocrine system vary widely among animals. For example, neurons that manufacture and secrete hormones are particularly important in insects, where they regulate molting, metamorphosis, and other processes. Salmon have an unusual gland that secretes a hormone responsible for regulating calcium ion concentration. And within a species, the diversity of endocrine system components can be impressive. For example, consider the major glands that have endocrine functions in humans (**Figure 47.3**).

- The **hypothalamus** is a region deep within the brain.
- The **pituitary gland** sits just below the hypothalamus and has distinct anterior and posterior regions.

- The **thyroid gland** is situated in the neck.
- The four **parathyroid glands** are embedded in the thyroid gland.
- The two **kidneys** lie in the posterior part of the abdominal cavity.
- The two **adrenal glands** sit atop the kidneys and have an outer cortex and a central medulla.
- The endocrine component of the **pancreas** is located in the anterior part of the abdominal cavity.
- The paired **ovaries** (in females) or **testes** (in males) are in or suspended below the pelvic cavity, respectively.

Although endocrine glands are a key part of the endocrine system, in many cases cells that secrete hormones are not organized into discrete glands. Instead, they are located in other organs. For example, the intestine produces secretin, the heart produces atrial natriuretic hormone, and the cells of fat tissue produce leptin. Secretin stimulates the exocrine portion of the pancreas, atrial natriuretic hormone causes the kidney to excrete salt, and **leptin** helps regulate the amount of fat stored in the body.

Finally, it's important to note that not all glands in the body are part of the endocrine system. **Exocrine glands**, in contrast to endocrine glands, deliver their secretions through outlets called ducts into a space other than the circulatory system. Most of the digestive glands introduced in Chapter 43 were either exocrine glands, such as the salivary glands, or mixed endocrine and exocrine glands, such as the pancreas. The exocrine portions of the pancreas secrete digestive enzymes through ducts into the intestine. The endocrine portion of the pancreas consists of cells in the **islets of Langerhans**. In this region of the pancreas, clusters of cells secrete insulin and glucagon directly into the bloodstream.

At first glance, the diversity of hormones, glands, and effects can seem almost overwhelming, especially considering that Figure 47.3 represents just a partial catalog for a single species. The picture is simplified somewhat, however, by recognizing that most animal hormones belong to one of just three major structural families: polypeptides, amino acid derivatives, or steroids. Let's take a closer look.

Chemical Characteristics of Hormones

The three major classes of chemicals that can act as hormones in animals are illustrated in **Figure 47.4**: (1) polypeptides, which are chains of amino acids linked by peptide bonds (see Chapter 3); (2) amino acid derivatives; and (3) steroids, which are a family of lipids distinguished by a four-ring structure (see

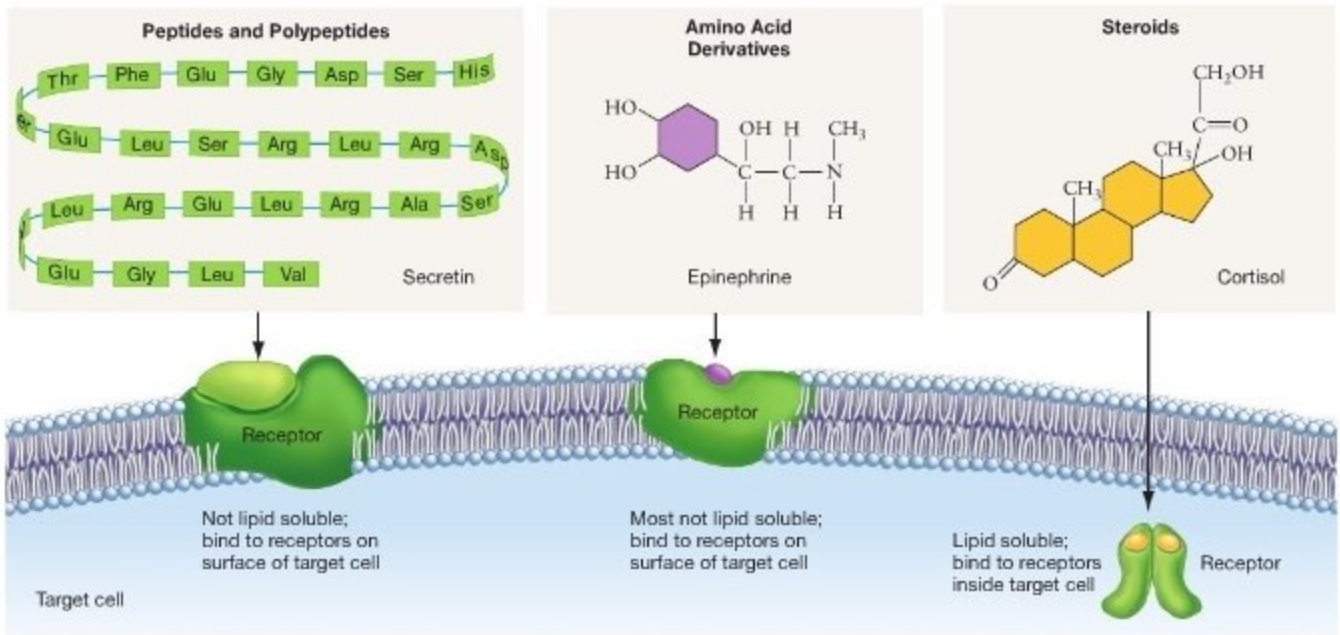

FIGURE 47.4 Most Animal Hormones Belong to One of Three Chemical Families.

QUESTION Secretin and epinephrine are not lipid soluble and do not cross plasma membranes readily. Cortisol, in contrast, is lipid soluble and diffuses through plasma membranes efficiently. How do the size and charge of these molecules explain the difference in lipid solubility?

Chapter 6). The secretin produced in the small intestine is a polypeptide; epinephrine is synthesized in the adrenal medulla from the amino acid tyrosine; and cortisol is synthesized in the adrenal cortex from the steroid cholesterol.

Polypeptide hormones, amino-acid–derived hormones, and steroid hormones have important similarities, as well as important differences. All animal hormones share several defining characteristics:

- All hormones are organic compounds.
- All hormones are secreted from the cells where they are synthesized.
- All hormones act on target cells remote from their point of origin.
- All hormones are present in extremely small concentrations yet have large effects.

To drive this last point home, consider work on **growth hormone** (**GH**), also known as somatotropin. Several researchers had noted that rats and other laboratory animals stopped growing when their pituitary glands were removed. Based on this observation, it was widely suspected that the pituitary produces a chemical signal that promotes cell division and other aspects of growth. A research group was able to purify a polypeptide from cow pituitary glands, inject the polypeptide into lab rats, and document rapidly accelerated growth. When the researchers injected 0.01 mg of the molecule each day for nine days into rats that lacked pituitary glands, the width of the growth plates in the leg bones increased by 50 percent, and the individuals gained an average of 10 g compared with rats that lacked a pituitary and did not receive the hormone treatment. Stated another way, the addition of a total of 0.09 mg of hormone led to a weight gain of 10,000 mg. Further, 1 kg of cow pituitary tissue yielded a mere 0.04 g of growth hormone. By weight, the hormone makes up just four one-thousandths of 1 percent of the cow pituitary.

Given that small amounts of polypeptide, amino-acid–derived and steroid hormones have large effects, how do the three types of hormones differ? The major difference is that steroids are lipid soluble, while polypeptides and most amino acid derivatives are not (see Figure 47.4). An important exception to this rule is thyroxine, which is produced by the thyroid gland. Thyroxine is derived from the amino acid tyrosine but is lipid soluble.

Differences in solubility are important because steroids and thyroxine cross plasma membranes much more readily than do other types of hormones. To affect a target cell, all polypeptides and most amino acid derivatives bind to a receptor on the cell surface. Lipid-soluble hormones, in contrast, can diffuse through the plasma membrane and bind to receptors inside the cell. Before exploring the consequences of this difference in more detail, let's consider how researchers discovered the array of hormones introduced here.

How Do Researchers Identify a Hormone?

Research on animal hormones began in earnest in the early 1900s with the discovery of **secretin**. You might recall from Chapter 43 that researchers who were investigating how secretions from the pancreas are regulated had cut all the nerves connected to the upper part of the small intestine and pancreas of a dog, to address the hypothesis that secretion was stimulated by electrical signals. The biologists then added a small amount of dilute hydrochloric acid (HCl) to the small intestine, mimicking the arrival of acidic material from the stomach. They found that the pancreas secreted compounds that buffered, or neutralized, the acid in the small intestine (**Figure 47.5**).

How could stimulating the small intestine lead to a response by the pancreas? The response could not have been mediated by the nervous system, since all the nerves to the pancreas had been cut. Instead, the biologists proposed that a chemical had traveled from the small intestine to the pancreas by way of the bloodstream to signal the arrival of acid. To test this hypothesis,

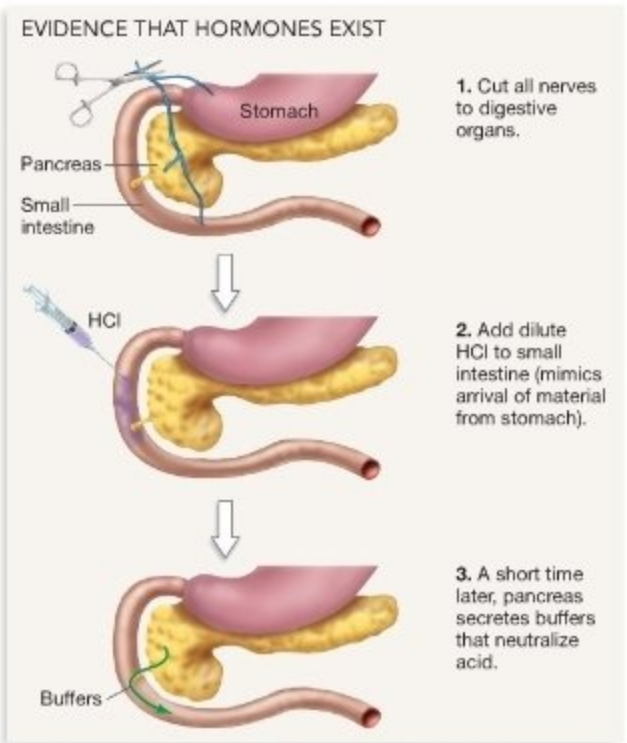

FIGURE 47.5 Experimental Evidence that a Hormone from the Small Intestine Signals Cells in the Pancreas, via Blood. The key assumption here was that a blood-borne signal was the only way for the small intestine to communicate with the pancreas.

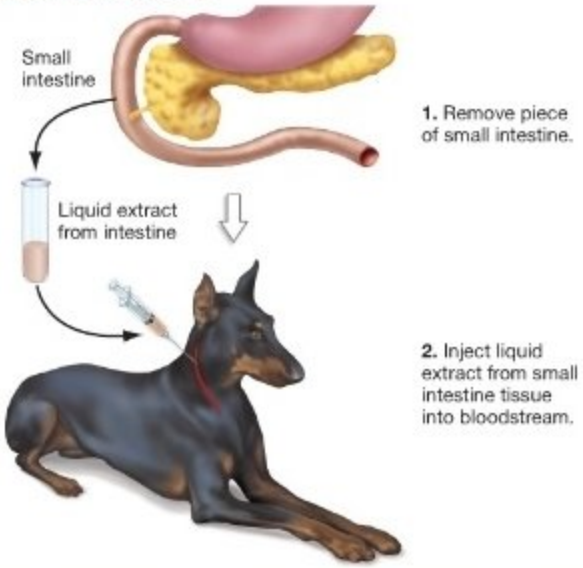
Experiment

Question: Can the hormone hypothesis for pancreatic secretion be tested rigorously?

Hypothesis: A chemical messenger from the small intestine reaches the pancreas via the bloodstream.

Null hypothesis: There is no blood-borne chemical messenger from the small intestine that acts on the pancreas.

Experimental setup:



Prediction: Liquid extract in bloodstream will signal pancreas to secrete buffer.

Prediction of null hypothesis: Liquid extract in bloodstream will not signal pancreas to secrete buffer.

Results:

Conclusion: The extract from the small intestine contains a hormone (secretin) that stimulates the pancreas.

FIGURE 47.6 Experimental Evidence that a Hormone from the Small Intestine Signals Cells in the Pancreas, via Blood. Follow-up work succeeded in isolating the molecule secretin from a soluble intestinal extract.

the researchers did the experiment diagrammed in **Figure 47.6**. An extract from the small intestine was injected into blood vessels in a dog's neck. A short time later, the biologists observed that the pancreas secreted an alkaline solution. This was strong evidence that the extract from the small intestine contained a hormone. The molecule was later purified and named secretin.

In addition to using liquid extracts to identify hormones, biologists have focused on analyzing the results of experimental or natural destruction of organs. For example, the experimental removal of the adrenal glands in animals or damage to the adrenal glands in humans by hemorrhage, tumor, or infection rapidly leads to death associated with very low levels of blood sugar and blood pressure. The injection of adrenal extracts into the blood of animals lacking adrenal glands corrects these abnormalities. Results like these provided strong evidence that hormones secreted by the adrenal glands help regulate blood sugar concentrations and blood pressure.

Documenting an association between a particular gland or hormone and an effect in the body is just the first step in understanding hormone action, however. Researchers gained deeper insights into the role of chemical signaling when they were able to step back and consider how the array of hormones they were cataloging help animals stay alive and produce offspring.

47.2 What Do Hormones Do?

At the beginning of this chapter, you read that hormones are chemical messengers. If so, what do hormones "say"? A first step in answering this question is to recognize that even a single type of hormone can exert a variety of effects. Consider thyroxine, for example. In humans, thyroxine stimulates metabolism and thus oxygen consumption throughout the body. But it also promotes growth, increases the heart rate, and stimulates the synthesis of many important macromolecules. (**Box 47.1** explores the medical implications of abnormalities in the production of thyroxine.) A second step in grasping what hormones do is recognizing that several different types of hormones may affect the same aspect of physiology. For example, the blood-glucose concentration is regulated by insulin, glucagon, epinephrine, and cortisol.

Some hormones have extremely diverse effects, whereas functions of other hormones appear to overlap. These observations begin to make sense when hormone action is viewed in the context of the whole organism. Hormones coordinate the activities of cells in response to three general situations: (1) environmental challenges; (2) growth, development, and reproduction; and (3) homeostasis. Let's analyze each in turn.

How Do Hormones Coordinate Responses to Environmental Change?

The challenges or stimuli that hormones respond to can be simple or complex. Digestive hormones are a good example of how hormones function in simple stimulus-and-response circuits. When acidic food material passes from the stomach to the upper reaches of the small intestine, the food triggers the release of secretin and cholecystokinin by intestinal

cells into the bloodstream. Recall that **secretin** induces the pancreas to secrete an alkaline solution that neutralizes acid. **Cholecystokinin** is a hormone that causes the pancreas to secrete digestive enzymes into the small intestine. Cholecystokinin also causes the gallbladder to eject bile salts into the intestine to emulsify fats. In this way, digestive hormones signal the arrival of food and regulate the release of molecules that aid digestion. But what about more complex environmental stimuli?

Short-Term Responses to Stress When a person is thrust into a dangerous or unpredictable situation, hormones are involved in both the short-term and long-term responses. The short-term reaction, called the **fight-or-flight response**, occurs in conjunction with the activation of the sympathetic nervous system, which was described in Chapter 45. Sympathetic nerves prepare organs for stressful situations. If you were being chased by a grizzly bear, action potentials from your sympathetic nerves would stimulate your adrenal medulla and lead to the release of **epinephrine**, also known as **adrenaline**. (The Greek word roots *epi* and *nephron* mean "top-kidney"; the Latin word roots *ad* and *renal* also mean "top-kidney.")

To understand the responses that occur, consider the experiment reported in **Figure 47.7**. To determine how epinephrine affects the body, human volunteers received injections of a saline solution or epinephrine. The graphs in the "Results" section of the figure document dramatic increases in the concentrations of free fatty acids and glucose in the blood following the injection of epinephrine. The data in the table confirm significant increases in pulse rate, blood pressure, and oxygen consumption by the brain. In addition, the volunteers reported strong subjective feelings of anxiety and excitement. Other experiments showed that epinephrine leads to dramatic changes in the distribution of blood. Specifically, the fight-or-flight response includes a redirection of blood toward the heart, brain, and muscles and away from the skin and digestive system. Epinephrine also relaxes smooth muscle and thereby opens blood vessels—increasing blood delivery to targeted tissues.

Taken together, the responses to epinephrine lead to a state of heightened alertness and increased energy use that prepares the body for rapid, intense action such as fighting or fleeing. By coordinating the activities of cells in many organs and systems throughout the body, epinephrine prepares an individual to cope with a life-threatening situation.

Experiment

Question: How does epinephrine affect the body?

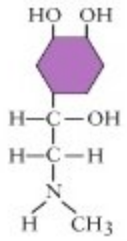
Hypothesis: Epinephrine causes changes involved in the fight-or-flight response.

Null hypothesis: Epinephrine does not affect the fight-or-flight response.

Experimental setup:

Control (Saline solution)

Epinephrine



1. Inject human volunteers with saline solution or epinephrine.

2. Document changes in fatty-acid and glucose concentrations in blood, pulse rate, blood pressure, and oxygen consumption in brain.

Prediction: Epinephrine increases fatty-acid and glucose concentrations in blood, pulse rate, blood pressure, and brain oxygen consumption relative to controls.

Prediction of null hypothesis: No differences in physiological state of individuals based on molecule injected.

Results:

	Control	Epinephrine
Pulse rate (beats/min)	78.3	89.6
Blood pressure (average, mm Hg)	90.9	108.7
O_2 consumption in brain (cc O_2/100 gm blood/min)	3.41	4.16

Conclusion: Epinephrine causes an array of changes associated with the fight-or-flight response.

FIGURE 47.7 What Effect Does Epinephrine Have on the Body? Each data point on the graphs represents a human volunteer. The data in the table are average values from seven volunteers.

Long-Term Responses to Stress If you have ever been in an acutely stressful situation and experienced the fight-or-flight response, you may recall that the state is short lived. Once an epinephrine "rush" has worn off, most people feel exhausted and want to rest and eat.

What happens if the stress continues and turns into a long-term condition? In the course of a lifetime, it is not unusual for a person to experience periods of starvation or fasting, prolonged emotional distress, or chronic illness. How do hormones help humans and other animals cope with extended stress?

Early studies of long-term stress in human subjects suggested a role for the hormone **cortisol**, which is produced in the adrenal cortex. Increased levels of cortisol were found in

BOX 47.1 A Closer Look at Thyroxine and the Thyroid Gland

The thyroid hormone **thyroxine** is an amino-acid–derived hormone that is synthesized from tyrosine. Thyroxine is an unusual molecule, however, because it contains four iodine atoms. This feature inspired its alternate name, T_4. A closely related thyroid hormone called triiodothyronine, or T_3, contains three iodine atoms.

In mammals, T_3 is the more active of the two hormones. Although the thyroid releases much more T_4 than it does T_3, cells in the liver and elsewhere convert T_4 to T_3.

The primary effect of the thyroid hormones on target cells is to trigger increased cellular metabolism. People who produce inadequate amounts of thyroid hormones are lethargic and unable to tolerate cold. In contrast, people who produce excessive amounts of T_3 and T_4 are restless, excitable, and prone to mood swings but have limited energy reserves and tend to tire easily. Other medical conditions have been traced to problems with the iodine atoms incorporated into T_3 and T_4:

- When radioactive iodine atoms are released into the environment, such as during the accident at the Chernobyl nuclear power plant in the Ukraine, people living in the area become highly susceptible to thyroid cancers. This pattern occurs because radioactive iodine molecules are sequestered in the thyroid and because radiation can damage DNA in a way that makes cells cancerous.
- If iodine is deficient in the diet, the thyroid gland cannot produce enough T_3 and T_4. As a result, it gets overstimulated with the hormone that controls release of T_3 and T_4 and may swell to huge proportions in response. The swelling produces the condition called endemic **goiter**. Endemic goiter is now rare in many parts of the world because iodine-containing salt is available for consumption.

airplane pilots and crew members during long flights, athletes who were training for intense contests, the parents of children undergoing treatment for cancer, and college students who were preparing for final exams. What do these signals do?

The primary role of cortisol during prolonged stress in humans is to ensure the continued availability of glucose for use by the brain. This hormone maintains glucose production by inducing the synthesis of the liver enzymes that make glucose from amino acids and other chemical precursors. It also causes adipose tissue —fat tissue—and resting muscles to become resistant to the effects of insulin. When the body is in an unstressed state, insulin stimulates **adipocytes**, or fat cells, and resting muscle cells to remove glucose from the bloodstream. When cortisol makes these cells resistant to insulin, the effect is to reserve glucose for use by the brain and exercising muscles, neither of which depend on insulin to stimulate glucose uptake. The hormone also promotes the release of the body's major fuel molecules, fatty acids, from adipose tissue for use by the heart and muscles. Because of its importance in regulating blood glucose, cortisol is referred to as a **glucocorticoid**.

The long-term stress response comes at a high price, however, as any victim of a serious injury or illness knows. Glucocorticoids make amino acids available for glucose synthesis by promoting the degradation of contractile proteins in muscle. The resulting loss of muscle mass may cause severe weakness. Glucocorticoids also conserve glucose by impairing wound healing and suppressing immune and inflammatory responses. Although these processes are costly in terms of energy use, suppressing them makes the body more susceptible to infection. The overall concept here is that the long-term stress response is a compromise—a fitness trade-off (see Chapter 41). The fuel requirements of the brain are met at the expense of other tissues and organs.

It is instructive to note that glucocorticoids may mediate the response to stressful environmental challenges in species other than humans. Recall from Chapter 42 that when moving from freshwater to saltwater, a salmon gains sodium ions via diffusion and loses water across its gills by osmosis. The salmon counteracts these stresses by actively pumping sodium and chloride ions out of its gills. The chloride cells that perform this pumping are induced to proliferate by a burst of cortisol. Cortisol release occurs as the salmon moves downstream toward the ocean. If this release fails to occur, salmon die shortly after reaching salt water.

In summary, hormones help regulate the body's response to environmental change, as in the human body's response to short- and long-term stresses. Epinephrine and the glucocortocoids are examples of molecules that alert cells and tissues to a particular environmental stimulus or challenge. Other hormones have dramatically different effects, however.

How Do Hormones Direct Developmental Processes?

In animals, as in plants, hormones play a key role in regulating growth and development. Growth hormones and sex hormones, for example, play crucial roles in promoting cell division, increasing overall body size, and promoting sexual differentiation as an individual matures. In addition, certain hormones direct the development of particular cells and tissues at critical junctures in an individual's life. Which hormones are involved in regulating development, and what specific effects do they have?

Let's answer this question by exploring two of the most dramatic examples of hormonal control of development—

metamorphosis in amphibians and insects—and then surveying other developmental processes that are affected by hormone action.

T_3's Role in Amphibian Metamorphosis Frogs, toads, and salamanders are called amphibians ("double-lives") because in most species juveniles live in water while adults live on land. The process of changing from an immature, aquatic tadpole to a sexually mature, terrestrial frog or toad or salamander is an example of **metamorphosis** ("change-form"; **Figure 47.8**).

Two sets of complementary experiments, published in 1912 and 1916, established that frog metamorphosis depends on thyroid hormones. Researchers could induce frog tadpoles to undergo metamorphosis by feeding them ground-up thyroid glands from horses; they could prevent metamorphosis by surgically removing the tadpoles' thyroid glands. Follow-up work showed that the thyroid hormone **triiodothyronine**, or T_3, is responsible for most of the changes observed in metamorphosis, and that T_3 is produced in response to signals from the brain—in the form of thyroid-stimulating hormone produced in the pituitary gland.

In juvenile amphibians, cells respond to increased levels of T_3 in one of three ways:

1. They may begin growing and form new structures, such as legs.
2. They may die, as in cells that form the tadpole's tail.
3. Or, they may change structure and function. For example, changes in existing cells are responsible for the switch from a long intestine specialized for digesting plant material to a short intestine specialized for digesting insects and prey. In the liver, cells respond to T_3 by manufacturing the enzymes required to excrete urea instead of ammonia.

● You should be able to suggest a hypothesis explaining why different cells can respond to the same hormone in different ways.

Some observers would argue that T_3's role in amphibian metamorphosis is the most spectacular example of how hormones affect development and how a tiny concentration of a cell-to-cell signal can trigger dramatic changes in animals. Others would claim instead that frog T_3 pales in comparison to the role that ecdysone plays in insect metamorphosis.

Hormone Interactions Regulate Insect Metamorphosis Chapter 32 introduced the two major patterns of juvenile-to-adult transition in insects, called hemimetabolous and holometabolous metamorphosis. You might recall that in hemimetabolous metamorphosis, juveniles are called nymphs. They look like miniature adults, live in similar habitats, and eat similar food. But in species that undergo holometabolous metamorphosis, juveniles are called larvae. They look completely different from adults, live in different habitats, and eat different food.

Larvae undergo a series of molts in which they shed their old exoskeleton, expand their bodies, and produce a new exoskeleton. After a specific number of these juvenile molts, however, they secrete a tough case called a pupa. Inside the pupal case, distinctive populations of larval cells give rise to a

Juvenile frog (tadpole)	
Locomotion	Swim via movements of muscular tail
Respiration	Gas exchange occurs in gills, across skin, and in lungs
Nutrition	Most are herbivorous; have a long gut specialized for digesting algae and plants
Excretion	Most nitrogenous wastes excreted as ammonia

Adult frog	
Locomotion	Tailless; walk or hop
Respiration	Gas exchange occurs across skin, and in lungs
Nutrition	Most are carnivorous; have a large mouth or long tongue for catching prey; short gut specialised for digesting proteins
Excretion	Most nitrogenous wastes excreted as urea

FIGURE 47.8 Amphibian Metamorphosis Is a Continuous Process. When metamorphosis begins in a frog, toad, or salamander, the individual stays active and feeding. The transition from juvenile to adult is continuous and gradual.

FIGURE 47.9 Insect Metamorphosis Occurs during a Resting Stage. When metamorphosis begins in a holometabolous insect, the individual enters a resting stage called the pupa.

completely new adult body. The rest of the larval body is torn down (**Figure 47.9**).

Like amphibian metamorphosis, insect metamorphosis is triggered by a hormone from the brain. In insects metamorphosis depends on interactions between two hormones. If **juvenile hormone** (**JH**) is present at a high concentration in the larva, then surges of the hormone 20-hydroxyecdysone, usually called **ecdysone**, induce the growth of a juvenile insect via molting. But if JH levels are low, ecdysone triggers metamorphosis and the transition to adulthood and sexual maturity.

Other Examples of How Hormones Regulate Development Amphibian and frog metamorphosis provide particularly spectacular examples of how hormones direct animal development. But long distance cell-to-cell signals play an array of key roles as embryos develop—frequently directing changes that occur throughout life.

- *Early embryonic development* Events early in development dictate whether the sex organs, or **gonads**, of an embryo become male (testes) or female (ovaries). This process is called primary sex determination. In mammals it is not dependent on hormone action. Once testes or ovaries develop, though, they begin producing male-specific or female-specific hormones. In humans, the early testes produce two hormones: A steroid hormone called **testosterone** induces early development of the male reproductive tract, and a polypeptide hormone called **Müllerian inhibitory substance** inhibits development of the female reproductive tract. Development of the female reproductive tract depends on the action of the steroid hormone **estradiol**, which is produced in the ovaries and is in the family of molecules called **estrogens**.
- *Juvenile-to-adult transition* When humans reach early adolescence, surges of sex hormones lead to the physical and emotional changes associated with **puberty**. These developmental changes create the adult phenotype and the ability to produce offspring. In boys, surges of sex hormones lead to changes that include enlargement of the penis and testes and growth of facial and body hair. In girls, increased concentrations of estradiol lead to the enlargement of breasts, the onset of menstruation, and other changes.
- *Attaining full adult stature* In humans and other mammals, the long bones in the limbs and the vertebrae of the spinal column must grow for full adult height to be achieved. Growth hormone produced in the pituitary gland regulates growth factors, which are signals that control the cell cycle (see Chapter 11). Puberty is associated with a growth spurt because the effect of growth hormone on the skeleton is enhanced by the action of sex hormones that are produced in increased amounts during adolescence. Even though growth hormone and sex hormones are produced in low levels throughout life, bone growth stops when sex hormone concentrations fall at the end of puberty.
- *Seasonal or cyclical sexual activity* Most long-lived animals reproduce seasonally. In many species, environmental cues such as increasing day length, warmth, or the onset of seasonal rains trigger the release of sex hormones. Chapter 51 details how this flush of testosterone or estrogen induces the development of seasonal traits, such as sexual receptivity in female lizards. Even though humans do not breed seasonally, sex hormones are instrumental in regulating sperm production and the menstrual cycle. Chapter 48 explores these processes in detail.

To summarize, hormones play key roles in growth and development. Growth hormones support overall size increases in juveniles. Sex hormones coordinate the activities of diverse groups of cells and tissues at three critical life stages: (1) the development of sexual structures in embryos, (2) physical and emotional changes at the juvenile-to-adult transition, and (3) the regulation of sexual activity in adults.

How Are Hormones Involved in Homeostasis?

Chapter 41 introduced the concept of homeostasis, the maintenance of relatively constant physical and chemical conditions inside the body. Recall that homeostatic systems depend on

(1) a sensory receptor that monitors conditions relative to a preferred value, or set point; (2) an integrator that processes information from the sensor; and (3) effector cells that return conditions to the set point. (Glance back at Figure 41.14.) In homeostatic systems, messages often travel from integrators to effectors in the form of hormones.

Several hormones that act as messengers in homeostatic systems have already been introduced. Recall from Chapter 42 that when an individual is dehydrated, **antidiuretic hormone** (**ADH**, also called vasopressin) is synthesized in the hypothalamus and released from the pituitary gland. ADH increases the permeability of the kidney's collecting ducts to water. As a result, water is reabsorbed from the urine and saved. In this way, ADH is instrumental in achieving homeostasis with respect to water balance. If ADH's action is inhibited, homeostasis fails and illness can occur. For example, the ethanol in alcoholic beverages inhibits the release of ADH from the pituitary. People who imbibe large quantities of these beverages produce large quantities of dilute urine. The resulting water loss can lead to dehydration and nausea—symptoms associated with an alcoholic hangover.

Chapter 42 also noted that aldosterone is released from the adrenal cortex when ion concentrations in body fluids are low. Because aldosterone increases reabsorption of in the distal tubules of the kidney, it plays a key role in homeostasis with respect to electrolyte concentrations and the overall volume of body fluids. Adrenal hormones with this effect are called **mineralocorticoids**.

Several of the hormones introduced in Figure 47.3 are involved in homeostatic systems. For example, **erythropoietin** (**EPO**) is released from the kidneys and other tissues when blood oxygen levels are low. EPO acts to achieve homeostasis with respect to oxygen by stimulating the production of red blood cells. The more red blood cells, the higher the oxygen-carrying capacity of blood is. In this way, EPO is a crucial element in the homeostatic system for blood oxygen levels.

Figure 47.10 provides a more detailed example by diagramming how the homeostatic system for blood calcium concentration works. The hormonally active form of Vitamin D is synthesized in the kidneys, and **parathyroid hormone** (**PTH**) is produced by the parathyroid glands. These two hormones work in tandem to keep Ca^{2+} levels in the blood close to the set

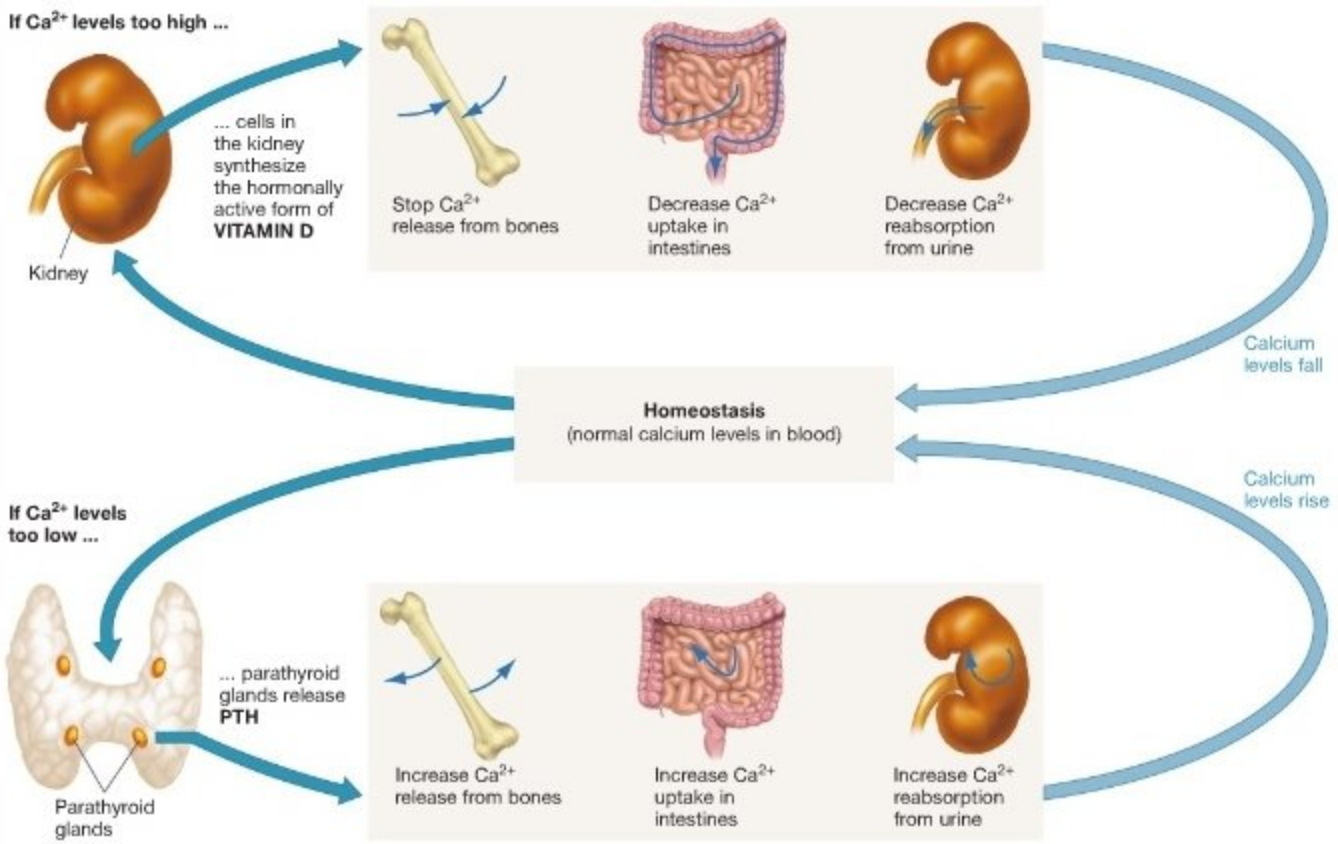


FIGURE 47.10 Hormones Act to Maintain Homeostasis. Parafollicular cells of the thyroid gland and the cells of the four adjacent parathyroid glands sense Ca^{2+} levels and secrete hormones in response to changes. Notice that this homeostatic system does not involve the CNS.

EXERCISE Draw a similar diagram to illustrate the action of EPO, ADH, aldosterone, or glucagon and insulin. (Hint: Look back at Figure 47.3.)

point, much as insulin and glucagon interact to maintain blood glucose concentrations at preferred levels (see Chapter 43).

To drive home how important hormones are in homeostatic processes, consider recent results on homeostasis in energy reserves. This research led to the discovery of new hormones and inspired research on the causes of obesity in humans.

Homeostasis of the Body's Energy Reserve Healthy animals keep energy in reserve for use during periods of decreased food availability. This energy reserve is typically in the form of the lipid called triglyceride. **Triglyceride** is an effective energy-storage molecule, because large amounts of ATP can be generated when its three fatty-acid subunits are oxidized (see Chapter 6). Although some triglyceride is present in muscle cells, most is stored in adipocytes. These cells make up the fat bodies found in insects and other species and the adipose tissue of mammals. Even a lean 70-kg human male stores enough energy in adipose tissue to survive for over 30 days without eating.

For decades researchers thought that total adipose tissue mass varied only in response to food intake—meaning it was not subject to homeostatic regulation. This view started to change in the 1970s, when biologists began studying mutations in mouse genes called *obese* and *diabetic*. Homozygous *obese* (*ob/ob*) and *diabetic* (*db/db*) mice eat large quantities of food and move much less than heterozygous or wild-type siblings do. The homozygotes also become extremely obese (**Figure 47.11**).

To test the hypothesis that the *obese* and *diabetic* gene products are involved in endocrine function, researchers turned to an experimental technique called parabiosis. **Parabiosis** has been used for more than 100 years to determine whether physiological phenomena are hormone mediated. In this technique, two closely related animals are surgically united by suturing the pelvis, shoulders, and abdominal walls together. The skin of the two animals is then joined over the surgical connection, and the newly created twin animal is allowed to recover from the procedure. Within a short time, capillaries form between the two parabiotic partners, and they develop a shared circulatory system. This circulatory system permits the passage of long-lived molecules, such as certain hormones, between the two partners. In contrast, it does not allow the exchange of molecules that are rapidly metabolized, such as glucose and fatty acids. Another key observation is that no new nerves grow between the two animals. As a result, they can influence one another through endocrine signals but not through electrical signals. If an experimental manipulation of one partner produces an effect in the other partner, biologists conclude that the effect is mediated by a hormone.

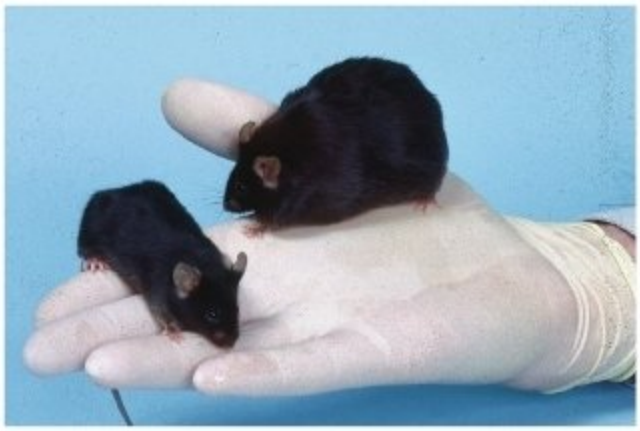

FIGURE 47.11 In Mice, Mutations in the Obese and Diabetic Genes Can Cause Obesity. These mice are siblings from the same litter. At the *ob* gene, the lean mouse is heterozygous and the obese mouse is homozygous. The phenotypes of *ob/ob* and *db/db* mice are indistinguishable.

QUESTION Suppose a mouse were doubly homozygous (*ob/ob db/db*). Would its phenotype be the same as or different from singly homozygous individuals?

Researchers performed parabiosis between *db/db*, *ob/ob*, and lean mice as shown in **Figure 47.12**. When a *db/db* animal was joined to either a lean animal or an *ob/ob* animal, the *db/db* mouse continued to eat and grow normally, but its partner stopped eating, lost weight, and eventually died of apparent starvation. But when two *db/db* animals were joined, both partners ate and grew as expected, and there was no difference between the two in survival. When *ob/ob* animals were joined to lean animals, the *ob/ob* mice ate less food and gained weight less rapidly than did *ob/ob* mice joined to other *ob/ob* mice. There was no difference in survival of pairs representing any combination of *ob/ob* and lean mice.

To interpret these results, the biologists hypothesized that mice produce a satiation, or "stop-eating," hormone. The interpretation was that *db/db* mice lack the receptor required for the hormone to affect target cells. As *db/db* mice got fatter and fatter, they would produce more and more hormone—to no avail. This model explained why the signal from *db/db* mice greatly reduced food intake in their parabiotic partners but continued to have no effect on the *db/db* mouse. The satiation hormone itself was postulated to be encoded by the *obese* gene. As a result, *ob/ob* mice do not produce the hormone. They respond to the signal if it is available from a normal partner, however. A key idea here is that the two genotypes produce the same phenotype because they disable different parts of the same hormone-signaling system.

This model was a dramatic break with traditional views of fat metabolism in mammals. It was not confirmed until 1994, when the *obese* gene product, now called leptin, was isolated and the *obese* gene characterized. **Leptin** is a polypeptide hormone secreted into the blood by adipocytes. Leptin signals by interacting with a specific receptor located in many tissues, including areas of the brain known to control feeding behavior. As the model in Figure 47.12 predicts, the administration of leptin corrects the obesity of *ob/ob* (leptin-deficient) mice but not of *db/db* (leptin receptor–deficient) mice. But as **Box 47.2** explains, leptin injections are not helpful for the vast majority of obese humans.

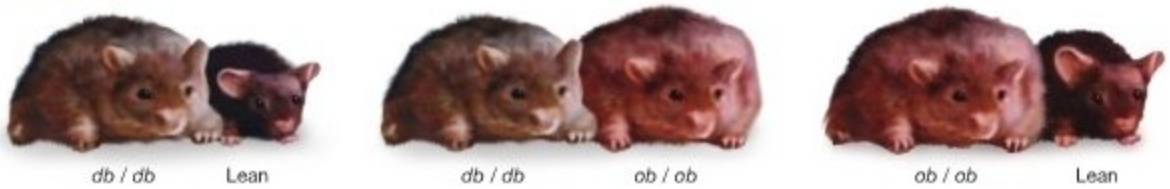
Experiment

Question: Are the *diabetic* (*db*) and *obese* (*ob*) gene products involved in endocrine function?

Hypothesis: The gene products are involved in hormonal signaling that affects appetite and activity level.

Null hypothesis: The gene products are not involved in hormonal signaling.

Experimental setup:



Perform parabiosis surgery on closely related mice with different genotypes, so that blood-borne products will pass between the mice in each pair.

Prediction: Phenotypes of at least some of the parabiotic mice will change.

Prediction of null hypothesis: No changes in phenotypes of parabiotic mice will occur.

Results:

db / db	Lean
↑ Body weight	↓ Body weight
↑ Adipose tissue mass	↓ Adipose tissue mass
	Death by starvation

db / db	*ob / ob*
↑ Body weight	↓ Body weight
↑ Adipose tissue mass	↓ Adipose tissue mass
	Death by starvation

ob / ob	Lean
↓ Body weight	↑ Body weight
↓ Adipose tissue mass	↑ Adipose tissue mass

Conclusion: The *diabetic* and *obese* gene products are involved in hormonal signaling that affects appetite and activity level.

Interpretation: The *obese* gene codes for a hormone that reduces appetite and increases activity in response to increases in fatness. The *diabetic* gene codes for the receptor for this hormone.

FIGURE 47.12 Parabiosis of Genetically Obese and Lean Mice Provides Evidence of a "Satiation Hormone."

BOX 47.2 Is Human Obesity Caused by Leptin Deficiency?

Immediately after leptin was discovered, researchers began testing the hypothesis that it could be used as a drug to treat human obesity. Unfortunately, it quickly became apparent that almost all obese individuals already have high leptin levels—consistent with their high adipose tissue mass. Administering more leptin to these individuals did not cause meaningful weight loss.

Worldwide, fewer than 20 humans with true genetic leptin deficiency have been identified. Just like *ob/ob* mice, these individuals eat vast quantities of food and are severely obese. Because these rare individuals lack the hormone, their obesity can be cured by administering leptin.

To explain why the vast majority of obese humans do not respond to their high leptin levels, researchers hypothesize that the hormone's effect on the brain is diminished for some reason. Identifying the factor or factors involved in diminishing the normal response to leptin is currently the subject of intense research. Does the response drop when specific types of food are ingested, or when meal portions get large, or when exercise is inadequate? One intriguing finding is that mice placed on a high-fat diet respond much less strongly to experimental leptin administration than do mice fed a normal diet. This result supports the hypothesis that the increased ingestion of fatty foods disrupts the normal human homeostatic system in some way. If so, then increased fat content in the diet not only increases energy intake but also blocks the normal appetite-diminishing response, leading to overeating and obesity.

Follow-up work has shown that leptin levels in the blood vary in proportion to total adipose tissue mass. When adipose mass falls below a set point, the leptin level in the blood also falls. The decrease in leptin level is sensed by the brain, which generates both an increase in appetite and a decrease in energy expenditure. These responses promote eating and restore energy balance. When sufficient food intake has occurred to restore triglyceride stores, leptin levels rise. The result is diminished appetite, increased energy expenditure, and the stabilization of adipose tissue mass. This is a striking example of homeostasis achieved by the process called feedback inhibition.

If you understand that...

- Hormones usually function in preparing an individual for environmental change, directing development and sexual maturation, or achieving homeostasis.

You should be able to...

Give an example of a hormone that functions in each of the capacities listed above and, for each, describe:

1) How the single molecule in your example acts on a variety of cells of tissues.
2) How the various responses that occur result in a coordinated set of changes to the same challenge.
3) How the overall effect of the hormone's action increases the individual's chances of surviving and reproducing.

47.3 How Is the Production of Hormones Regulated?

Most hormones are released in response to either an environmental cue or a message from an integrator in a homeostatic system. In both cases, the nervous system may be closely involved. For example, environmental cues that signal the onset of the breeding season or the presence of a predator are received by sensory receptors and interpreted by the brain. Similarly, integration in most homeostatic systems occurs in groups of neurons in the central nervous system (CNS)—that is, the brain and spinal cord (see Chapter 45).

Based on these observations, the short answer to the question posed in the title of this section is simple: In many cases, hormone production is directly or indirectly controlled by the nervous system. How, then, does the nervous system direct the endocrine system? To explore this question, let's focus on how cortisol and epinephrine are regulated by the hypothalamus and pituitary gland.

The Hypothalamus and Pituitary Gland

Researchers who were interested in how hormone production is controlled quickly focused on the pituitary gland. As **Figure 47.13** shows, the pituitary is located at the base of the brain and is directly connected to the brain region called the hypothalamus. This physical link between the hypothalamus and pituitary is the basis of the connection between the CNS and the endocrine system. The pituitary has two distinct segments: the **anterior pituitary** and the **posterior pituitary**. In 1930 a biologist showed that laboratory rats exhibit a variety of debilitating symptoms when their pituitary is removed. The animals stop growing and cannot maintain a normal body temperature. In addition, their genitals, thyroid glands, and adrenal cortexes atrophy (shrink). Not surprisingly, their life span is also dramatically shortened.

These experiments suggested that, in addition to secreting growth hormone, the pituitary secretes substances affecting the gonads, thyroid, and adrenals. Based on this observation, the pituitary took on the nickname "master gland." Follow-up work confirmed that the nickname is apt. The pituitary secretes hormones that regulate the production of a wide array of other hormones. As a case study, let's look at the pituitary hormone that acts on the adrenal glands.

Controlling the Release of Glucocorticoids Early work on rats suggested that a molecule from the pituitary gland affects the adrenal gland. This molecule came to be called **adrenocorticotropic hormone**, or **ACTH**. (*Adreno* refers to the

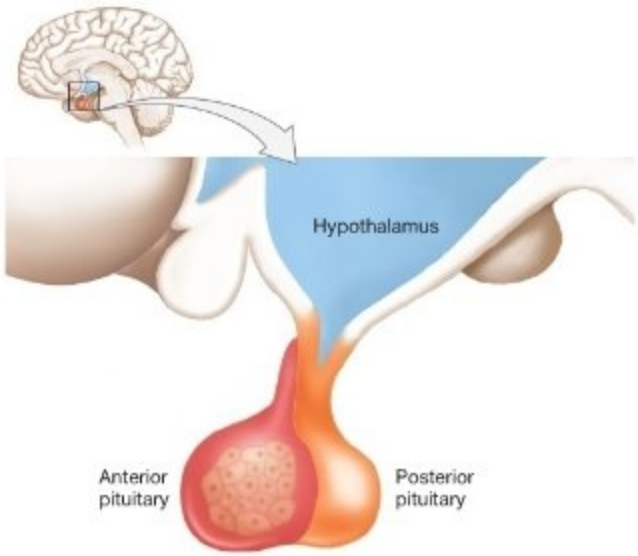

FIGURE 47.13 The Hypothalamus and the Pituitary Gland Are Physically Connected. The pituitary has two distinct segments, designated the anterior and posterior pituitary.

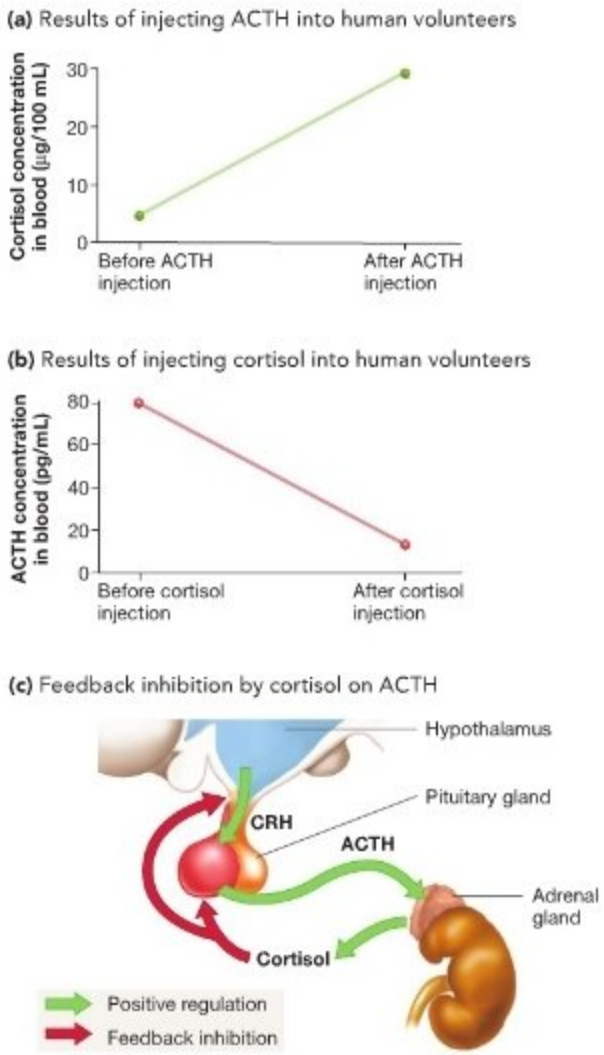

FIGURE 47.14 Feedback Inhibition by Cortisol on ACTH Release. **(a)** ACTH stimulates release of cortisol. **(b)** Cortisol reduces ACTH. **(c)** The interaction between cortisol, ACTH, and CRH is an example of feedback inhibition.

EXERCISE How would you use the data in part (b) to devise a test for adrenal failure in humans?

adrenal glands; *cortico* refers to the outer portion, or cortex, of the gland; and *tropic* means "affecting the activity of.") In 1943 ACTH was purified and characterized. The biologists who did the work confirmed that glucocorticoids are secreted from the adrenal cortex in response to ACTH released from the pituitary. As **Figure 47.14a** shows, when human volunteers are injected with ACTH, cortisol levels in their blood rise. Thus, ACTH is a regulatory hormone.

Not long after ACTH was isolated, biologists from two laboratories simultaneously and independently showed that it is released in response to a molecule produced by the hypothalamus. Researchers initially called this hormone corticotropin-releasing factor, or CRF. After years of effort, a different team of researchers finally succeeded in purifying CRF. It is a peptide—just 41 amino acids long—that has been renamed **corticotropin-releasing hormone** (**CRH**). When CRH is released from the hypothalamus, cells in the anterior pituitary are stimulated to secrete ACTH into the bloodstream.

Why is glucocorticoid secretion controlled by the two hormones CRH and ACTH? The key to answering this question is to recognize that glucocorticoids themselves are able to suppress ACTH production by the pituitary gland. As the data in **Figure 47.14b** show, when human volunteers are injected with cortisol, ACTH levels in their bloodstream drop dramatically. Cortisol also inhibits release of CRH from the hypothalamus. Thus, if glucocorticoid levels become too high, then ACTH levels fall. The result is feedback inhibition: glucocorticoid production decreases and levels of glucocorticoid in the blood return to normal. But if glucocorticoid levels become too low, then ACTH levels rise and drive a compensatory increase in glucocorticoid production.

Figure 47.14c summarizes the relationships among CRH, ACTH, and the glucocorticoid cortisol. The importance of feedback inhibition in their interactions can best be appreciated by observing what happens when it fails. Certain pituitary tumors diminish the ability of cortisol to suppress ACTH production. This results in a medical condition called **Cushing's disease**, which is characterized by persistently high blood ACTH and cortisol levels. In essence, Cushing's disease is an unrelenting stress response that results in progressive depletion of the body's protein reserves. It is fatal if not treated.

If the feedback relationship between cortisol and ACTH stabilizes blood cortisol levels, what is the role of CRH? In essence, CRH changes cortisol's ability to suppress ACTH production in the pituitary. Increasing the production of CRH by the hypothalamus is equivalent to raising the temperature setting on a thermostat—it makes things hotter. Under ordinary circumstances, the production of CRH by the hypothalamus displays a daily rhythm, with the highest level in the early morning hours. This drives a corresponding daily rhythm in ACTH production and blood cortisol level, as shown in **Figure 47.15.** The peak in blood cortisol levels that occurs in the morning ordinarily coincides with arousal and initiation of the day's activities—saving glucose for use by the brain. As an aside, the unpleasant symptoms of jet lag are due to the daily cortisol rhythm being out of synchrony with local time for a period of several days after you arrive in a new time zone.

Based on this observation, it should make sense to learn that the long-term stress response is initiated when stimuli that produce pain or anxiety are processed by the brain and result in a

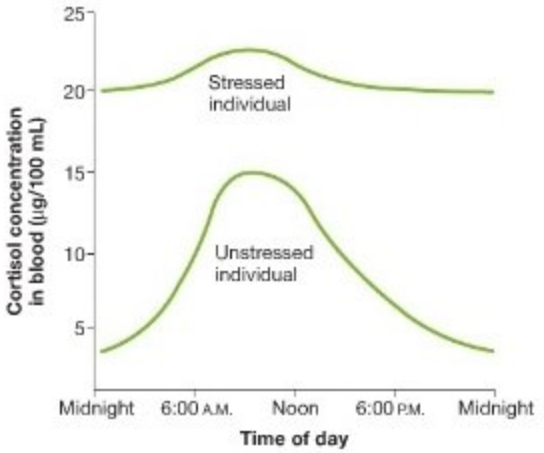

FIGURE 47.15 Blood Cortisol Levels Have a Daily Rhythm. Blood cortisol levels are usually highest in the early morning and drop in the late afternoon and evening. Under stressful circumstances, blood cortisol levels are elevated throughout the day.

sustained increase in CRH production. Increased CRH production causes blood ACTH and cortisol levels to remain higher throughout the day than they are in the unstressed state (see Figure 47.15).

The Hypothalamic-Pituitary Axis—an Overview Six decades of research have revealed that the CRH-ACTH-glucocorticoid relationship is just one example in an array of hormone systems based on interactions among the hypothalamus, pituitary, and target glands or cells. As **Figure 47.16** illustrates, the **hypothalamic-pituitary axis** actually forms two anatomically distinct systems. The anterior pituitary develops from cells in an embryo's mouth and throat lining, while the posterior pituitary is an extension of the brain.

The posterior and anterior sections of the pituitary gland are each influenced by different populations of neurons in the hypothalamus. These populations of hypothalamic neurons are called **neurosecretory cells**, because they are neurons that

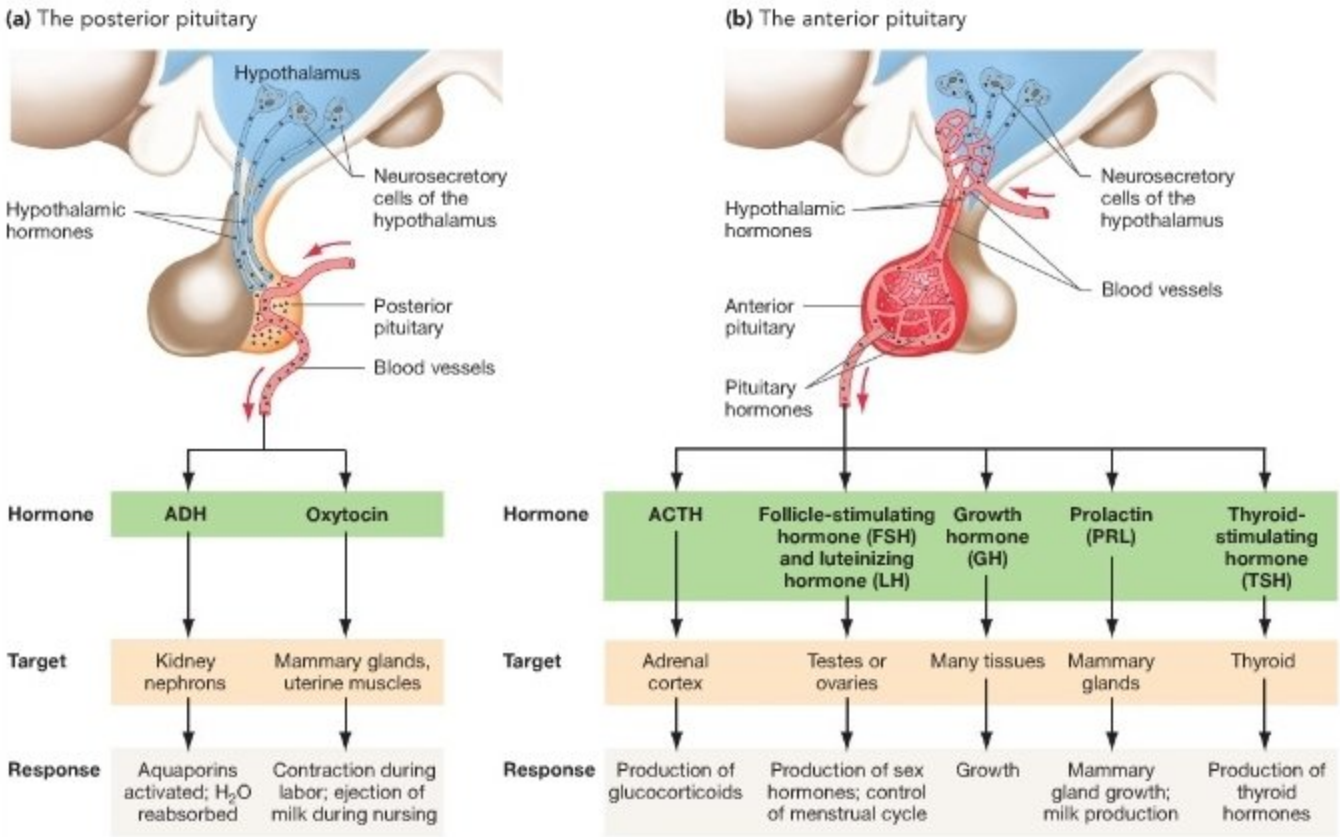

FIGURE 47.16 The Hypothalamus and Pituitary Interact Closely. (a) Developmentally and anatomically, the posterior pituitary is an extension of the hypothalamus. Neurosecretory cells in the hypothalamus extend directly into the posterior pituitary and secrete ADH (vasopressin) and oxytocin. **(b)** The hypothalamus and the anterior pituitary communicate indirectly, via blood vessels. Hormones produced by neurosecretory cells in the hypothalamus travel to the anterior pituitary in blood, where they control the release of pituitary hormones.

QUESTION Which of these hormones act via the neuroendocrine pathway? Which act via the neuroendocrine-to-endocrine pathway?

synthesize and release hormones. The release of hormones by cells in the hypothalamus is under the control of brain regions responsible for integrating information about the external or internal environment. For example, information about the approach of an important exam or athletic contest might trigger action potentials that lead to the release of CRH from neurosecretory cells in the hypothalamus.

It's important to recognize that the anterior pituitary and posterior pituitary function in different ways. As Figure 47.16a indicates, the posterior portion of the pituitary is actually an extension of the hypothalamus itself. Neurosecretory cells that project from the hypothalamus produce the hormones ADH and oxytocin, which are then stored in the posterior pituitary. From there, ADH and oxytocin are released into the bloodstream. This is an example of the neuroendocrine pathway of hormone action. Recall that ADH aids in the reabsorption of water by the kidneys. **Oxytocin** helps induce labor and milk production in females.

Neurosecretory cells in the hypothalamus do not project into the anterior portion of the pituitary, however. As Figure 47.16b illustrates, the hypothalamus and anterior pituitary are connected indirectly, by blood vessels. What happens when neurosecretory cells from the hypothalamus secrete hormones into these blood vessels? In response to the arrival of stimulatory releasing hormones from the hypothalamus, including CRH and others listed in Figure 47.3, the anterior pituitary secretes hormones that enter the bloodstream and act on target tissues or glands. This is an example of the neuroendocrine-to-endocrine pathway of hormone action.

The anterior pituitary hormones include ACTH; **follicle-stimulating hormone** (**FSH**) and **luteinizing hormone** (**LH**), which are involved in the production of sex hormones and which regulate the menstrual cycle; GH; **prolactin**, which stimulates mammary gland growth and milk production; and **thyroid-stimulating hormone** (**TSH**), which triggers the production of thyroid hormones. Hypothalamic inhibitory hormones, in contrast, stop the secretion of certain pituitary hormones. These pituitary hormones include somatostatin (also produced by the pancreas), which inhibits GH production, and **dopamine**, or prolactin-inhibiting hormone (PIH), which limits prolactin production.

In several cases, the production of a pituitary hormone is controlled by both a stimulatory and an inhibitory hypothalamic hormone. The realization that many of the hormones produced by the anterior pituitary stimulate the production of other hormones justified the structure's designation as the master gland.

MB **Web Animation** at www.masteringbio.com
Endocrine System Anatomy

To summarize, interactions between the hypothalamus and pituitary gland furnish a key mechanism for the control of hormone action by the CNS. The hypothalamic-pituitary axis consists of two anatomically and functionally distinct systems. The posterior pituitary serves as a storage and release site for hormones produced by neurosecretory cells in the hypothalamus; the anterior pituitary serves as a hormone production and release site that is controlled by hypothalamic hormones.

Control of Epinephrine by Sympathetic Nerves

When biologists analyze how the nervous system and endocrine system interact to control the release of epinephrine, the distinction between the two systems begins to blur. Section 47.2 introduced how epinephrine acts as a hormone. During the fight-or-flight response, sympathetic nerves trigger the release of epinephrine from the adrenal medulla into the bloodstream. But in addition, some sympathetic nerves release the related molecule, **norepinephrine**, directly onto target cells. In effect, the nervous system delivers a chemical messenger directly to particular cells while the endocrine system broadcasts a similar messenger by secreting it into the bloodstream. Epinephrine and norepinephrine, which differ from one another only by the presence of an additional methyl group on epinephrine, are members of the family of molecules called **catecholamines**.

Catecholamines function as neurotransmitters as well as hormones. The close functional similarity between hormones and neurotransmitters does not end there, however. In some cases, the mode of action of hormones and neurotransmitters is similar. To drive this point home, recall from Chapter 45 that neurotransmitters have two major types of effects on target cells. All neurotransmitters trigger a postsynaptic potential, which can make the postsynaptic neuron more or less likely to deliver an action potential. In addition, certain neurotransmitters may initiate changes in gene expression in neurons. Chapter 45 illustrated the effect of neurotransmitters on transcription by reviewing experiments on the sea slug *Aplysia*. Repeated application of serotonin led to gene activation and changes in the behavior of the synapse. By altering synapses in this way, neurotransmitters play a central role in learning and memory. Similarly, many hormones exert their effects by activating particular genes in target cells. Understanding how gene activation occurs in response to neurotransmitters and hormones is currently the subject of intense research at laboratories around the world.

3) Explain how the nervous system and endocrine system interact during the short-term response to stress.

47.4 How Do Hormones Act on Target Cells?

The key to understanding how hormones act on target cells is recognizing that some animal hormones are lipid soluble and cross plasma membranes readily, while others are not (see Figure 47.4). More specifically, steroid hormones are small lipids that enter cells without difficulty. But the peptide and polypeptide hormones and most amino acid derivatives do not cross plasma membranes easily, because of their large size and electrical charge.

Differences in the lipid solubility of hormones are important because they influence where a target cell receives the chemical message. Steroids often act inside the cell, while most amino acid derivatives and all polypeptides act at the cell surface. To explore these two distinct paths of hormone action, let's consider how estrogen and epinephrine affect target cells. As a steroid and a nonsteroid, they serve as model systems for hormone action.

Steroid Hormones and Intracellular Receptors

Estrogens are steroids that direct the development of female secondary sex characteristics in many animal species. In humans and other mammals, the most important estrogen is the molecule estradiol (formally, 17 β-estradiol). Because of its importance in reproduction by humans and domesticated animals, estradiol's mode of action has been the topic of intense investigation for over 50 years. How do target cells receive the signal carried by estradiol?

Identifying the Estrogen Receptor A key advance in research on how hormones affect target cells occurred in 1964, when biologists succeeded in isolating the estradiol receptor in laboratory rats. As **Figure 47.17** indicates, the researchers began by labeling purified estradiol with a radioactive atom and injecting a small amount into five adult female rats. Twenty minutes later, the biologists removed the uterus from each female and homogenized the tissue. The uterus, a muscular sac where embryonic development takes place, is one of the organs that changes in response to changes in the amounts of estradiol secreted from the ovaries.

After centrifugation, the soluble fraction of the homogenized cells was removed from the pellet and placed in another centrifuge tube that contained a sucrose gradient. As Chapter 7 explained, sucrose density centrifugation allows researchers to separate molecules by density. When centrifugation was complete, the biologists found that the radioactivity was concentrated in a narrow band in the tube. The band contained radioactive estradiol bound to the estradiol receptor. When the investigators purified the receptor molecule, they found that it could readily be destroyed by treatment with proteinase enzymes. As a result, they inferred that the estradiol receptor was a protein.

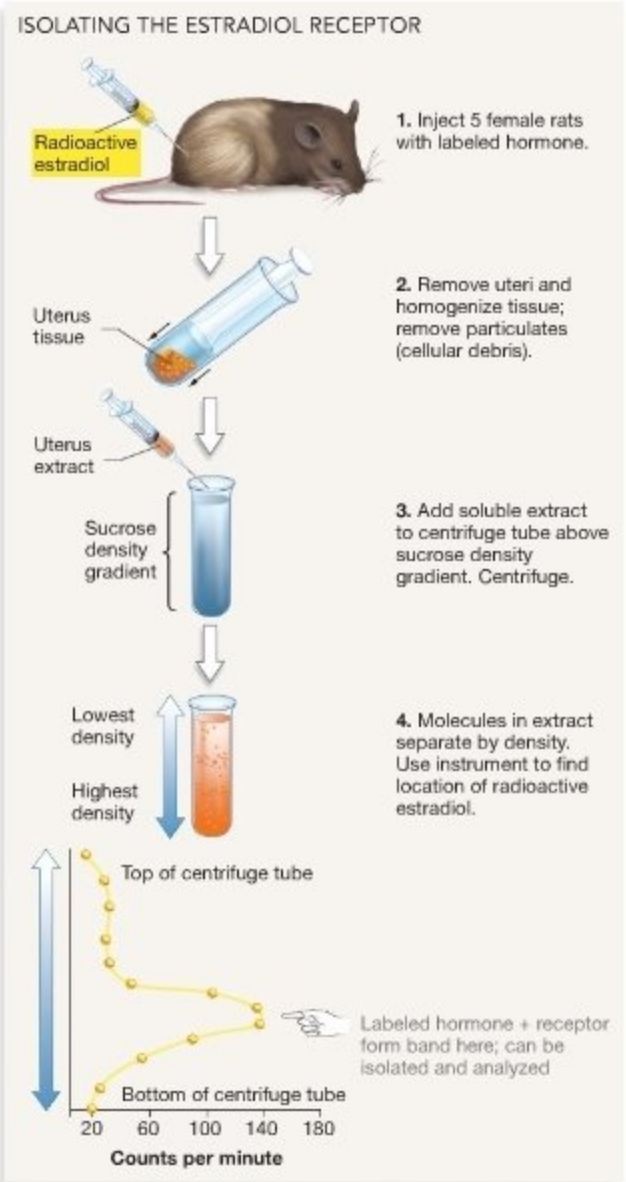

FIGURE 47.17 Discovery of the Estradiol Receptor. If radioactive estradiol bound to its receptor in the uterus, then the hormone-receptor complex should form a distinct band of radioactivity when molecules from uterine cells were separated by centrifugation.

Follow-up experiments established that the estradiol receptor is located in the nucleus but is not associated with the nuclear envelope. Further, the receptor is found only in estradiol target tissues, including the uterus, hypothalamus, and mammary glands. The latter finding was particularly exciting, because it clarified how hormones act in a tissue-specific way. This is a crucial point: Hormones are broadcast throughout the body via the bloodstream, but they act only on cells that express the appropriate receptor. Target cells respond to particular hormones because they contain a receptor for that hormone.

Later, biologists found that the gene for the estradiol receptor is similar to the genes that encode receptors for the glucocorticoids, testosterone, and other steroids. This result suggested that all steroid receptors are related by descent from an ancestral receptor molecule and that the binding of any steroid hormone to its receptor might affect the target cell in a similar way.

Biologists have answered some of the most basic questions about the nature and location of the estradiol receptor. What happens once the hormone-receptor complex forms inside the nucleus of a target cell?

Documenting Changes in Gene Expression During the 1970s and 1980s, work in several laboratories suggested that estradiol and other steroid hormones affect gene transcription after they bind to their receptors. For example, researchers were able to inject laboratory animals with estradiol or other steroid hormones and document changes in the mRNAs and proteins produced in target cells. These data showed that steroid hormones can cause dramatic changes in the amount or timing of mRNA production by a large number of genes.

An important insight into the molecular mechanism of hormone action came when researchers found a distinctive DNA-binding region in the **steroid-hormone receptor**. The region contains the DNA-binding domain called a zinc finger. Follow-up work showed that zinc fingers are found in all proteins in the steroid-hormone receptor family. To understand why this observation is significant, recall from Chapter 18 that DNA-binding domains are protein regions that make physical contact with DNA. The presence of a zinc finger in the estradiol receptor suggested that once estradiol had bound to it, it might affect gene expression by binding directly to DNA.

Follow-up work confirmed that steroid hormone-receptor complexes bind to specific sites in DNA, which came to be called **hormone-response elements**. Hormone-response elements are located just "upstream" (in the 5′ direction) from the start of target genes. Gene expression changes when a regulatory protein such as a steroid hormone-receptor complex binds to the hormone-response element for that gene.

The model in **Figure 47.18** summarizes the current state of thinking about how steroid hormones affect target cells. When estradiol or another steroid hormone enters a target cell, the hormone binds to its receptor (steps 1 and 2 of the figure). The binding event causes a conformational change in the receptor. In response, the hormone-receptor complex binds to DNA along with other proteins required for transcription initiation (step 3), and the expression of specific genes begins. Because each hormone-receptor complex leads to the production of many copies of the gene product, the signal from the hormone is amplified (steps 4 and 5). In this way, a small number of hormone molecules produces a large change in the activity of target cells and tissues.

Currently, research on steroid hormone action is focused on (1) the details of how the hormone-receptor protein interacts with the other proteins required to initiate gene transcription, and (2) how interactions between the hormone-receptor complex and other regulatory proteins alter the timing and the degree of expression of target genes. Researchers are also following up on the relatively recent discovery that at least some mammals, including humans, have two distinct receptors for estradiol. As experiments continue, it will be interesting to learn whether or not these two receptors trigger different responses to the same hormone.

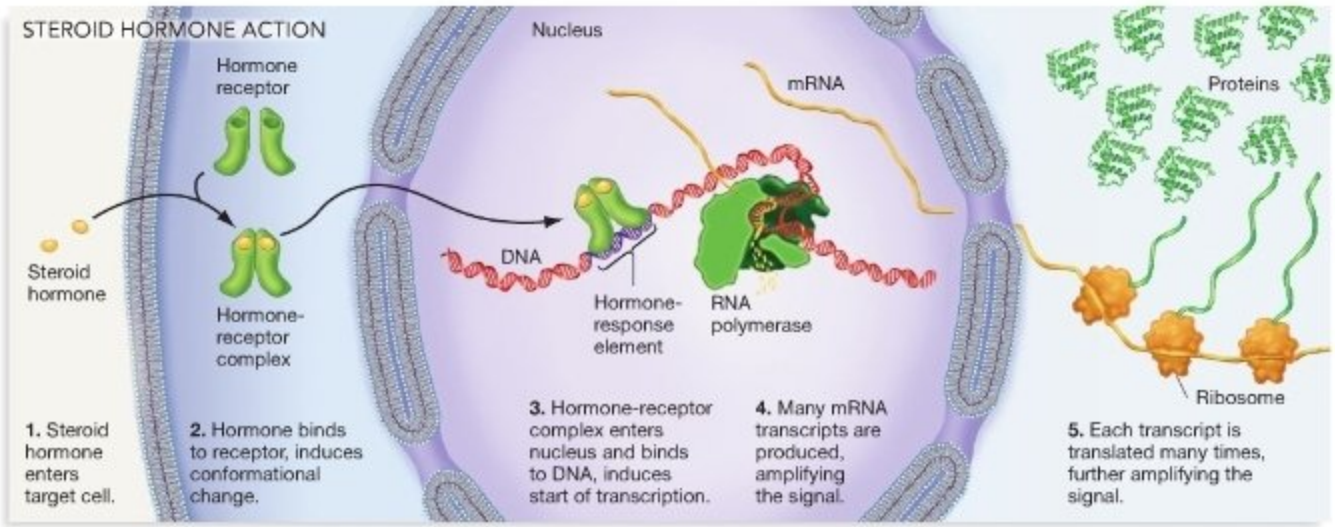

FIGURE 47.18 Steroid Hormones Bind to Receptors inside Cells and Change Gene Expression.

EXERCISE Tamoxifen is a drug that blocks estrogen receptors in breast tissue cells. (Estrogen stimulates growth of breast cells, so tamoxifen is often prescribed as a treatment for breast cancer.) Add symbols and labels to this diagram illustrating tamoxifen's mode of action and its consequences.

Hormones That Bind to Cell-Surface Receptors

Epinephrine, norepinephrine, and the polypeptide hormones are not lipid soluble. For these molecules to affect a cell, they have to bind to receptors on the cell surface. The messenger never enters the target cell, so its message must be transduced—changed into a form that is active inside the cell. Recall from Chapter 8 that this phenomenon is known as **signal transduction.**

To explore how signal transduction occurs, let's first examine the nature of the hormone receptors residing in the plasma membrane. Then we can explore research on the molecules that are responsible for processing the message inside the cell. In both cases, we'll focus on epinephrine as a model system.

Identifying the Epinephrine Receptor In 1948 a biologist published the results of an exhaustive set of studies on how epinephrine affects dogs, cats, rats, and rabbits. The responses observed fell into two distinct categories, depending on the tissue being considered. To explain this observation, the researcher suggested that epinephrine binds two distinct types of receptor. He called these hypothetical proteins the alpha receptor and the beta receptor.

Follow-up work with molecules that block epinephrine receptors confirmed this hypothesis. In fact, experiments documented that there are two types of alpha receptor and two types of beta receptor. In short, there are four distinct epinephrine receptors. Each receptor type is found on a distinct tissue type, and each induces a different response from the cell.

The discovery of four epinephrine receptors reinforces the concept of tissue specificity observed in experiments on the estradiol receptor. Hormones are transmitted throughout the body, not unlike a radio or television signal that is broadcast through the atmosphere. Their message is received only by cells with the appropriate receptor, however—just as a radio or TV signal is received only by equipment with an appropriate antenna. In the case of epinephrine, there are four distinct receptors instead of just one. As a result, the same hormone can trigger different effects in different cells. What happens once epinephrine binds to one of these receptors?

Signal Transduction and the Role of Second Messengers Signal transduction occurs when a chemical message at the cell surface elicits a response inside the cell. In effect, receptors "read" the message that is carried by a hormone and, through a sequence of events, initiate an appropriate response by the target cell. Signal transduction is currently an exceptionally active area of research, and research on epinephrine has produced fundamental insights into how the process works at a molecular level.

Recall from Section 47.2 that one of epinephrine's major effects is to increase glucose levels in the blood. To understand how this happens, biologists focused on phosphorylase. **Phosphorylase** is an enzyme that was discovered in the mid-1940s by biologists who were studying how cells cleave glucose molecules

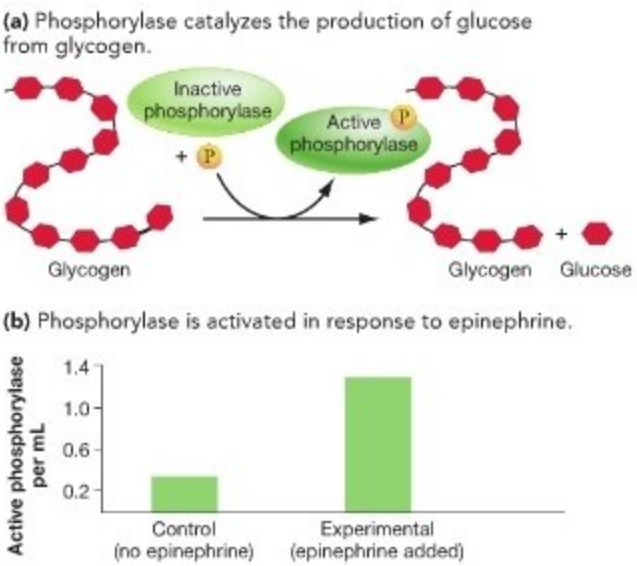

FIGURE 47.19 Epinephrine Activates the Enzyme That Catalyzes the Formation of Glucose from Glycogen. (a) Phosphorylase is activated when an enzyme adds a phosphate group to it. **(b)** When epinephrine is added to cell-free extracts from liver tissue, the amount of activated phosphorylase increases dramatically.

off glycogen. As **Figure 47.19a** shows, phosphorylase catalyzes this reaction. The researchers found that phosphorylase exists in active and inactive forms, and that the enzyme switches between these states when it is phosphorylated or dephosphorylated by another enzyme. Phosphorylase was the first of many enzymes shown to be activated by the addition of a phosphate group.

Investigators in a different laboratory followed up on these results by exploring whether phosphorylase is activated in response to epinephrine. During the fight-or-flight response, the primary source for the glucose that enters the bloodstream is glycogen that is stored in the liver. Does epinephrine stimulate glucose production by activating phosphorylase in liver cells where glycogen is stored?

To answer this question, the research team worked out techniques for homogenizing liver cells and studying the production of glucose from glycogen in vitro—outside of cells. As **Figure 47.19b** shows, the team found that when they added epinephrine to their cell-free system, large amounts of phosphorylase were activated. This observation suggested there was something in the homogenized cells that activated phosphorylase in response to the presence of epinephrine. By purifying the components of the homogenized cells and testing them in the cell-free system, the researchers eventually found the ingredient that activated phosphorylase. It was a molecule called cyclic adenosine monophosphate, or **cyclic AMP** (**cAMP**).

The role of cAMP in signal transduction was confirmed when researchers studied the effects of epinephrine on the activity of the rat heart. During the fight-or-flight response, both the heart rate and the contractile force of the heart rise dramatically—

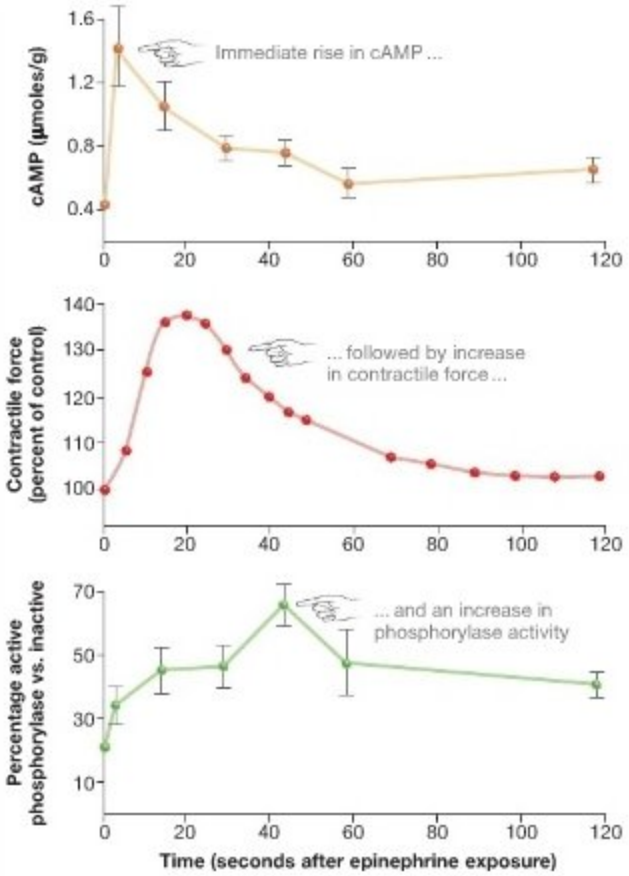

FIGURE 47.20 Chemistry and Activity of Heart-Muscle Cells Change in Response to Epinephrine. When epinephrine is added to heart-muscle cells, there is a rapid and dramatic rise in intracellular cAMP concentration. The contractile force of muscle fibers shows a sharp increase soon thereafter; slightly later, phosphorylase activity increases significantly.

EXERCISE In part (a), draw a line showing what the expected cAMP concentration would be if it had no role in activating phosphorylase.

increasing cardiac output. Cardiac output is a measure of the efficiency of the heart's pumping. As the graphs in **Figure 47.20** show, there is a striking increase in cAMP levels inside heart-muscle cells soon after the cells are treated with epinephrine (at time 0). Investigators confirmed that the contractile force of the heart-muscle cells increased along with phosphorylase activity in these cells.

To capture the importance of cAMP in triggering these effects, biologists referred to it as a second messenger. Recall from Chapter 8 that a **second messenger** is a nonprotein signaling molecule that increases in concentration inside a cell in response to a received signal—a molecule that binds at the surface. What does cAMP do? Follow-up work showed that cAMP binds to an enzyme called cAMP-dependent protein kinase A. The enzyme responds by phosphorylating the enzyme phosphorylase kinase, which then phosphorylates phosphorylase. This chain of events, called a signal transduction cascade, is initially triggered by the synthesis of cAMP, which is produced from ATP in a reaction that is catalyzed by the enzyme adenylyl cyclase. Adenylyl cyclase is activated by a G protein (see Chapter 8), which is activated when epinephrine binds to its receptor.

To pull all these details and reactions together, researchers proposed the model for epinephrine action diagrammed in **Figure 47.21.** In studying this model, it is crucial to recognize two points: First, the second messenger cAMP transmits the signal from the cell surface to the signaling cascade. Second, the other events in the sequence amplify that signal. To drive the latter point home, consider that, in response to stimulation by the hormone-receptor complex, adenylyl cyclase is thought to catalyze the formation of at least 100 molecules of cAMP. In turn, each of these cAMP molecules then activates many molecules of cAMP-dependent protein kinase A. Subsequently, each protein kinase molecule activates many molecules of phosphorylase kinase, and so on. In this way, the binding of just a single molecule of epinephrine may trigger the release of millions

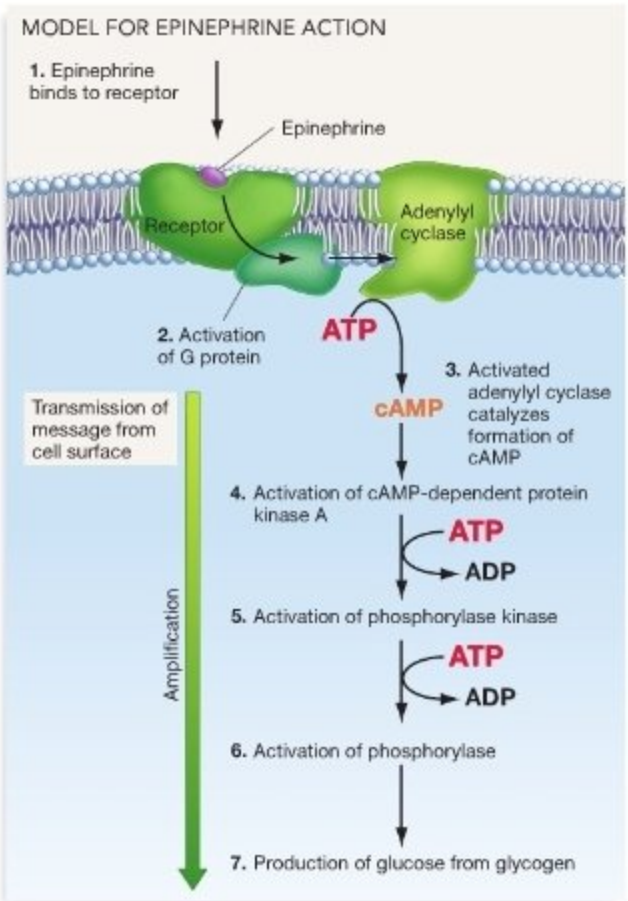

FIGURE 47.21 Epinephrine Triggers a Signal Transduction Cascade.

EXERCISE Using information in the text, label the approximate amount of amplification that occurs in each of steps 3–7.

or even billions of glucose molecules. Amplification through a signal transduction cascade explains why tiny amounts of hormones can have such huge effects on an individual.

The model in Figure 47.21 was inspired by experiments on the epinephrine receptor called the beta-1 receptor. But other groups showed that when epinephrine binds to an alpha-1 receptor, a completely different signal transduction event occurs. In this and many other receptor systems, calcium ions (Ca^{2+}) serve as the second messenger in conjunction with a second-messenger molecule called IP_3. Diacylglycerol (DAG) and 3′, 5′ cyclic GMP (cGMP) are also common second messengers in hormone response systems.

Researchers are increasingly impressed with the diversity and complexity of signal transduction cascades. For example, target cells that have the same receptor protein may have different second messengers or enzyme systems. As a result, the same hormone and receptor can give rise to different responses in different target cells. This observation helps explain one of the most fundamental observations about hormones: that the same chemical messenger can trigger different responses in cells from different organs or in cells at different developmental stages. The reason is that the cells contain different receptors, second messengers, protein kinases, or amplification steps.

Although they are highly diverse, the receptors and signal transduction cascades that are affected by polypeptide and amino-acid–derived hormones lead to a common response: the activation of a specific protein or set of proteins, usually by phosphorylation. In contrast, steroid hormones tend to exert their effects through changes in gene expression. Steroid hormones activate transcription factors that lead to the production of new proteins; nonsteroid hormones trigger signal transduction cascades that activate existing proteins.

Check Your Understanding

If you understand that...

- Hormones act on target cells by binding to receptors.
- The response to a hormone is tissue specific because only certain cells contain receptors for particular hormones.
- In response to binding, hormone-receptor complexes either bind to DNA and induce changes in gene expression or induce the production of second messengers and the activation of signal transduction cascades that result in the phosphorylation of existing proteins.

You should be able to...

1) Draw diagrams that summarize both sequences of events.
2) Predict how the systems you diagrammed would respond to a change in the DNA sequence of the hormone-response element or the enzyme responsible for production of the second messenger.

Hormone Actions on Target Cells

Chapter Review

SUMMARY OF KEY CONCEPTS

Animals use at least six major types of chemical signals. Hormones are chemical signals that are present in tiny concentrations and travel throughout the body to affect target cells.

Hormones are chemical messengers that are released from neurons or cells of the endocrine system, circulate in the blood or other body fluids, and trigger a response in distant target cells containing an appropriate receptor. Hormones have a variety of chemical structures. Most animal hormones are polypeptides, amino acid derivatives, or steroids. Although they are produced in tiny concentrations, hormones have large effects because they trigger gene expression or because their message is amplified through a signal transduction cascade.

You should be able to explain the relationship between electrical signals from the nervous system and chemical signals from the nervous system and endocrine system, as they work in combination to coordinate the body's response to environmental change.

MB **Web Animation** at www.masteringbio.com
Endocrine System Anatomy

The information in hormonal signals helps animals respond to environmental change, develop as embryos, undergo sexual maturation, and achieve homeostasis.

With the nervous system, hormones coordinate the activities of diverse cells and tissues. A single hormone may affect a wide array of cells and tissues and induce a variety of responses.

Epinephrine and cortisol are examples of hormones that help individuals cope with environmental changes. These hormones activate the short-term and long-term responses to stress, triggering the fight-or-flight response or inducing changes that conserve glucose for use by the brain.

Estradiol is an example of a hormone that regulates development and sexual maturation. Estradiol stimulates the formation

of female sex characteristics in human embryos and the maturation of these tissues in adolescence.

Hormones are involved in a wide array of homeostatic interactions. For example, hormones are involved in directing cells that modify the concentrations of glucose, Na^+, Ca^{2+}, O_2, water, and other molecules in the blood and interstitial fluid. Homeostasis with respect to triglyceride stores is also under endocrine control.

You should be able to explain why electrical signals from the nervous system are not primarily responsible for regulating responses to environmental change, embryonic and sexual development, and homeostasis.

The production of a hormone is tightly regulated by input from the nervous system and by other hormones.

In many cases, the release of a hormone is regulated by chemical messengers from the anterior pituitary. The pituitary gland is located near the base of the brain in humans and other mammals. Hormone-secreting cells in the anterior pituitary are regulated by hormones released by the hypothalamus region of the brain. For example, the brain responds to long-term stress by triggering the release of the hypothalamic hormone CRH. CRH activates the release of ACTH by the pituitary gland, which stimulates the production of cortisol by cells in the adrenal cortex. Because cortisol inhibits the production of ACTH and CRH, the chain of events is regulated by feedback inhibition.

You should be able to predict the consequences of negative feedback failing to occur after the release of CRH.

Some hormones bind to receptors inside target cells and change gene expression. Other hormones bind to receptors at the cell surface and lead to changes in protein activation.

Animal hormones have two basic modes of action. Steroid hormones are lipid soluble, cross plasma membranes readily, and often bind to receptors inside cells. Most polypeptide and amino-acid–derived hormones are not lipid soluble and bind to receptors located in the membranes of target cells. In both cases, the response to a hormone is tissue specific because only certain cells express certain receptors.

Most steroid hormones act by inducing a change in gene expression. Steroid-hormone receptors are closely related structurally and have a distinctive DNA-binding domain. The hormone-receptor complex binds to hormone-response elements near the starting point of one or more genes. In response, the transcription of specific genes is activated or repressed.

Polypeptide and amino-acid–derived hormones trigger a complex sequence of events when they bind to a receptor on the plasma membrane. These signal transduction cascades induce a change in the concentration of a second messenger, such as cAMP, inside the target cell. In many cases, the endpoint of the process is the activation of a target protein by phosphorylation and a dramatic change in the cell's activity.

You should be able to predict whether a cell can respond to more than one hormone at a time, and explain why or why not.

Hormone Actions on Target Cells

QUESTIONS

Test Your Knowledge

1. Both epinephrine and cortisol are involved in the body's response to stress. How do the two molecules differ?
   a. Cortisol is an amino acid derivative; epinephrine is a steroid.
   b. Cortisol binds to receptors on the plasma membranes of target cells; epinephrine binds to receptors in the interior of target cells.
   c. Epinephrine mediates the short-term response; cortisol mediates the short- and long-term responses.
   d. Cortisol controls the release of epinephrine from the adrenal glands.
2. How do steroid hormones differ from the polypeptide hormones and most amino-acid–derived hormones?
   a. Steroids are lipid soluble and cross plasma membranes readily.
   b. Polypeptide and amino-acid–derived hormones are longer lived in the bloodstream and thus amplify signals more highly.
   c. Polypeptide hormones are the most structurally complex and induce permanent changes in target cells.
   d. Only polypeptide and steroid hormones bind to receptors in the plasma membrane.
3. What is signal transduction?
   a. the binding of a steroid hormone-receptor complex to DNA
   b. the release of a hormone from the anterior pituitary in response to a hypothalamic hormone
   c. the release of a hormone from the posterior pituitary in response to action potentials from the hypothalamus
   d. the production of a second chemical messenger inside a cell in response to the binding of a hormone at the cell surface
4. Which of the following developmental processes is *not* controlled by hormones?
   a. the initial development of male and female gonads, soon after fertilization
   b. overall growth
   c. molting in insects and other invertebrate animals
   d. metamorphosis in insects and other invertebrate animals
5. What is a hormone-response element?
   a. a receptor for a steroid hormone
   b. a receptor for a polypeptide hormone
   c. a segment of DNA where a hormone-receptor complex binds
   d. an enzyme that is activated in response to hormone binding and produces a second messenger
6. In hormone systems, when does feedback inhibition occur?
   a. when the presence of a hormone inhibits its release
   b. when the presence of a hormone stimulates its release
   c. when a second messenger triggers the phosphorylation of an inhibitory protein
   d. when a hormone from the hypothalamus inhibits the release of a hormone from the anterior pituitary

Test Your Knowledge answers: 1. c; 2. a; 3. d; 4. a; 5. c; 6. a

Test Your Understanding

Answers are available at www.masteringbio.com

1. Compare and contrast the functions of electrical signaling and chemical signaling in animals. How do the nervous system and endocrine system interact during the fight-or-flight response? What role does the nervous system play during hormonal control of homeostasis?
2. Compare and contrast the modes of action of steroid and nonsteroid hormones.
3. The pituitary is often referred to as the "master gland." Why?
4. Why is the observation that one hormone may bind to more than one type of receptor important?
5. Hormones are present in tiny concentrations yet have large effects on target cells and on the individual as a whole. How is this possible?
6. Compare and contrast the short-term and long-term responses to stress in humans. Which hormones are involved? Why are their effects logical, in terms of maximizing an individual's ability to survive a potentially life-threatening situation?

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Suppose that during a detailed anatomical study of a marine invertebrate, you found a small, previously undescribed structure. How would you test the hypothesis that the structure is a gland that releases one or more hormones?
2. Cortisone is a glucocorticoid that suppresses inflammation and other aspects of wound healing. Cortisone was once widely used to treat athletes with joint injuries and people with arthritis. In the short term, cortisone is extremely effective in reducing swelling and pain. Over time, however, physicians found that repeated large doses of cortisone had damaging side effects. Predict what these side effects are. Explain your logic.
3. You are a physician supervising a patient's recovery from the surgical removal of the posterior pituitary. Name a hormone that you will have to administer to this patient artificially. Which symptom(s) will you monitor to assess whether the dosage and timing of your injections are having the desired effect?
4. Suppose that a researcher announces the discovery of a hormone that affects the metabolism of fats in lab rats. Preliminary data indicate that the hormone is a polypeptide, about 50 amino acids long. How would you go about isolating the receptor for this hormone? Using fat cells growing in vitro, how could you test the hypothesis that hormone binding causes a change in a second messenger?

48 Animal Reproduction

The swollen, red rump of this female Hamadryas baboon indicates that she is about to produce an egg and will accept courtship and possibly copulation from males. She will probably mate with several males before the egg is fertilized. This chapter discusses an array of questions about animal reproduction, including how hormones control the female reproductive cycle and the consequences of multiple mating.

KEY CONCEPTS

- The reproductive systems of animals are highly variable. Many animals can switch between asexual and sexual reproduction. When sexual reproduction occurs, fertilization may be external or internal and egg development may take place inside or outside the mother's body, depending on the species.
- In humans, the male reproductive system is composed of structures specialized for the production and storage of sperm, the synthesis of important molecules found in semen, or the transport and delivery of semen. The female reproductive system is composed of structures specialized for producing eggs, receiving sperm, and nourishing offspring during early development.
- In humans, the menstrual cycle is regulated by hormones from the pituitary gland and female reproductive organs. These hormones may interact with each other via positive or negative feedback. Pregnancy is maintained by hormonal signals from the embryo and from the mother's reproductive organs.

All the cells, tissues, organs, and systems introduced in Unit 8 exist for one reason: They allow animals to survive long enough and gather enough resources to reproduce. The shark rectal gland, the fish gill, the squid giant axon, the infrared sensors of pit vipers, and the human adrenal glands are all adaptations that help individuals survive in particular environments, acquire energy, and produce offspring. Stated another way, producing offspring is the reason that adaptations exist. Reproduction is the unconscious goal of virtually everything that an animal does.

Evolution by natural selection explains why animals reproduce; the goal of this chapter is to explore *how* reproduction occurs. Section 48.1 begins by introducing research on animals that cycle between asexual and sexual modes of reproduction and then explains how both modes occur at the cellular level. Section 48.2 surveys the diversity of ways in which animals accomplish fertilization once gametes have formed. The final three sections focus on mammalian reproduction, using humans as the primary model organism. The discussion begins by analyzing male and female reproductive organs, explores how hormones control changes in those

organs, and concludes with a description of human pregnancy and birth.

In the course of investigating research on the molecular and cellular mechanisms of reproduction, we'll also consider topics of urgent practical interest. These topics include the dangers of steroid hormone use by athletes and bodybuilders, and the recent and dramatic declines in the death rate of mothers during childbirth. Understanding and manipulating animal reproductive systems is an important issue in the working lives of physicians, veterinarians, farmers, zookeepers, and many others in biology-related professions.

48.1 Asexual and Sexual Reproduction

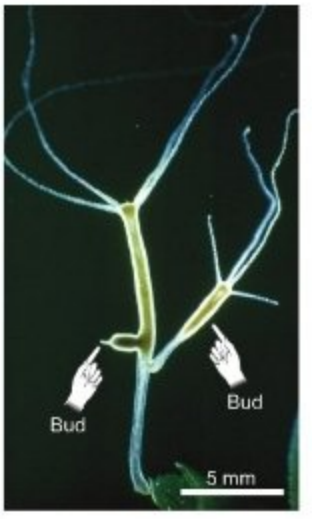
Several earlier chapters have explored how asexual and sexual reproduction differ. **Asexual reproduction** occurs without fusion of gametes. It is usually based on mitosis and results in offspring that are genetically identical to their parent. **Sexual reproduction**, in contrast, is based on meiosis and fusion of gametes. Due to genetic recombination during meiosis and the fusion of haploid gametes—usually from different parents—during fertilization, sexual reproduction results in offspring that are genetically different from each other and from their parents. Let's first consider how animals make genetically identical copies of themselves, then review the mechanisms responsible for sexual reproduction.

How Does Asexual Reproduction Occur?

In thousands of animal species, individuals can **clone** themselves—that is, produce large numbers of identical copies of themselves asexually. Which animals produce offspring asexually, and how is asexual reproduction accomplished? **Figure 48.1** addresses both questions. The hydra in Figure 48.1a is generating offspring by budding. When **budding** occurs, an offspring begins to form within or on a parent. Budding is completed when the offspring—a miniature version of the parent—breaks free and begins to grow on its own. Figure 48.1b illustrates a flatworm undergoing **fission**, in which an individual simply splits into two or more descendants. In some populations of the western whiptail lizard (Figure 48.1c), reproduction occurs solely by **parthenogenesis** (literally, "virgin-origin"), in which female offspring develop from unfertilized eggs. In most cases, parthenogenetic eggs are produced either by mitosis or by meiosis that occurs without crossing over and recombination, after chromosome number has doubled. In both cases, offspring are genetically identical to the mother. If a species reproduces exclusively via parthenogenesis, no males exist. Parthenogenesis occurs in a wide diversity of lineages, including certain guppies, crustaceans, and rotifers as well as lizards.

In addition, many animal species regularly switch between reproducing asexually and reproducing sexually. Why?

(a) Budding in hydra



(b) Fission in flatworms

(c) Parthenogenesis in lizards

FIGURE 48.1 Mechanisms of Asexual Reproduction in Animals Are Diverse.

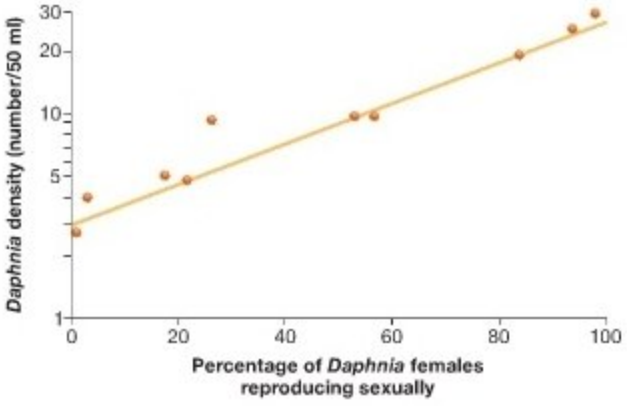
Switching Reproductive Modes: A Case History

Daphnia are crustaceans that live in freshwater habitats throughout the world. In a typical year, *Daphnia* produce only diploid female offspring throughout the spring and summer, via parthenogenesis. As **Figure 48.2a** shows, the eggs produced by parthenogenesis develop in a structure called a brood pouch. They are released when the female molts her exoskeleton.

In late summer or early fall, however, many *Daphnia* females begin producing unfertilized, asexually produced eggs that develop into males as well as females. Once the males have matured, sexual reproduction ensues: Haploid **sperm** (male gametes) produced by meiosis in the males fertilize haploid **eggs** (female gametes) that females produce via meiosis. **Fertilization** is the fusion of sperm and egg. The fertilized eggs are released into a durable case that falls to the bottom of the pond or lake

(a) *Daphnia* produce diploid eggs asexually.

(b) Sexual reproduction is more common in crowded populations than in sparse populations.



(c) Which environmental cues trigger the switch to sexual reproduction?

Water quality	Food concentration	Day length	% Sexual broods
Clean	Low	Short	0
Crowded	Low	Short	44
Clean	Low	Long	0
Crowded	Low	Long	0
Clean	High	Short	0
Crowded	High	Short	0
Clean	High	Long	0
Crowded	High	Long	0

FIGURE 48.2 In *Daphnia*, Environmental Cues Signal the Switch from Asexual to Sexual Reproduction. (a) The diploid eggs shown here will hatch into offspring that are genetically identical to the mother. **(b)** Graph plotting the percentage of *Daphnia* females that reproduce sexually versus *Daphnia* density (log scale). **(c)** Environmental conditions were varied experimentally for *Daphnia*. "Crowded" water was taken from tanks containing dense populations.

● **QUESTION** How would you go about determining which molecule or molecules in crowded water serve as a signal that triggers sexual reproduction?

for the winter. In spring, the sexually produced offspring hatch and begin reproducing asexually.

Biologists try to explain observations like this at two levels (see Chapters 12 and 51). At the ultimate level, the issue is how the behavior affects fitness. Researchers hypothesize that *Daphnia* offspring do better the following year, when conditions are likely to be different from those the year before, if they are genetically unlike their parent. But at the proximate level, the issue is explaining the mechanism responsible for the observation. For example, what cues trigger the change in *Daphnia*'s modes of reproduction?

For decades, most researchers contended that day length triggered the asexual-sexual switch. The idea was that the shortening days of late summer or fall induced the production of males and haploid eggs. Then in 1965 biologists showed that high population densities are also a factor in causing the switch. Researchers who brought *Daphnia* populations into the lab and kept day length constant found a strong correlation between population density and the percentage of females reproducing sexually (**Figure 48.2b**).

In 1992 another group of investigators extended this result by pinpointing the specific aspects of crowding that were affecting the animals. To do this work, the biologists brought *Daphnia* into the laboratory and altered day length, the amount of food available to individuals, and the quality of the water they occupied. (To vary water quality, the investigators used either clean water or water taken from tanks where *Daphnia* were being maintained at high density.) As **Figure 48.2c** shows, individuals in the study population switched to sexual reproduction only if they were exposed to water from crowded populations, low food availability, and short day lengths. In short, *Daphnia* need three different cues from the environment to switch to sexual reproduction.

These experiments don't address the question of why *Daphnia* make the switch, however. Why is it adaptive to reproduce sexually under the adverse conditions dictated by high population density, nutrient stress, and shortened days? The leading hypothesis is that because sexually produced offspring are genetically diverse, they are more capable of thriving when they hatch the following spring than are asexually produced offspring, which are genetically identical to each other and to their parents. This hypothesis is consistent with research introduced in Chapter 12. You might recall that sexual reproduction in a snail species is associated with high rates of parasite infection. The general idea is that genetically variable offspring have higher fitness in environments with rapidly evolving parasites, deteriorating physical conditions, or other types of rapid environmental change. ● If you understand this concept, you should be able to predict the conditions under which asexual reproduction would be found as the only method of producing offspring. You should also be able to discuss the costs and benefits of propagating crop plants like bananas solely through asexual reproduction.

To date, however, the variable-environment hypothesis for the evolution of sexual reproduction has not been tested rigorously in *Daphnia*. Research on the adaptive significance of sex in this species and other organisms continues.

Mechanisms of Sexual Reproduction: Gametogenesis

The mitotic cell divisions, meiotic cell divisions, and developmental events resulting in the production of male and female gametes, or sperm and eggs, are collectively called **gametogenesis** (see Chapter 22). **Spermatogenesis** is the formation of sperm, and **oogenesis** is the formation of eggs. In the vast majority of animals, gametogenesis occurs in a sex organ, or **gonad**. Male gonads are called **testes**; female gonads are called **ovaries**. Early in development, reproductive cells known as *germ cells* enter the testes and ovaries and give rise to diploid cells that will undergo gametogenesis.

Figure 48.3 summarizes the events that take place during gametogenesis in humans. It's important to note that in the male and female gonads, diploid cells called **spermatogonia** (singular: **spermatogonium**) and **oogonia** (singular: **oogonium**), respectively, divide by mitosis. Some of these daughter cells continue to function as spermatogonia or oogonia; others change to form specialized cells that are committed to producing gametes. In males, these specialized cells are called **primary spermatocytes**. They undergo meiosis I and produce two **secondary spermatocytes**, which then undergo meiosis II. The result is four haploid cells called **spermatids**. Each haploid spermatid matures into a sperm. The production of spermatogonia and primary spermatocytes occurs continuously throughout adult life.

Gametogenesis is markedly different in human females. The specialized cells produced by an oogonium are called **primary oocytes**. When these cells undergo meiosis, only one of the four haploid products, known as an **ovum**, matures into an egg. The other cells produced by meiosis in females have a tiny amount of cytoplasm and do not mature into eggs. Because the distribution of cytoplasm is so unequal during each meiotic division in females, the smaller cells are called **polar bodies**. (Recall that *polar* refers to inequality or opposites.) Further, the production of primary oocytes stops early in development in many species; in humans, it stops before birth. And in humans and many

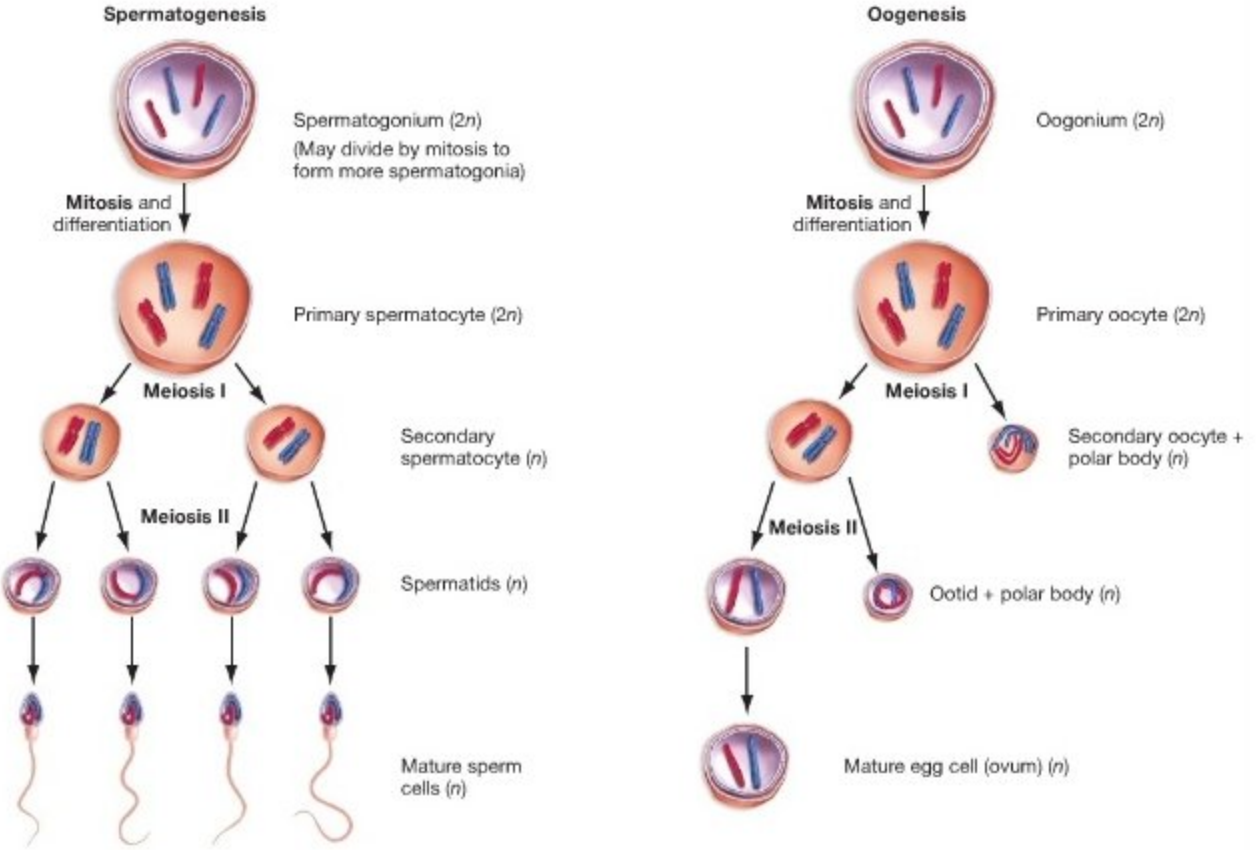


FIGURE 48.3 Gametogenesis in Humans. During gametogenesis, spermatogonia produce sperm and oogonia produce eggs.

EXERCISE In each diagram, label the haploid cells and the diploid cells.

other mammals, the primary oocytes enter prophase of meiosis I during embryogenesis but then stop developing for a period of months or years.

Human Gametogenesis

48.2 Fertilization and Egg Development

Fertilization is the joining of a sperm and an egg to form a diploid **zygote**. Chapter 22 introduced this process by describing how a sperm makes contact with an egg and penetrates the egg's membrane. That discussion focused on the molecular mechanisms of fertilization, using the sea urchin as a model organism. The objectives of this section are to introduce the variety of fertilization mechanisms observed among animals and to explore what happens to fertilized eggs. Why are eggs laid into the environment in some species but retained to develop inside the mother's body in other species? An equally striking contrast occurs in modes of fertilization. In many species, individuals release their gametes into their environment and external fertilization occurs. In other animals, males deposit sperm into the reproductive tracts of females and internal fertilization occurs.

External Fertilization

Most animals that rely on external fertilization live in aquatic environments. The correlation between external fertilization and aquatic environments is logical, because gametes and embryos must be protected from drying. If external fertilization occurred in a terrestrial environment, either the gametes or the resulting zygote would likely die of desiccation.

Another general observation is that species with external fertilization tend to produce exceptionally large numbers of gametes. For example, a female sea star *Asterias amurensis* typically releases 100,000,000 eggs into the surrounding seawater during spawning. Males release many times that number of sperm. The leading hypothesis to explain this pattern is that the probability of a sperm and egg meeting in an ocean or lake is extremely small unless extremely large numbers of gametes are present.

If sperm and eggs from different individuals must be released into the environment synchronously (at the same time) for external fertilization to work, how is gamete release coordinated? The answer has two parts. Most research to date indicates that gametogenesis occurs in response to environmental cues such as lengthening days and warmer water temperatures. These results are logical, because the cues indicate a favorable season for breeding. But what triggers the actual release of gametes? In fishes and other aquatic animals with well-developed eyes and external fertilization, spawning is often the culmination of an elaborate courtship ritual between a male and female. In contrast, courtship behavior appears to be much less important—or even absent—in species such as clams, sea urchins, and sea cucumbers. How do animals that cannot see their mates time the release of their gametes?

Researchers have long hypothesized that the chemical messengers called **pheromones** might be involved in synchronizing gamete release. The idea is that when it is ready to mate, a sea star will release a pheromone, which then triggers gamete release in other individuals. Data to back this claim have begun to emerge only recently, however. For example, in one recent test of the pheromone hypothesis for spawning synchronization, biologists maintained two groups of sea cucumbers under natural conditions of light and temperature for 15 months. In one treatment, individuals were kept in isolated tanks; in another, they were kept in tanks with other sea cucumbers. The researchers found that all the individuals that were maintained in groups released gametes during the normal spawning period. In contrast, only about 10 percent of the individuals maintained in isolation released gametes.

Although these data suggest that pheromones might be involved in coordinating external fertilization in sea stars, they are not definitive. Most biologists will not be convinced that the pheromone hypothesis is valid until a chemical messenger is purified and can be shown to induce spawning in isolated individuals.

Internal Fertilization and Sperm Competition

Internal fertilization occurs in the vast majority of terrestrial animals as well as in a significant number of aquatic animals. Internal fertilization occurs after copulation—in which males deposit sperm directly into the female reproductive tract with the aid of a copulatory organ, usually called a **penis**. Alternatively, males may package their sperm into a structure called a **spermatophore**, which is then placed into the female's reproductive tract by the male or female. In some salamander species, for example, the male places the spermatophore on the ground within its territory. Later the female picks it up with her **cloaca**, a chamber used by both the reproductive and excretory systems that opens to the environment. In this case, the result is internal fertilization without any direct physical contact between the sexes.

Although internal fertilization appears to be straightforward, research on the topic has produced some unexpected results. In terms of understanding animal behavior, perhaps the most important insight about internal fertilization originated with Geoff Parker in the 1970s. Parker realized that in many animal species, females mate with more than one male before fertilization occurs. As a result, sperm from different males compete with each other to fertilize the eggs.

In 1970 Parker published the results of experiments on dung flies that confirmed the existence of sperm competition—competition between sperm from different males to fertilize the

eggs of the same female. Parker's experiments consisted of a series of carefully controlled matings between one female and two males. In each experiment, the two males were selected in such a way that Parker could distinguish their offspring. As predicted by the sperm competition hypothesis, the proportion of offspring fathered by each male was not 50:50. Instead, whichever male was last to copulate fathered an average of 85 percent of the offspring produced.

Follow-up research has confirmed that this **second-male advantage** is widespread, although not quite universal, in insects and some other animal groups. How does it occur? To answer this question, biologists turned to the fruit fly *Drosophila melanogaster*. A research group was able to introduce a gene into male fruit flies that resulted in the production of sperm with green tails (**Figure 48.4**). When a mating by a green-spermed male was followed with a mating by a male having normal-colored sperm, most of the green-tailed sperm disappeared from the female's sperm-storage area. To interpret this finding, the biologists suggested that the sperm of the second male physically dislodged the first male's gametes and inserted themselves in their place. The researchers also showed that the fluid that accompanies sperm during fertilization is able to displace stored sperm from competing males. These two mechanisms resulted in the second male's sperm fertilizing most of the eggs laid.

Besides documenting the mechanisms responsible for second-male advantage, research on sperm competition has recently contributed another major result. In species in which multiple mating is common, males have extraordinarily large testes for their size and produce proportionately larger numbers of sperm. Although this pattern was first documented in primates, it has now been observed in a wide variety of animal groups. For example, males from species of fruit bats that live in large social groups produce more sperm, on average, than do male fruit bats from species that live in small groups. The leading hypothesis to explain this observation is that fertilization is similar to a lottery in which each sperm represents a ticket. According to the lottery hypothesis, the more tickets a male enters in the competition, the higher his chance of "winning" fertilizations and passing his alleles on to the next generation. As a result, it is logical to observe exceptionally large testes in species in which sperm competition occurs.

The lottery model has recently been challenged, however, by evidence that in some species if not most, females store sperm and exert control over which sperm are successful in fertilization. In other words, females do not always accept the results of sperm competition passively. Females of some species actively choose which male performs the last copulation before fertilization takes place. In other species, females physically eject sperm from undesirable males. This phenomenon has been dubbed *cryptic female choice*. The name is appropriate because the selection of sperm by females is hidden from males.

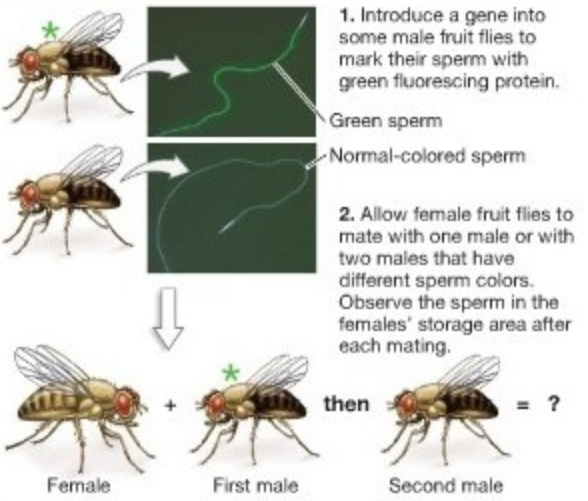
Experiment

Question: How does the "second-male advantage" occur in sperm competition?

Hypothesis: Sperm from the second male displaces sperm from the first male.

Null hypothesis: The mechanism does not involve sperm displacement.

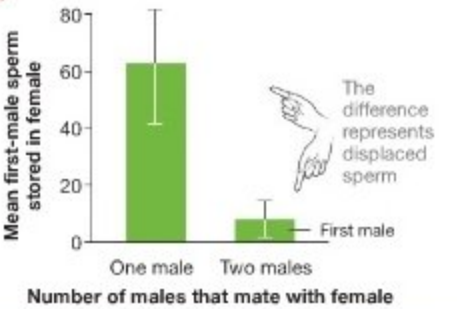
Experimental setup:



Prediction: When females mate twice, few sperm from the first male remain in storage.

Prediction of null hypothesis: When females mate twice, all of the sperm deposited by the first male are still present.

Results:



Conclusion: The sperm from the second male displaces the sperm from the first male.

FIGURE 48.4 Experimental Evidence for Second-Male Advantage during Sperm Competition in *Drosophila*. Researchers created fruit-fly males with green-tailed sperm to explore why the second male to mate tends to father more offspring than does the first male in many species. The graph shows the results when males with green sperm were the only male to mate or the first of two males to mate. When sperm competition occurred, the first male to mate fathered a tiny percentage of offspring, probably because most of its sperm disappeared from the sperm-storage organ in females.

Why Do Some Females Lay Eggs while Others Give Birth?

Once fertilization is accomplished, the embryo is either laid as an egg outside the mother's body or retained so that it can develop inside. In **oviparous** ("egg-bearing") animals, the embryo develops in the external environment. In some oviparous species such as sea stars, sea urchins, and most insects, neither the male nor the female provides any further care; the eggs and embryos are left to fend for themselves. But a substantial number of oviparous species continue to care for their young after eggs have emerged from the mother's body. For example, birds incubate their eggs and feed the young after hatching; fish may guard their eggs from predators and fan the clutches to oxygenate them.

In **viviparous** ("live-bearing") species, embryonic development takes place within the mother's body. More specifically, the embryo attaches to the reproductive tract of the mother and receives nutrition directly from the mother—via diffusion from her circulatory system. When **ovoviviparity** occurs, offspring develop inside the mother's body but are nourished by nutrient-rich yolk stored in the egg.

Why does oviparity exist in some groups and viviparity or ovoviviparity in others? Biologists tackled this question by studying the lizard genus *Sceloporus* (**Figure 48.5a**). Some of the populations they studied are oviparous while others are ovoviviparous; all live in the highlands of the southwestern United States and central Mexico, where temperatures can be cool. To understand how oviparity and ovoviviparity evolved, the biologists analyzed a phylogenetic tree—based on molecular and morphological data—of many *Sceloporus* species (**Figure 48.5b**; see **BioSkills 2** for help with interpreting phylogenetic trees). One of the researchers' first conclusions was that because most *Sceloporus* populations are oviparous, egg laying probably represents the original or ancestral condition. As the red branches on the tree show, however, ovoviviparity evolved independently in two groups. Using a similar research strategy, biologists have found that ovoviviparous populations of sea stars have evolved from oviparous populations on several occasions.

Why did natural selection favor these changes between egg laying and live birth? Ovoviviparity or viviparity should evolve when it leads to higher numbers of surviving young. Researchers have long hypothesized that natural selection favoring live birth should be especially strong in cold habitats. Low temperatures slow the development of embryos, so in cold habitats, it might be advantageous for females to retain eggs inside their bodies so that offspring can develop at a more favorable temperature. In support of this hypothesis, a researcher has shown that in at least one oviparous species of lizard, lowering nest temperatures leads to a higher percentage of deformities in offspring. In addition, offspring that developed in colder nests run more slowly than do individuals of the same age that developed at higher temperatures. Research into why ovoviviparity and viviparity has evolved in certain populations continues.

(a) Some *Sceloporus* lizards lay eggs; other members of the same genus bear live young.

(b) Phylogeny of *Sceloporus* from central Mexico

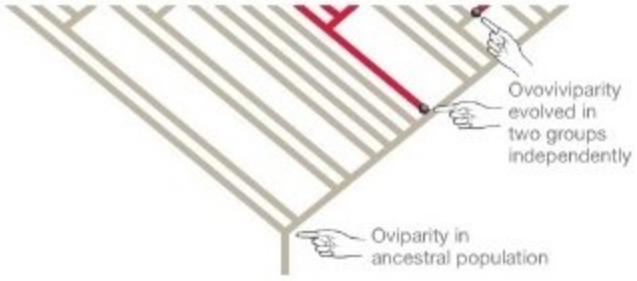


FIGURE 48.5 Ovoviviparity Has Evolved Multiple Times in *Sceloporus* Lizards. (a) *Sceloporus* is a genus of lizards from desert areas in North America. **(b)** Each twig on this phylogenetic tree represents a *Sceloporus* species or population from North America. According to these data, ovoviviparity evolved twice as the lineage diversified.

Check Your Understanding

If you understand that...

Some of the most basic aspects of reproduction are variable among animal populations or species: whether reproduction is sexual or asexual, whether fertilization is external or internal, and whether fertilized eggs develop in the environment or in the mother's body.

You should be able to...

1) Describe the advantages and disadvantages of each of these modes of reproduction.
2) Design experiments to test the following hypotheses:
   - A particular molecule is a gamete-releasing pheromone in sea stars.
   - A particular molecule is a toxin active in sperm competition.
   - In ovoviviparous and oviparous populations of the same species, ovoviviparous populations have higher reproductive success in cold environments.

48.3 Reproductive Structures and Their Functions

The first two sections of this chapter considered the broad contrast between asexual and sexual reproduction and examined general patterns in fertilization and egg care. Now let's narrow the focus and explore the mechanics of sexual reproduction in more detail. The first task is to understand the anatomy of the male and female reproductive systems.

The Male Reproductive System

In humans, the external anatomy of the male reproductive system is simple: It consists of the scrotum and the penis. The saclike **scrotum** holds the testes; the penis functions as the organ of copulation prior to internal fertilization.

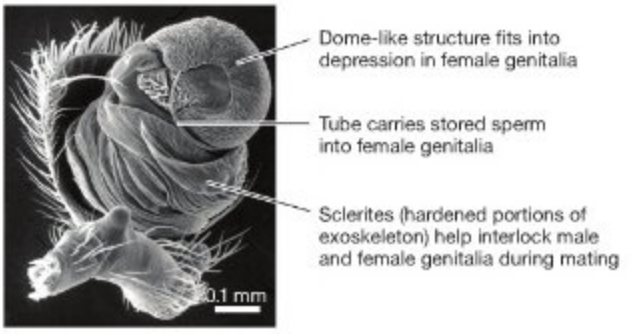
Biologists who have compared these structures among animal species have been struck by their variability and complexity. For example, a scrotum occurs only in certain mammal species. Whales, elephants, hedgehogs, moles, and many other mammal groups lack the structure entirely and instead have testes that are located well within the abdominal cavity. Among species that do have a scrotum, the structure's size and shape vary. In numerous species of primates, the scrotum is brightly colored and appears to function in sexual display behaviors.

How Does External Anatomy Affect Sperm Competition?

Diversity in scrotal morphology pales in comparison with variation in the structure of the penis or other types of male **genitalia**. (*Genitalia* is the term used when the copulatory organ has distinct parts.) In many groups of insects and spiders, examining the animals' genitalia is the only way that biologists can distinguish species. **Figure 48.6a** shows one elaborate structure typically observed in spiders. Even among closely related species, the sizes and shapes of these organs tend to be strikingly different. Why are insect genitalia so diverse?

Researchers recently offered data that might help answer this question, based on the hypothesis that certain genitalia shapes are advantageous when sperm competition occurs. To test this idea, biologists studied how much second-male advantage varied among males with different-shaped genitalia when water-strider females mated with two males. As the data in **Figure 48.6b** show, there is substantial variation in the size and shape of two important parts of the male genitalia in this species. When sperm competition occurred, the researchers found that males with certain types of genitalia—those with genitalia shapes plotted at the lower left of Figure 48.6b—fathered a higher percentage of offspring than did others. In this and perhaps many other species, variation in the size and shape of male genitalia has a strong impact on male reproductive success. The exact mechanism responsible for this pattern is not known.

(a) Male genitalia in the spider *Zosis geniculatus*



(b) In a population of water striders, male genitalia shape is highly variable.

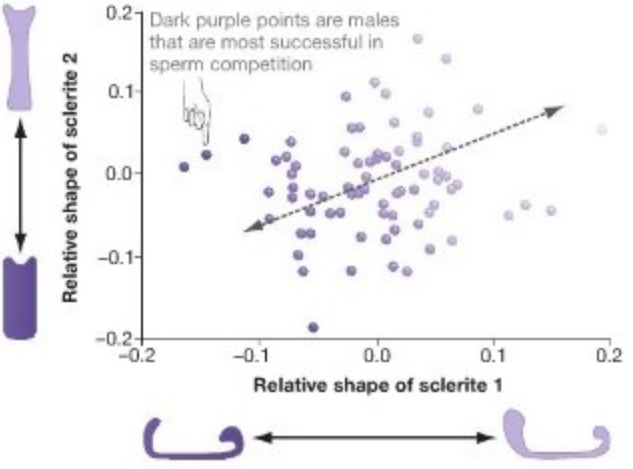


FIGURE 48.6 In Insects, Male Genitalia May Vary among Species and Individuals and May Affect Reproductive Success. (a) An elaborate male reproductive structure, used to transfer sperm to the female, in a species of spider. In insects and spiders, species that look identical often have distinctive genitalia. **(b)** Plot of the relationship between the size and shape of two parts of male genitalia in water striders.

External and Internal Anatomy of Human Males

Figure 48.7 furnishes side and front views of the internal reproductive structures in a human male. Although numerous structures are involved, notice that the reproductive system in males has just three basic functional components:

1. *Spermatogenesis and sperm storage* Sperm are produced in the testes and stored in the **epididymis** nearby.
2. *Production of additional fluids* Complex solutions form in the **seminal vesicles**, **prostate gland**, and **bulbourethral gland**. These solutions, called accessory fluids, are added to sperm prior to **ejaculation**, or expulsion from the body. **Table 48.1** lists some components of these accessory fluids. **Semen** is the combination of sperm and accessory fluids.

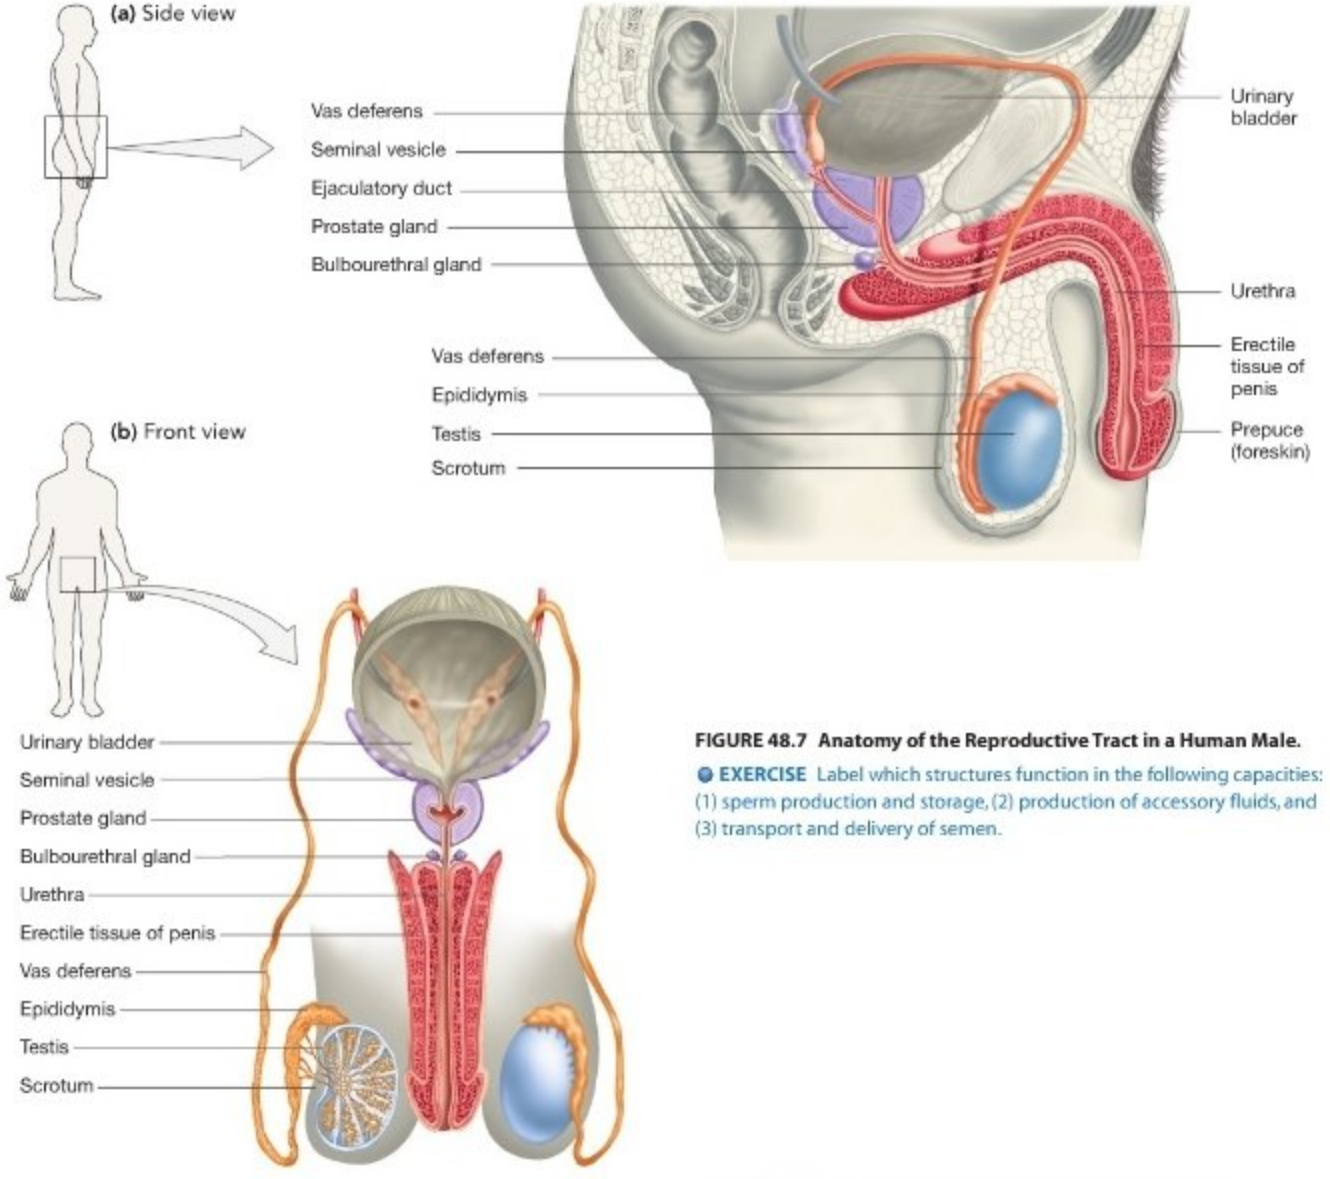

FIGURE 48.7 Anatomy of the Reproductive Tract in a Human Male.

EXERCISE Label which structures function in the following capacities: (1) sperm production and storage, (2) production of accessory fluids, and (3) transport and delivery of semen.

3. *Transport and delivery* The **vas deferens** are a pair of muscular tubes that store sperm and transport semen from the epididymis to the short **ejaculatory duct**. The semen then enters the **urethra**, a longer tube that passes through the penis and services both the reproductive and urinary systems in males. The semen is expelled during ejaculation.

How do these structures vary among animals? Variation in relative testis size among mammal species has already been discussed. In addition, the composition of the accessory fluids varies widely. In many insects, spiders, and vertebrates, molecules in the accessory fluids congeal after they arrive in the female reproductive tract and plug it. Experiments have shown that these copulatory plugs can serve as an effective deterrent

TABLE 48.1 **Accessory Fluids in Human Semen**

Source	Content	Function
Seminal vesicles	Fructose (a sugar)	Source of chemical energy for sperm movement
	Prostaglandins	Stimulate smooth-muscle contractions in uterus
Prostate gland	Antibiotic compound	Prevent urinary tract infections in males?
	Citric acid	Nutrient used by sperm
Bulbourethral gland	Alkaline mucus	Lubricates tip of penis; neutralizes acids in urethra

to future matings; in some species, though, females or second males actively remove them.

Another diverse aspect of male internal anatomy is a bone inside the penis called the **baculum**. Some mammal species, including humans, lack this feature. But among rodents, the shape of the baculum is so variable that it can be used as a characteristic that distinguishes species. And in seals, baculum size appears to correlate with mating system. In seal species in which females routinely mate with several males before becoming pregnant, males have not only large testes for their size, but a large baculum as well. In all species in which it appears, the baculum helps stiffen the penis during copulation. **Box 48.1** introduces other usual aspects of male reproductive organs and fertilization.

The Female Reproductive System

The most important part of the reproductive system in female animals is the ovary, the organ in which meiosis occurs and mature egg cells, or ova, are produced. In the vast majority of species, the mature egg cell is a membrane-bound structure consisting of a haploid nucleus, a full complement of other organelles, and a large supply of nutrients in the form of yolk (see Chapter 22).

Earlier chapters have analyzed variations on the basic theme of egg structure. Chapter 22 introduced the complex outer membranes of sea urchin eggs, which play a key role in binding sperm from the same species and initiating fertilization. The amniotic egg was featured in Chapter 34 as an innovation that allowed tetrapods to reproduce efficiently in dry environments. Chapter 41 pointed out that the amount of yolk present in an egg correlates strongly with the size of offspring at hatching. That chapter also presented data indicating that females face a trade-off between egg size and the total number of eggs they can produce.

To probe variation in egg structure and female reproductive systems further, let's consider two highly specialized examples: The reproductive systems of female birds and humans. Birds are an example of a vertebrate that lays an amniotic egg protected by a hard shell; humans are an example of a viviparous vertebrate.

The Reproductive Tract of Female Birds **Figure 48.8** diagrams the bird reproductive system. Starting with the ovary, the labels on the drawing indicate the sequence of events that takes place as the egg moves down the reproductive tract. The result is a hard-shelled egg—like the familiar chicken eggs you buy in the store—that can be laid into the environment and incubated. From the time the egg is released from the ovary until the zygote undergoes mitosis and the embryo begins to develop, a bird egg is a single cell. The ostrich egg, which can be over 15 cm (6 in) in diameter, contains one of the largest single cells known in animals. The structure contains enough nutrients and water to sustain development until hatching.

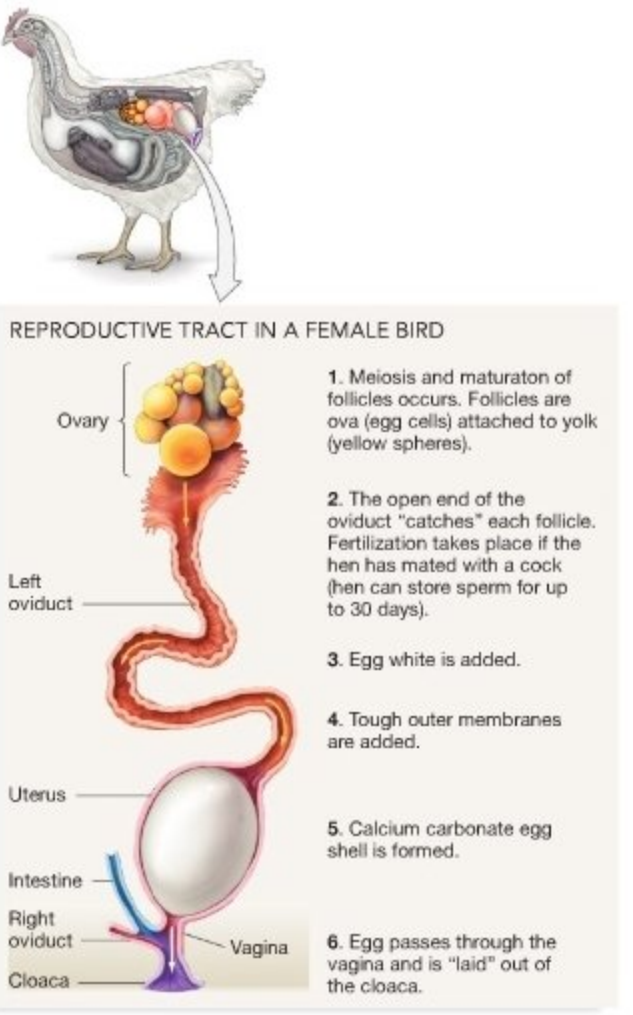

FIGURE 48.8 Anatomy of the Reproductive Tract in a Female Bird.

EXERCISE Two branches of the female reproductive tract empty into the cloaca, but only one is functional. Circle the vestigial branch.

Note that although male birds have two testes, females have just one ovary. The presence of a single ovary is thought to be an adaptation that reduces weight and makes flight more efficient.

External and Internal Anatomy of Human Females **Figure 48.9** shows side and front views of the anatomy of the human female reproductive system. The external anatomy features the **labia minora** (singular: **labium minus**) and the **labia majora** (singular: **labium majus**), the opening of the urethra, and the opening of the vagina. The labia are folds of skin that cover the urethral and vaginal openings. The **clitoris** is a sensitive organ that develops from the same population of embryonic cells that give rise to the penis in males. It likewise becomes erect during sexual stimulation and is covered with a protective sheath called the *prepuce*, homolo-

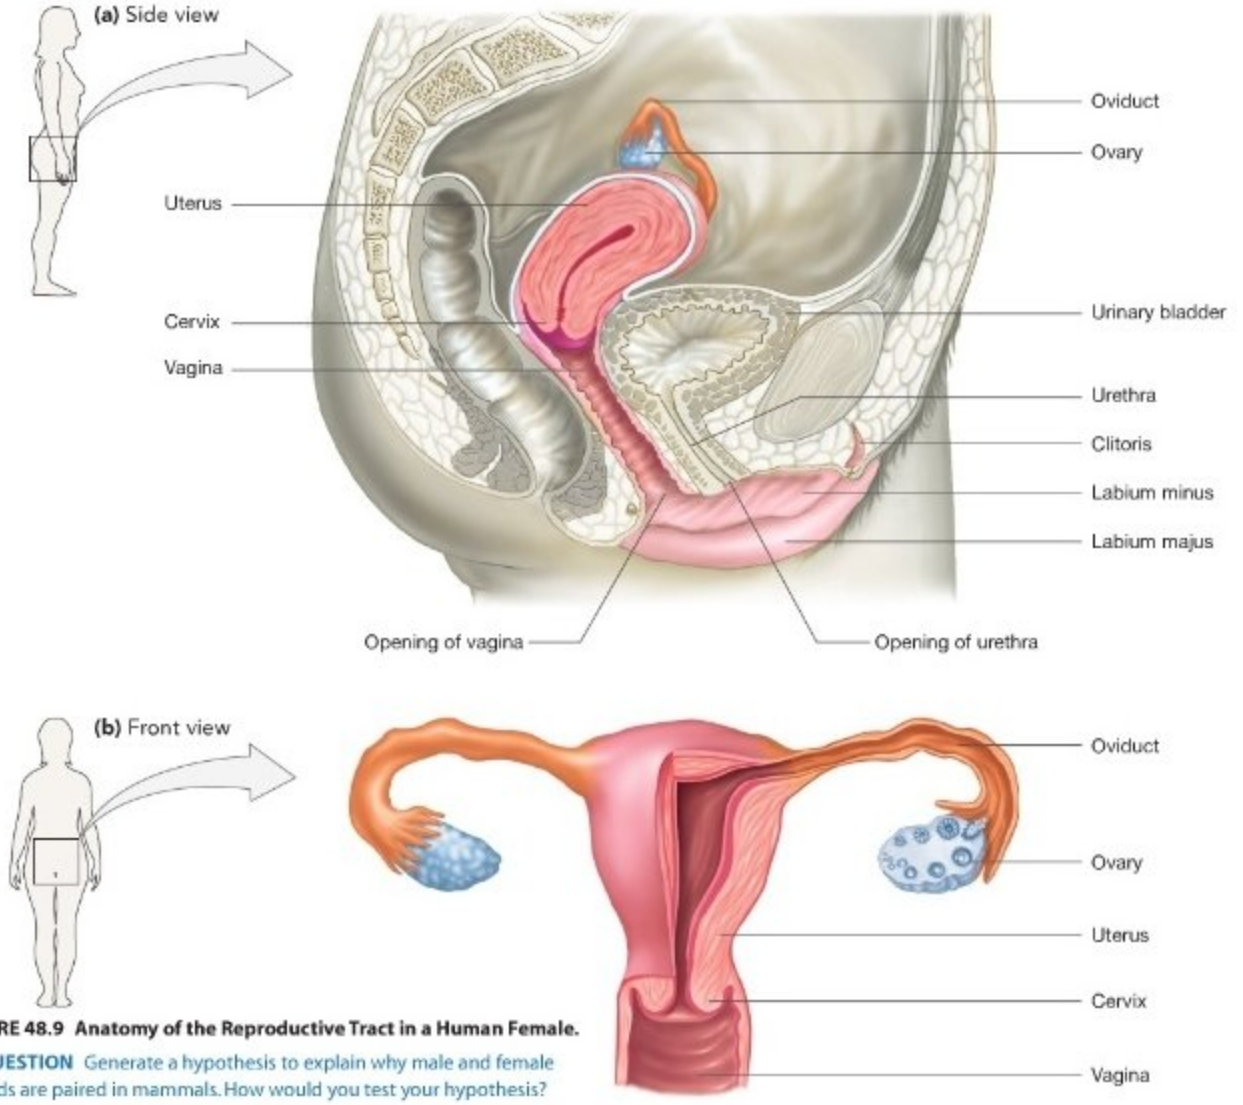

FIGURE 48.9 Anatomy of the Reproductive Tract in a Human Female.

QUESTION Generate a hypothesis to explain why male and female gonads are paired in mammals. How would you test your hypothesis?

gous with the prepuce (foreskin) that covers the end of the penis. In females, however, the urethral opening, where urine is expelled, is separate from the reproductive structures. The **vagina**, or birth canal, is the chamber where semen is deposited during sexual intercourse and where the baby is delivered during childbirth.

The internal anatomy of the female reproductive system in humans and other mammals is dominated by structures with two functions:

1. *Production and transport of eggs* Eggs are produced in the paired ovaries. During **ovulation**, a developing oocyte (egg) is expelled from the ovary and enters the **oviduct**, also known as the **fallopian tube**, where fertilization may take place. As Section 48.5 will detail, fertilized eggs are then transported from the oviduct to the muscular sac called the **uterus**.
2. *Development of offspring* The uterus is where embryonic development takes place. During childbirth, the developed embryo (now called a fetus) passes through the opening of the uterus, known as the **cervix**, and into the vagina.

To appreciate how the ovaries and uterus work in humans, it's essential to explore the monthly menstrual cycle and pregnancy in much more detail. It is not possible to understand either event, though, without investigating the hormones that regulate them. Let's turn now to research investigating the sex hormones of mammals.

BOX 48.1 Unusual Aspects of Fertilization

Studies on animal sexual reproduction have documented some of the most remarkable behaviors and structures observed in nature. The list that follows is by no means exhaustive. It is a sample, offered simply because the diversity of mating arrangements in animals is fascinating to biologists and laypeople alike.

- *Femme fatales* When Australian redback spiders mate, the male does a somersault after inserting his penis-like organ. The somersault behavior places his dorsal surface in front of the female's mouthparts. The female then eats the male. (Biologists refer to females who cannibalize males as femme fatales—a phrase used to describe murderous human females in movies.) Experiments have shown that males that are eaten copulate longer and fertilize more eggs than do males that survive copulation, probably because sperm transfer continues until the meal is over.
- *Giant sperm* In the fruit fly *Drosophila bifurca*, males average 1.5 mm in total body length. Their sperm, however, are each 6 cm long. Recent research suggests that the coiled sperm fill the female's sperm storage area and prevent fertilization by competing males—the bulk of the sperm makes it impossible for another male's sperm to enter.
- *False penises* Although very few bird species have a penis, the red-billed buffalo weaver has a false penis that becomes erect during copulation (**Figure 48.10**). It does not function in sperm transfer, but appears to stimulate the female's reproductive tract and trigger an orgasm-like state in males. Female buffalo weavers have a similar, but smaller, organ of unknown function.
- *Infidelity* Researchers who use genetic markers to assess paternity in birds that appear to be monogamous find that up to 60 percent of nests contain at least one offspring fathered by a male that is not mated to the resident female. In most cases, females actively solicit copulations from males holding nearby territories.
- *Love darts* Many snails and slugs are **hermaphroditic**, meaning an individual has both male and female gonads. During mating, two individuals simultaneously receive and deposit sperm to fertilize each other's eggs. In some species, individuals fire mucus-covered "love darts" from their genitalia into the mating partner. Recent experiments have shown that a substance in the mucus increases the chance that sperm will successfully fertilize eggs. In other species, the penis frequently becomes stuck in the female reproductive tract and is bitten off by one partner.
- *Hypodermic insemination* Some bedbugs have hypodermic penises, meaning that they function like a hypodermic needle. Males force the organ through the female's abdominal wall and deposit sperm directly into her body cavity.

Did the process of sexual selection, introduced in Chapter 25, lead to the evolution of these structures and behaviors? If so, how and why? In many or even most cases, the answers to these questions are not known.

FIGURE 48.10 A False Penis in a Weaverbird. The organ shown here, in the erect state, is called a false penis because it is not inserted in the female's reproductive tract and does not transmit semen.

48.4 The Role of Sex Hormones in Mammalian Reproduction

Chapter 47 introduced the male sex hormone **testosterone** and the female sex hormone **estradiol**, which belongs to a class of hormones known as **estrogens**. Recall that both testosterone and estradiol are steroids, that both bind to receptors inside the nucleus of target cells, and that the resulting hormone-receptor complexes bind to DNA and trigger changes in gene expression. Both are also considered gonadal hormones because they are produced in the gonads. Testosterone is synthesized in specialized cells inside the testes; estradiol and other estrogens are synthesized in the ovaries. More specifically, the female sex hormones are produced by cells that surround each developing egg. These surrounding cells form a structure called a follicle around the egg.

As Chapter 47 pointed out, the human sex hormones play a key role in three events: (1) the development of the reproduc-

TABLE 48.2 **Changes That Take Place during Puberty**

Pediatricians use the five stages of puberty listed here to diagnose the developmental stage of their patients.

	Boys	Girls
Stage 1 (Prepubertal)	No sexual development	No sexual development
Stage 2	Testes enlarge Body odor	Breast budding First pubic hair Body odor Height spurt
Stage 3	Penis enlarges First pubic hair Ejaculation (wet dreams)	Breasts enlarge Pubic hair darkens, becomes curlier Vaginal discharge
Stage 4	Continued enlargement of testes and penis Penis and scrotum deepen in color Pubic hair curlier and coarser Height spurt Male breast development (temporary)	Onset of menstruation Nipple is distinct from surrounding areola Pelvis begins to widen
Stage 5 (Fully mature adult)	Pubic hair extends to inner thighs Increases in height slow, then stop Increased muscle mass	Pubic hair extends to inner thighs Increases in height slow, then stop Deposition of fat in hips, buttocks, thighs, and breasts

tive tract in embryos, (2) the maturation of the reproductive tract during the transition from childhood to adulthood, and (3) the regulation of spermatogenesis and oogenesis in adults. To begin exploring the action of sex hormones in more detail, let's take a closer look at their role in the transition from juveniles to adults.

Which Hormones Control Puberty in Mammals?

Table 48.2 lists some of the changes that occur in boys and girls as they undergo **puberty**—the process that leads to sexual maturation in humans. Chapter 47 pointed out that in amphibians, the juvenile-to-adult transition is triggered by the hormone T_3; in insects the transition to adulthood occurs in response to ecdysone. But in humans, physicians and researchers have long known that the transition occurs in response to increased levels of gonadal hormones—testosterone in boys and estradiol in girls. A group of physicians recently offered dramatic evidence for testosterone's role. They were presented with a 2-year-old boy who showed signs of entering puberty. His symptoms included an increased penis size, the development of pubic hair, and facial acne. Through careful interviewing, the doctors determined the cause of his condition. The child's father was a bodybuilder who was smearing a testosterone cream on his own shoulders and arms in an attempt to build muscle mass. The child was apparently absorbing enough testosterone from being carried by his father to trigger puberty-like symptoms. Fortunately for the 2-year-old, all his symptoms except for penile enlargement subsided once his father discontinued the use of testosterone creams. **Box 48.2** introduces other unfortunate side effects of steroid use by athletes and bodybuilders.

Although the roles of testosterone and estradiol in puberty are well documented, understanding how the process is initiated proved to be a stubborn problem. Some researchers hypothesized that the sex hormones are regulated by the hypothalamic-pituitary axis, introduced in Chapter 47. Recall that chemical signals from the hypothalamus region of the brain lead to the release of regulatory hormones from the pituitary gland, which then cause the release of hormones from other glands. Are the hypothalamus and pituitary involved in regulating the release of sex hormones?

Two advances made it possible to answer this question definitively and affirmatively. First, researchers isolated a hormone called **gonadotropin-releasing hormone** (**GnRH**) from the hypothalamus. Second, investigators noted that boys and girls who were entering puberty experienced distinctive pulses in the concentration of two pituitary hormones, called **luteinizing hormone** (**LH**) and **follicle-stimulating hormone** (**FSH**). Researchers hypothesized that pulses of LH and FSH occurred in response to the release of GnRH and were responsible for increases in testosterone and estradiol. To test the hypothesis of hypothalamus and pituitary control that is diagrammed in **Figure 48.11**, researchers administered pulses of GnRH to boys and girls who had deficits in their hypothalamus and were

BOX 48.2 Abuse of Synthetic Steroids

Among bodybuilders and athletes, the use of synthetic testosterone-like molecules, commonly called **androgens**, has recently exploded in popularity. Both men and women use these drugs because they support the development of increased muscle mass during weight training, just as testosterone supports increased muscle mass during puberty.

Research on bodybuilders has confirmed a wide variety of damaging side effects, however. Women who use synthetic androgens routinely experience voice deepening and growth of facial hair. Both male and female users may develop acne, the emotional changes dubbed 'roid rage (for steroid rage), fluid retention, and liver ailments. There is some evidence that males may also experience fertility problems. The leading hypothesis to explain infertility is that the synthetic androgens mimic the negative feedback that testosterone exerts on luteinizing hormone (LH) production from the pituitary. LH is required to support spermatogenesis, so high doses of androgens may reduce LH concentrations to a level that precludes sperm production.

Unfortunately, opinion polls have shown that most bodybuilders and athletes are willing to tolerate these side effects in hopes of increasing their performance in competitions. In response, some regulatory agencies actively test for synthetic androgens in the urine of competitors and ban individuals who are using them.

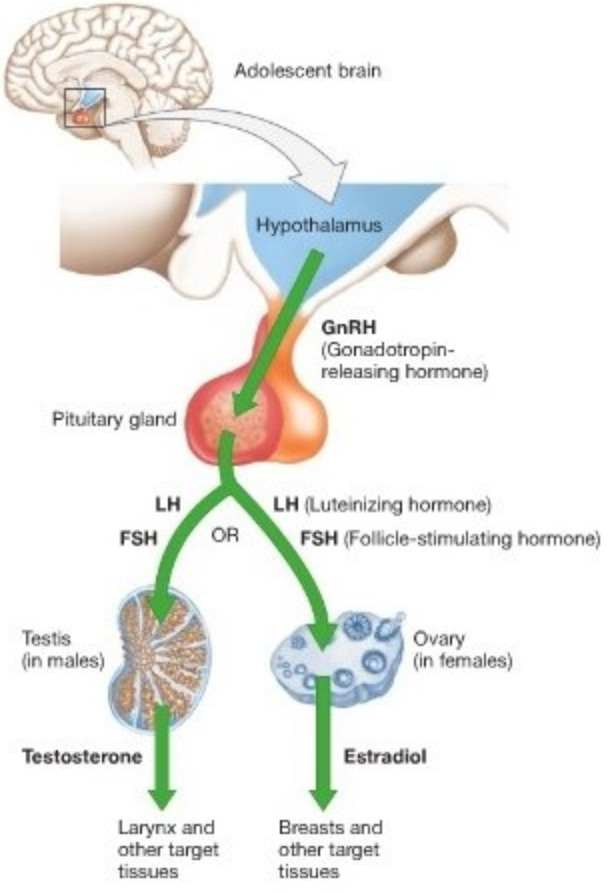

FIGURE 48.11 In Humans, Puberty Is Triggered by Hormones from the Hypothalamus and Pituitary.

QUESTION How does control of testosterone and estradiol production compare with control of cortisol release by the adrenal gland? (See Figure 47.14c.)

experiencing delays in the onset of puberty. As predicted, the GnRH treatment induced surges in LH and FSH that triggered the developmental events listed in Table 48.2. This result provided strong support for the hypothesis that a hormone from the hypothalamus is responsible for initiating puberty.

What triggers GnRH increases at the appropriate age? This is the most pressing question facing researchers and physicians interested in hormonal control of sexual development. Although the question remains unanswered, there is some evidence that nutritional state is involved. For example, girls with large fat stores tend to enter puberty earlier than do girls who are thin. In addition, the current average age for the onset of menstruation in females in the United States is slightly over 12 years. This is much earlier than the average of 17 years of age that had been observed in the United States during the eighteenth and nineteenth centuries, when the general nutritional state of the population was poorer. Research continues on how age, nutritional condition, and perhaps other factors interact to promote the release of GnRH.

If you recall the discussion in Chapter 47 of how the adrenal hormone cortisol is controlled, however, you might suspect that the model of sex-hormone regulation diagrammed in Figure 48.11 is probably simplified. Chapter 47 emphasized that many hormones participate in negative feedback—also called feedback inhibition—meaning that the presence of a hormone inhibits the factor that triggers its release. Do sex hormones participate in negative feedback? The short answer to this question is yes. To appreciate the details, let's investigate hormonal control of the human menstrual cycle.

Which Hormones Control the Menstrual Cycle in Mammals?

Figure 48.12 illustrates the sequence of events in the human **menstrual cycle**, a monthly reproductive cycle that occurs in the uterus. Although the length of this cycle varies among

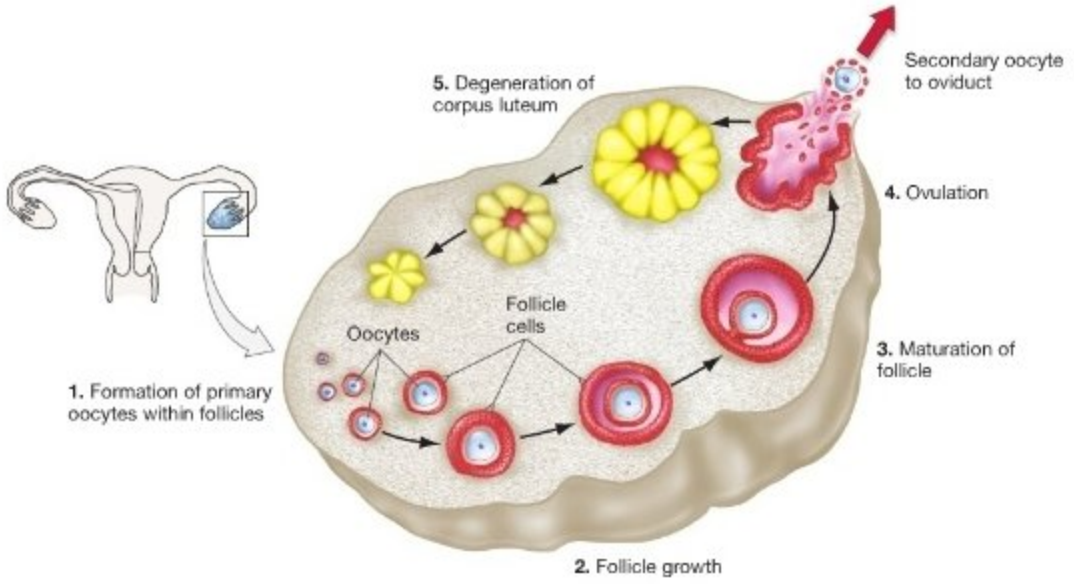

FIGURE 48.12 The Ovary Changes over the Course of a Menstrual Cycle. As a follicle matures, primary oocytes complete meiosis I. The secondary oocyte that results is expelled from the ovary and then travels down the oviduct. (Follicles don't actually move in a circle during the menstrual cycle; they are shown that way for illustrative purposes only.)

QUESTION Which events illustrated here occur during the follicular phase of the menstrual cycle? Which occur during the luteal phase?

women, 28 days is about average. In conjunction with changes in the ovary illustrated in the figure, the lining of the uterus undergoes a dramatic thickening and regression; ultimately, part of the lining sloughs off and is expelled through the vagina. The onset of the combined ovarian and uterine cycles is the start of **menstruation**—the expulsion of the uterine lining. This event is designated as day 0 in the menstrual cycle.

The cycle itself has two distinct phases. A follicle matures during the **follicular phase**, which lasts an average of 14 days. Primary oocytes complete meiosis I during this phase (illustrated in Figure 48.3). Ovulation occurs when the follicle is mature and releases its secondary oocyte into the oviduct. (Researchers are still unsure what controls which ovary—right or left—will release an egg during ovulation.) Although the timing of ovulation is highly variable, the subsequent **luteal phase** also averages 14 days in length. Its name was inspired by the formation and subsequent degeneration of a structure called the **corpus luteum** ("yellowish-body") from the ruptured follicle. Meiosis II occurs only if the ovulated cell is actually fertilized (see Section 48.5).

The regular occurrence of a menstrual cycle throughout the year makes human females extremely unusual among mammals. Although some mammals ovulate multiple times during the year, most ovulate only during a prescribed breeding season—often in response to environmental cues; more infrequently in response to cues from males. In addition, only humans and other great apes menstruate. In the vast majority of mammals, the lining of the uterus is reabsorbed if pregnancy does not occur. Females that do not menstruate have an estrous cycle and are sexually receptive only during estrus—also known as being "in heat." But whether an estrous or menstrual cycle occurs, the basic sequence of events, with a follicular phase preceding ovulation and a luteal phase following ovulation, is shared among mammals. As it turns out, hormonal control of the estrous and menstrual cycles is also similar.

How Do Pituitary and Ovarian Hormones Change during a Menstrual Cycle? Signals from hormones are responsible for the changes that occur in the uterus and ovaries during a menstrual cycle. For biologists who wanted to probe how hypothalamic, pituitary, and ovarian hormones interact to regulate the menstrual cycle, the first task was to document how each hormone changed over time. By monitoring hormone concentrations in the blood or urine of a large number of women, researchers were able to document dramatic changes in the concentrations of estradiol and several other hormones. LH and FSH are produced in the pituitary gland during each cycle in response to GnRH; the steroid hormone **progesterone** is produced along with estrogens, including estradiol, in the ovaries.

Several observations jump out of the data in **Figure 48.13.** LH levels are fairly constant except for a spike that begins just prior to ovulation, suggesting that LH might be the trigger

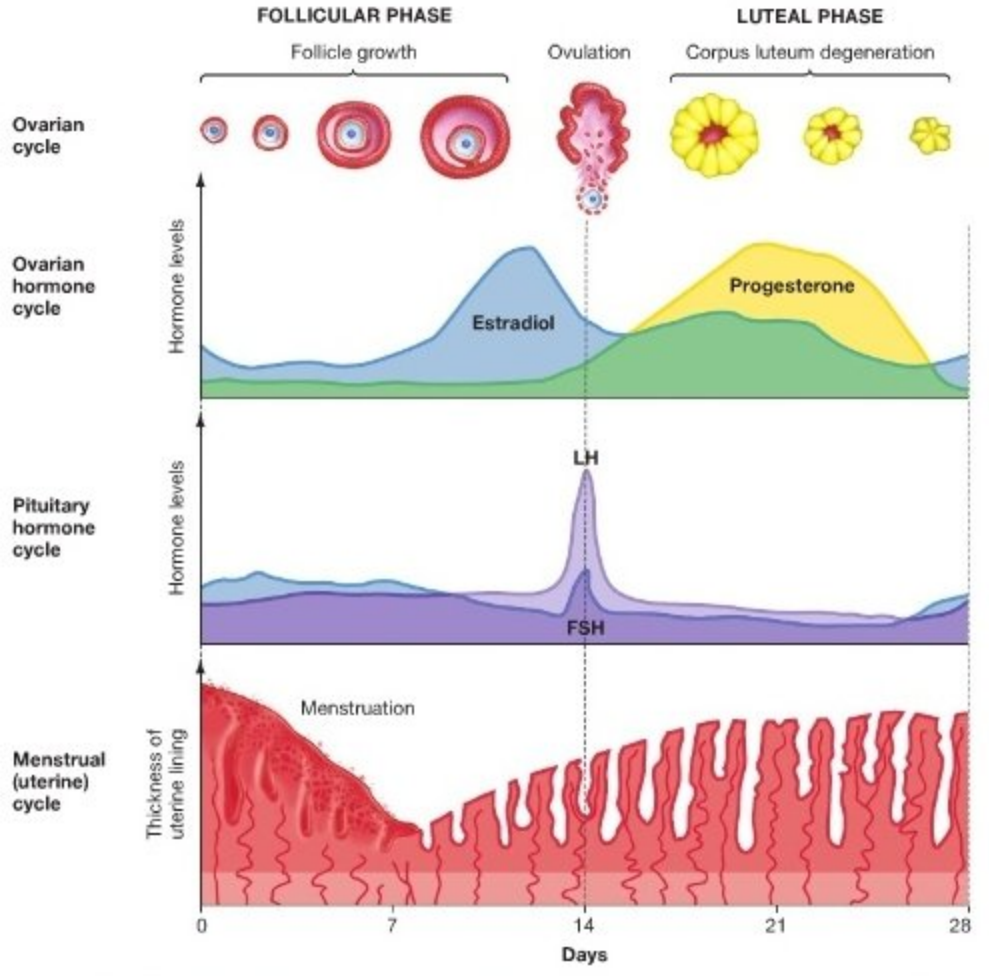

FIGURE 48.13 Changes That Occur during a Menstrual Cycle in a Human Female. During a menstrual cycle, changes occur in the concentrations of the pituitary hormones LH and FSH, the ovary, concentrations of the ovarian hormones estradiol and progesterone, and the lining of the uterus. At the beginning of the cycle, the thickened lining of the uterus sloughs off and is expelled through the vagina.

for this event. FSH concentrations, in contrast, are relatively high during the follicular phase and low during the luteal phase, though they also make a small spike prior to ovulation. Progesterone is present at very low levels during the follicular phase but at high levels during the luteal phase. This observation suggested that progesterone might support the maturation of the thickened uterine lining. Estradiol concentrations change in a much more complex way, highlighted by a peak late in the follicular phase. In general, estradiol surges during the follicular phase while progesterone surges during the luteal phase. Similar patterns are observed in other mammals, ranging from marsupials to mice. How are these changes regulated?

Human Reproduction

How Do the Pituitary and Ovarian Hormones Interact?

Experiments helped establish that changes in the concentration of estradiol and progesterone affect the release of the pituitary hormones LH and FSH. Researchers worked with three volunteers whose ovaries had been removed because of cancerous growths or other problems. The women were receiving low, maintenance-level doses of estradiol, which appeared to exert negative feedback on LH and FSH. But when the investigators injected the women with larger doses of estradiol or with progesterone, the situation changed dramatically. For example, a large increase in estradiol stimulated a dramatic spike in LH levels. This suggested that positive feedback was occurring—that is, high levels of estradiol increased the release of its regulatory hormone, even though low doses of estradiol suppressed it. Injections of progesterone, in contrast, appeared to inhibit both FSH and LH. Progesterone exerts only negative feedback on the pituitary hormones.

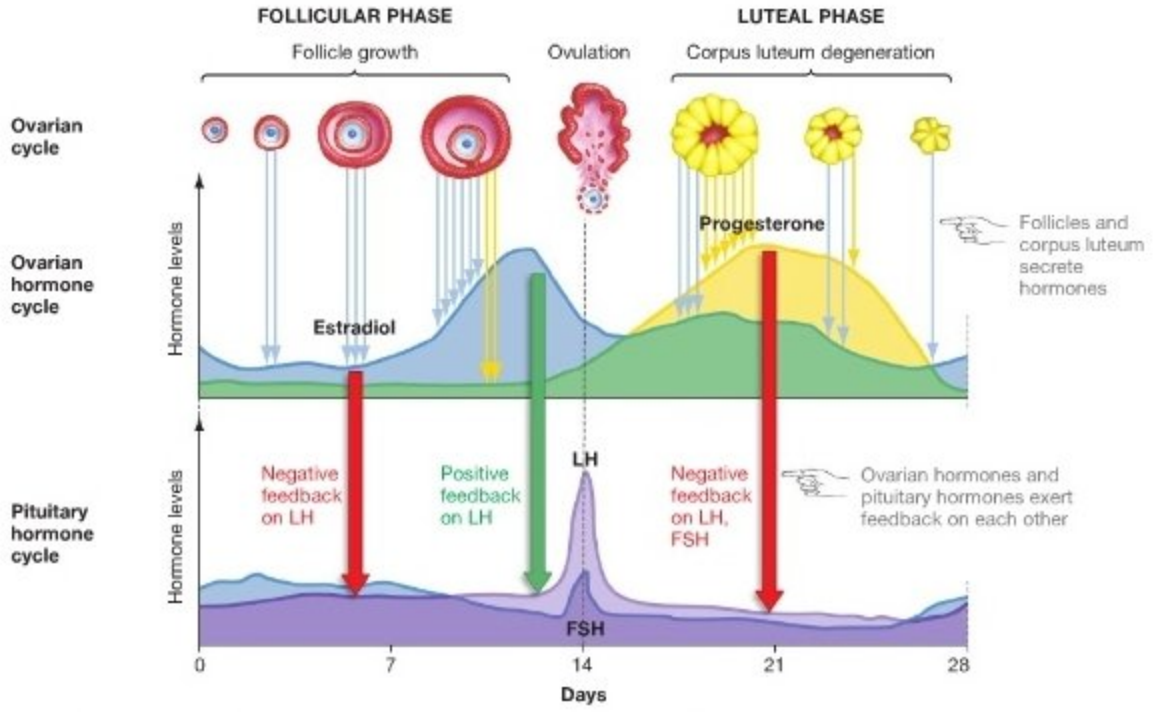

FIGURE 48.14 The Menstrual Cycle Is Regulated by Complex Interactions among Hormones. The pituitary hormones FSH and LH control the release of estradiol and progesterone from reproductive tissues. Estradiol and progesterone may exert negative feedback, positive feedback, or both—depending on their concentration—on the pituitary hormones.

Thanks to dozens of experiments like these, conducted in a wide variety of labs over the past several decades, researchers now have a fairly good grasp of how the various hormones interact. To summarize the interplay between LH, FSH, estradiol, and progesterone, let's start at day 0 and follow key events as the cycle progresses.

As a cycle begins, the uterus is shedding much of its lining during menstruation. In the ovary, a follicle is being stimulated to develop under the influence of FSH. As the follicle grows, its production of estradiol gradually begins to increase. The increase in estradiol stimulates mitosis and an increase in cell number in the uterine lining. The follicle also produces a small amount of progesterone. While estradiol levels are still relatively low, that hormone suppresses LH secretion through negative feedback inhibition. Once the follicle has grown enough to produce large quantities of estradiol, however, the hormone begins to exert positive feedback on LH secretion. As Figure 48.13 shows, this positive feedback results in a spike in LH levels just after estradiol concentrations peak. The LH surge triggers ovulation and ends the follicular phase. If you understand how estradiol's effect on LH changes from negative regulation to positive regulation, you should be able to predict the effect of (1) injecting a female volunteer with high estradiol concentrations early in a cycle, and (2) using a drug to keep estradiol production low throughout the cycle.

As the corpus luteum develops from the remains of the ruptured follicle, it secretes large amounts of progesterone and small quantities of estradiol in response to LH. This rise in progesterone lowers production of LH and FSH and activates the thickened uterine lining, creating a spongy tissue with a well-developed blood supply. In this way, progesterone creates an environment that supports embryonic development if fertilization occurs.

If fertilization does not occur, however, the corpus luteum degenerates approximately 12 days after ovulation. Progesterone levels fall as a result, which causes the thickened lining of the uterus to degenerate. Once progesterone levels have declined, the hypothalamus and pituitary are released from the inhibitory control progesterone exerts. LH and FSH levels rise, and a new cycle begins. The interactions between FSH, LH, estradiol, and progesterone are summarized in **Figure 48.14**, and the interplay between ovarian and pituitary hormones is similar in other mammal species that have been studied to date.

Manipulating Hormone Levels to Prevent Pregnancy

Data on hormonal control of the menstrual cycle opened new avenues in birth control research. Specifically, researchers have found that manipulating levels of progesterone and estrogen can prevent ovulation and serve as a safe and effective method of preventing unwanted pregnancies.

TABLE 48.3 **Comparing Methods of Contraception**

See text for explanation of "Percent Effectiveness."

Type	Name	Mode of action	Percent Effectiveness
Hormone-based methods	The Pill, the Patch, the Ring, the Shot, the Implant	Provides continuous or cyclical delivery of progesterone, or progesterone plus estradiol	92 to 99.9*
Barrier methods	Condom	Covers penis and prevents sperm from entering vagina	85
	Female condom	Covers labia, vagina, and cervix and prevents sperm from entering uterus	79
	Diaphragm	Covers cervix and prevents sperm from entering uterus	84
	Sponge	Covers cervix and prevents sperm from entering uterus; also contains a molecule that immobilizes sperm	84
	Spermicide	Foam or jelly covers cervix and prevents sperm from entering uterus; contains a molecule that immobilizes sperm	71
Behavioral methods	Rhythm method	Couple refrains from vaginal intercourse around time of ovulation	80
	Withdrawal	Man withdraws penis prior to ejaculation	73
Prevent implantation	Intrauterine device (IUD)	Small T-shaped structure inserted into uterus; mode of action not known	99
	Emergency contraception	Delivers progesterone or progesterone and estradiol after unprotected vaginal intercourse	92
	RU-486	Blocks progesterone receptors so menstruation occurs even after fertilization and implantation	92

*Depends on delivery system used.

Hormone-based birth-control methods deliver synthetic versions of progesterone or progesterone and estradiol. These hormones suppress the release of GnRH and FSH through negative feedback inhibition. Because an LH spike does not occur during the follicular phase of the cycle, the follicle does not mature and ovulation does not occur.

If a woman uses the hormones in pill form, they are taken in a cyclic fashion. Hormone-containing pills are taken for three weeks and then stopped for one week to allow menstruation to occur. A newer method of inhibiting ovulation involves inserting a small implant of synthetic hormone under the skin; these implants are extremely effective and last for up to five years. In the United States, birth control pills are the most widely used contraceptive method.

As **Table 48.3** indicates, however, hormone-based methods are just one of several distinct approaches to preventing pregnancy. Other types of methods work by preventing sperm from contacting the oocyte, or by interfering with implantation of the embryo.

The "Percent Effectiveness" column on the far right of the table indicates the average percentage of women who do not become pregnant during one year of typical use of a method. In many cases percent effectiveness increases dramatically if couples are able to use a method "perfectly"—meaning, exactly as specified for optimal effectiveness, during every episode of sexual intercourse.

When sperm and egg do unite successfully, the menstrual cycle is interrupted. The corpus luteum does not degenerate, and progesterone and estradiol levels stay high. Menstruation does not occur. Instead, the mother is now pregnant.

Check Your Understanding

If you understand that...

An array of hormones interacts in complex ways to regulate the human menstrual cycle.

You should be able to...

1) Describe the function of FSH, LH, estradiol, and progesterone during one cycle.
2) Explain the consequences of positive feedback between estradiol and LH and negative feedback between progesterone and LH and FSH.
3) Predict the consequences of a drug that inhibits the release of any one of these four hormones during a cycle.

48.5 Pregnancy and Birth in Mammals

Recall from Section 48.2 that viviparity allows the mother to provide a warm, protected environment for offspring during early development. Oviparous species that guard or incubate

their eggs are also providing warm, safe surroundings for young offspring. The investments that parents make in each offspring comes at a cost, however: The more a mother invests in each offspring, the lower the number of offspring she can produce. This fitness trade-off between the quantity and quality of offspring was explored in detail in Chapter 41.

Pregnancy and **lactation**—providing milk that nourishes offspring after birth—represent some of the most extreme forms of parental care known in animals. And in some mammal species, parental care continues long after lactation ends. Humans, for example, are largely or completely dependent on their parents for protection and nutrition until puberty or young adulthood.

Let's examine how eutherian mammals make this investment, starting with fertilization and ending with birth, again using humans as a well-studied model organism.

Major Events during Pregnancy

Once it is released from the human ovary, a secondary oocyte is viable for less than 24 hours. Human sperm, in contrast, remain capable of fertilizing an egg for up to five days. Therefore, sexual intercourse in humans has to occur less than five days prior to ovulation, or immediately after ovulation, for pregnancy to result.

Although an ejaculate may contain hundreds of millions of sperm, most die as they travel through the uterus. Only 100 to 300 actually succeed in reaching the oviduct, where fertilization takes place.

Chapter 22 detailed how sperm and oocyte (egg) interact when they meet. Recall that contact between sperm and oocyte triggers the **acrosomal reaction**, in which enzymes released from the head of the sperm chew a path through the material surrounding the oocyte membrane. Once the membranes of the oocyte and sperm have fused, the oocyte nucleus completes meiosis II. The two nuclei then unite to form a diploid zygote.

Smooth-muscle contractions in the oviduct gradually move the zygote toward the uterus. As it travels, the cell begins to divide by mitosis. By the time it reaches the lining of the uterus, the embryo consists of a hollow ball of cells. It then undergoes **implantation,** becoming embedded in the thickened, vascularized wall of the uterus. It will stay in the uterus for the full period of development, or **gestation**, of approximately 270 days (9 months) in humans. **Box 48.3** contrasts the long gestation periods observed in humans and other eutherian mammals with the pattern observed in marsupials.

BOX 48.3 How Do Gestation and Early Development Occur in Marsupials?

You might recall from Chapter 34 that mammals comprise three major monophyletic groups: the monotremes, the eutherians, and the marsupials. Although all mammals are endothermic, have fur, and lactate, the three lineages are distinguished by their mode of reproduction. **Monotremes** lay eggs and incubate them until hatching. In the **eutherians**, mothers carry offspring for relatively long periods of development during gestation and nourish them via a placenta. But in **marsupials**, the corpus luteum is not maintained as it is in eutherians, and no placenta forms. Instead, young are ejected from the mother's body at the end of the estrous cycle, when they are far less developed than eutherian mammal offspring completing gestation.

Figure 48.15a shows a newly born kangaroo. The jaws, gut, lungs, and forelimbs are relatively well developed at birth. As a result, the offspring is able to climb from its mother's vagina to a nipple, which is usually enclosed in a pouch created by a flap of skin. The offspring clamps on and continues to develop, fed by the mother's milk (**Figure 48.15b**). Even after growing large enough to leave the pouch and begin moving and feeding on its own, offspring will return to the pouch for protection (**Figure 48.15c**).

(a) Red kangaroo at birth

(b) 4 weeks after birth

(c) 4 months after birth

FIGURE 48.15 Marsupials Trade a Long Gestation Period for a Long Lactation Period. Eutherian offspring spend a long time inside the mother being fed and protected and a relatively short time being fed milk after birth. Marsupial offspring spend a short time inside the mother and a relatively long time being fed milk after birth and being protected in a pouch.

Once the embryo has become implanted in the uterine lining, its cells begin synthesizing and secreting a hormone called **human chorionic gonadotropin** (**hCG**). The hormone hCG is a chemical messenger that prevents the corpus luteum from degenerating. When hCG is present, the ovary continues secreting progesterone and the menstrual cycle is arrested. Enough hCG is produced by the embryo and excreted in the mother's urine to be used as an indicator in pregnancy tests.

The First Trimester In humans, gestation is divided into 3-month stages called trimesters. Not long after implantation is complete, mass movements of cells result in the formation of the three major embryonic tissues called ectoderm, endoderm, and mesoderm (see Chapter 22). By 8 weeks of age, these tissues have differentiated into the various organs and systems of the body. Also by this time, the heart has begun pumping blood through a circulatory system. The embryo at this stage is called a **fetus** (**Figure 48.16a**).

Also in the first trimester, the embryonic ectoderm contributes to several important membranes. One of these membranes, called the **amnion**, completely surrounds the embryo. The amnion eventually fills with amniotic fluid, which provides the embryo with a protective cushion.

The other key event in the first trimester is the formation of the **placenta**. This organ starts to form on the uterine wall a few weeks after implantation. The placenta is composed of tissues from both mother and embryo. Because it contains a dense supply of blood vessels from the mother, it is the primary source of nutrition for the growing fetus. Arteries transport blood from the circulatory system of the fetus, through the **umbilical cord**, to an extensive capillary bed in the placenta. In this way, the placenta provides a large surface area for the exchange of gases, nutrients, and wastes between maternal and fetal blood, even though maternal and fetal blood do not commingle. The placenta also secretes a variety of hormones. For example, by the end of the first trimester, placental cells synthesize and secrete large amounts of progesterone and estrogens—more than replacing the hormones produced by the corpus luteum, which has degenerated by this time. These hormones suppress the release of GnRH, LH, and FSH through negative feedback, and thus prevent the maturation and ovulation of additional follicles. ● If you understand how hormones influence pregnancy, you should be able to explain (1) why women who produce low levels of progesterone from the corpus luteum are prone to miscarriage, and (2) why progesterone therapy to help these women can be safely discontinued after the first trimester.

The Second and Third Trimesters After the fetal organs and placenta form during the first trimester, the remainder of development focuses on growth (**Figures 48.16b** and **48.16c**). During the last weeks of pregnancy, the brain and lungs undergo particularly dramatic growth and development. If a baby is born prematurely, the primary challenge to caregivers is to maintain an adequate oxygen supply. In many cases, dramatic intervention is required to keep the baby alive until the lungs can complete their development (see Box 44.1).

The machinery and level of hospital care required by premature infants emphasize just how superbly adapted mothers are to nourishing a growing fetus in the uterus. Let's take a closer look at this critical aspect of pregnancy.

FIGURE 48.16 Development of the Human Fetus.

● **EXERCISE** On each photograph, label the hands, eye, and umbilical cord. Estimate the ratio of head length to total body length in each photograph.

How Does the Mother Nourish the Fetus?

In oviparous species, mothers provide their eggs with all of the nutrients and fluids they need to develop until hatching. But in some viviparous species, eggs are relatively small and contain almost no nutrient supply. In these species, the developing embryo depends on the mother's body for oxygen, chemical energy in the form of sugars, amino acids and other raw materials for growth, and waste removal. What physiological changes occur in human mothers to accommodate these demands?

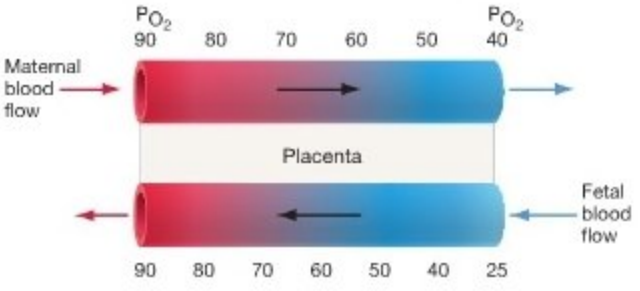
To answer this question, researchers have focused on the body's basic transport and delivery systems: the heart, lungs, and blood vessels. During pregnancy, a mother's respiratory and circulatory systems change in ways that increase the efficiency of nutrient transfer and gas exchange with the fetus. For example, a woman's total blood volume expands by as much as 50 percent during pregnancy. To accommodate this increase, maternal blood vessels dilate (widen) and blood pressure drops. In addition, dramatic increases occur in the pumping capacity, or stroke volume, of the heart as well as in the heart rate. The mother's heart enlarges and begins to beat faster. The result is that a mother's total cardiac output increases by almost 50 percent over the course of a pregnancy.

The mother's breathing rate and breathing volume also increase to accommodate the fetus's demand for oxygen and its production of carbon dioxide. Important adaptations heighten the efficiency of gas exchange between the mother and the embryo as well. As **Figure 48.17a** shows, maternal and fetal blood flows in the placenta occur in a countercurrent fashion in many species. As Chapter 41 explained, countercurrent flows maintain a concentration gradient that increases the efficiency of diffusion or other types of exchange. The data for partial pressures of oxygen given in Figure 48.17a are from experiments on sheep.

Countercurrent flow does not occur in the human placenta, so fetal blood does not become as highly oxygenated as sheep blood. Still, several traits make oxygen exchange between mother and fetus efficient. For example, maternal arteries in humans empty into a space at the junction of the maternal and fetal portions of the placenta. This space is packed with small projections called villi, which contain the fetal blood vessels. Thus, a large surface area from the fetus is bathed with highly oxygenated maternal blood. The fetal villi are analogous to the alveoli of the lungs (Chapter 44), which provide a large surface area for gas exchange.

Figure 48.17b illustrates another adaptation that increases the rate of oxygen delivery to the fetus. Notice that the axes on this graph give the partial pressure of oxygen in blood or tissue versus the percentage of hemoglobin that holds oxygen at that pressure. (Recall from Chapter 44 that this type of graph is called an **oxygen-hemoglobin equilibrium curve.**) The

(a) Countercurrent blood flow in the placenta



(b) Oxygen-hemoglobin saturation curves in the fetus and mother

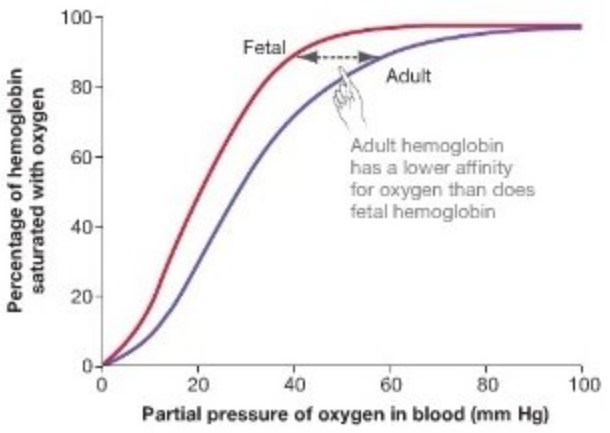


FIGURE 48.17 Adaptations That Increase Delivery of Oxygen to the Fetus.

EXERCISE In part (a), draw oxygen arrows passing from maternal blood to fetal blood.

key point here is that the data for fetal hemoglobin are shifted to the left of the data for adult hemoglobin. As a result, the fetus's blood always has a higher affinity for oxygen than does the mother's blood. Biologists interpret this pattern as an adaptation. The high oxygen affinity of fetal hemoglobin ensures that the fetus is always able to acquire oxygen from the mother.

Before leaving the topic of pregnancy, it is important to acknowledge that mothers and embryos exchange more than nutrients and wastes. For example, consider the thalidomide tragedy. During the 1950s, hundreds of children were affected by their mothers' consumption of the tranquilizer thalidomide, which diffused into the fetal bloodstream and caused birth defects—often a dramatic shortening of the arms. Although thalidomide is now banned for use by pregnant women, alcohol use continues to take a similar toll. Children of mothers who drink alcohol are at high risk of experiencing hyperactivity, severe learning disabilities, and

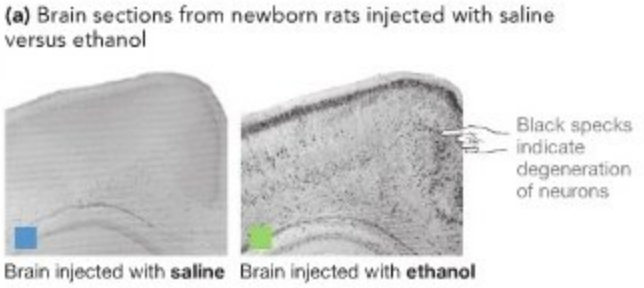

FIGURE 48.18 Ethanol Kills Brain Cells in Newborn Rats.

QUESTION This study was designed to test the effects of a single drinking event. How would you modify the study to test the effects of long-term exposure to alcohol during pregnancy?

depression. Collectively, these symptoms are termed **fetal alcohol syndrome** (**FAS**).

To understand why FAS exists, recall that the brain undergoes especially rapid growth in the third trimester of development, and then consider the data shown in **Figure 48.18**. Figure 48.18a shows two slices from the brains of newborn rats. A day before these photographs were taken, one group of pregnant rats was given two injections of a harmless salt solution at a dosage of 2.5 g per kg body weight; the other group was given the same injections, except that the salt solution contained 20 percent ethanol. For a female human of average weight, this would be equivalent to drinking 2.5 cans of beer or glasses of wine. The black specks in the brains of ethanol-treated rats indicate degenerating neurons. The histograms in Figure 48.18b illustrate one consequence: The ethanol-treated rats had smaller brains than the saline-treated individuals did. The messages of these data are that ethanol destroys growing neurons and that even a single, "moderate" dose of alcohol can have a devastating effect. Based on these results, public health officials strongly advise pregnant women against drinking *any* amount of alcohol.

Birth

Although the mechanisms responsible for triggering the birthing process are not completely understood, the pituitary hormone **oxytocin** is clearly important in stimulating smooth-muscle cells in the uterine wall to begin contractions. The contractions that expel the fetus from the uterus and out of the mother's body constitute **labor.**

During the first stage of birth, the uterus contracts at relatively low frequency. As labor progresses, the cervix at the base of the uterus begins to open, or dilate (**Figure 48.19**). Once the cervix is fully dilated, uterine contractions become more

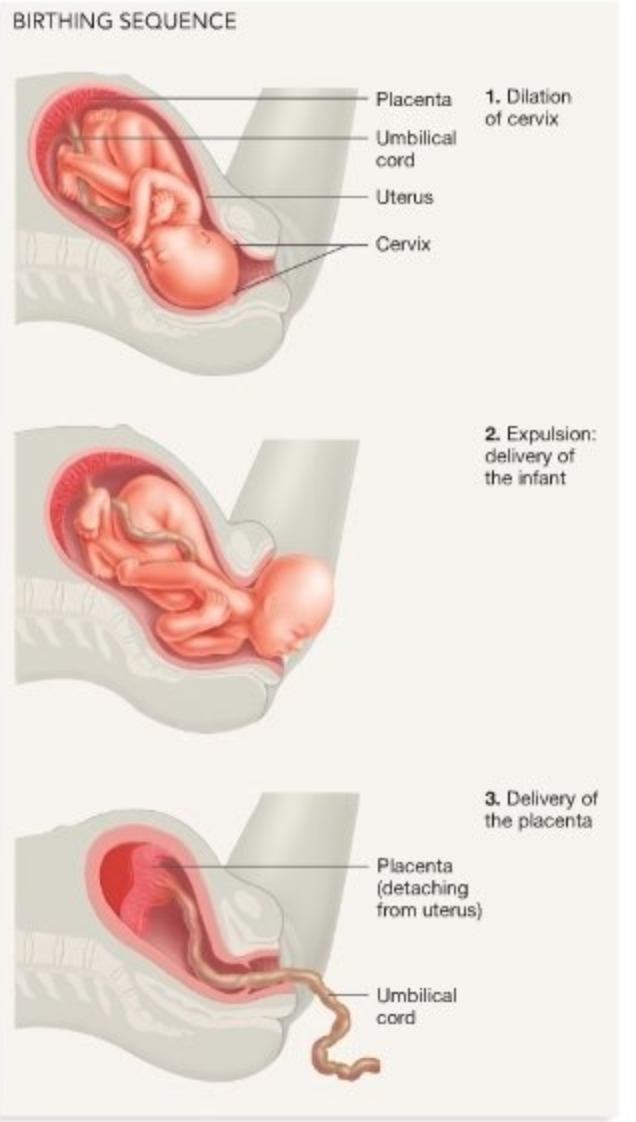

FIGURE 48.19 The Birthing Sequence in Humans.

QUESTION Human babies are normally born face down, as shown. Predict the consequences of a baby positioned face up, or feet first, in the birth canal.

forceful, longer, and more frequent. Eventually, the fetus is expelled through the cervix and into the vagina.

After the baby is delivered, the placenta remains attached to the uterine wall. At this point, caregivers clamp and then cut the umbilical cord that connects the child and the placenta. By gently tugging on the cord, the caregiver helps the mother deliver the placenta and accompanying membranes, and birth is complete.

Although this description sounds straightforward, in reality a large number of complications are possible. Consider the data in **Figure 48.20**. The graph shows the number of Swedish mothers who died, per 100,000 live births, in five-year intervals between 1760 and 1980. In 1760, approximately 1.4 mothers died for every 100 infants successfully delivered. In most cases, the cause of death was blood loss or infection following delivery. Note that the vertical axis is logarithmic, and that the steepest drop in mortality rate occurred with the introduction of hand-washing in the late 1870s. As a result of sterile techniques, antibiotics, and blood transfusion technology, Sweden's mortality rate has now declined to less than 0.007 percent. The advent of cesarean sections, better care for premature infants, and improved treatments for Rh disease have also resulted in steep declines in infant mortality rates in many countries. Although it is generally unheralded, this huge reduction in the rate of death associated with childbirth qualifies as one of the great triumphs of modern medicine. Unfortunately, because many developing nations lack sterile facilities and appropriate antibiotics, the mortality of mothers and infants remains high in those countries.

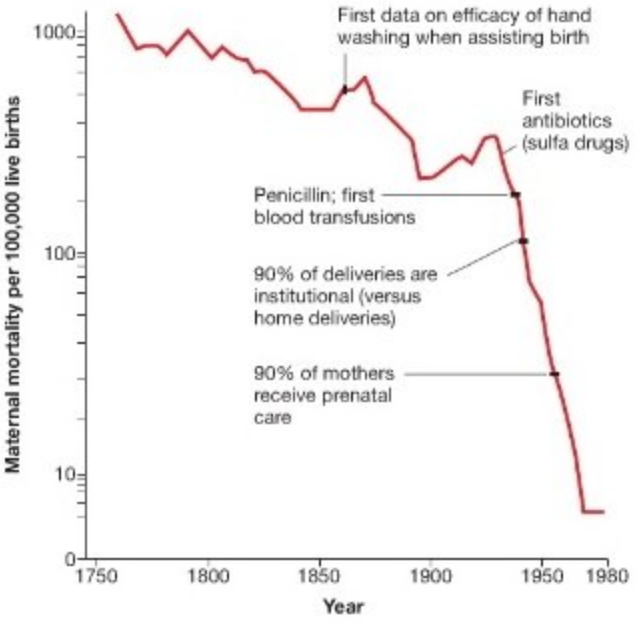

FIGURE 48.20 Maternal Mortality in Childbirth Has Decreased Dramatically. These data are from Sweden; the scale on the vertical axis is logarithmic. Note: In 1861 a researcher published convincing data that hand washing dramatically reduced maternal mortality during childbirth, but doctors resisted the idea until well after Pasteur had published the germ theory of disease in 1878.

QUESTION If a woman living in Sweden in 1760 had 10 children over the course of her lifetime, what was her overall chance of dying in childbirth?

Chapter Review

SUMMARY OF KEY CONCEPTS

The reproductive systems of animals are highly variable. Many animals can switch between asexual and sexual reproduction. When sexual reproduction occurs, fertilization may be external or internal and egg development may take place inside or outside the mother's body, depending on the species.

Only a few animal species reproduce exclusively by asexual means, but many alternate between asexual and sexual reproduction. Asexual reproduction results in offspring that are genetically identical to the parent. In contrast, every sexually produced offspring is genetically unique because of recombination during meiosis and the fusion of haploid gametes from different parents during fertilization.

In humans, the production of sperm and eggs differs in several respects. Spermatogenesis is continuous throughout the adult life of males, but in females all of the cells that divide mitotically to begin oogenesis are formed early in development. Meiosis in females is also arrested for long periods of time. Finally, cell division during meiosis is so unequal in females that just one egg (instead of four) is produced from each primary oocyte.

Fertilization is external in many aquatic animals but internal in almost all terrestrial species. Release of gametes during external fertilization may be synchronized by courtship displays or possibly by pheromones. Research on internal fertilization has documented that multiple mating and sperm competition are widespread. Two important generalizations have emerged from studies of sperm competition. First, the last male to mate usually fathers a disproportionately large number of offspring. Second, males of species that engage in sperm competition have relatively large testes for their overall size.

Once eggs are fertilized, females may lay the eggs or retain them and give birth to live offspring. By estimating the evolutionary relationships among closely related species with viviparity and oviparity, researchers have determined that viviparity has evolved many times independently. In some groups at least, viviparity may be an adaptation that increases the survival of young in cold habitats.

You should be able to explain why fish that care for their young are expected to produce fewer eggs per year than fish that do

not care for their young, whether sperm competition can occur in fish, and when internal fertilization would be expected to occur in fish.

Web Animation at www.masteringbio.com
Human Gametogenesis

In humans, the male reproductive system is composed of structures specialized for the production and storage of sperm, the synthesis of important molecules found in semen, or the transport and delivery of semen. The female reproductive system is composed of structures specialized for producing eggs, receiving sperm, and nourishing offspring during early development.

In humans, the external anatomy of the male reproductive tract consists of the penis and scrotum. Biologists are unsure why the scrotum evolved in mammals but have documented that sexual selection has produced striking variation in the genital morphology of male insects and spiders. The internal anatomy of the human male reproductive tract includes structures devoted to sperm production and storage, synthesis of accessory fluids, and transport and delivery of semen. The external anatomy of the human female reproductive tract consists of the vaginal opening and clitoris. The internal anatomy of the human female reproductive tract is devoted to egg production and transport or to the development of offspring.

You should be able to predict how surgeons alter the male and female reproductive tracts of human volunteers to sterilize them.

In humans, the menstrual cycle is regulated by hormones from the pituitary gland and female reproductive organs. These hormones may interact with each other via positive or negative feedback. Pregnancy is maintained by hormonal signals from the embryo and from the mother's reproductive organs.

The development and activity of male and female reproductive structures are under hormonal control. In mammals, experiments confirmed that GnRH from the hypothalamus triggers the release of FSH and LH from the pituitary gland. The pituitary hormones, in turn, regulate the production of the gonadal hormones, testosterone and estradiol, in the testes and ovaries, respectively. Research on the human menstrual cycle has confirmed that estradiol and progesterone exert negative and positive feedback on the production of FSH and LH. Interactions between the pituitary and ovarian hormones are responsible for regulating cyclical changes in the ovaries and uterus.

If fertilization occurs, the developing embryo secretes the hormone hCG, which arrests the menstrual cycle and allows pregnancy to continue. During the first trimester, the embryo becomes implanted in the thickened uterine wall, organs develop, and the nutritive organ called the placenta forms. To make rapid growth possible during the second and third trimesters, the mother's heart rate and pumping volume increase. Nutrients and gases are exchanged efficiently in the placenta.

You should be able to explain why administration of progesterone is an effective method of birth control in humans.

Human Reproduction

QUESTIONS

Test Your Knowledge

1. What term describes the mode of asexual reproduction in which offspring develop from unfertilized eggs?
   a. parthenogenesis
   b. budding
   c. regeneration
   d. fission
2. In sperm competition, what is "second-male advantage"?
   a. the observation that when females mate with two males, each male fertilizes the same number of eggs
   b. the observation that when females mate with two males, the second male fertilizes most of the eggs
   c. the observation that females routinely mate with at least two males before laying eggs or becoming pregnant
   d. the observation that accessory fluids prevent matings by second males—for example, by forming copulatory plugs
3. How are the human penis and clitoris similar?
   a. They develop from the same population of embryonic cells.
   b. Both develop during the earliest stages of puberty.
   c. Both contain the urethra.
   d. Both produce accessory fluids required during sexual intercourse.
4. In hormone production, how do the follicle and corpus luteum compare?
   a. Both produce primarily estradiol.
   b. Both produce primarily progesterone.
   c. The follicle produces more estradiol than progesterone; the corpus luteum produces more progesterone than estradiol.
   d. The follicle produces mostly progesterone; the corpus luteum produces estradiol and progesterone.
5. What pituitary hormones are involved in regulating the human menstrual cycle?
   a. GnRH and LH
   b. estradiol and progesterone
   c. oxytocin and LH
   d. FSH and LH
6. The corpus luteum is retained upon fertilization due to the presence of which hormone?
   a. LH
   b. estradiol
   c. progesterone
   d. human chorionic gonadotropin (hCG)

Test Your Knowledge answers: 1. a; 2. b; 3. a; 4. c; 5. d; 6. d

Test Your Understanding

Answers are available at www.masteringbio.com

1. Summarize the experimental evidence that *Daphnia* require three cues to trigger sexual reproduction. Discuss what these cues indicate about the environment. Generate a hypothesis for why sexual reproduction is adaptive for these animals.
2. Compare and contrast spermatogenesis with oogenesis. How do these two processes differ with respect to numbers of daughter cells produced, gamete size, and timing of the second meiotic division?
3. The drug RU-486 blocks progesterone receptors in the uterus. Why does this drug end pregnancy in humans, even if implantation has occurred?
4. Explain the difference between negative feedback and positive feedback in hormonal control of the human menstrual cycle. How is it possible that estrogen inhibits LH release at one point of the reproductive cycle but stimulates its release at another point?
5. Why are pregnant mothers advised to refrain from smoking, and from drinking alcoholic or caffeinated beverages?
6. Suppose that females of a certain insect species routinely mate with two males and choose their mates based on courtship displays or other traits. Predict whether females should be choosier about the first male or the second male that they mate with, or equally choosy about both males. Explain the logic behind your prediction.

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Researchers have recently developed methods for cloning mammals. In effect, biologists can now induce asexual reproduction in species that do not normally reproduce asexually. Suppose this practice becomes so widespread in the future that most of the sheep in the world become genetically identical. Discuss some possible consequences of this development.
2. The text claims that species with external fertilization produce extraordinarily large numbers of gametes. How would you test this hypothesis rigorously? In answering, assume that you have data on the average number of gametes produced by different species, along with data on their average body size.
3. Suppose that you've been given a chance to study populations of *Sceloporus* lizards—some of which are viviparous, and others of which are oviparous. Which populations would you expect to produce especially large eggs, relative to their overall body size? How would you go about testing this prediction?
4. When marsupial eggs are developing, a shell membrane appears for a short time and then disintegrates. State a hypothesis to explain this observation.

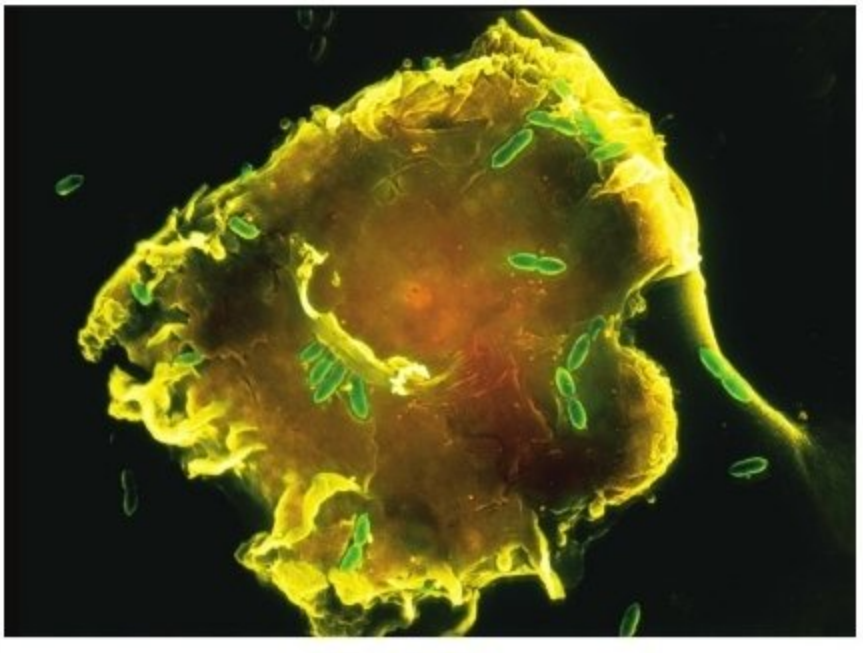
49 The Immune System in Animals

KEY CONCEPTS

- The innate immune response to infection is mounted by leukocytes that respond in a nonspecific way to pathogens. The acquired immune response is mounted by leukocytes called lymphocytes. Each individual lymphocyte responds to a specific pathogen.
- The acquired immune response begins when cell-surface proteins on lymphocytes bind to an antigen—usually a protein from a disease-causing agent.
- The humoral response tags pathogens for destruction with antibodies that are produced by lymphocytes called B cells.
- The cell-mediated response destroys infected cells via lymphocytes called cytotoxic T cells.



Scanning electron micrograph of an immune system cell engulfing and destroying bacteria (the small green cells). This chapter explores how immune system cells are able to recognize bacteria and viruses as foreign and eliminate them.

Disease threatens every animal. Humans alone are victimized by hundreds of different disease-causing bacteria and viruses and a wide array of parasitic worms, fungi, and protists. Given the ability of these pathogens to cause illness and death, it is remarkable that so many animals stay healthy for most of their lives.

To understand how humans and other animals are protected against disease, biologists have focused on investigating three observations. First, wounds usually heal, even if they become infected. Second, most people who contract a bacterial or viral illness eventually recover, even without help from medications. Third, people who acquire bacterial or viral infections and recover are frequently immune (literally, "safe") to that disease—that is, they do not contract the same disease in the future. **Immunity** is a resistance to or protection from disease-causing pathogens.

This last observation is particularly intriguing. Why do people who get measles or chickenpox fail to get these diseases again later, after a second exposure to the same disease-causing pathogen? Thucydides commented on this pattern in 430 B.C. He wrote that when plague struck Athens, only people who had recovered from the illness could nurse the sick, because they would not become ill a second time. In the middle ages, Chinese and Turkish practitioners protected people from smallpox by intentionally exposing individuals to the dried crusts of smallpox pustules taken from infected people. These are examples of **immunization**—the conferring of immunity to a particular disease.

In the late 1700s Edward Jenner had a key insight that allowed him to refine this immunization technique. In Jenner's day, milkmaids were considered pretty because their faces were not pockmarked with scars from smallpox infections. Jenner knew that cows suffered from a smallpox-like disease called cowpox, and he reasoned that milkmaids were immune to smallpox because they had been exposed to cowpox while milking cows. To test this hypothesis, he injected a boy with fluid taken from a cowpox pustule, then later injected the same child with fluid from a smallpox pustule. That is, he inoculated the boy with cowpox pathogens and then with smallpox pathogens. As predicted, the boy did not contract smallpox. Jenner's technique was quickly adopted throughout Europe and was later named **vaccination**. (The Latin root *vacca* means "cow.")

Why did Jenner's technique work? More precisely, what is the molecular basis of a person's ability to fight off a bacterial or viral infection and achieve immunity? To answer these questions, we need to explore how the human immune system recognizes and eliminates pathogens. We'll consider the body's response to two events: a bacterial infection and an assault by a virus. Both infections could afflict anyone on any given day. For example, suppose that several days ago you were on a crowded bus next to someone with a persistent cough and runny nose, and 30 minutes later you stumbled while sprinting across campus and skinned your elbow. Now you realize that the wound on your arm has gotten sore and red. Worse yet, you are developing a sore throat, runny nose, and fever. Your elbow has become infected with bacteria, and your upper respiratory tract is supporting a growing population of influenza, or "flu," virus. Let's start by analyzing what is happening in the wound at your elbow.

49.1 Innate Immunity

When biologists first began analyzing the immune system, they realized that certain immune system cells are ready to respond to foreign invaders at all times, while other components must be activated first. Cells that are always ready confer **innate immunity**; cells that are selectively activated to eliminate a specific pathogen confer **acquired immunity**. The key to understanding the two types of immunity is to recognize that the cells involved provide different responses to antigens. An **antigen** is any foreign molecule that can initiate an immune system response. Most antigens are proteins or glycoproteins from bacteria or viruses or other invaders, but foreign carbohydrates and lipids can also function as antigens.

The cells involved in innate immunity are nonspecific in their response to antigens. Stated another way, the innate immune system responds in the same way to all antigens. The innate immune response to a wound in your elbow, for example, is the same no matter what species of bacteria or viruses or fungi enter the tissue. In contrast, cells involved in acquired immunity respond in an extremely specific way to each particular strain of bacterium, virus, or fungus that enters the body. In combination, the innate and acquired immune responses form an extremely powerful system for protecting individuals against a formidable and ever-changing array of parasitic bacteria, viruses, and eukaryotes.

To launch this investigation into immune system function, let's focus on how the body prevents entry by foreign invaders. Then we can consider what happens once some do get in.

Barriers to Entry

The most effective way to avoid getting sick is to avoid contact with pathogens. In humans and other animals, the most important barrier to pathogen entry is the skin. In addition to providing a physical barrier that is thick and tough, human skin offers a chemical deterrent. Skin cells are covered by fatty acids, which lower the pH of the surface to between 3 and 5. The dry, acidic environment prevents the growth of most bacterial species that might be a threat to the body. Many bacteria do live on the skin, but most of them are adapted to the acidic conditions and are **commensal**—meaning they do not harm the host organism. The bodies of insects and other animals with exoskeletons are difficult for pathogens to enter because they are covered with the tough layer called cuticle, introduced in Chapter 42.

An animal's body has gaps in these barriers, however, where the digestive tract, reproductive tract, gas-exchange surfaces, and sensory organs make contact with the environment. As **Figure 49.1** shows, these gaps have a protective physical barrier in the form of mucus or other features that discourage pathogen

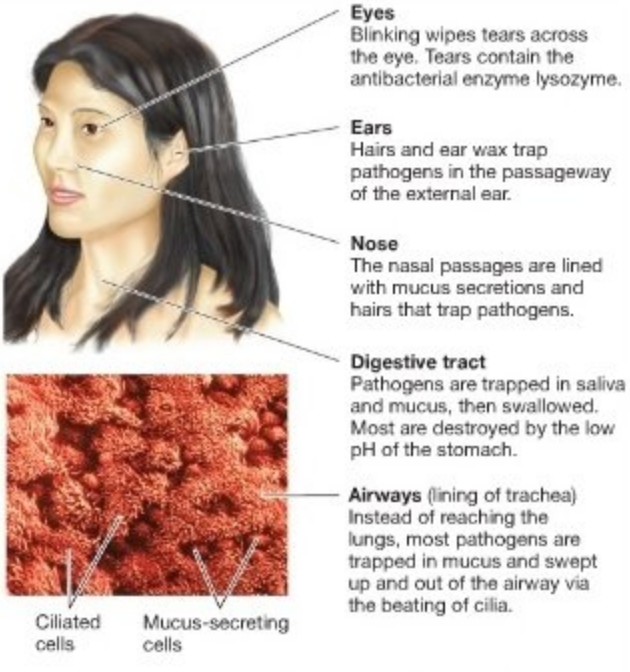


FIGURE 49.1 How Does the Body Keep Pathogens Out?

QUESTION Why is a combination of hair and sticky secretions effective at trapping pathogens?

entry. **Mucus** is a solution secreted by cells within the epithelium. It is rich in proteoglycans—large polysaccharides bonded to proteins. The bodies of slugs, snails, earthworms, and other soft-bodied animals are covered with a layer of mucus that shields their epithelial cells from pathogens in the environment. Mucus is equally important in vertebrates. For example, many of the pathogens that you breathe in or ingest while eating or drinking stick to the mucus that lines your airways and gastrointestinal tract. Pathogens that are stuck in mucus cannot come in contact with the plasma membranes of epithelial tissues. In mammals, these pathogens are coughed out or swallowed and killed in the acidic environment of the stomach. Gaps in the body that are not covered with mucus layers, such as the eyes, are often protected by other types of secretions. Your ears are protected by waxy secretions, and your eyes by tears that contain the enzyme **lysozyme**. Lysozyme acts as an antibiotic by digesting bacterial cell walls.

With regularity, though, preventive measures fail and some pathogens gain entry to tissues beneath the skin. Flu viruses, for example, have an enzyme on their surface that disrupts the mucous lining of the respiratory tract. When the outer surface of the virus makes contact with a host cell beneath the mucous layer, the virus is able to enter the cell and begin an infection. When a fall or other physical trauma breaks your skin, bacteria and other pathogens enter and gain direct access to the tissues inside. To viruses, bacteria, and fungi, your body is a tropical paradise, brimming with resources. Within minutes, they can begin growing. What happens then?

The Innate Immune Response

When bacteria enter your body at the site of a wound, the cells pictured in **Figure 49.2** implement the **innate immune response**—the body's nonspecific response to pathogens. As a group, these cells are called **leukocytes** ("white-cells"); all of them reside in the blood. Leukocytes are sometimes referred to as white blood cells. They include macrophages, neutrophils, and other cells involved in the innate response as well as the lymphocytes responsible for acquired immunity. Like the red blood cells that carry oxygen in the bloodstream, leukocytes are produced in the bone marrow.

The leukocytes involved in the innate response are alerted to the presence of foreign invaders by specific molecules that are found on the surfaces of bacterial or other types of invading cells, but not on host cells. Some of the cells in the innate system have proteins on their plasma membranes that bind to these bacteria-specific compounds. These proteins are known as **pattern-recognition receptors**. When they are activated by antigens, the cells respond.

Figure 49.3 summarizes the major steps in the **inflammatory** ("in-flames") **response**, which is a type of innate immune response observed in mammals. As step 1 shows, a break in the skin allows bacteria to enter the body. If capillaries and other small blood vessels are broken by the wound, blood leaves. Almost immediately (step 2), blood components called **platelets** release proteins that form clots and lessen bleeding. Other clotting proteins in the blood form cross-linked structures that help wall off the wound and reduce blood loss.

Step 3 shows leukocytes called **macrophages** at the wound site, in the process of secreting signaling molecules called **chemokines** ("chemical-movers"). Chemokines are also secreted by wounded tissues. Chemokines are important because they form a gradient that marks a path to the wound site.

Soon after macrophages begin their response, leukocytes called **mast cells** release chemical messengers that cause blood vessels near the wound to constrict. As a result, blood flow and thus blood loss at the wound decreases. Step 4 indicates that mast cells also release **histamine** and other signaling molecules that induce blood vessels slightly farther from the wound to dilate and become more permeable. As these vessels get bigger and increasingly permeable, the delivery of leukocytes and other blood components to the general region increases. Thus,

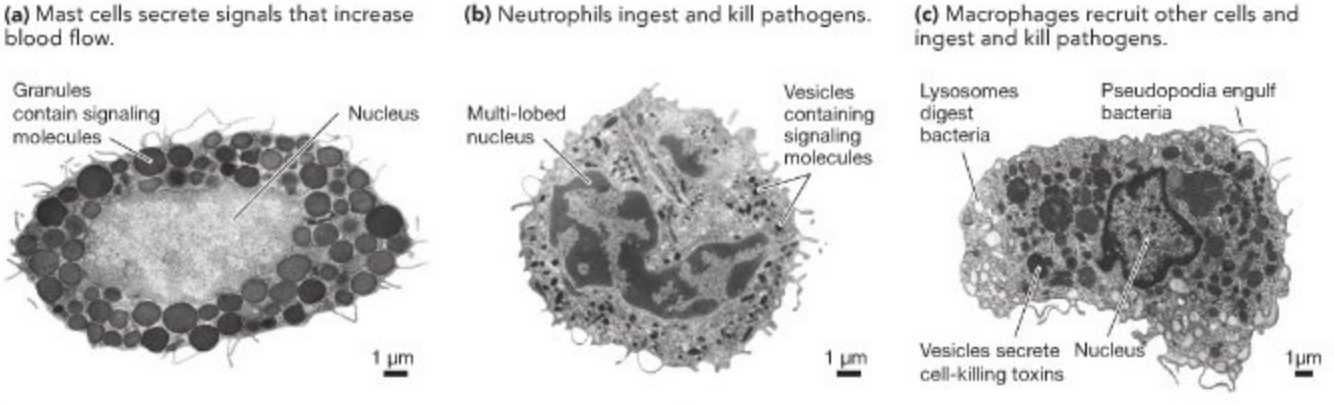

FIGURE 49.2 Several Cells Are Involved in the Innate Immune Response. Transmission electron micrographs illustrating a few of the leukocytes responsible for innate immunity.

QUESTION How does the structure of these cells correlate with their function?

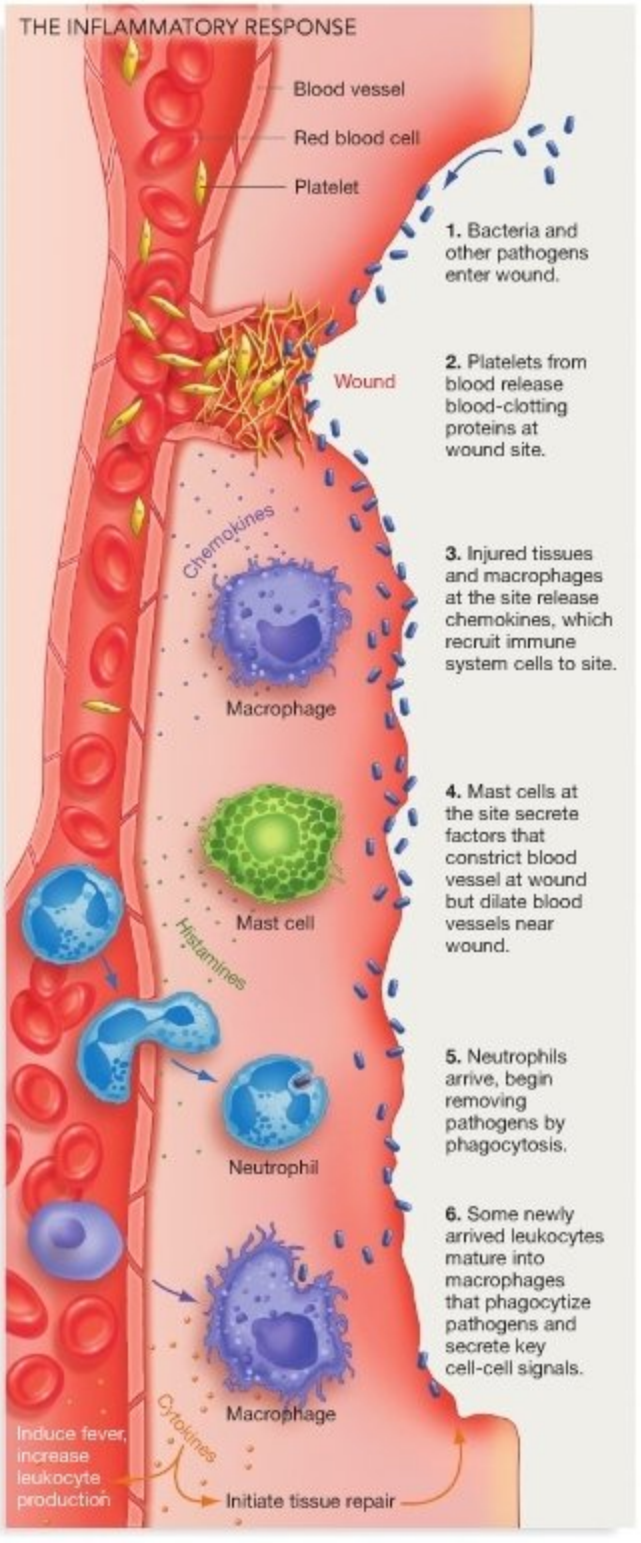

FIGURE 49.3 The Inflammatory Response of Innate Immunity Has Many Elements.

QUESTION Only one blood vessel is shown, for simplicity. If you had space to draw in other vessels in the wound area, where would they be constricted and where would they be dilated?

signals from mast cells stop blood loss at the wound site itself but increase blood flow to surrounding tissues.

The combination of dilated blood vessels and a chemokine gradient is like a 911 call that provides specific directions to the scene of a fire. Step 5 shows a key part of the response: leukocytes called **neutrophils** moving out of dilated blood vessels and migrating to the site of the infection. Neutrophils are major players in the innate response. They destroy invading cells by **phagocytosis** ("eating-cell")—meaning that they engulf them. Once invading cells are inside neutrophils, they are killed with a complex array of toxic compounds. These molecules include lysozyme—which degrades bacterial cell walls—free radicals, nitric oxide (NO), and molecules called **reactive oxygen intermediates** (**ROIs**), including hydrogen peroxide (H_2O_2).

After neutrophils begin arriving in large numbers, cells that will mature into macrophages arrive. In addition to phagocytizing bacteria at the wound, the growing population of macrophages secretes chemical messengers called **cytokines** ("cell-movers"), which have an array of effects (step 6). Cytokines from macrophages attract other immune system cells to the site, stimulate bone marrow to make and release additional neutrophils and macrophages, induce fever—an elevated body temperature that aids in healing—and activate cells involved in tissue repair and wound healing.

The site of inflammation often becomes swollen due to increased numbers of cells and fluids in the area—red and warm due to increased blood flow, and painful due to signals from pain receptors. The inflammatory response continues until all foreign material is eliminated and the wound is repaired. **Table 49.1a** summarizes some of the key cells in the response, while **Table 49.1b** summarizes some of the key molecules involved.

Humans and other vertebrates are not the only animals that have sophisticated innate immune responses. Innate responses make up the entire immune system observed in millions of species of invertebrates. The spectacular abundance and diversity of invertebrate animals supports the hypothesis that their innate immune systems provide efficient protection against invading bacteria, viruses, and fungi. For example, if a pathogen succeeds in entering the main body cavity of an insect through a wound or other break in the barriers to entry, cells respond by synthesizing and secreting peptides with potent antibacterial or antifungal properties. Sea stars have specialized cells that are similar in function to neutrophils and macrophages—they secrete cytokines or engulf and destroy pathogens by phagocytosis. But biologists still have a great deal to learn about defense systems in invertebrates.

What happens when the innate immune system of a vertebrate fails to contain and eliminate an infection that starts at a wound? And what happens to the viruses that blast through the mucous membrane of the human respiratory tract and enter the cells underneath?

MB **Web Animation** at www.masteringbio.com
The Inflammatory Response

SUMMARY TABLE **49.1 The Innate Immune System**

(a) Key Cells

Name	Primary function
Mast cells	Release signals that increase blood flow to wound site
Neutrophils	Kill invading cells via phagocytosis
Macrophages	Release cytokines that recruit other cells to wound site; kill invading cells via phagocytosis

(b) Key Signaling Molecules

Name	Produced by:	Received by:	Message/Function:
Histamine	Mast cells	Blood vessels	Causes blood vessels to constrict next to wound; dilate in nearby areas
Chemokines*	Injured tissues and macrophages in tissues	Neutrophils and macrophages	Mark path to wound; promote dilation and increased permeability of blood vessels
Cytokines other than chemokines	Macrophages	Leukocytes	Mark path to wound
		Bone marrow	Increase production of macrophages and neutrophils
		CNS	Induce fever by increasing set point for control of body temperature
		Local tissues	Stimulate cells involved in wound repair

* Note that chemokines are a subset of cytokines.

Check Your Understanding

If you understand that...

- The innate immune response occurs when macrophages and mast cells that reside in tissues, and neutrophils that circulate in the blood, react in a nonspecific way to signals from invading pathogens.

You should be able to...

Describe how events in the innate response relate to the following steps, which are implemented by first-aid workers when treating a wound:

1) Apply direct pressure to close blood vessels.
2) Apply bandages containing compounds that recruit platelets to the site.
3) Clean the wound once bleeding has stopped.
4) Apply antibiotics.

49.2 The Acquired Immune Response: Recognition

Recall from Chapter 35 that viruses actually enter cells to infect them. Once a virus succeeds in entering a cell, the virus is hidden from the host's innate immune response. In vertebrates, the acquired immune system is responsible for limiting the spread of infections at wound sites and responding to invading viruses and other pathogens. The **acquired immune response** is based on interactions between specific immune system cells and a specific antigen. This observation raises an important question: Given the array of different pathogens that exist, an individual animal is almost certain to be exposed to an enormous variety of antigens in the course of its lifetime. How many different antigens can its acquired immune system respond to?

Research conducted in the early 1920s answered this question. Researchers synthesized organic compounds that do not exist in nature, injected the novel molecules into rabbits, and observed whether the acquired immune system in these animals was activated in response. To the amazement of the scientists involved, the rabbits were able to mount an immune response to antigens that did not exist in nature. More specifically, the animals produced a different antibody against each antigen. **Antibodies** are proteins that are produced and secreted by certain lymphocytes and that bind to a specific part of a specific antigen. The take-home message of these early injection experiments was that the immune system can produce an almost limitless array of antibodies.

In combination with insights from Jenner's work on vaccines—reviewed in the preceding section—early work on antibodies helped focus attention on four key characteristics of the acquired immune response:

- *Specificity* Antibodies and other components of the acquired immune system bind only to specific sites on specific antigens.
- *Diversity* The acquired response recognizes an almost limitless array of antigens.
- *Memory* The acquired response can be reactivated quickly if it recognizes antigens from a previous infection.

- *Self-nonself recognition* Molecules that are produced by an individual do not act as antigens, meaning that the acquired immune system can distinguish between self and nonself. Nonself molecules are antigens; self molecules are not.

To explore these characteristics in detail, let's begin by reviewing the cells and organs that are responsible for the acquired immune response.

An Introduction to Lymphocytes and the Immune System

The cells that carry out the major features of the acquired immune response are called **lymphocytes**. Lymphocytes originate in the immune system and are subsequently activated and transported inside it (**Figure 49.4**):

1. *Lymphocyte origin* All lymphocytes and blood cells are produced in **bone marrow**, tissue that fills the internal cavities in bones.

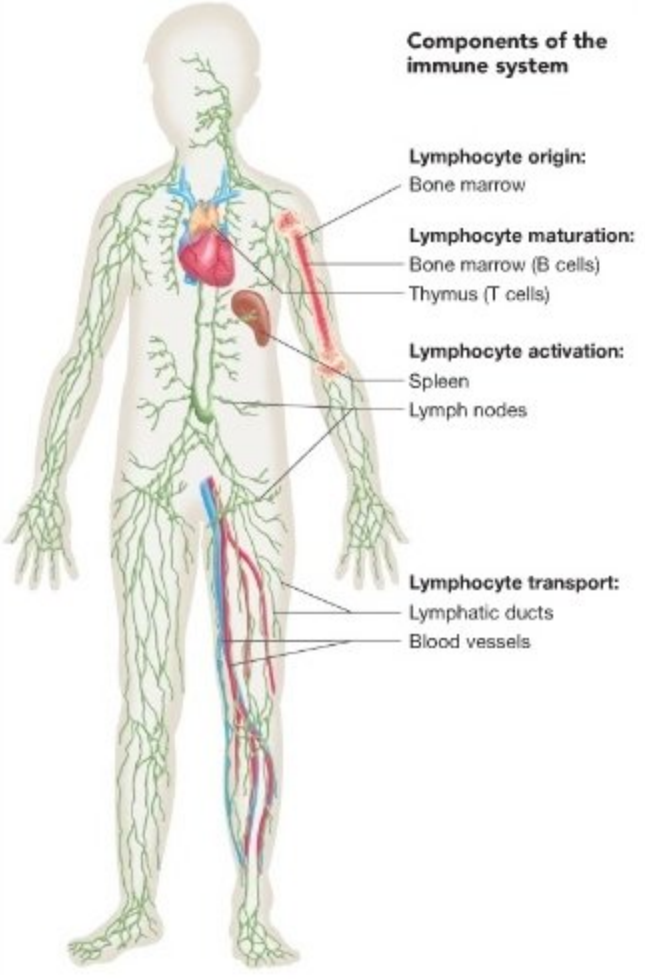

FIGURE 49.4 Lymphocytes Are Created, Activated, and Transported in the Immune System.

2. *Lymphocyte maturation* Certain lymphocytes (called B cells) mature in the bone marrow where they originate. Other lymphocytes (called T cells) mature in the **thymus**, an organ located in the upper part of the chest of vertebrates (just behind the breastbone in humans).
3. *Lymphocyte activation* Lymphocytes recognize antigens and become activated in the spleen and lymph nodes. The **spleen** is a lymphatic organ located in the abdominal cavity. In addition to its function in the immune response, the spleen destroys old blood cells and stores iron from red blood cells. **Lymph nodes** are small, oval organs that are located all around the body. Lymph nodes filter the lymph passing through them. Recall from Chapter 44 that **lymph** is a mixture of fluid and lymphocytes. The liquid portion of lymph originates in fluid that is forced out of capillaries by blood pressure.
4. *Lymphocyte transport* Lymphocytes circulate through the blood and the secondary organs of the immune system—lymph nodes, spleen, and lymphatic ducts. Lymphatic ducts are thin-walled, branching tubules that transport lymph throughout the body in the **lymphatic system**.

In addition to being found inside the structures shown in Figure 49.4, large numbers of leukocytes and lymphocytes are associated with skin cells and with epithelial tissues that secrete mucus—primarily in the digestive tract and respiratory tract. Collectively, the immune system cells found in gut and respiratory organs are called the **mucosal-associated lymphoid tissue** (**MALT**). Leukocytes in the skin and MALT are important because they guard points of entry for pathogens.

Lymphocytes are normally in a resting, or inactive, state as they circulate through the bloodstream and lymphatic system or reside in skin or MALT. As **Figure 49.5a** shows, inactive lymphocytes have a large nucleus, little cytoplasm, few mitochondria, and a ruffled membrane. Over the course of a day, an inactive lymphocyte might migrate through the spleen, enter the blood, cross over into the lymphatic vessels, migrate through a lymph node, return to the blood, and so on.

If an inactive lymphocyte does not encounter the antigen to which it is programmed to respond, then the cell eventually dies. But a lymphocyte that encounters an appropriate antigen becomes activated. **Figure 49.5b** shows an activated lymphocyte that has a massive amount of rough ER. It also has a large number of mitochondria. Recall from Chapter 7 that many of the proteins synthesized in a cell's rough ER are inserted into the plasma membrane or secreted from the cell. The increased rough ER in this activated lymphocyte suggests that it is manufacturing and possibly secreting proteins.

Activation clearly produces dramatic changes in lymphocytes. Now the question is, what *are* these cells? What types of cells execute the acquired immune response?

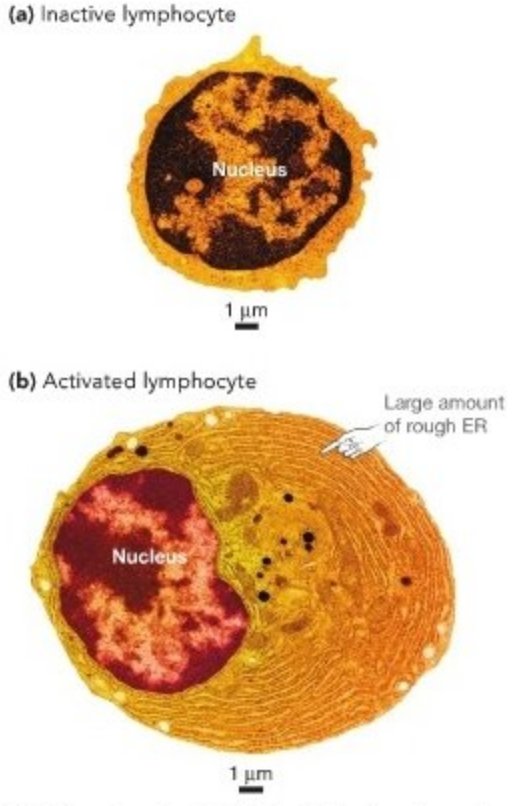

FIGURE 49.5 Lymphocytes Exist in Two States: Inactive and Activated. (a) This inactive lymphocyte has a small amount of cytoplasm and few organelles. **(b)** This activated lymphocyte has extensive rough endoplasmic reticulum. This observation suggests that a great deal of protein synthesis is taking place.

The Discovery of B Cells and T Cells

In 1956 a group of researchers provided an important insight into the acquired immune system, quite by accident. The biologists were investigating the immune system's response to the bacterium *Salmonella typhimurium*, which is a common cause of food poisoning in humans. To do this work, they needed to produce and isolate antibodies to a particular antigen from *S. typhimurium*—an antigen that is toxic. Their plan was to inject a large number of chickens with the antigen and collect the antibodies that the treated animals produced in response.

In addition to injecting many normal chickens, though, the biologists happened to include some chickens that had undergone experimental removal of an organ called the bursa. Six of the nine chickens that lacked a bursa and that were injected with the antigen died. The other three birds without a bursa survived but failed to produce antibodies to the antigen. In contrast, chickens with the bursa intact produced large quantities of antibodies and survived. To make sense of these results, the researchers proposed that the bursa is critical for antibody production and that antibodies are important in neutralizing antigens.

Not long after this observation was published, three groups of scientists independently conducted a related experiment. To explore the function of the thymus in mammals, these groups removed the organ from newborn mice. Mice lacking a thymus developed pronounced defects in their immune systems. For example, when pieces of skin from other mice were grafted onto the experimental individuals, their immune systems did not recognize the tissue as foreign. In contrast, individuals with an intact thymus quickly mounted an immune response to the foreign skin cells and killed them.

The results of these and follow-up experiments showed that lymphocytes from the bursa and thymus have different functions. The two types of lymphocytes became known as bursa-dependent and thymus-dependent lymphocytes, or B cells and T cells, respectively. **B cells** produce antibodies. (The lymphocytes in Figure 49.5 are B cells.) **T cells** are involved in an array of functions, including recognizing and killing host cells that are being infected with a virus. Later work showed that in humans and other species that lack a bursa, B cells mature in bone marrow.

Now let's turn to one of the most fundamental of all questions in immunology: How are B cells and T cells able to recognize so many different antigens?

Antigen Recognition and Clonal Selection

By the 1950s biologists had made a series of important general observations about the immune system. It was clear that antibodies to a seemingly limitless number of antigens could be produced and that each antibody is specific to an antigen. By studying the time course of antibody production in rabbits and other experimental animals, researchers established that the immune response intensified through time after an infection had begun. In addition, the response is "remembered"—meaning individuals do not get sick at all, or recover extremely quickly, if they are exposed to the same pathogen again in the future.

To explain these patterns, researchers developed the **clonal-selection theory** of immune system function. This theory made three central claims about how the acquired immune system works:

1. Each lymphocyte formed in the bone marrow or thymus has thousands of copies of a unique receptor on its surface. The receptor is a membrane protein and recognizes one antigen. Stated another way, there is a one-to-one correspondence between the receptors found on B cells and T cells and the antigens to which they respond.

2. When the receptor on a lymphocyte binds to an antigen, the lymphocyte is activated. An activated lymphocyte divides and makes many identical copies of itself. In this way, specific cells are selected and cloned in response to an infection.

3. Some of the cloned cells descended from an activated lymphocyte persist long after the pathogen is eliminated. As a result, the cloned cells are able to respond quickly and effectively if the infection recurs.

The clonal-selection theory provided a coherent explanation for most major attributes of the acquired immune system. Just as important, it made a number of specific predictions that could be tested. Which aspects of the theory have been supported, and which rejected?

The Discovery of B-Cell Receptors and T-Cell Receptors

To test the prediction that lymphocytes have unique receptors on their surfaces, researchers injected experimental animals with radioactively labeled antigens. The presence of these labeled antigens allowed researchers to isolate and purify a protein on the surface of B cells that bound to the antigens. Chemical analysis of this **B-cell receptor** (**BCR**) showed that the protein has the same structure as the antibodies in the blood produced by B cells. This was a crucial result and led to the realization that both the BCR and the antibodies produced by B cells belong to a family of proteins called the gamma globulins. Any one gamma globulin is referred to as an **immunoglobulin** (**Ig**). These proteins are the key to the acquired immune response.

As **Figure 49.6a** shows, the BCR has three distinct components. The first is a protein called the **light chain**. The second component is roughly twice the size of the light chain and is called the **heavy chain**. Each BCR has two copies of the light chain and two copies of the heavy chain. Within the heavy chain, transmembrane domains anchor the protein in the plasma membrane of the B cell. B-cell antibodies are identical in structure to the BCR, except that they lack the transmembrane domains. Instead of being inserted into the plasma membrane, antibodies are secreted from the cell.

Table 49.2 shows the five classes of immunoglobulin proteins that act as B-cell receptors or antibodies. The five types are symbolized IgG, IgD, IgE, IgA, and IgM. Each class is distinguished by unique amino acid sequences in the heavy-chain region, and each has a distinct function in the immune response.

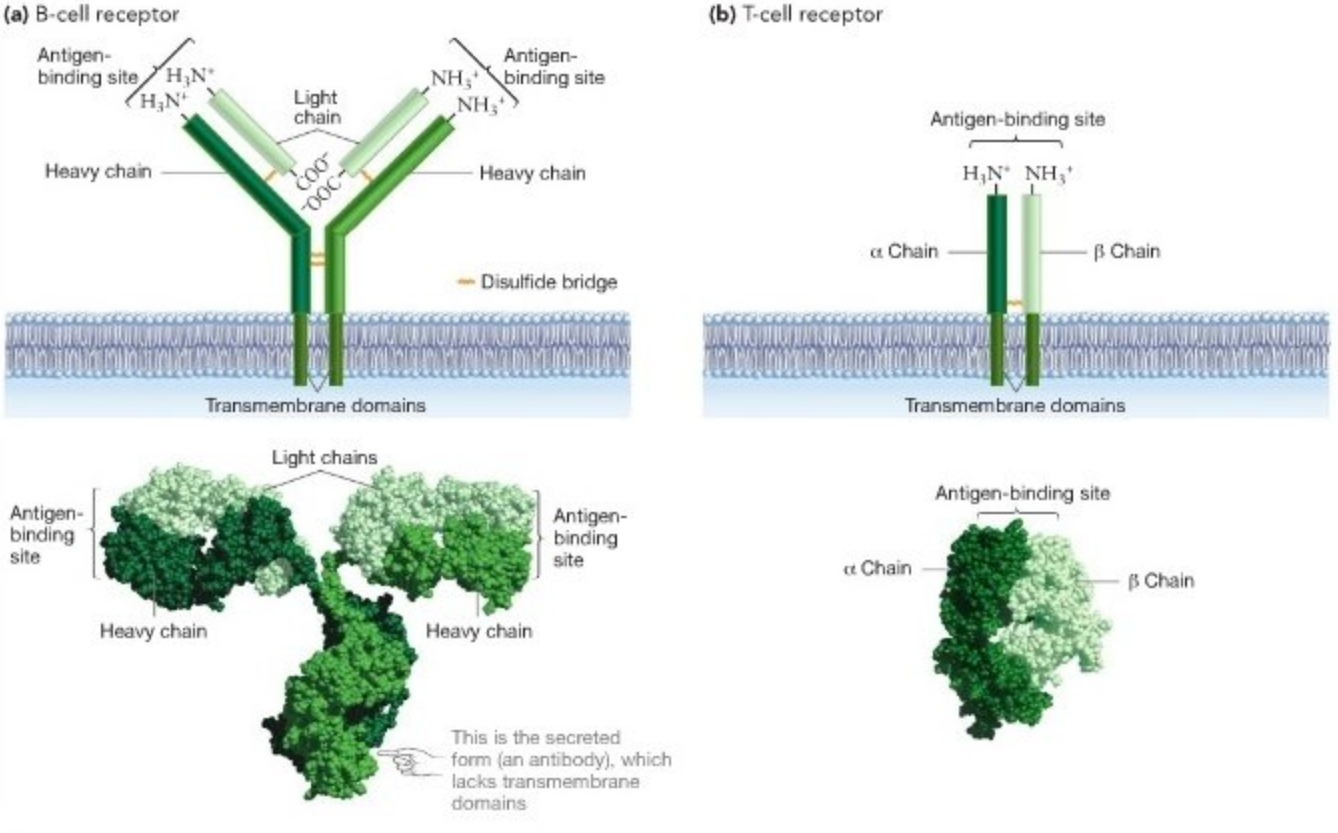

FIGURE 49.6 B-Cell Receptors and T-Cell Receptors Have Transmembrane Domains and Antigen-Binding Sites.
(a) Schematic model of the B-cell receptor, which is shaped like a Y. The antibodies and receptors produced by each B cell are identical, except that antibodies, shown below as a space-filling model, lack the transmembrane domain and are secreted. **(b)** The shape of the T-cell receptor resembles one "arm" of the Y-shaped B-cell receptor.

TABLE 49.2 **Five Classes of Immunoglobulins**

Name	Structure (secreted form)	Function
IgG	Monomer	The most abundant type of secreted antibody. Circulates in blood and interstitial fluid. Protects against bacteria, viruses, and toxins.
IgD	Monomer	Present on membranes of immature B cells; rarely secreted. Function is unknown.
IgE	Monomer	Secreted in minute amounts. Involved in hypersensitive reaction that produces allergies.
IgA	Dimer	Most common antibody in breast milk, tears, saliva, and the mucus lining the respiratory and digestive tracts. Prevents bacteria and viruses from attaching to mucous membranes; helps immunize breastfed newborns.
IgM	Pentamer	First type of secreted antibody to appear during an infection. Binds many antigens at once; effective at clumping viruses and bacteria so that they can be destroyed.

It took much longer for researchers to isolate and characterize the **T-cell receptor** (**TCR**). It turns out that the TCR only binds to antigens that have been modified by other cells and then presented, or displayed, on the plasma membranes of these cells, a complex process called **antigen presentation.** This is a fundamentally important distinction: B cells can bind to antigens directly; T cells bind only to antigens that are displayed by other cells. Other data showed that the TCR is composed of two protein chains: an alpha (α) chain and a beta (β) chain. The overall shape of the TCR is very similar to the "arm" of an antibody or BCR molecule (**Figure 49.6b**).

Antibodies, BCRs, and TCRs do not bind to the entire antigen but to a selected region of the antigen called an **epitope.** To understand the relationship between an antigen and an epitope, consider that every bacterium, virus, fungus, and protist is made up of a large number of different molecules. Each of these molecules is an antigen, because each is foreign to your cells. And each antigen may have many different epitopes, where binding by antibodies and lymphocyte receptors actually takes place. **Figure 49.7** illustrates a protein called hemagglutinin, which is found on the surface of the influenza virus. This antigen has six epitopes, identified by the blue and red lines in the figure. Each of these epitopes is recognized by a particular antibody, BCR, or TCR. It is not unusual for an antigen to have between 10 and 100 different epitopes.

How are the immunoglobulins able to recognize specific epitopes? The answer to this question came through detailed studies of the BCR's heavy and light chains.

What Is the Molecular Basis of Antibody Specificity and Diversity? In the 1950s biologists developed an important model system for studying BCR and antibody production. The cells involved were B-cell tumors, or myelomas, that could be grown in laboratory culture. Like other cancers, myelomas grow in an uncontrolled fashion. Further, each type of

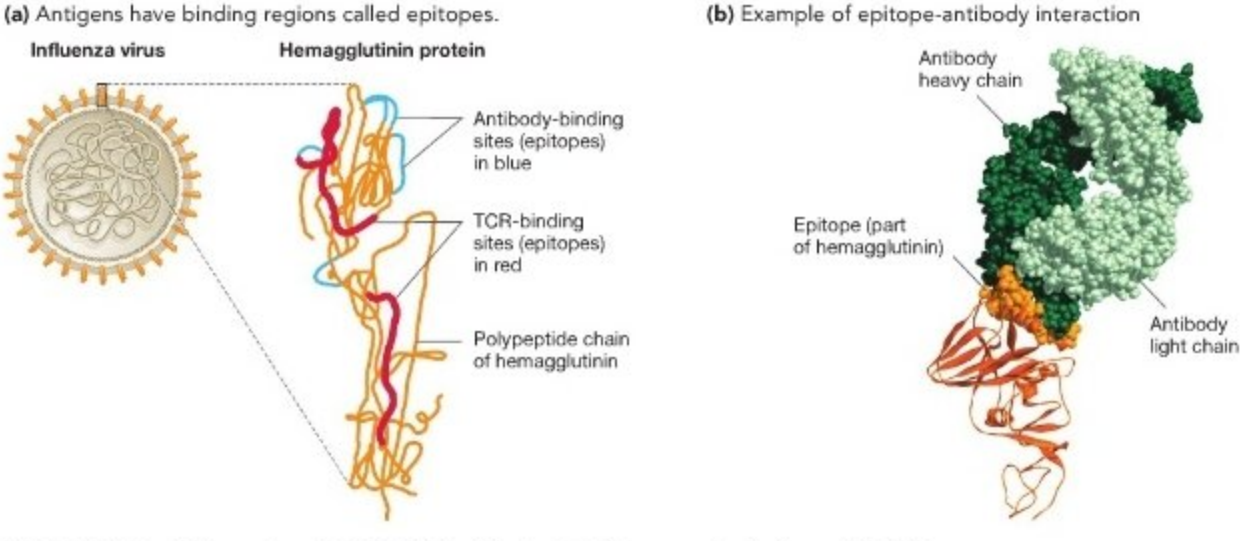

FIGURE 49.7 Most Antigens Have Multiple Binding Sites for B-Cell Receptors, Antibodies, and T-Cell Receptors. **(a)** The envelope of the influenza virus includes the protein hemagglutinin. This version of hemagglutinin has four different sites where antibodies bind and two distinct places where T-cell receptors bind. **(b)** The space-filling model shows how closely one of hemagglutinin's epitopes fits into an antibody.

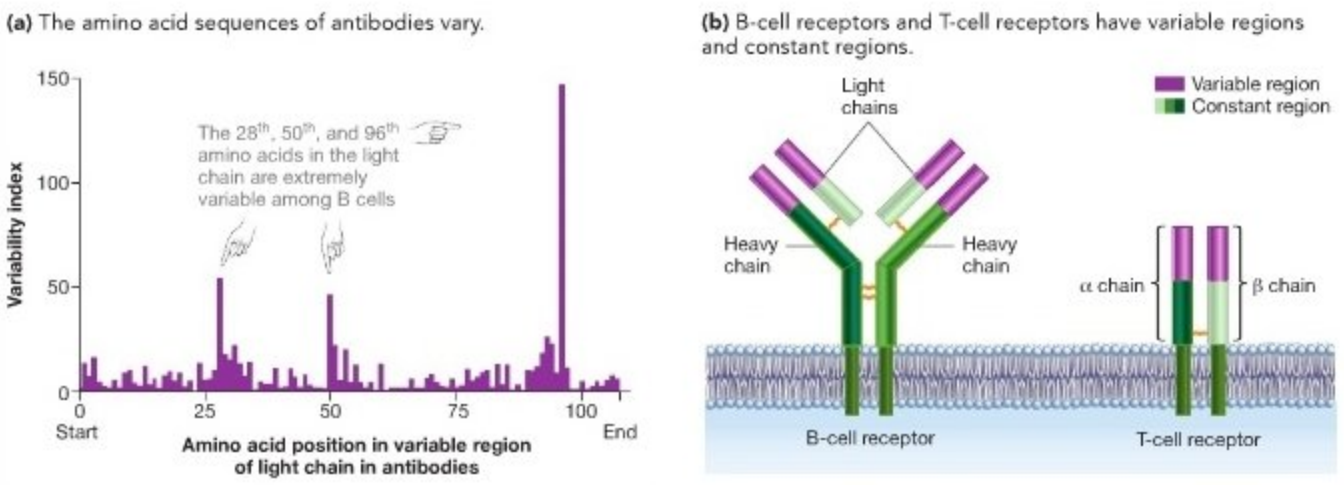

FIGURE 49.8 In B-Cell Receptors and T-Cell Receptors, the Amino Acid Sequence of the Light Chain Is Highly Variable. (a) Data indicating which amino acids in the immunoglobulin light chain are variable when 77 different antibody molecules are compared. "Variability index" is the number of antibodies that had a different amino acid at a position in the light chain, divided by the frequency of the most common amino acid at that position. The data for all 110 amino acids in the light chain are shown. The equivalent graph for the constant chain shows almost no variation. **(b)** The variable regions of a B-cell receptor and T-cell receptor face away from the plasma membrane.

EXERCISE Label the transmembrane domains of the receptors shown in part (b). Circle the antigen-binding sites on both molecules. Label the amino and carboxy terminus of each polypeptide.

myeloma produces a single type of antibody. By isolating and comparing the light chains produced by different myelomas, researchers were able to (1) document that each light chain is different, and (2) infer why different antibodies bind to different epitopes on antigens.

The initial studies exploring the composition of BCRs and antibodies used enzymes to chop the light chains from different B cells into pieces. Researchers used the technique called electrophoresis to separate the pieces and noticed that light chains from different B cells appeared to have one segment in common. In addition, there seemed to be light-chain regions that were unique to each B cell. These light-chain segments came to be known as the **constant (C) regions** and **variable (V) regions**, respectively.

When techniques to determine the amino acid sequence of proteins became available, the resulting data confirmed that both the light chain and the heavy chain consist of a variable (V) region at the amino terminus and a constant (C) region at the carboxy terminus. For example, when biologists compared the amino acid sequences of light chains from 77 different antibodies, they found that certain amino acids were extremely variable among B cells (**Figure 49.8a**). These portions of the light chain are within the V region. In contrast, the amino acid sequences of the C regions were almost identical. Similar patterns are found in the V and C regions of the heavy chain.

Why is this observation important? First, the presence of unique amino acids at certain positions in the light chain and heavy chain explains why the BCR and antibodies bind to unique epitopes: Receptors with different amino acid sequences bind to different epitopes. Second, the binding of epitopes occurs at the variable regions on the "end" (amino terminus) of the BCR molecule's and antibody's arms (**Figure 49.8b**). Analogous studies showed that the TCR also has a variable region near its amino terminus of both the α and β chains.

This observation solved one of the most fundamental questions about the acquired immune system: Your body can respond to an almost limitless number of antigens because there are a virtually limitless number of different BCRs, antibodies, and TCRs. If you understand this concept, you should be able to explain why variation in the composition of the variable region is responsible for the acquired immune system's ability to recognize so many different antigens. You should also be able to explain the molecular basis of specificity in the acquired immune system—meaning, why each BCR, antibody, and TCR binds to one epitope.

Analyses of the variable region raised a paradox, however. The acquired immune system can produce an almost limitless number of antibodies and receptors, but the genome of animals is not limitless. How does the genome code for so many different immune system proteins?

The Discovery of Gene Recombination In 1965 W. J. Dryer and J. Claude Bennett proposed a controversial explanation for how immunoglobulin genes code for so many dif-

ferent variable regions and thus so many different proteins. Dryer and Bennett suggested that a single gene codes for the C region of the light chain and that a separate gene codes for the V region. In addition, they hypothesized that early in the life of a lymphocyte, a segment from the *V* gene is combined with a segment from the *C* gene to form a new "*V* + *C* gene" for the light-chain protein. In effect, Dryer and Bennett hypothesized that as a B cell is maturing, the gene encoding the BCR is recombined in a way that results in the production of a sequence unique to that particular cell. The type of DNA cutting and pasting they were proposing had never been observed, however. (The introns and alternative splicing introduced in Chapter 16 had not been discovered yet.) As a result, most researchers considered the hypothesis wildly implausible.

In 1976, however, Nobumichi Hozumi and Susumu Tonegawa published data supporting the recombination hypothesis. Hozumi and Tonegawa reasoned that if light-chain diversity was produced by DNA recombination, then the variable and constant regions of immature B cells, which are not producing antibodies, should be longer than the same region in mature, activated B cells, which are producing BCR and antibodies. The amount of DNA in the *V* + *C* region should be shorter in mature cells than it is in embryonic cells, because it contains only a portion of the complete *V* and *C* gene regions (**Figure 49.9**). When they examined the *V* + *C* regions from immature B cells versus mature B cells, this is exactly what they found.

Hozumi and Tonegawa's result inspired a flurry of studies on the mechanism of DNA recombination. One central finding is that mammals have two genes that code for the light chain and one for the heavy chain. Each of these genes contains distinctive segments, however. For example, one of the light-chain genes in humans includes about 40 different variable (*V*) segments, 5 joining (*J*) segments, and a single constant (*C*) segment. The heavy-chain locus includes about 51 *V* segments, 27 diversity (*D*) segments, and 6 *J* segments along with the constant (*C*) segment. A light-chain protein is made up of portions encoded by a *V*, a *J*, and a *C* segment; a heavy-chain protein is made up of portions encoded by a *V*, a *D*, a *J*, and a *C* segment. The genes that encode the α and β chains of the TCR have a similar arrangement of distinct segments, each with multiple versions.

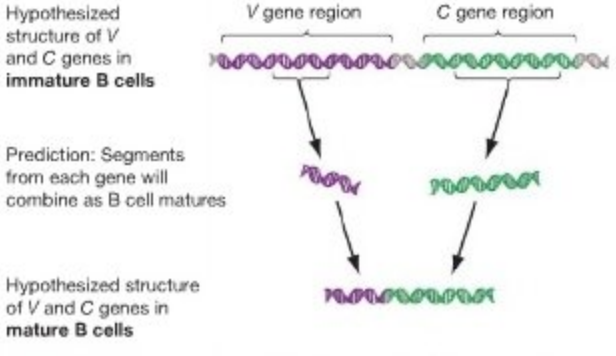

FIGURE 49.9 The Gene Recombination Hypothesis for Antibody Formation in B Cells.

Figure 49.10 summarizes the current model for how these gene segments are processed as a B cell matures. The structure of the *V*, *J*, and *C* regions of light-chain and heavy-chain DNA are illustrated in Figure 49.10a. This is what the genes look like in an immature B cell and all non-B cells. Figure 49.10b walks through the processing steps as a B cell matures, using one of the immunoglobulin light-chain genes as an example (step 1). Early in lymphocyte development, the gene segments are brought closer together by DNA recombination (step 2). For example, in B cells any one of the 40 *V* light-chain segments can recombine with any one of the 5 *J* segments. Thus, $40 \times 5 = 200$ different light chains can be produced by recombination. In the heavy chain, any one of the 51 *V* segments, 27 *D* segments, and 6 *J* segments can recombine, giving a total of $51 \times 27 \times 6 = 8262$ possible heavy chains. Because light-chain and heavy-chain rearrangements occur independently, DNA recombination can produce $200 \times 8262 = 1{,}652{,}400 = 1.65 \times 10^6$ different antigen-specific BCRs. And this number does not include BCRs that result from recombination in the other light-chain gene. The functional gene is then transcribed, and the resulting mRNA is processed and translated into a light-chain protein (steps 3–5).

● If you understand these events, you should be able devise a system for generating a high diversity of lottery numbers that is analogous to gene recombination, but uses only the digits 0–9.

The story does not end here. Gene segments are not always joined precisely during DNA recombination. Some variation occurs where the *V* and *D* segments join and where the *D* and *J* segments join. This junctional diversity results in many additional novel sequences. Thus, by recombining small DNA segments in the two light-chain genes, an estimated 10^{10} to 10^{14} different BCRs can be created. A similar number pertains for the TCRs, which undergo the same type of recombination process. These results revealed why each B cell and T cell in the body can have a different receptor on its surface. Due to gene recombination, each receptor has a unique amino acid sequence. As a result, it has the ability to bind a unique epitope on an antigen. Gene recombination is the molecular mechanism responsible for the acquired immune system's combination of specificity and diversity.

How Does the Immune System Distinguish Self from Nonself?

As B cells and T cells mature and begin producing receptors for specific antigens, an important problem arises: How does the immune system ensure that the receptors on these cells don't respond to molecules that are part of normal host cells? If a

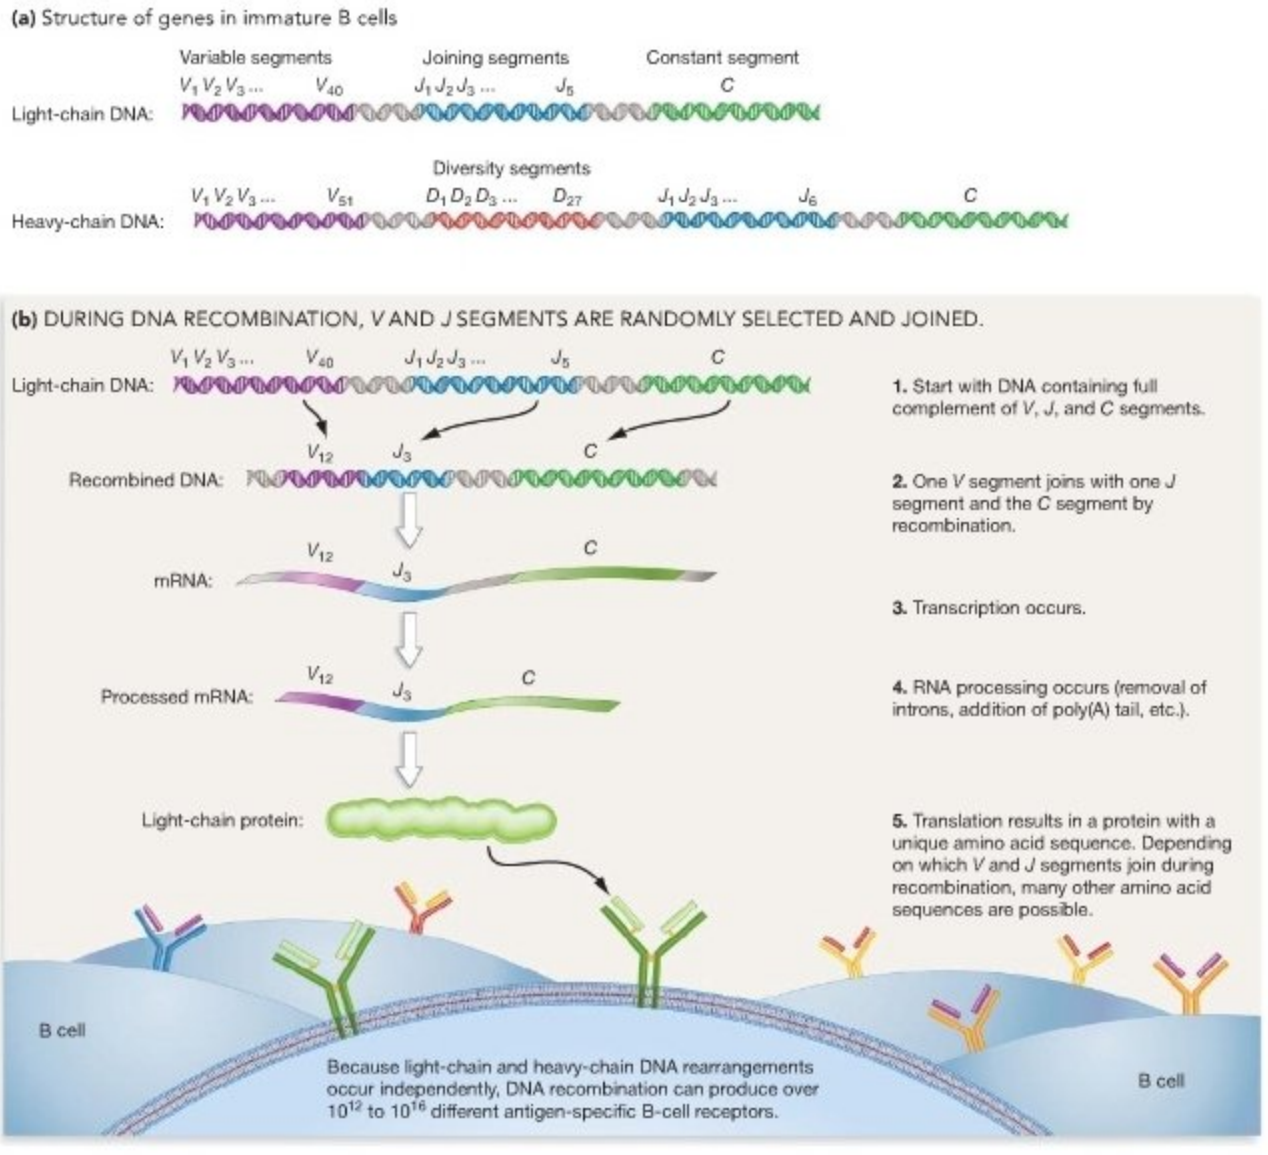

FIGURE 49.10 DNA Recombination Results in Antibodies with Unique Amino Acid Sequences. Diagram summarizing current data on how light-chain proteins are produced as a B cell matures.

B-cell receptor or T-cell receptor responded to a **self** molecule—that is, a molecule belonging to the host—the receptor would trigger an immune response. An anti-self reaction such as this is known as **autoimmunity** and can lead to immune system cells destroying parts of the host's own body.

Biologists predicted that there must be some mechanism for eliminating young B cells and T cells that have receptors for self molecules. This prediction was confirmed when researchers injected B cells and T cells with anti-self receptors into mice and found that these experimental lymphocytes were eliminated. Follow-up work showed that if B cells and T cells that are maturing in the bone marrow and thymus have anti-self receptors, the cells are destroyed before they leave these organs.

A great deal of research is currently focused on understanding the molecular mechanisms responsible for eliminating lymphocytes with anti-self receptors. In addition to the intrinsic interest it offers, this research has important implications for human health. If the elimination process breaks down, lymphocytes are produced that react to self proteins, and illness results.

For example, multiple sclerosis (MS), introduced in Chapter 45, results from the production of anti-self T cells. The T cells attack the myelin sheath of nerve fibers. Because damage to myelin reduces the efficiency of nerve signaling, muscular and coordination problems result. Other autoimmune diseases include rheumatoid arthritis, type 1 diabetes mellitus, myasthenia gravis, and lupus (systemic lupus erythematosus). In the vast majority of cases, however, cells in the bone marrow and thymus correctly eliminate maturing B cells and T cells that have receptors for self proteins.

To summarize, each B cell and T cell has thousands of copies of a unique receptor. These receptors are checked to make sure that they do not respond to self molecules. Now the question is, How do B cells and T cells interact with the antigens from invading bacteria and viruses that flood into your blood and lymph from an infected elbow or a blossoming case of the flu?

Check Your Understanding

If you understand that...

- The acquired immune response is performed by lymphocytes that circulate in the lymph, blood, and organs of the immune system.
- The acquired response is specific because it is initiated by receptors on the surface of lymphocytes that bind to unique epitopes on antigens.
- Lymphocytes can respond to a wide array of antigens because immunoglobulin gene segments recombine to produce a receptor unique to each cell.

You should be able to...

1) Describe the difference between an epitope and an antigen.
2) Draw and label the structure of a B-cell receptor and a T-cell receptor.
3) Describe the difference between a B-cell receptor and an antibody.
4) Predict the consequences of a mutation that disrupts selection against cells that respond to self molecules.

49.3 The Acquired Immune Response: Activation

When the cell-surface receptor of a B cell or T cell binds to an antigen, the event is like pushing the button that launches a "smart bomb"—a missile that is programmed to destroy a specific target. The binding of a B cell or T cell to an antigen unleashes a series of events that results in the destruction of the antigen. The lethal power of activated B cells and T cells is nothing short of awesome.

Perhaps because lymphocytes are so destructive, the activation of the relevant B cells and T cells is a carefully controlled, stepwise process. The mechanism is reminiscent of the precautions that nations with powerful missiles take to avoid accidental deployment. For the most dangerous weapons, the signal to launch is checked and cross-checked, using a series of codes and signals. In the immune system, the checking and cross-checking occurs through protein-protein interactions on the surfaces of cells, and the release and receipt of cytokines and other signaling molecules.

For T lymphocytes, the sequence that leads to activation begins when antigens are taken up by a specific type of leukocyte or an infected cell, cut into pieces, packaged with specific cell proteins, and then transferred to the cell surface. Once antigens are presented in this way, T cells can bind to them via the TCR and begin their transformation from an inactive to an activated state.

The antigen-presentation step is crucial to the activation of the acquired immune response. How does all this happen?

Antigen Presentation by MHC Proteins: Activating T Cells

If the innate immune response is overwhelmed and bacteria begin to multiply rapidly at a wound site, leukocytes called dendritic ("tree-like") cells are recruited to the area. **Dendritic cells** ingest some of the antigens present and migrate to the nearest lymph node. There they interact with two distinctive types of T cells. T cells are classified as $CD4^+$ or $CD8^+$, based on the presence of key proteins called **CD4** or **CD8** on their plasma membranes. $CD4^+$ T cells and $CD8^+$ T cells have distinct functions in the acquired immune response.

Figure 49.11 details how antigens and $CD8^+$ T cells interact in the lymph node. As Figure 49.11a shows, dendritic cells process the peptides they have ingested (step 1). An enzyme complex inside the cell breaks the peptides into small pieces (step 2). These pieces then become bound to a **major histocompatibility (MHC) protein** inside the endoplasmic reticulum (step 3). MHC proteins are antigen-presenting proteins. As the figure shows, MHC proteins have a groove where small peptide fragments, typically from 8 to 20 amino acids in length, bind. MHC proteins come in two types, called **Class I** and **Class II MHC proteins**. In dendritic cells, peptide fragments attach to Class I proteins and are transported to the cell surface (step 4). When the MHC protein-peptide complex is displayed on the cell surface, antigen presentation is complete (step 5).

Each individual has several genes encoding Class I and Class II MHC proteins, so each person can produce several distinct proteins of each type. Further, the MHC genes are among the most polymorphic of any genes known—meaning that many different alleles exist in the population (see Chapter 13). Because so many distinct alleles exist, most individuals are heterozygous for the Class I and Class II MHC genes. Heterozygous individuals produce an even greater diversity of Class I and Class II MHC proteins. Having a wide array of

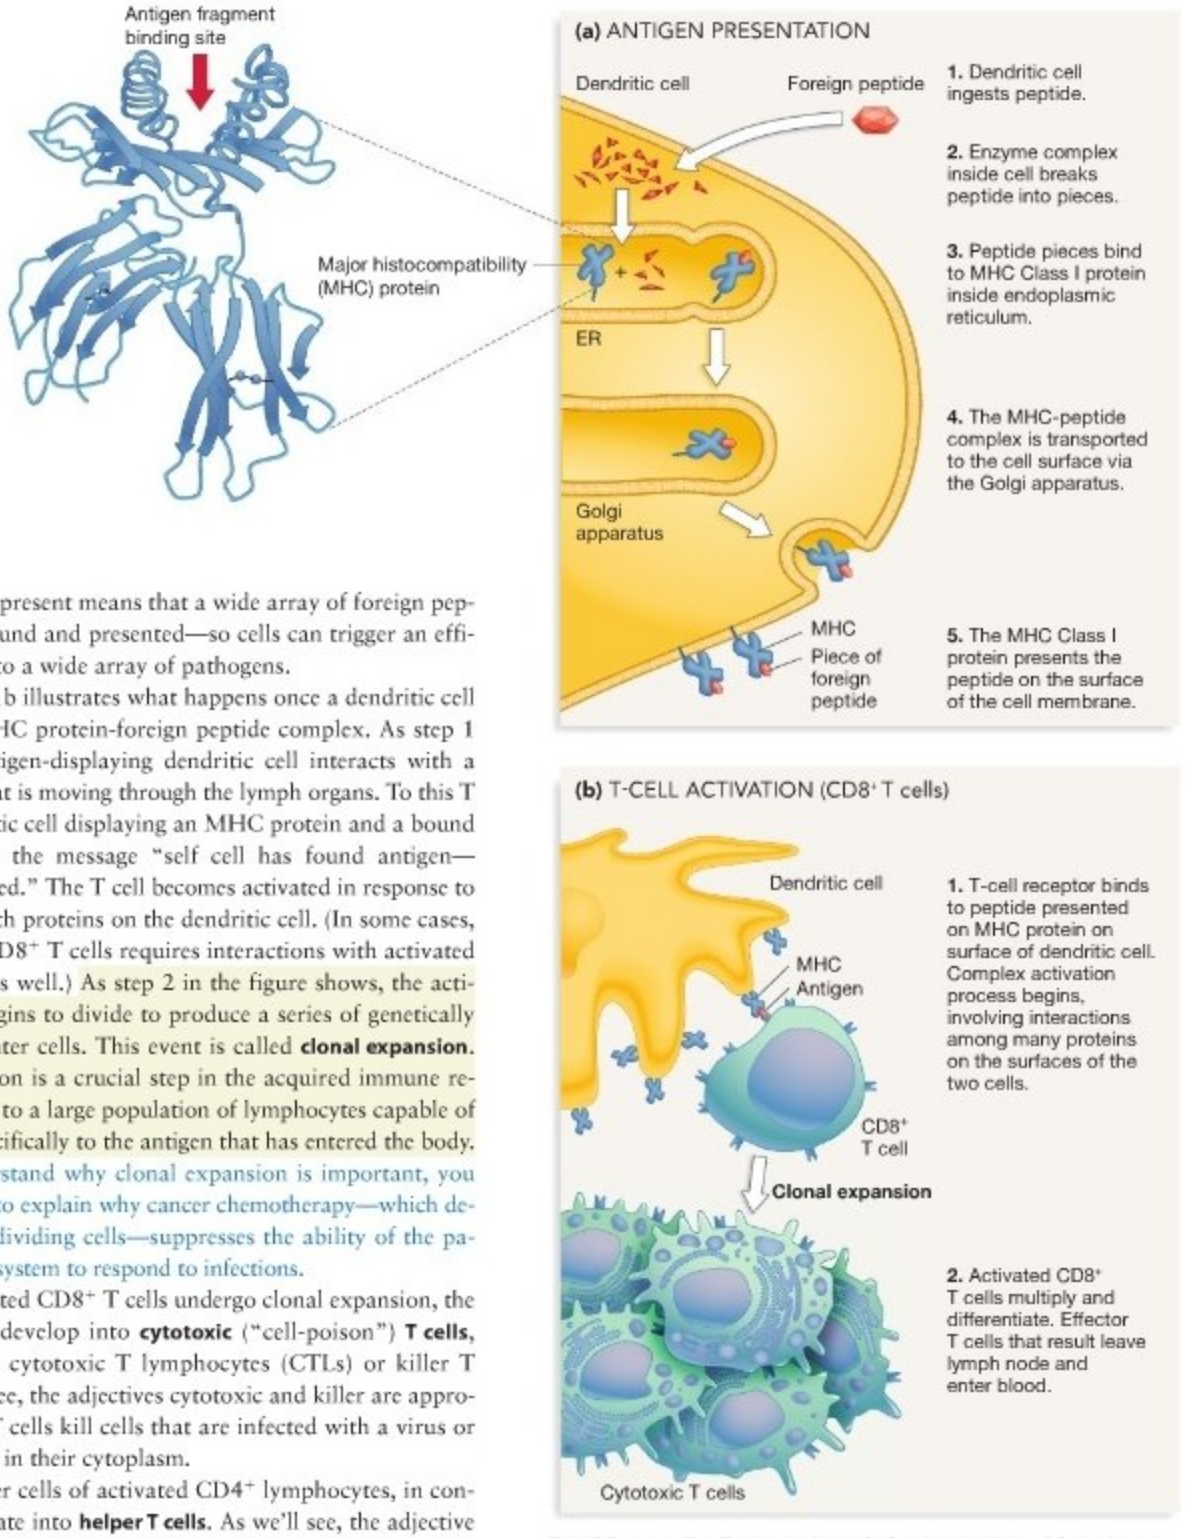

FIGURE 49.11 T Cells Are Activated after Interacting with Antigens Presented by Dendritic Cells. (a) Dendritic cells take in antigens, break them into pieces, and then present the fragments in the groove of an MHC protein. **(b)** If a $CD8^+$ T cell has a receptor that is complementary to the MHC-antigen complex presented on the surface of a dendritic cell, the T cell will begin activation.

MHC proteins present means that a wide array of foreign peptides can be bound and presented—so cells can trigger an efficient response to a wide array of pathogens.

Figure 49.11b illustrates what happens once a dendritic cell displays an MHC protein-foreign peptide complex. As step 1 shows, the antigen-displaying dendritic cell interacts with a $CD8^+$ T cell that is moving through the lymph organs. To this T cell, the dendritic cell displaying an MHC protein and a bound peptide carries the message "self cell has found antigen—response required." The T cell becomes activated in response to interactions with proteins on the dendritic cell. (In some cases, activation of $CD8^+$ T cells requires interactions with activated $CD4^+$ T cells as well.) As step 2 in the figure shows, the activated T cell begins to divide to produce a series of genetically identical daughter cells. This event is called **clonal expansion**. Clonal expansion is a crucial step in the acquired immune response. It leads to a large population of lymphocytes capable of responding specifically to the antigen that has entered the body.

● If you understand why clonal expansion is important, you should be able to explain why cancer chemotherapy—which destroys rapidly dividing cells—suppresses the ability of the patient's immune system to respond to infections.

When activated $CD8^+$ T cells undergo clonal expansion, the daughter cells develop into **cytotoxic** ("cell-poison") **T cells**, also known as cytotoxic T lymphocytes (CTLs) or killer T cells. As we'll see, the adjectives cytotoxic and killer are appropriate: $CD8^+$ T cells kill cells that are infected with a virus or other pathogen in their cytoplasm.

The daughter cells of activated $CD4^+$ lymphocytes, in contrast, differentiate into **helper T cells**. As we'll see, the adjective helper is also appropriate—helper T cells assist with the activation of other lymphocytes. There are two types of helper T cells, designated T_H1 and T_H2, and they have distinct functions: T_H1 cells help activate cytotoxic T cells, while T_H2 cells help activate B cells.

Helper T cells and cytotoxic T cells are often referred to as effector T cells. Following clonal expansion and maturation, effector T cells leave the lymph node through a lymphatic duct. Later they enter the blood and migrate to the site of infection. Once there, cytotoxic T cells interact only with cells that display antigens presented on Class I MHC proteins. Virtually all nucleated cells in the body can display antigens bound to Class I MHC proteins. Helper T cells, in contrast, interact only with antigens presented on Class II MHC protein molecules, which are found only on the surfaces of B cells and other leukocytes that present antigens.

An antigen on a Class I MHC protein is a signal that can be found on virtually any cell of the body. It means that the cell is infected with a pathogen. When a cell displays an antigen bound to a Class I MHC protein, it sends a simple message to cytotoxic T cells: "Kill me." But if a leukocyte displays an antigen on a Class II MHC protein, the message to helper T cells is "Activate me." ● If you understand the role of antigen presentation by MHC proteins, you should be able to (1) state which cells express Class I versus Class II MHC proteins, (2) state which types of T cells respond to peptides bound to Class I versus Class II MHC proteins, and (3) summarize the message provided by MHC-peptide complexes on a dendritic cell, an infected cell, and a leukocyte.

Effector T cells are ready for action. A key part of the acquired immune response is now under way.

B-Cell Activation and Antibody Secretion

$CD8^+$ and $CD4^+$ lymphocytes are activated by interactions with dendritic cells and other leukocytes that present antigens. How are B cells activated? As **Figure 49.12** shows, the answer has two parts. The BCRs on B cells interact directly with the bacterial or viral antigens that are floating free in lymph or blood. Once a free antigen is bound, B cells internalize the molecule and process it with a Class II protein. As a result, a B cell that encounters its antigen displays the antigen's epitope on its own surface, with the antigen cradled in the groove of a Class II MHC protein (step 1 of Figure 49.12). The second part of the activation process occurs when an activated $CD4^+$ T_H2 cell with a complementary receptor arrives. This helper T cell binds to the antigen-MHC complex on the B cell (step 2). The interaction between a B cell and a helper T cell supplies activation signals that stimulate the helper T cell. Once the helper T cell is stimulated in this way, it responds by activating the B cell through the release of stimulatory cytokines.

After receiving these activation signals, a B cell begins to divide and form daughter cells. Some of the daughters differentiate into activated B lymphocytes called **plasma cells**. Plasma cells produce and secrete large quantities of antibodies (step 3). Recall that antibodies are identical to B-cell receptors, except that they lack a transmembrane domain and are secreted instead of being found in the plasma membrane.

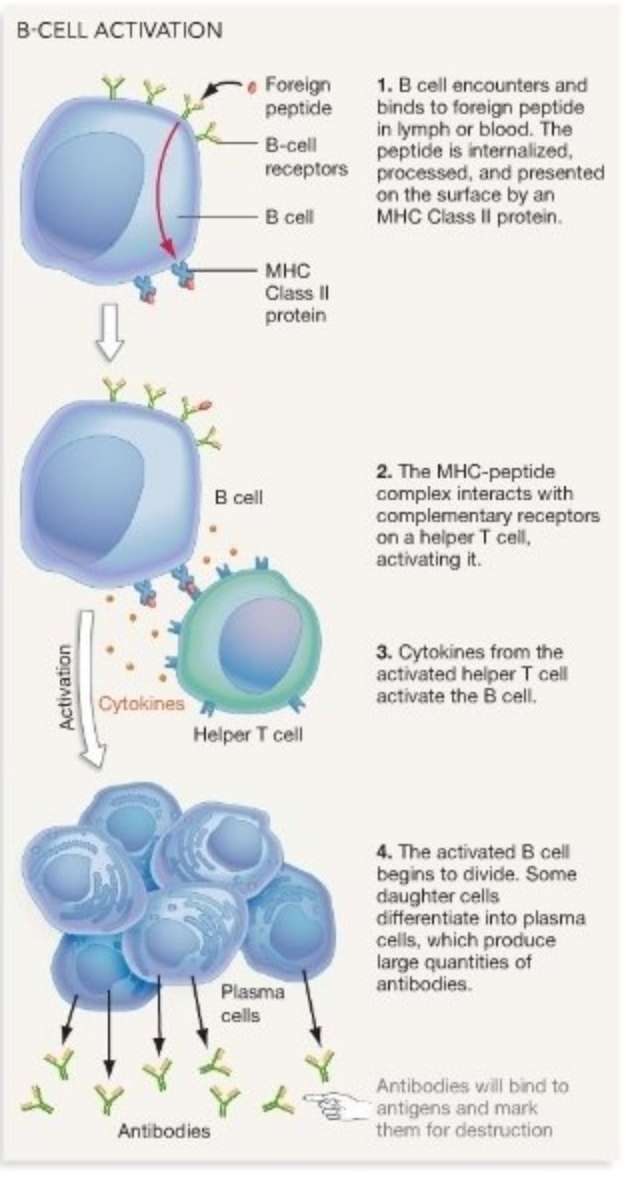

FIGURE 49.12 B Cells Are Activated after Interacting with Helper T Cells. A series of steps are involved in activating B cells. Once receptors on a helper T cell have bound to MHC-antigen complexes on a B cell, the helper T cell releases cytokines that activate the B cell. (Other proteins on the surface of a B cell and T cell must also interact for activation to occur.) Activation eventually leads to the production of antibodies by plasma cells.

Once B cells are activated, the acquired immune response gains an important dimension. Antibodies specific to the invading bacterium or virus begin to circulate in the blood.

Table 49.3 summarizes how B cells and T cells are activated. (The memory cells mentioned in the table are introduced in Section 49.4.) Once these lymphocytes have been activated, most of the major elements in the acquired immune response are in place.

SUMMARY TABLE **49.3 Activation of the Acquired Immune System**

Type of Lymphocyte	Method of Activation	Cells That Result from Activation and Clonal Expansion
B cell	Receptor binds to free antigen, then interacts with T_H2 cell.	Plasma cells Memory B cells
$CD4^+$ T cell	Receptor binds to antigen-MHC Class II protein complex on dendritic cell or other antigen-presenting cell.	T_H1 (helper T cell) T_H2 (helper T cell) Memory T cells
$CD8^+$ T cell	Receptor binds to antigen-MHC Class I protein complex on infected cell; may also interact with T_H1 cells.	Cytotoxic T cells Memory cells

Check Your Understanding

If you understand that...

- T cells are activated when their receptor binds to an antigen presented by the MHC proteins on a dendritic cell or an infected cell.
- B cells are activated when their receptor binds to an antigen, the antigen is presented by an MHC protein on their surface, and they are stimulated by a helper T cell activated by the same antigen.
- Activated lymphocytes undergo dramatic changes in morphology and divide rapidly.

You should be able to...

Generate a hypothesis to explain the observation that humans who are heterozygous for the genes encoding MHC proteins tend to be healthier than individuals who are homozygous for these genes.

49.4 The Acquired Immune Response: Culmination

Activated B cells, helper T cells, and cytotoxic T cells present a formidable response to invading pathogens. In combination with the leukocytes involved in the innate immune system, the cells of the acquired immune system are almost always successful in eliminating threats from bacteria, parasites, fungi, and viruses. To drive this point home, consider what happens when the acquired immune system does *not* work. For example, children who are born with severe combined immunodeficiency (SCID) have a genetic defect in one of the enzymes responsible for DNA recombination in maturing lymphocytes. As a result, they are unable to generate normal T-cell and B-cell receptors and lack a normal immune system (see Chapter 19). In particular, it is their acquired immune response that is badly impaired. Afflicted individuals suffer debilitating illness from infections that other children fight off easily, and they die before they are two years old. Similarly, people who are infected with the **human immunodeficiency virus** (**HIV**) suffer a progressive loss of $CD4^+$ T cells, because HIV kills $CD4^+$ T cells and macrophages. Eventually, HIV-infected people develop **AIDS—acquired immune deficiency syndrome**. They succumb to illnesses that physicians almost never see in people with healthy immune systems.

To understand how the acquired response actually kills pathogens, let's again return to a bacterial infection in a wounded elbow and an upper respiratory tract infection caused by the flu virus. How do activated B cells and T cells eliminate these invaders?

How Are Bacteria and Other Foreign Cells Killed?

During the innate immune response to bacteria and other pathogenic cells that enter a wound, macrophages at the site phagocytize some of the invaders. In addition to killing the foreign cells, these leukocytes process and present antigens via the MHC Class II proteins. As a result, macrophages at the site of infection display epitopes on their surfaces that can be recognized by helper T cells activated during an acquired immune response. If an activated T_H1 cell binds to these antigen-laden macrophages, two things happen: First, the phagocytic activity of the macrophages is enhanced. Second, the T_H1 cells secrete cytokines that recruit additional phagocytic cells to the site, and increase the inflammatory response.

Bacteria, fungi, and other foreign cells at the infection site also begin to be coated with antibodies from plasma cells. In many cases, antibody action causes **agglutination**, or clumping of cells. Each antibody has at least two binding sites, so a single antibody can bind epitopes on foreign cells and link them, forming a clump. Clumped or single cells that are tagged with antibodies are readily destroyed by macrophages by phagocytosis. Antibodies that are bound to antigens also stimulate a group of proteins called the **complement system**. Complement proteins circulate in the bloodstream and assemble at antigen-antibody complexes. When complement proteins activate, they punch lethal holes in the plasma membranes of invading cells. Within a few days, this combination of killing mechanisms usually eliminates all foreign cells.

How Are Viruses Destroyed?

Just as the acquired immune system has an array of mechanisms to dispose of bacteria, it has two major ways to eliminate viruses. One route involves cytotoxic T cells (activated $CD8^+$ cells) and is called the **cell-mediated response**; the other route involves antibodies and is called the **humoral response**. (The Latin root *humor* means "fluid." The humoral response takes place in blood and lymph; the cell-mediated response takes place at the surface of cells.) Let's take a closer look at both.

Cell-Mediated Response Infected cells respond to the arrival of a virus by processing antigens from the invader. MHC Class I proteins attach to the viral antigens and present the antigens on the surface of the infected cell. Every nucleated cell in the body expresses MHC Class I proteins and has the ability to signal that it is infected. Cells that display viral antigens bound to Class I MHC molecules are effectively waving a flag that says, "I'm infected. If you destroy me, you'll destroy them."

As $CD8^+$ cells migrate into the area, they recognize and bind to the antigen's epitopes and the MHC protein displayed on infected cells. Once binding occurs, the $CD8^+$ cell secretes molecules that assemble on the surface of the infected cell's plasma membrane and produce pores. Granules from the cytotoxic T cell then enter the cell and activate a self-destruct response (**Figure 49.13a**).

Once the infected cell is destroyed, the cytotoxic T cell releases and seeks out another infected cell to kill. Over time, all virus-infected cells are eliminated. Because viruses can reproduce only inside host cells, the cell-mediated response limits the spread of the infection by preventing new generations of virus particles from maturing.

Humoral Response Even as cytotoxic T lymphocytes swing into action, plasma cells are producing antibodies to viral proteins. In most cases, the most effective antibodies are those that bind to epitopes on the surface of the virus. As **Figure 49.13b** shows, two things happen when antibodies bind to the outside of a virus: First, the virus is blocked from making contact with plasma membranes and entering new host cells. Second, macrophages and other phagocytic cells recognize the antibody-coated particles and phagocytize them. Because of this humoral response, the number of virus particles floating free in lymph and blood is eventually reduced to zero.

Why Does the Immune System Reject Foreign Tissues and Organs?

Antibodies and cytotoxic T cells have devastating effects on invading bacteria and viruses. Unfortunately, they are equally deadly in response to tissues or organs that are introduced into a patient in the hopes of healing a wound or curing a disease. To understand why, consider the problems that can arise

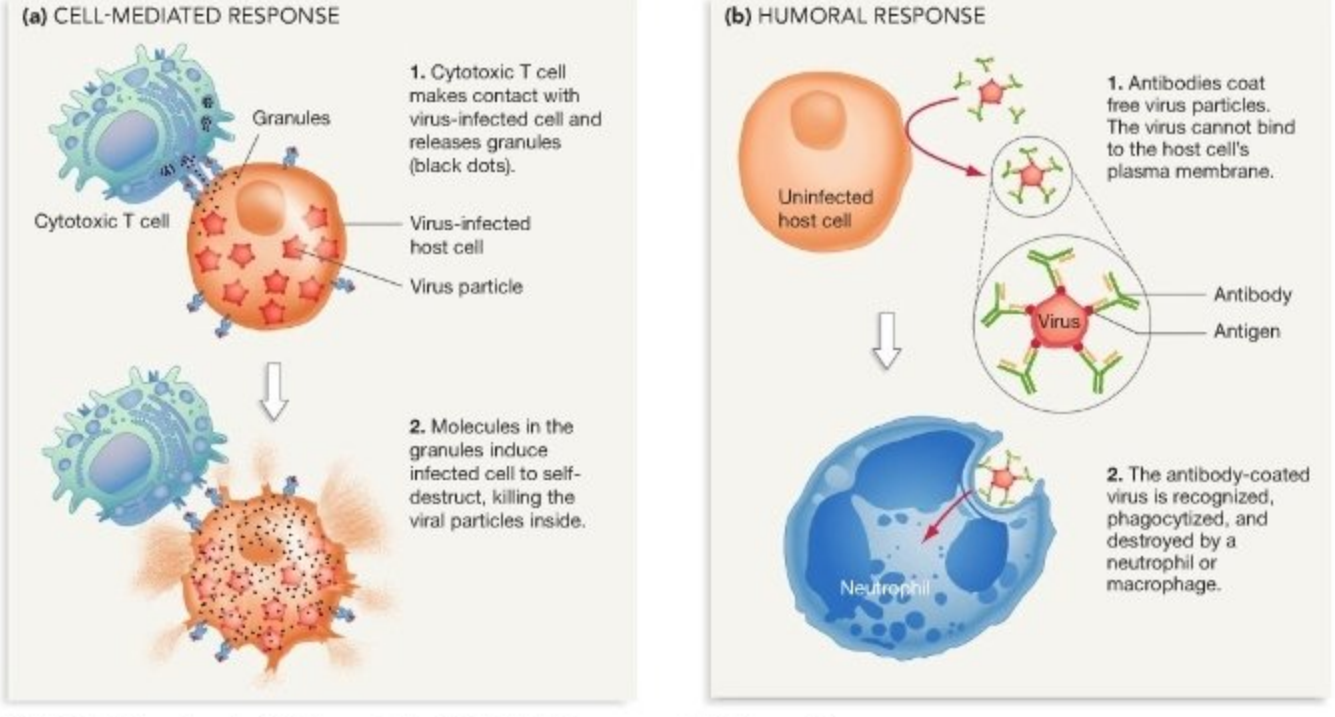

FIGURE 49.13 Lymphocytes Kill Viruses via the Cell-Mediated Response and the Humoral Response.

with blood transfusions. Certain individuals have red blood cells with membrane proteins called A and B. These proteins act as antigens if they are introduced into a person whose own blood cells lack those proteins. For example, if you have type A blood, it means that your blood cells have the A antigen. If your blood is introduced to a person who lacks the A antigen—meaning a person who has type B or type O blood—the recipient's immune system will recognize the A antigen as foreign and mount a devastating response against it. For a blood transfusion to be successful, a recipient has to receive blood that lacks the A and B proteins entirely or that contains the same antigens found in his or her own blood.

Similar problems arise in organ transplants, except that the antigenic molecules in foreign organs are the MHC proteins found on the surfaces of their cells. To prevent strong immune reactions to a transplanted kidney, heart, or liver, physicians do two things: (1) obtain the organ to be transplanted from a sibling or other donor whose MHC proteins are extremely similar in structure to those of the recipient and (2) treat the recipient with drugs that suppress the immune response. Thanks to steady improvements in drug development and in systems for matching MHC types between donors and recipients, the success rate for organ transplants has improved dramatically in recent years.

As the blood transfusion and organ transplant examples show, the immune system rejects foreign tissues because they contain nonself proteins—antigens. To your T cells and B cells, a blood transfusion or an organ transplant is indistinguishable from a massive influx of bacteria, viruses, or other foreign invaders.

Responding to Future Infections: Immunological Memory

When B cells and T cells are activated and undergo clonal expansion, their daughter cells differentiate into plasma cells, helper T cells, and cytotoxic T lymphocytes. **Table 49.4** summarizes what these cells do. But in addition to producing the cells that implement the humoral and cell-mediated responses, activated B cells and T cells produce specialized daughter cells called memory cells. **Memory cells** do not participate in the initial acquired response, or **primary immune response**. Instead, they provide a surveillance service after the original infection has been cleared. Memory cells remain in the spleen and lymph nodes for years or decades, ready to provide an extremely rapid response should an infection with the same antigen recur. The production of memory cells is a hallmark of the vertebrate immune response. It occurs only to a limited degree, if at all, in invertebrates.

If the same antigen enters the body a second time, memory cells bind the antigen and trigger a second acquired response, or **secondary immune response**. The launching of a secondary immune response by means of memory cells is known as **immunological memory**. The secondary response is faster and more efficient than the primary response. It is faster because the presence of memory T and B cells increase the likelihood that lymphocytes with the correct antigen-specific receptors will find the antigen and activate quickly. It is more efficient because some of the memory B cells that respond to the returning antigen migrate to a specialized area in the lymph node called the germinal center. There the DNA sequences that code for the variable region of the immunoglobulin gene begin to undergo rapid mutation. Mutations in the DNA of the variable region modify the receptors produced by the memory cell. Memory B cells with receptors that bind best to the antigen's epitope live and produce daughter cells; those that bind to antigens less well die.

In effect, this process of somatic hypermutation leads to a fine-tuning of the immune response. The antibodies that result from somatic hypermutation bind to the antigen more tightly than the antibodies produced by plasma cells during the primary immune response. As the secondary immune response proceeds and somatic hypermutation continues, better-fitting antibodies are produced.

SUMMARY TABLE **49.4** **Function of Acquired Immune System Components**

Type of Lymphocyte	Cells That Result from Activation and Clonal Expansion	Function of Resulting Cells
B cell	Plasma cells	Secrete antibodies
	Memory cells	Participate in secondary response (secrete antibodies)
$CD4^+$ T cell	T_H1 (helper T cell)	Activates cytotoxic T cells, regulates inflammatory response
	T_H2 (helper T cell)	Activates B cells
	Memory cells	Participate in secondary response
$CD8^+$ T cell	Cytotoxic T cells	Kill infected host cells
	Memory cells	Participate in secondary response

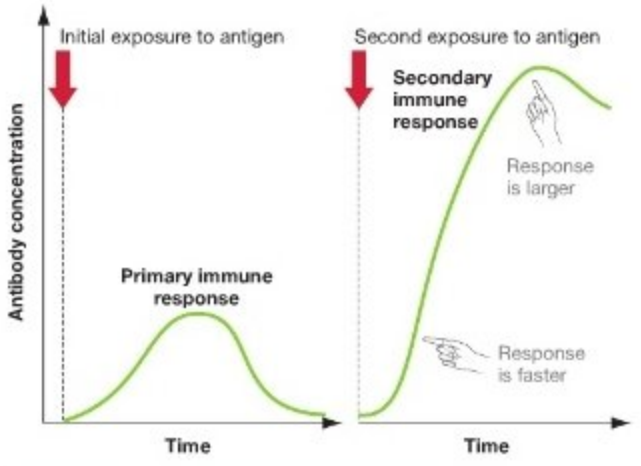

FIGURE 49.14 The Secondary Immune Response Is Faster and Stronger than the Primary Response. The data shown here summarize what happens when biologists inject a mouse with an antigen, document changes in antibody concentration over time, inject the same individual with the same antigen later, and measure the response in antibody concentration.

EXERCISE The primary response takes 10–17 days; the secondary response takes 3–5 days. Add appropriate labels to scale the *x*-axes.

Figure 49.14 underlines the effectiveness of the secondary immune response by comparing the rate of antibody production during the first and second exposures to a virus. The graphs are based on data that researchers collect by inoculating a laboratory mouse with influenza virus, collecting blood from the mouse every other day, and then measuring the amount of antiviral antibodies present in the fluid phase of the blood. (**Box 49.1** explains how researchers measure antibody concentrations in blood.)

The data in Figure 49.14 also explain why vaccination is an effective defense against certain viruses. A **vaccine** contains epitopes from a pathogen or a killed or weakened version of the pathogen itself. After vaccination (inoculation with a vaccine), the body mounts a primary immune response that results in the production of memory cells. If an actual infection occurs later, these memory cells respond quickly and eliminate the threat before illness occurs. Edward Jenner's vaccination strategy worked because the antigens presented by cowpox are extremely similar to the antigens presented by smallpox. As a result, exposing people to cowpox virus elicited the production of memory cells that effectively thwarted future infections by smallpox virus.

BOX 49.1 The ELISA Test

One of the common strategies used to measure protein concentrations in blood is called an ELISA (enzyme-linked immunosorbent assay). The standard screening test for HIV infection, for example, is an ELISA for antibodies that the immune system produces in response to this virus. Pregnancy tests are ELISAs that test for the presence of human chorionic gonadotropin in urine. There are several distinct ELISA tests; **Figure 49.15** illustrates how an indirect ELISA might be used to determine the amount of antibody present in a mouse that has been infected with influenza.

To begin an ELISA test, each well in a plastic plate containing many wells is coated with antigen (step 1 of Figure 49.15). In our example, the antigen is purified hemagglutinin protein from the influenza virus. Next, a defined amount of plasma from the patient is added to the plate. (Recall from Chapter 44 that plasma is the cell-free, fluid fraction of the blood.) If antibodies are present, they bind to the antigen (step 2). To continue the assay, a secondary antibody is added to the mixture of antigen and plasma (step 3). The secondary antibody is an antibody that can attach to the constant region of antibodies in the plasma added to the well. In ELISA tests, the secondary antibody is attached to an enzyme such as alkaline phosphatase (shown in the figure as AP). Alkaline phosphatase is useful because it catalyzes a reaction with a substrate to generate a product that changes the color of the solution. As a result, the presence of color in a well indicates a positive reaction—meaning the antibody to hemagglutinin is present (step 4). A positive result confirms that the patient is infected with influenza virus.

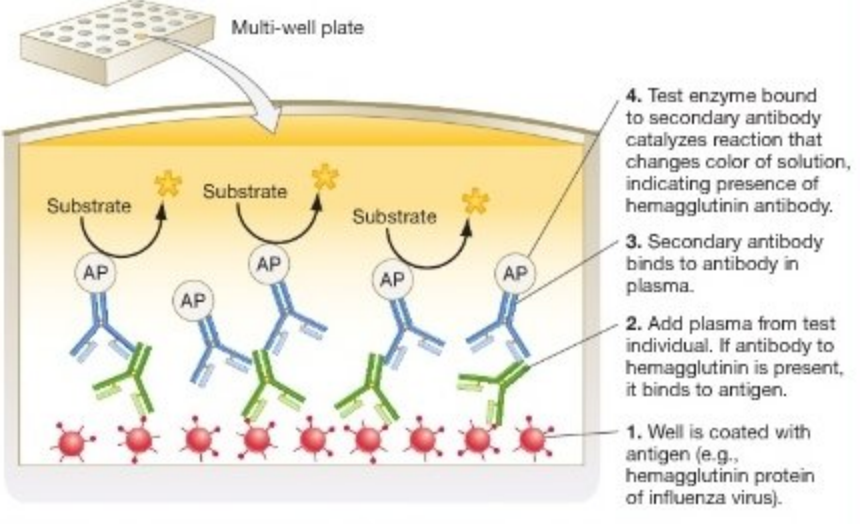

FIGURE 49.15 The ELISA Test Measures Antibody Concentrations in Blood.

Unfortunately, viruses such as influenza and HIV mutate so rapidly that they present the immune system with a constantly changing array of epitopes. Memory cells that were effective during a previous infection by these viruses are unlikely to bind to the changed epitopes and trigger a response to a later infection. As a result, it is extremely difficult for biologists to design an effective vaccine against these agents. Currently, the only "cure" for HIV infection is prevention; to keep up with rapidly mutating flu populations, flu vaccines must be redesigned and administered every year. The high mutation rates observed in these viruses are thought to be an adaptation that helps them escape detection by the immune system.

The Acquired Immune Response

Check Your Understanding

If you understand that...

- The antibodies produced by activated B cells mark invading pathogens for destruction.
- Activated cytotoxic T cells recognize epitopes displayed by infected cells and kill them before the pathogens inside can replicate.
- Memory cells produced during B-cell and T-cell activation remain in the body and provide secondary immunity against future infections.

You should be able to...

1) Explain how vaccination works.
2) Propose a strategy for developing a vaccine for HIV or the cold virus.

Chapter Review

SUMMARY OF KEY CONCEPTS

The innate immune response to infection is mounted by leukocytes that respond in a nonspecific way to pathogens. The acquired immune response is mounted by leukocytes called lymphocytes. Each individual lymphocyte responds to a specific pathogen.

The innate response occurs in the same way no matter which pathogens have entered the body, but the acquired response is specific to the pathogen present. During the innate immune system's inflammatory response, mast cells release chemical messengers that result in increased blood flow to wounds or areas of tissue damage. After neutrophils migrate to the site, they respond to bacteria that stimulate their pattern-recognition receptors by phagocytizing the invading cells and destroying them. Macrophages also phagocytize pathogens and release chemical messengers that activate other leukocytes and raise body temperature.

You should be able to explain what would happen if blood vessels near a wound did not dilate and become more permeable in response to chemical signals from leukocytes and damaged tissues.

MB Web Animation at www.masteringbio.com
The Inflammatory Response

The acquired immune response begins when cell-surface proteins on lymphocytes bind to an antigen—usually a protein from a disease-causing agent.

Lymphocytes are activated when T-cell receptors and B-cell receptors recognize an epitope on an antigen. The receptor protein on the surface of a T cell or B cell is generated through DNA recombination, a rearrangement of gene segments. Because every receptor that results from this process is slightly different, the immune system is able to recognize and respond to an almost limitless array of antigens.

You should be able to explain how a drug that bound to a particular epitope of an antigen would affect the activation of T cells with receptors specific to that antigen, the activation of B cells with receptors specific to that antigen, and the cell-mediated response to that antigen.

The humoral response tags pathogens for destruction with antibodies that are produced by lymphocytes called B cells.

During the humoral response, activated B cells produce antibodies to specific epitopes on the pathogen that has invaded the body. Viruses that become coated with antibodies are unable to enter host cells and are destroyed by macrophages. Bacteria that are tagged with antibodies are destroyed by complement proteins or by macrophages.

You should be able to explain why antibodies to a specific pathogen would act as an effective drug.

The cell-mediated response destroys infected cells via lymphocytes called T cells.

During the cell-mediated response, host cells that are infected with a virus display antigens on their surface and are destroyed by cytotoxic T cells. As a result, the virus particles inside are destroyed and cannot contribute further to the infection.

Because memory cells are created as activated B cells and T cells undergo clonal expansion, the immune system is able to respond rapidly and effectively to future infections by the same antigen. A vaccine triggers the production of memory cells because it contains epitopes from antigens.

You should be able to explain why the boy that Edward Jenner inoculated with cowpox became immune to smallpox.

The Acquired Immune Response

QUESTIONS

Test Your Knowledge

1. What is the primary difference between the innate and acquired responses?
   a. The innate response is modified over time; the acquired response occurs in the same way throughout life.
   b. Only the acquired response is triggered by antigens.
   c. The acquired response is specific and is "remembered"; the innate response is nonspecific.
   d. There is no nonself recognition component in the innate response.
2. All of the following events are involved in the inflammatory response *except*:
   a. Cytotoxic T cells kill infected host cells.
   b. Neutrophils phagocytize pathogens that stimulate their pattern-specific receptors.
   c. Mast cells secrete chemical messengers that lead to increased blood flow.
   d. Macrophages release chemical messengers that lead to increased body temperature.
3. What is the difference between an epitope and an antigen?
   a. An epitope is any foreign substance; an antigen is a foreign protein.
   b. An epitope is the part of an antigen where an antibody or lymphocyte receptor binds.
   c. An antigen is the part of an epitope where an antibody or lymphocyte receptor binds.
   d. Antigens are recognized by B cells and antibodies; epitopes are recognized by T cells.
4. How do B-cell receptors and antibodies differ?
   a. B-cell receptors are made up of heavy chains; antibodies are made up of light chains.
   b. B-cell receptors are made up of light chains; antibodies are made up of heavy chains.
   c. Only antibodies include a variable region.
   d. Antibodies lack a transmembrane domain and are secreted.
5. How do memory cells become activated?
   a. They undergo somatic hypermutation.
   b. They encounter an antigen complexed with an MHC protein.
   c. They undergo clonal expansion.
   d. They are stimulated by histamines.
6. In terms of morphology, T cells come in two major types. How are they distinguished?
   a. They have a CD4 or CD8 protein on their surfaces.
   b. They have extensive ER and many mitochondria.
   c. Only one type has pattern-recognition receptors.
   d. One type functions in the primary response; the other in the secondary response.

Test Your Knowledge answers: 1. c; 2. a; 3. b; 4. d; 5. b; 6. a

Test Your Understanding

Answers are available at www.masteringbio.com

1. To a physician, the classical signs of the inflammatory response are rubor (reddening), calor (heat), dolor (pain), and tumor (swelling). Explain why each symptom occurs. Mention at least two of the leukocytes and two of the chemical messengers that are involved in the inflammatory response.
2. Compare and contrast the general structure of a B-cell receptor and a T-cell receptor (make a sketch of each). Explain how each interacts with an antigen.
3. What do vaccines need to contain in order to be effective? Why don't we have vaccines for HIV? Why do people need to get a new flu shot every year?
4. Summarize the clonal-selection theory of acquired immune system function. How was the theory tested and verified?
5. Compare and contrast the interaction between (a) pathogens and the pattern-recognition receptors on leukocytes versus (b) antigens and BCRs or TCRs.
6. Explain how DNA recombination leads to the production of almost limitless numbers of different B-cell receptors, T-cell receptors, and antibodies.

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. If you were being treated for a badly skinned knee from a bicycle accident, health care workers would irrigate the wound with large volumes of sterile water, scrub it as thoroughly as possible with warm, soapy water, and then apply antibiotics. Explain why these measures are effective, in the context of how the innate and acquired immune responses operate.
2. Suppose you had an antibody to insulin. Explain how you would use this antibody to study the presence and concentration of insulin in the blood under different conditions (e.g., before and after a meal) and at different times in the development of an individual.
3. It seems astonishing that the immune system can produce antibodies to compounds that were recently synthesized for the first time in the lab. But because viruses and other pathogens are constantly mutating and producing new antigens over time, this observation should not be surprising at all. Explain.
4. During World War II, physicians discovered that if they removed undamaged skin from a patient and grafted it onto the site of a burn on the same patient, the tissue healed well. But if the grafted tissue came from a different individual, the skin graft was rejected—the cells were killed by the immune system. Explain why.

An Introduction to Ecology

50

In addition to providing habitat for a frog, the puddle of water inside this plant provides an environment for an array of microscopic species. The plant itself is growing in the branch of a rain forest tree, and is just one of hundreds of plant, fungal, bacterial, and insect species that live in association with the tree.

KEY CONCEPTS

- Ecology focuses on how organisms interact with their environment. Because its goal is to understand the distribution and abundance of organisms, ecology provides a scientific foundation for the conservation of species and natural areas.
- Physical structure—particularly water depth—is the primary factor that limits the distribution and abundance of aquatic species. Climate—specifically, both the average value and annual variation in temperature and in moisture—is the primary factor that limits the distribution and abundance of terrestrial species.
- Climate varies with latitude, elevation, and other factors. Climate is changing rapidly around the globe.
- In addition to abiotic aspects of the environment such as physical structure and climate, species distribution is constrained by historical and biotic factors.

Ecology is the study of how organisms interact with their environment. Except for the episode 65 million years ago, when a mountain-sized asteroid struck Earth, environments are changing more rapidly right now than they have at any time in the past 3.5 billion years. As human impacts on the planet accelerate, ecology is becoming an increasingly prominent field in biological science. Efforts to maintain human health and welfare depend on our ability to understand and predict the consequences of the rapid environmental changes occurring all around us.

One of ecology's central goals is to understand the distribution and abundance of organisms. In many cases an ecologist's job is to identify factors that dictate why certain species live where they do, and how many individuals can live there. Some biologists ask why orangutans are restricted to forests in Borneo and why their numbers are declining so rapidly. Other biologists create mathematical models to predict how quickly the human immunodeficiency virus will increase in India, or how long it will take for the current human population of 6.6 billion to double. The distribution and abundance of these species is dictated by their ecology.

This chapter has two goals: to explore how biologists go about studying ecology, and to analyze the major types of environments that organisms occupy. It is a springboard to subsequent chapters in this unit, which analyze how organisms interact with their environment and the consequences of

environmental change. In terms of understanding the biological problems that humans currently face, this may be the most important unit in the book.

50.1 Areas of Ecological Study

To understand why organisms live where they do and in what numbers, biologists break ecology into several levels of analysis. This is a common strategy in biological science. Cell biologists study how cells work at increasingly complex levels of organization—from individual molecules to complex multicellular organisms—while physiologists analyze processes at the level of ions and molecules as well as whole cells, tissues and organs, or a complete system. In ecology, researchers work at four main levels: (1) organisms, (2) populations, (3) communities, and (4) ecosystems. Let's examine each.

Organismal Ecology

At the finest level of organization, ecology focuses on how individuals interact with their environment. Researchers who study organismal ecology explore the morphological, physiological, and behavioral adaptations that allow individuals to live successfully in a particular area. The study of behavior is an important aspect of organismal ecology; it focuses on how organisms respond to particular stimuli from their environment (see Chapter 51). The environmental stimuli that trigger behavior may consist of changes in temperature or moisture, an escape response from prey, or a rival challenging for a mate. Organismal ecology also focuses on the physiological adaptations that allow individuals to thrive in heat, drought, cold, or other demanding physical conditions.

As an example, consider the sockeye salmon. After spending four or five years feeding and growing in the ocean, these salmon travel hundreds or thousands of kilometers to return to the stream where they hatched (**Figure 50.1a**). Females create nests in the gravel stream bottom and lay eggs. Nearby males compete for the chance to fertilize eggs as they are laid. When breeding is finished, all of the adults die.

At the level of organismal ecology, biologists want to know how these individuals interact with their physical surroundings and with other organisms in and around the stream. Which females get the best nesting sites and lay the most eggs, and which males are most successful in fertilizing eggs? How do individuals cope with the transition from living in salt water to living in freshwater?

Population Ecology

A **population** is a group of individuals of the same species that lives in the same area at the same time. When biologists study population ecology, they focus on how the numbers of individuals in a population change over time. Some of the tools that

(a) Organismal ecology

How do individuals interact with each other and their physical environment?

Salmon migrate from saltwater to freshwater environments to breed

(b) Population ecology

How and why does population size change over time?

Each female salmon produces thousands of eggs. Only a few will survive to adulthood. On average, only two will return to the stream of their birth to breed

(c) Community ecology

How do species interact, and what are the consequences?

Salmon are prey as well as predators

(d) Ecosystem ecology

How do energy and nutrients cycle through the environment?

Salmon die and then decompose, releasing nutrients that are used by bacteria, archaea, plants, protists, young salmon, and other organisms

FIGURE 50.1 Biologists Study Ecology at Four Main Levels.

population ecologists have developed to analyze and predict changes in population size are now being used to evaluate the fate of endangered species. For example, mathematical models of population growth have been used to predict the future of particular salmon populations (**Figure 50.1b**). Many salmon populations have declined precipitously as their habitats have become dammed or polluted, and salmon are an important source of food for both people and wildlife. If the factors that affect population size can be described accurately enough, mathematical models can assess the impact of proposed dams, changes in weather patterns, altered harvest levels, or specific types of protection efforts.

Community Ecology

A biological **community** consists of the species that interact with each other within a particular area. Researchers who study community ecology ask questions about the nature of the interactions between species and the consequences of those interactions. The work might concentrate on predation, parasitism, or competition. At this level of organization in ecology, biologists also analyze how groups of species respond to disturbances such as fires, floods, and volcanic eruptions. Because human activities are driving species to extinction and disturbing communities on a massive scale, community ecologists are being called on to generate hypotheses and data on how human impacts can be lessened.

As an example of the types of questions asked at the level of community ecology, consider the interactions among salmon and other species in the marine and stream communities where they live. When they are at sea, salmon eat smaller fish and are themselves hunted and eaten by orcas, sea lions, humans, and other mammals; when they return to freshwater to breed, they are preyed on by bears and bald eagles (**Figure 50.1c**). In both marine and freshwater habitats, salmon are subject to parasitism and disease. They are also heavily affected by disturbances—particularly changes in their food supply due to overfishing and the damming and degradation of breeding streams.

Ecosystem Ecology

Ecosystem ecology is an extension of community ecology. An **ecosystem** consists of all the organisms in a particular region along with nonliving components. These physical, or **abiotic** (literally, "not-living"), components include air, water, and soil. At the ecosystem level, biologists study how nutrients and energy move among organisms and between organisms and the surrounding atmosphere and soil or water. Because humans are adding massive amounts of nutrients to ecosystems all over the world and affecting energy flows and climate through global warming, this work has direct public policy implications. Ecosystem ecologists are responsible for assessing the impact of pollution and increased temperature on the distribution and abundance of species—in fact, on Earth's ability to support life.

Salmon are interesting to study at the ecosystem level because they form a link between marine and freshwater ecosystems. They harvest nutrients in the ocean and then, when they die and decompose, transport those molecules to streams (**Figure 50.1d**). In this way, salmon transport chemical energy and nutrients from one habitat to another. Because salmon are sensitive to pollution and to changes in water temperature, human-induced changes in marine and freshwater ecosystems have a large impact on their populations.

How Do Ecology and Conservation Efforts Interact?

The four levels of ecological study are synthesized and applied in conservation biology. **Conservation biology** is the effort to study, preserve, and restore threatened populations, communities, and ecosystems. Ecologists study how interactions between organisms and their environments result in a particular species being found in a particular area at a particular population size; conservation biologists apply these data to preserve species and restore environments. Conservation biologists are like physicians, except that instead of drawing on results from research in molecular biology and physiology, they draw on research in ecology and evolution. Instead of prescribing drugs for sick people, they prescribe remedies for threatened species and manage land to produce a diversity of species, clean air, pure water, and productive soils.

50.2 Types of Aquatic Ecosystems

If ecology is the study of how species interact with their environment, what makes up the environment? The short answer is that an organism's environment has both physical and biological components. The abiotic or physical components include temperature, precipitation, sunlight, and wind. The **biotic** ("living") components consist of other members of the organism's own species as well as individuals of other species.

Chapters 51–53 focus on biological interactions—how individuals interact with offspring, mates, competitors, predators, prey, and parasites. This chapter focuses on how the physical environment affects organisms. The discussion offers two payoffs: (1) Once you understand key aspects of the physical environment, you'll be able to think intelligently about the consequences of altering those conditions through global warming; and (2) knowledge of the physical environment will help you make sense of a fundamental observation—that no species lives everywhere. Organisms have a restricted set of physical conditions in which they can survive and thrive. Why?

Let's answer this question by analyzing the physical attributes of aquatic ecosystems in this section and focusing on the physical structure of terrestrial ecosystems in Section 50.3. Section 50.4 considers how global warming is affecting both types of environments.

What Physical Factors Play a Key Role in Aquatic Ecosystems?

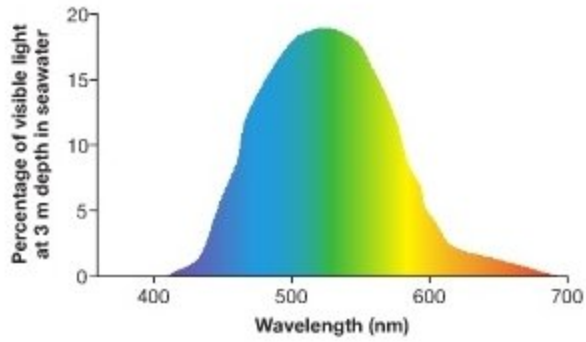
In aquatic ecosystems, water depth and the rate of water movement qualify as the key physical factors that shape the environment. Water depth dictates how much light reaches the organisms that live in a particular region. Water movement presents a physical challenge: It can literally sweep organisms off their feet.

Water absorbs and scatters light, so the amount and types of wavelengths available to organisms change dramatically as water depth increases. As **Figure 50.2a** shows, ocean water specifically removes light in the blue and red regions of the visible spectrum. This is important because wavelengths in the blue and red regions are required for photosynthesis in many species (see Chapter 10). The total amount of light available to organisms also diminishes rapidly with increasing depth. In pure seawater, the total amount of light available at a depth of 10 m is less than 40 percent of what it is at the surface, and virtually no light reaches depths greater than 40 m in pure seawater (**Figure 50.2b**). In seawater that contains organisms or debris, light penetration is dramatically less than that observed in pure seawater. Light has a major influence on **productivity**—the total amount of carbon fixed by photosynthesis per unit area per year. Different species are found at different depths in aquatic environments, simply because the physical environment changes so radically.

The type and amount of water movement or flow is the other major influence in aquatic environments. Organisms that live in fast-flowing streams have to cope with the physical force of the water, which constantly threatens to move them downstream. Marine organisms that live in intertidal regions are exposed to the air periodically each day, as well as to violent wave action during storms.

Different water depths and types of water movement define the array of aquatic environments that are available to organisms. The boxes that follow summarize the types of freshwater and marine environments that organisms occupy.

(a) Only certain wavelengths of light are available under water.



(b) Intensity of light declines with water depth.

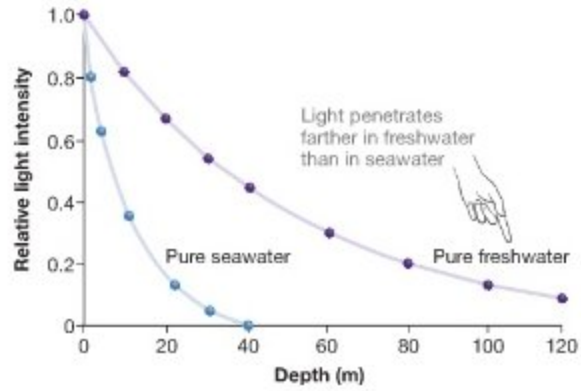


FIGURE 50.2 Availability of Light Changes Dramatically with Increasing Water Depth. (a) Graph showing the wavelengths of light available at a depth of 3 meters in seawater near an ocean coastline. **(b)** Graphs showing how rapidly the amount of light declines with depth of pure freshwater and pure seawater. When water contains organisms and organic debris, light availability declines even faster.

EXERCISE In green algae, photosynthesis is driven most efficiently by wavelengths of about 425 nm and 680 nm. Mark and label these wavelengths in part (a).

QUESTION What is the maximum depth you'd expect to find any photosynthetic organisms in freshwater? In salt water?

Freshwater Environments > Lakes and Ponds

Lakes and ponds are distinguished from each other by size. Ponds are small; lakes are large enough that the water in them can be mixed by wind and wave action. Most lakes and ponds occur in northern latitudes—they formed in depressions that were created by the scouring action of glaciers thousands of years ago. In the tropics, most lakes consist of old river channels. Elsewhere, many of the lakes and ponds that exist now were dug recently by people.

Water Depth Biologists describe the structure of lakes and ponds by naming five zones (**Figure 50.3**).

- The **littoral** ("seashore") **zone** consists of the shallow waters along the shore, where flowering plants are rooted.
- The **limnetic** ("lake") **zone** is offshore and comprises water that receives enough light to support photosynthesis.
- The **benthic** ("depths") **zone** is made up of the substrate.
- Regions of the littoral, limnetic, and benthic zones that receive sunlight are part of the **photic zone**.
- Portions of a lake or pond that do not receive sunlight make up the **aphotic zone**.

(Continued on next page)

Water Flow Water movement in lakes and ponds is driven by wind and temperature. The littoral and limnetic zones are typically much warmer and better oxygenated than the benthic zone, simply because they receive so much more solar radiation and are in contact with oxygen in the atmosphere. The benthic zone, in contrast, is relatively nutrient rich because dead and decomposing bodies sink and accumulate there. But as the temperature of the surface changes throughout the year, water from different depths can mix (see **Box 50.1**). Mixing driven by wind and changes in temperature allows well-oxygenated water from the surface to reach the benthic zone and nutrient-rich water from the benthic zone to enter the littoral and limnetic zones.

Organisms Cyanobacteria, algae, and other microscopic organisms, collectively called **plankton**, live in the photic zone, as do the fish that eat them. Animals (invertebrates and fish) that consume dead organic matter, or **detritus**, are common in the benthic zone.

● You should be able to predict which zone of lakes and ponds produces the most grams of organic material per m^2 per year, and explain your logic.

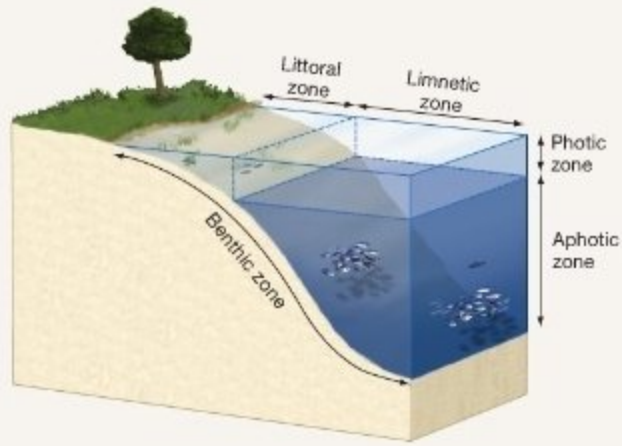

FIGURE 50.3 Lakes Have Distinctive Zones Defined by Water Depth and Distance from Shore.

BOX 50.1 Thermoclines and Lake Turnover

The northern and temperate regions of the world host many lakes. Each year, these bodies of water undergo remarkable changes known as the spring and fall **turnovers**.

The spring and fall lake turnovers occur in response to changes in air temperature. To see how this happens, examine the temperature profiles in **Figure 50.4**. In winter, water at the surface is locked up in ice at a temperature of 0°C. The water just under the ice is slightly warmer and is relatively oxygen rich, because it was exposed to the atmosphere as winter set in. The water at the bottom of the lake, in contrast, is at 4–5°C. A gradient in temperature such as this is called a **thermocline** ("heat-slope"); thermal stratification is said to occur. The water at the bottom is also oxygen poor, because organisms that decompose falling organic material use up available oxygen.

When spring arrives, the ice begins to melt. The temperature of the water rises until it reaches 4°C. This is important, because the density of liquid water is highest at 4°C. The water at the surface of the lake is now heavier than the water below it. As a result, it sinks. The water at the bottom of the lake is displaced and comes to the surface, completing the spring turnover. During the spring turnover, water at the bottom of the lake carries sediments and nutrients from the benthic zone up to the limnetic zone. This flush of nutrients triggers a rapid increase in the growth of algae and bacteria that biologists call the spring bloom.

When temperatures cool in the fall, the water at the surface reaches a temperature of 4°C and sinks, displacing water at the bottom and creating the fall turnover. The fall turnover is important because it brings oxygen-rich water from the surface down to the benthic layer, and because it again brings nutrients from the benthic zone up to the limnetic zone.

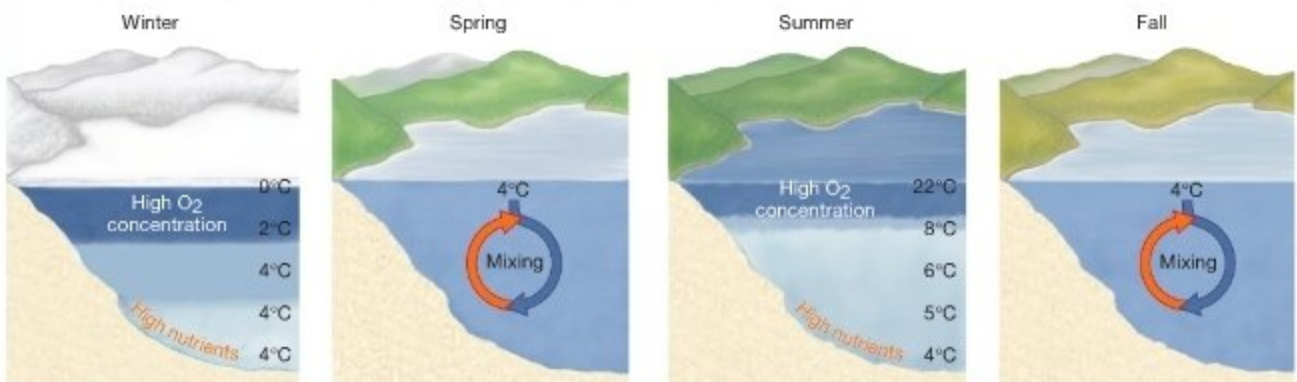

FIGURE 50.4 In Temperate Regions, Lakes Turn Over Each Spring and Fall.

● **QUESTION** In lakes like the one pictured here, there is a dramatic burst of photosynthesis each spring and fall. Why?

Freshwater Environments > Wetlands

Wetlands are shallow-water habitats where the soil is saturated with water for at least part of the year.

Water Depth Wetlands are distinct from lakes and ponds for two reasons: They have only shallow water, and they have **emergent vegetation**—meaning plants that grow above the surface of the water. All or most of the water in wetlands receives sunlight, and emergent plants capture sunlight before it strikes the water.

Water Flow Freshwater marshes and swamps are wetland types characterized by a slow but steady flow of water. **Bogs** (**Figure 50.5a**), in contrast, develop in depressions where water flow is low or nonexistent. If water is stagnant, oxygen is used up during the decomposition of dead organic matter faster than it enters via diffusion from the atmosphere. As a result, bog water is oxygen poor or even anoxic. Once the oxygen in the water is depleted, decomposition slows. Organic acids and other acids build up, lowering the pH of the water. At low pH, nitrogen becomes unavailable to plants (see Chapter 38).

Organisms The combination of acidity, lack of available nitrogen, and anoxic conditions makes bogs extremely unproductive habitats. Marshes and swamps, in contrast, offer ample supplies of oxygenated water and sunlight and are extraordinarily productive. **Marshes** lack trees and typically feature grasses (**Figure 50.5b**); **swamps** are dominated by trees and shrubs (**Figure 50.5c**). Because their physical environments are so different, there is little overlap in the types of species found in bogs, marshes, and swamps.

● You should be able to explain why carnivorous plants, which capture and digest insects, are relatively common in bogs but rare in marshes and swamps.

(a) Bogs are stagnant and acidic.

(b) Marshes have nonwoody plants.

(c) Swamps have trees and shrubs.

FIGURE 50.5 Wetland Types Are Distinguished by Water Flow and Vegetation.

Freshwater Environments > Streams

Streams are bodies of water that move constantly in one direction. Creeks are small streams; rivers are large. In terms of the environment that is available to organisms, the major physical variables in streams are the speed of the current and the availability of oxygen and nutrients.

Water Depth Most streams are shallow enough that sunlight reaches the bottom. Availability of sunlight is usually not a limiting factor for organisms.

Water Flow The structure of a typical stream varies along its length (**Figure 50.6**). Where it originates at a mountain glacier, lake, or spring, a stream tends to be cold, narrow, and fast. As it descends toward a lake, ocean, or larger river, a stream accepts water from tributaries and becomes larger, warmer, and slower.

Oxygen levels tend to be high in fast-moving streams because water droplets are exposed to the atmosphere when moving water splashes over rocks or other obstacles. Oxygen from the atmosphere diffuses into the droplets. In contrast, slow-moving streams that lack riffles or rapids tend to become relatively oxygen poor. Also, cold water holds more oxygen than warm water does (see Chapter 44).

(Continued on next page)

Freshwater Environments > Streams *continued*

Organisms It is rare to find photosynthetic organisms in small, fast-moving streams; nutrient levels tend to be low and most of the organic matter present consists of leaves and other materials that fall into the water from outside the stream. Fish, insect larvae, molluscs, and other animals have adaptations that allow them to maintain their positions in the fast-moving portions of streams. As streams widen and slow down, conditions become more favorable for the growth of algae and plants, and the amount of organic matter and nutrients increases. As a result, the same stream often contains completely different types of organisms near its source and near its end, or mouth.

● You should be able to explain why, in terms of their ability to perform cellular respiration, fish species found in cold, fast-moving streams tend to be much more active than fish species found in warm, slow-moving streams.

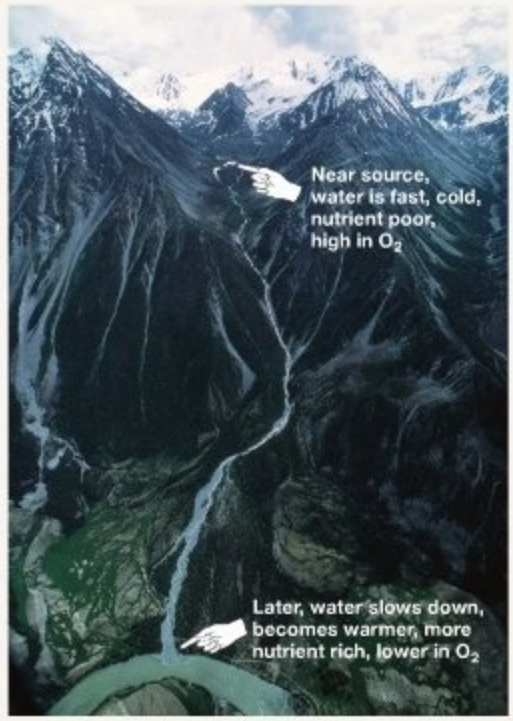

FIGURE 50.6 Distinctive Environments Appear along a Stream's Length.

Freshwater/Marine Environments > Estuaries

Estuaries form where rivers meet the ocean—meaning that freshwater mixes with salt water (**Figure 50.7**). In essence, an estuary includes slightly saline marshes as well as the body of water that moves in and out of these environments. Salinity varies with changes in river flows and with proximity to the ocean. Salinity has dramatic effects on osmosis and water balance (see Chapters 37 and 42); species that live in estuaries have adaptations that allow them to cope with variations in salinity.

Water Depth Most estuaries are shallow enough that sunlight reaches the substrate. Water depth may fluctuate dramatically, however, in response to tides, storms, and floods.

Water Flow Water flow in estuaries fluctuates daily and seasonally due to tides, storms, and floods. The fluctuation is important because it alters salinity, which in turn affects which types of organisms are present.

Organisms Because the water is shallow and sunlit, and because nutrients are constantly replenished by incoming river water, estuaries are among the most productive environments on Earth. They are often packed with young fish, which feed on abundant vegetation and plankton while hiding from predators.

● You should be able to compare and contrast the characteristics of estuaries and marshes, and explain why few of the same species are found in both.

FIGURE 50.7 Estuaries Are Highly Productive Environments. This photo was taken at low tide.

● **EXERCISE** Label freshwater environments, saltwater environments, and areas where freshwater and salt water are mixing.

Marine Environments > The Ocean

The world's oceans form a continuous body of salt water and are remarkably uniform in chemical composition. Regions within an ocean vary markedly in their physical characteristics, however, with profound effects on the organisms found there.

Water Depth Biologists describe the structure of an ocean by naming six regions (**Figure 50.8**).

- The **intertidal** ("between tides") **zone** consists of a rocky, sandy, or muddy beach that is exposed to the air at low tide but submerged at high tide.
- The **neritic zone** extends from the intertidal zone to depths of about 200 m. Its outermost edge is defined by the end of the **continental shelf**—the gently sloping, submerged portion of a continental plate.
- The **oceanic zone** is the "open ocean"—the deepwater region beyond the continental shelf.
- The bottom of the ocean is the **benthic zone**.
- The intertidal and sunlit regions of the neritic, oceanic, and benthic zones make up a **photic zone**.
- Areas that do not receive sunlight are in an **aphotic zone**.

Water Flow Water movement in the ocean is dominated by different processes at different depths. In the intertidal zone, tides and wave action are the major influences. In the neritic zone, currents that bring nutrient-rich water from the benthic zone of the deep ocean toward shore have a heavy impact. More specifically, nutrient-rich water is carried toward the surface when it hits the steep slope of the continental plate. Throughout the ocean, large-scale currents circulate water in the oceanic zone in response to prevailing winds and the Earth's rotation.

Organisms Each zone in the ocean is populated by distinct species that are adapted to the physical conditions present. Organisms that live in the intertidal zone must be able to withstand physical pounding from waves and desiccation at low tide. Productivity is high, however, due to the availability of sunlight and nutrients contributed by estuaries as well as by currents that sweep in nutrient-laden sediments from offshore areas.

Productivity is also high on the outer edge of the neritic zone, due to nutrients contributed by upwellings at the edge of the continental plate. Almost all of the world's major marine fisheries exploit organisms that live in the neritic zone. In the tropics, shallow portions of the neritic zone may host **coral reefs**. Because the water is warm and sunlight penetrates to the ocean floor in these habitats, coral reefs are among the most productive environments in the world (see Chapter 54).

If coral reefs are the rain forests of the ocean, then the oceanic zone is the desert. Sunlight is abundant in the photic zone of the open ocean, but nutrients are extremely scarce. When the photosynthetic organisms and the animals that feed on them die, their bodies drift downward out of the photic zone and are lost. In the open ocean, there is no mechanism for bringing nutrients back up from the bottom, as there is in the neritic zone or in most lakes (see Box 50.1). The aphotic zone of the open ocean is also unproductive because light is absent and photosynthesis is impossible. Most organisms present in the aphotic zone survive on the rain of dead bodies from the photic zone.

● You should be able to predict the following characteristics of fish that live in the aphotic zone: what they eat, whether they have eyes, whether they are capable of swimming, and whether they are rare or abundant.

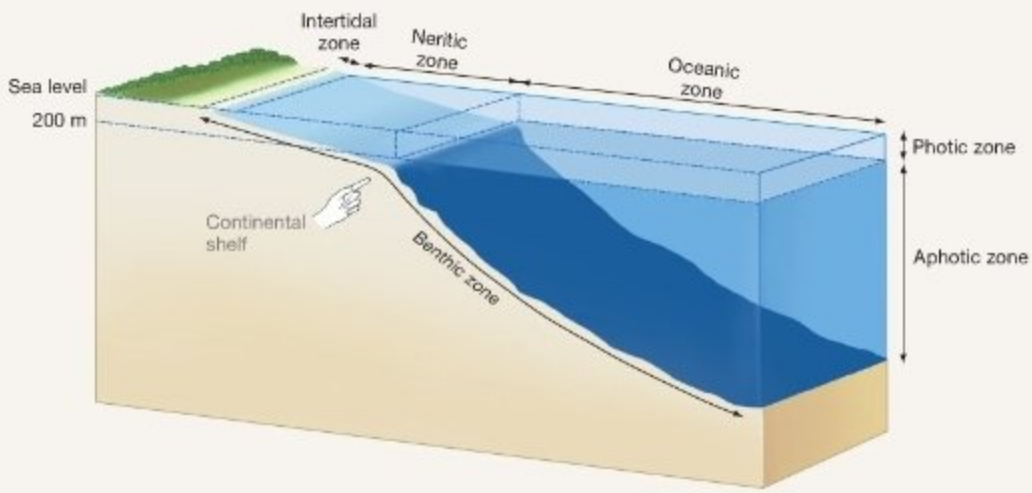

FIGURE 50.8 Oceans Have Distinctive Zones Defined by Water Depth and Distance from Shore.

Check Your Understanding

If you understand that...

- Aquatic environments are distinguished by the depth of water and the rate at which it moves.

You should be able to...

1) Explain why coastal environments are the most productive areas in the ocean.
2) Explain why bogs and marshes differ in productivity.

50.3 Types of Terrestrial Ecosystems

If you could walk from the equator in South America to the North Pole, you would notice startling changes in the organisms around you. Lush tropical forests with broad-leaved evergreen trees would give way to seasonally dry forests and then to deserts. The deserts would yield to the vast grasslands of central North America, which terminate at the boreal forests of the subarctic. If you pressed on, you would reach the end of the trees and the beginning of the most northerly community—the arctic tundra.

Broad-leaved evergreen forests, deserts, and grasslands are **biomes**: major groupings of plant and animal communities defined by a dominant vegetation type. **Figure 50.9** shows the global distribution of the most common types of biomes. Many distinct communities exist within each of these broad regions. For example, the Finger Lakes region of the northeastern United States is part of the temperate forest biome. However, the cool, wet, north-facing slopes in the area host plant communities dominated by eastern hemlock trees; warmer and drier south-facing slopes feature communities with red oak trees; and mild slopes and flat areas are covered with forests consisting of sugar maples and white oaks (**Figure 50.10**). The characteristics of these forest communities are similar enough to place them in the same biome, even though the specific species present vary with local conditions.

Each of the biomes found around the world is associated with a distinctive set of abiotic conditions. Just as water depth and movement have an overriding influence on aquatic ecosystems, the type of biome present in a terrestrial region depends on **climate**—the prevailing, long-term weather conditions found in an area. **Weather** consists of the specific short-term atmospheric conditions of temperature, moisture, sunlight, and wind.

- Temperature is critical because the enzymes that make life possible work at optimal efficiency only in a narrow range of temperatures (see Chapter 3). Temperature also affects the availability of moisture: Water freezes at low temperatures and evaporates rapidly at high temperatures.
- Moisture is significant because it is required for life, and because terrestrial organisms constantly lose water to the environment through evaporation or transpiration. To stay alive, they must reduce water loss and replace lost water.
- Sunlight is essential because it is required for photosynthesis.
- Wind is important because it exacerbates the effects of temperature and moisture. Wind increases heat loss due to evaporation and convection, and it increases water loss due to evaporation and transpiration. It also has a direct physical impact on organisms such as birds, flying insects, and plants by pushing them around.

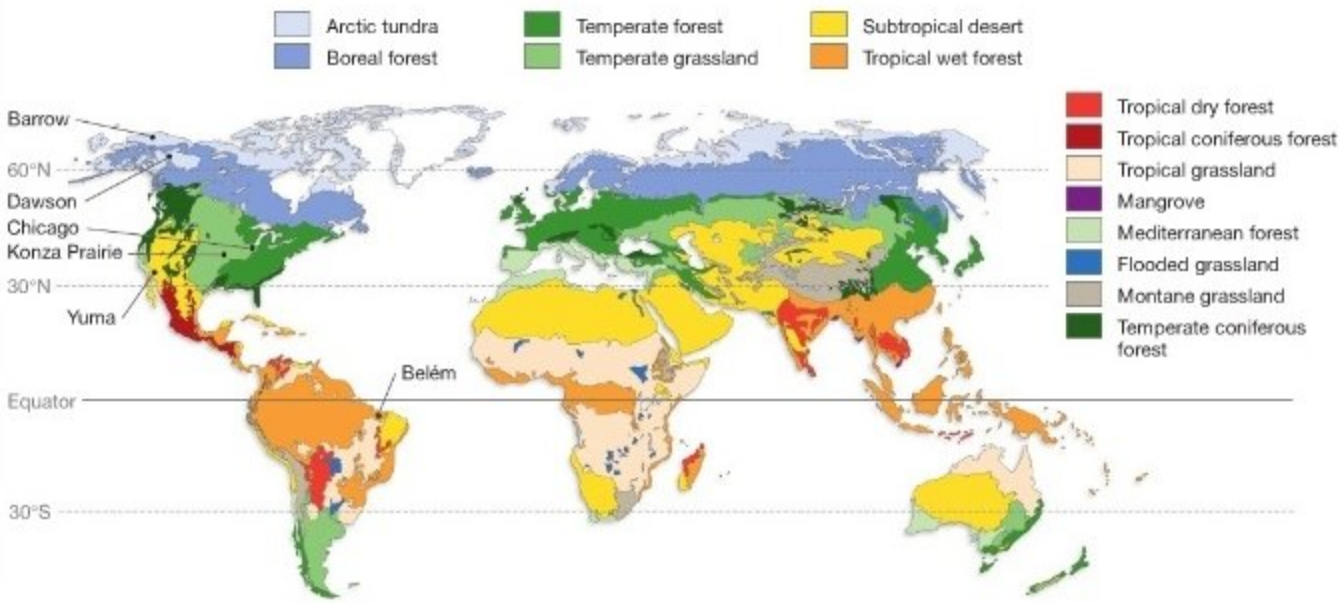

FIGURE 50.9 Distinct Biomes Are Found throughout the World. A recent classification identified the 14 major biomes shown here.

(a) Temperate forest biome: **Eastern hemlock community**

(b) Temperate forest biome: **Red oak community**

(c) Temperate forest biome: **Sugar maple community**

FIGURE 50.10 Biomes Contain Distinct Communities. Within even a small area, the same biome can contain several distinct plant and animal communities.

QUESTION These communities are found in the northeastern United States and southeast Canada. How would temperate forest communities in New Zealand or northern France compare?

Of the four components of climate, temperature and moisture are far and away the most important to plants. More specifically, the nature of the biome that develops in a particular region is governed by (1) average annual temperature and precipitation, and (2) annual variation in temperature and precipitation. Each biome contains species that are adapted to a particular temperature and moisture regime.

The amount and variability of heat and precipitation structure terrestrial environments, much as water depth and flow rate structure aquatic environments. On land, photosynthesis and plant growth are maximized when temperatures are warm and conditions are wet; conversely, photosynthesis cannot occur efficiently at low temperatures or under drought stress. Biologists are particularly concerned with **net primary productivity** (**NPP**), which is the total amount of carbon that is fixed per year minus the amount of fixed carbon oxidized during cellular respiration. Fixed carbon that is consumed in cellular respiration provides energy for the organism but is not used for growth—that is, production of **biomass**. NPP is key because it represents the organic matter that is available as food for other organisms. In terrestrial environments NPP is often estimated by measuring **aboveground biomass**—the total mass of living plants, excluding roots.

To help you understand how temperature and precipitation influence biomes, let's take a detailed look at the six biomes that represent Earth's most extensive vegetation types, ranging from the wet tropics to the arctic. In each case, you'll be analyzing temperature and precipitation data from a specific location, typical of the biome in question.

Check Your Understanding

If you understand that...

- In terrestrial environments, distinctive biomes develop based on two aspects of temperature and moisture: average value and variability over the year.

You should be able to...

Predict whether tropical dry forests, which have high year-round temperatures but a distinct dry season, are more or less productive than tropical wet forests.

Terrestrial Biomes > Tropical wet forest

Tropical wet forests—also called tropical rain forests—are found in equatorial regions around the world. Plants in this biome have broad leaves as opposed to narrow, needle-like leaves, and are evergreen. Older leaves are shed throughout the year, but there is no complete, seasonal loss of leaves.

Temperature The data in **Figure 50.11** are from Belém, Brazil, where mean monthly temperatures never drop below 25°C and never exceed 30°C. Compared to other biomes, tropical wet forests show almost no seasonal variation in temperature. This is important because temperatures are high enough to support growth throughout the year.

Precipitation Even in the driest month of the year, November, this region receives over 5 cm (2 in.) of rainfall—considerably more than the *annual* rainfall of many deserts.

Vegetation Favorable year-round growing conditions produce riotous growth, leading to extremely high productivity and aboveground biomass (**Figure 50.12**). Tropical wet forests are also

(Continued on next page)

Terrestrial Biomes > Tropical wet forest *continued*

renowned for their species diversity. It is not unusual to find over 200 tree species in a single 10 m × 100 m study plot. And based on counts of the insects and spiders collected from single trees, some biologists contend that the world's tropical wet forests may hold up to 30 million species of arthropods alone.

The diversity of plant sizes and growth forms in wet forest communities produces extraordinary structural diversity. In tropical wet forests, a few extremely large trees tower over a layer of large trees that form a distinctive **canopy** (the uppermost layers of branches). From the canopy to the ground, there is a complex assortment of vines, **epiphytes** (plants that grow entirely on other plants), small trees, shrubs, and herbs. This diversity of growth forms presents a wide array of habitat types for animals.

You should be able to explain which aspects of structural diversity in a rain forest are lacking in the biome where you live.

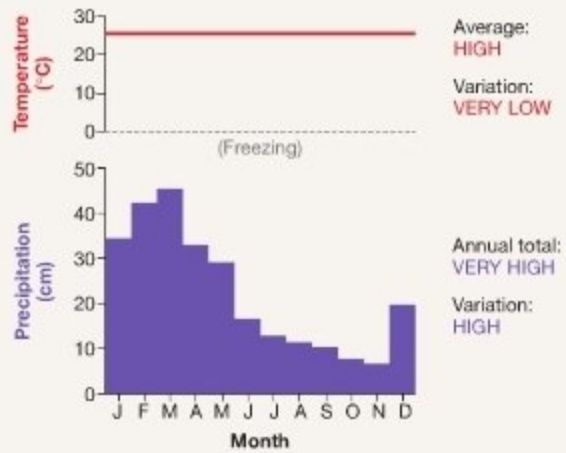

FIGURE 50.11 Belém, Brazil.

FIGURE 50.12 Tropical Wet Forest.

Terrestrial Biomes > Subtropical deserts

Subtropical deserts are found throughout the world in two distinctive locations: 30 degrees latitude, or distance from the equator, both north and south. Most of the world's great deserts—including the Sahara, Gobi, Sonoran, and Australian outback—lie on or about 30°N or 30°S latitude.

Temperature The data in **Figure 50.13** are from Yuma, Arizona, in the Sonoran Desert of southwestern North America. Mean monthly temperatures in subtropical deserts vary more than in tropical wet climates, but in Yuma temperatures still never fall below freezing. (Freezing nighttime temperatures are common elsewhere in the Sonora and in other subtropical deserts.)

Precipitation The most striking feature of the subtropical desert climate is low precipitation. The average annual precipitation in Yuma is just 7.5 cm (3 in.).

Vegetation The scarcity of water in deserts has profound implications. Conditions are rarely adequate to support photosynthesis, so the productivity of desert communities is a tiny fraction of average values for tropical forest communities. Further, as the photo in **Figure 50.14** shows, individual plants are widely spaced—a pattern that may reflect intense competition for water.

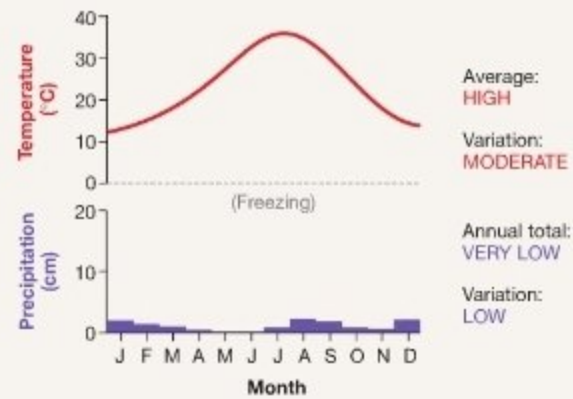

FIGURE 50.13 Sonoran Desert.

(Continued on next page)

Desert species adapt to the extreme temperatures and aridity in one of two ways: Growing at a low rate year-round, or breaking dormancy and growing rapidly in response to any rainfall. Cacti can grow year-round because they possess adaptations to cope with hot, dry conditions: small leaves or no leaves; a thick, waxy coating on leaves and stems; and the CAM pathway for photosynthesis (Chapter 10). The desert shrub called ocotillo, in contrast, is usually dormant. Individuals sprout leaves within days of a rainfall and drop them a week or two later when soils dry out again. The seeds of annual plants can also lie dormant for many years, then germinate after a rain.

- You should be able to be able to state hypotheses explaining why desert species are not found in rain forests, and why rain forest species are not found in deserts.

FIGURE 50.14 Subtropical Desert.

Terrestrial Biomes > Temperate grasslands

Temperate grassland communities are found throughout central North America and the heartland of Eurasia (see Figure 50.9). In North America they are commonly called prairies; in central Eurasia they are known as steppes.

Temperature A region of the world is called **temperate** if it has pronounced annual fluctuations in temperature—typically hot summers and cold winters—but not the temperature extremes recorded in the tropics or arctic. Temperature variation is important because it dictates a well-defined growing season. In the temperate zone, plant growth is possible only in spring, summer, and fall months when moisture and warmth are adequate. **Figure 50.15** presents climate data for a typical grassland community—in this case, the Konza Prairie near Manhattan, Kansas.

Precipitation Precipitation at Konza is over four times greater than that in Yuma, Arizona. Nonetheless, conditions are still quite dry; in no month is there more than 5 cm (2 in.) of precipitation.

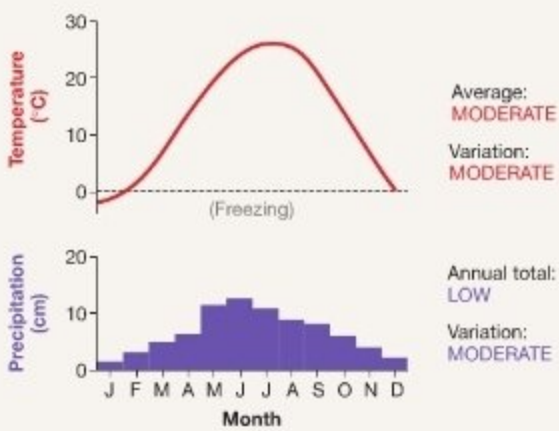

FIGURE 50.15 Konza Prairie.

Vegetation Grasses are the dominant life-form in temperate grasslands **Figure 50.16** for one of two reasons: (1) Conditions are too dry to enable tree growth, or (2) encroaching trees are burned out by fires. Prairie fires are ignited by lightning strikes or by native people managing land for game animals.

Although the productivity of temperate grasslands is generally lower than that of forest communities, grassland soils are often highly fertile. The subsurface is packed with roots and rhizomes, which add organic material to the soil as they die and decay. Further, grassland soils retain nutrients, because rainfall is low enough to keep key ions from dissolving and leaching out of the soil. It is no accident, then, that the grasslands of North America and Eurasia are the breadbaskets of those continents. The conditions that give rise to natural grasslands are ideal for growing wheat, corn, and other cultivated grasses.

- You should be able to explain why fires are much more common in grasslands than in deserts, even though deserts are drier.

FIGURE 50.16 Temperate Grassland.

In temperate areas with relatively high precipitation, grasslands give way to forests. Temperate forests are the most common biome found in eastern North America, western Europe, east Asia, Chile, and New Zealand.

Temperature As **Figure 50.17** shows, temperate forests experience a period in which mean monthly temperatures fall below freezing and plant growth stops. The data in this graph are from Chicago, Illinois, which was forested before being settled.

Precipitation Compared to grassland climates, precipitation in temperate forests is moderately high and relatively constant throughout the year. Chicago, for example, has an annual precipitation of 85 cm (34 in.); during most months, precipitation exceeds 5 cm (2 in.).

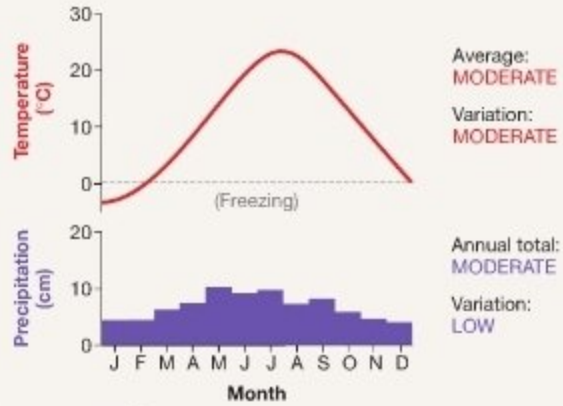

FIGURE 50.17 Chicago Temperate Forest.

FIGURE 50.18 Temperate Forest.

Vegetation In North America and Europe, temperate forests are dominated by deciduous species, which drop their leaves in autumn and grow new leaves in spring (**Figure 50.18**). Needle-leaved evergreens are also common. But in the temperate forests of New Zealand and Chile , broad-leaved evergreens predominate.

Most temperate forests have productivity levels that are lower than those of tropical forests yet higher than those of deserts or grasslands. The level of diversity is also moderate. A temperate forest in southeastern North America may have more than 20 tree species; similar forests to the north may have fewer than 10.

- You should be able to predict the type of biome that is found in regions with climate characteristics intermediate between those of grasslands and temperate forests.

The boreal forest, or **taiga**, stretches across most of Canada, Alaska, Russia, and northern Europe. Because these regions are just south of the Arctic Circle, they are referred to as subarctic.

Temperature The data in **Figure 50.19** are from Dawson, in the Yukon Territory of Canada. The region is characterized by very cold winters and cool, short summers. Temperature variation is extreme; in the course of a year, subarctic areas may be subject to temperature ranges of more than 70°C.

Precipitation Annual precipitation in boreal forests is low, but temperatures are so cold that evaporation is minimal; as a result, moisture is usually abundant enough to support tree growth.

Vegetation Boreal forests are dominated by highly cold-tolerant conifers, including pines, spruce, fir, and larch trees. Except for larches, these species are evergreen. Two hypotheses have been offered to explain why evergreens predominate in cold environ-

(Continued on next page)

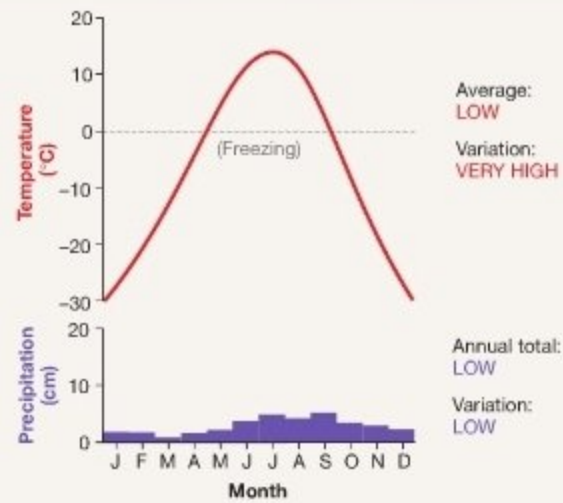

FIGURE 50.19 Yukon Territory.

Terrestrial Biomes > Boreal forests *continued*

ments, even though they do not photosynthesize in winter (**Figure 50.20**). The first is that evergreens can begin photosynthesizing early in the spring, even before the snow melts, when sunshine is intense enough to warm their needles. The second hypothesis is based on the observation that boreal forest soils tend to be acidic and contain little available nitrogen. Because leaves are nitrogen rich, species that must produce an entirely new set of leaves each year might be at a disadvantage. To date, however, these hypotheses have not been tested rigorously.

Based on these observations, it is not surprising that the productivity of boreal forests is low. Aboveground biomass is high, however, because slow-growing tree species may be long lived and gradually accumulate large standing biomass. Boreal forests also have exceptionally low species diversity. The boreal forests of Alaska, for example, typically contain seven or fewer tree species.

● You should be able to predict how the global distribution of boreal forests will change in response to global warming.

FIGURE 50.20 Boreal Forest.

Terrestrial Biomes > Arctic tundra

The arctic **tundra** biome, which lies poleward from the subarctic, is found throughout the arctic regions of the Northern Hemisphere and in regions of Antarctica that are not covered in ice.

Temperature Tundra develops in climatic conditions like those in Barrow, on the northern coast of Alaska (**Figure 50.21**). The growing season is 6–8 weeks long at most; for the remainder of the year, temperatures are below freezing.

Precipitation Precipitation on the arctic tundra is extremely low. The annual precipitation in Barrow is actually less than that in the Sonoran Desert of southwestern North America. Because of the extremely low evaporation rates, however, arctic soils are saturated year-round.

Vegetation The arctic tundra is treeless. The leading hypothesis to explain the lack of trees is that the growing season is too short and cool to support the production of large amounts of non-photosynthetic tissue. Also, tall plants that poke above the snow in winter experience substantial damage from wind-driven snow and ice crystals. Woody shrubs such as willows, birch, and blueberries are common, but they rarely exceed the height of a child. Most arctic tundra species hug the ground.

(Continued on next page)

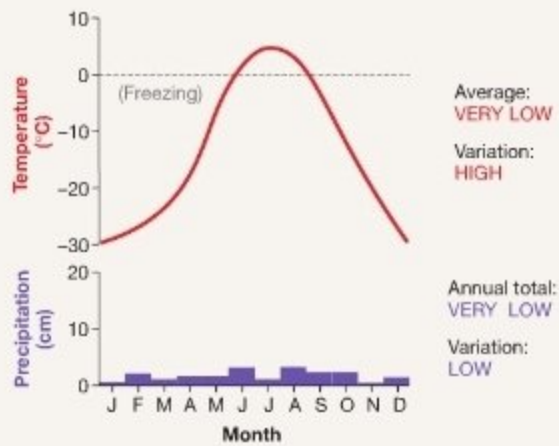

FIGURE 50.21 Barrow, Alaska.

Terrestrial Biomes > Boreal forests *continued*

Arctic tundra has low species diversity, low productivity, and low aboveground biomass. Most tundra soils are in the perennially frozen state known as **permafrost**. The low temperatures inhibit both the release of nutrients from decaying organic matter and the uptake of nutrients into live roots. Unlike desert biomes, however, the ground surface in tundra communities is completely covered with plants or lichens (**Figure 50.22**). Animal diversity also tends to be low in the arctic tundra, although insect abundance—particularly of biting flies—can be staggeringly high.

● You should be able to predict how arctic tundras compare and contrast to alpine tundras, which are found at high elevation.

FIGURE 50.22 Arctic Tundra.

50.4 The Role of Climate and the Consequences of Climate Change

Each type of aquatic environment and terrestrial biome hosts species that are adapted to the abiotic conditions present at that location. Global warming—due to rising concentrations of atmospheric CO_2 (see Chapter 54)—is having a profound impact on these abiotic factors. Runoff from melting glaciers and pole ice is changing water depths along coasts, and warming ocean waters are disturbing long-established patterns in the direction and intensity of ocean currents. On land, higher air temperatures are altering growing seasons and water availability in biomes around the globe.

To understand how global warming is affecting the distribution and abundance of organisms, biologists begin by studying why climate varies in predictable ways around the planet. Then they ask how changes in these climate patterns are affecting the organisms present, with the aim of predicting the consequences of continued change. Let's do the same.

Global Patterns in Climate

Simple questions often have fascinating answers. This turns out to be true for questions about why climate varies around the globe. For example, why are some parts of the world warmer and wetter than others? Why do seasons exist?

Why Are the Tropics Warm and the Poles Cold? In general, areas of the world are warm if they receive a large amount of sunlight per unit area; they are cold if they receive a small amount of sunlight per unit area. Over the course of a year, regions at or near the equator receive much more sunlight per unit area—and thus much more energy in the form of heat—than regions that are closer to the poles. At the equator, the Sun is often directly overhead. As a result, sunlight strikes Earth there at or close to a 90° angle. At these angles, Earth receives a maximum amount of solar radiation per unit area (**Figure 50.23**). But because Earth's surface slopes away from the equator, the Sun strikes the surface at lower and lower angles moving toward the poles. When sunlight arrives at a low angle, much less energy is received per unit area. The pattern of decreasing average temperature with increasing latitude is a result of Earth's spherical shape.

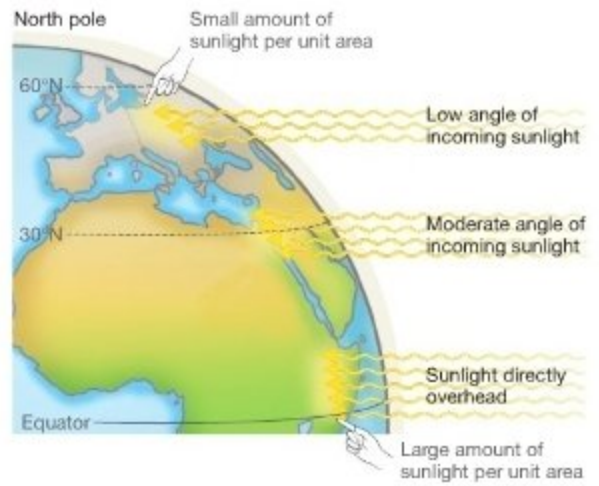

FIGURE 50.23 Solar Radiation per Unit Area Declines with Increasing Latitude. Over the course of a year, the Sun is frequently almost directly overhead at the equator. As a result, equatorial regions receive a large amount of solar radiation per unit area. At latitudes greater than 23.5°, the Sun is never directly overhead. As a result, high-latitude regions receive less solar radiation per unit area than do low-latitude regions.

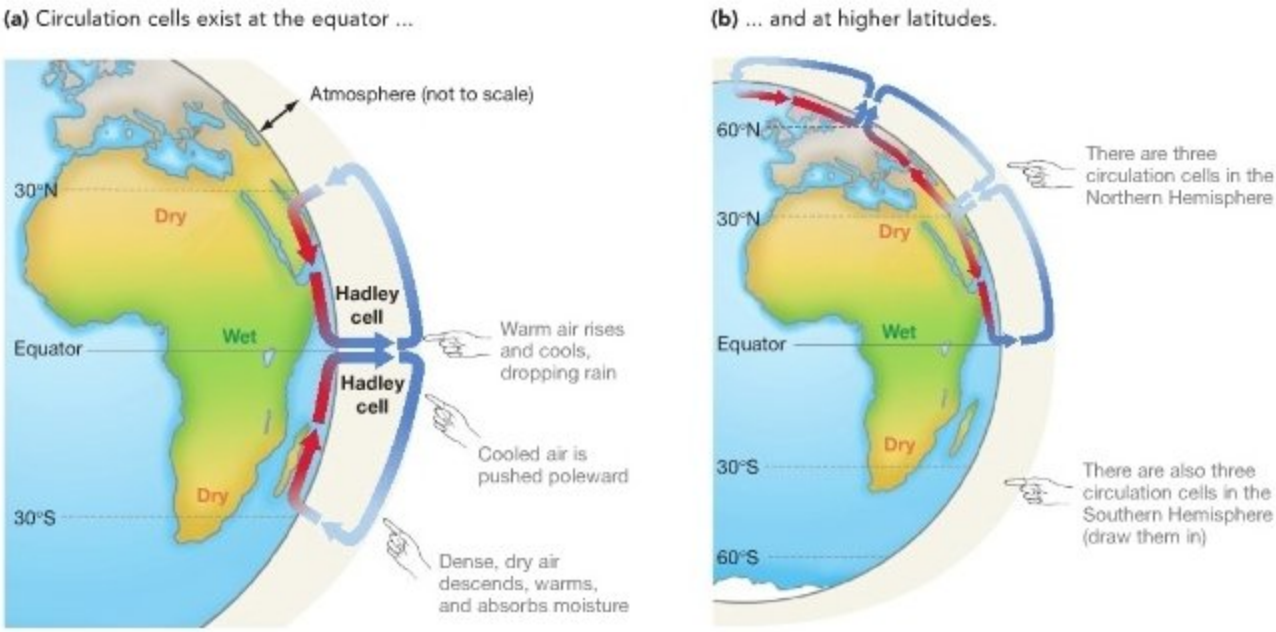

FIGURE 50.24 Global Air Circulation Patterns Affect Rainfall. Hadley cells explain why the tropics are much wetter than regions near 30° latitude north and south. Regions with rising air, such as those at the equator, tend to be wetter than regions with descending air.

● **QUESTION** Is air at the North Pole wet or dry? Is your answer consistent with the data in Figure 50.21?

Why Are the Tropics Wet? One of the most striking weather patterns on Earth involves precipitation. When average annual rainfall is mapped for regions around the globe, it is clear that areas along the equator receive the most moisture, while locations about 30 degrees latitude north and south of the equator are among the driest on the planet. Why do these patterns occur?

A major cycle in global air circulation, called a **Hadley cell**, is responsible for making the Amazon River basin wet and the Sahara Desert dry. Hadley cells are named after George Hadley, who in 1735 conceived of the idea of enormous air circulation patterns. As **Figure 50.24a** indicates, air that is heated by the strong sunlight along the equator expands and rises. Warm air can hold a great deal of moisture, because warm water molecules tend to stay in vapor form instead of condensing into droplets. As the air rises, however, it radiates heat to space. It also expands into the larger volume of the upper atmosphere, which lowers its density and temperature—a phenomenon known as adiabatic cooling. As rising air cools, its ability to hold water declines. When water vapor cools, water condenses. The result? High levels of precipitation occur along the equator.

As more air is heated along the equator, the cooler, "older" air above Earth's surface is pushed poleward. When the air mass has cooled enough, its density increases and it begins to sink. As it sinks, it absorbs more and more solar radiation reflected from Earth's surface and begins to warm. As the air warms, it also gains water-holding capacity. Thus, the air approaching the Earth "holds on" to its water and little rain occurs where it returns to the surface; the area is bathed in warm, dry air. The result is a band of deserts in the vicinity 30° latitude north and south. As this air moves toward each pole, it continues to pick up more moisture.

Similar air circulation cells occur between 30° and 60° of latitude, and between 60° latitude and the poles (**Figure 50.24b**).

● If you understand how Hadley cells work, you should be able to add diagrams to Figure 50.24b showing the three cells that occur in the Southern Hemisphere.

What Causes Seasonality in Weather? The striking global patterns in temperature and moisture that we've just reviewed are complicated by the phenomenon of seasons: regular, annual fluctuations in temperature, precipitation, or both. As **Figure 50.25** shows, seasonality occurs because Earth is tilted on its axis by 23.5 degrees. As a result of this incline, the Northern Hemisphere is tilted toward the Sun in June and faces the Sun most directly. Thus the Northern Hemisphere presents its least-acute angle to the Sun and receives the largest amount of solar radiation per unit area in June. The Southern Hemisphere, in contrast, is tilted away from the Sun in June, presents a steep angle for incoming sunlight, and receives its smallest quantity of solar radiation per unit area. As a result, in June it is summer in the Northern Hemisphere, and winter in the Southern Hemisphere. Conversely, in De-

FIGURE 50.25 Earth's Orbit and Tilt Create Seasons at High Latitudes. Seasons occur due to annual variation in the amount of solar radiation that different parts of the Earth receive.

cember it is summer in the Southern Hemisphere, and winter in the Northern Hemisphere. In March and September the equator faces the Sun most directly, so the tropics receive the most solar radiation then. If Earth did not tilt on its axis, there would be no seasons.

Mountains and Oceans: Regional Effects on Climate

The broad patterns of climate that are dictated by global heating patterns, Hadley cells, and seasonality are overlain by regional effects. The most important of these are due to the presence of mountain ranges and proximity to an ocean.

Figure 50.26 shows how mountain ranges affect regional climate, using the Cascade Mountain range along the Pacific Coast of North America as an example. In this area of the world, the prevailing winds are from the west. These winds bring moisture-laden air from the Pacific Ocean onto the continent. As the air masses begin to rise over the mountains, the air cools and releases large volumes of water as rain. As a result, the area along the Pacific Coast from northern California to southeast Alaska hosts some of the only high-latitude rain forests in the world. One area along the Pacific Coast of Washington State gets an average of 340 cm (134 in.) of precipitation each year. (Mountain ranges also occur along the Pacific Coast of Southern California and Mexico; but these areas are arid because they are dominated by dry air that is part of the Hadley circulation.)

Once cooled air has passed the crest of a mountain range, the air is relatively dry because much of its moisture content has already been released. Areas that receive this dry air are said to be in a **rain shadow**. One of the only high-latitude deserts in the world exists to the east of the Cascade Mountains. It is created by a rain shadow and averages less than 25 cm (10 in.) of moisture annually. Similar rain shadows create the Great Basin desert of western North America, the Atacama Desert of South America, and the dry conditions of Asia's Tibetan Plateau.

While the presence of mountain ranges tends to produce extremes in precipitation, the presence of an ocean has a moderating influence on temperature. To understand why this is so, recall from Chapter 2 that water has an extremely high **specific heat**, meaning that it has a large capacity for storing heat energy. Because water molecules form hydrogen bonds with each other, it takes a great deal of heat energy to boil water or melt ice—in fact, to change the temperature of water at all. The hydrogen bonds have to be broken before the water molecules

FIGURE 50.26 Mountain Ranges Create Rain Shadows. When moisture-laden air rises over a mountain range, the air cools enough to condense water vapor. As a result, moisture falls to the ground as precipitation. On the other side of the mountain, little water is left to provide precipitation.

QUESTION What conditions would create the wettest spots on Earth? The driest spots?

themselves can begin to absorb heat and move faster, which we measure as increased temperature.

Because water has a high specific heat, it can absorb a great deal of heat from the atmosphere in summer, when the water temperature is cooler than the air temperature. As a result, the ocean moderates summer temperatures on nearby landmasses. Similarly, the ocean releases heat to the atmosphere in winter, when the water temperature is warmer than the air temperature. As a result, islands and coastal areas have much more moderate climates than do nearby areas inland.

Tropical Atmospheric Circulation

How Will Global Warming Affect Ecosystems?

Climate—particularly the amount and variability of heat and precipitation—has a dramatic effect on terrestrial ecosystems. Climate also has a significant impact on aquatic ecosystems. Heat and precipitation influence ocean currents and lake turnover, as well as water levels in lakes, streams, and oceans.

It is now well established that CO_2 pollution is causing climate change (see Chapter 54). Climate has changed frequently and radically throughout the history of life, but recent increases in average temperatures around the globe, combined with a projected increase of up to 5.8°C over the next 100 years, represents one of the most rapid periods of climate change since life began.

Biologists use three tools to predict how global warming will affect aquatic and terrestrial ecosystems.

1. *Simulation studies* are based on computer models of weather patterns in local regions. By increasing average temperatures in these models, researchers can predict how wind and rainfall patterns, storm frequency and intensity, and other aspects of weather and climate will change. In effect, simulation studies predict how temperature and precipitation profiles, like those in Figures 50.11, 13, 15, 17, 19, and 21, will change.
2. *Observational studies* are based on long-term monitoring at fixed sites around the globe. Researchers are documenting changes in key physical variables—water depth, water flow, temperature, and precipitation—as well as changes in the distribution and abundance of organisms. By extrapolation, they can predict how change may continue at these sites.
3. *Experiments* are designed to simulate changed climate conditions, and to record responses by the organisms present.

Experiments That Manipulate Temperature Even though the scientific community did not become alert to the reality of global warming until the 1980s, a large number of multiyear experiments have already been done to test how increased temperature affects organisms in nature. Because arctic regions are projected to experience particularly dramatic changes in temperature and precipitation, many of these experiments have been done in the tundra biome.

FIGURE 50.27 Experimental Increases in Temperature Change Species Composition in Artic Tundra. The transparent, open-topped chambers shown here are an effective way to increase average annual temperature. Inside the chambers, species composition changes relative to otherwise similar sites nearby.

QUESTION Why does a clear chamber like this increase average temperature inside?

Figure 50.27 shows how the most successful of these experiments are done. Transparent, open-topped chambers are placed at random locations around a study site, and the characteristics of the vegetation inside the chambers are recorded annually. The same measurements are made in randomly assigned study plots that lack chambers.

Across experiments, the average annual temperature inside the open-topped chambers increases by 1–3°C. This increase is consistent with conservative projections for how temperatures will change over the next century. In a recent analysis of data from 11 such study sites scattered throughout the arctic in North America and Eurasia, several strong patterns emerged: Overall, species diversity decreases. Compared with control plots, grasses and shrubs increase inside the chambers, and mosses and lichens decrease. These results support simulation and observational studies predicting that arctic tundra environments are giving way to boreal forest. Biomes are changing right before our eyes.

Experiments That Manipulate Precipitation Recent simulation and observational studies have converged on a remarkable conclusion: Increases in average global temperature are increasing variability in temperature and precipitation. Stated another way, global warming is making climates more extreme. For example, the amount of precipitation and the wind speeds associated with monsoon rains, cyclones, hurricanes, and other types of storm events is increasing, even though their frequency may be unchanged.

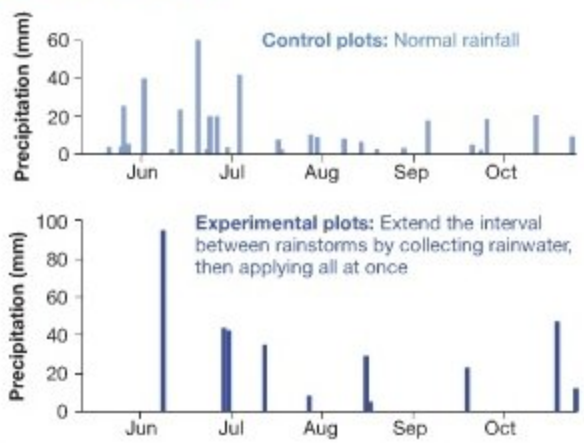
Experiment

Question: How does increasing variation in rainfall—without changing total amount—affect grassland biomes?

Hypothesis: Increasing variability in rainfall affects soil moisture, net primary productivity (NPP), and species diversity.

Null hypothesis: Increasing variability in rainfall has no effect on grassland biomes.

Experimental setup:

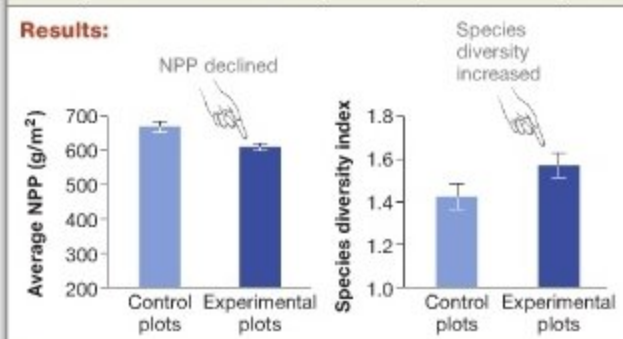


Record soil moisture, aboveground biomass (as an index of NPP), and species diversity, over a 4-year period.

Prediction: Soil moisture, NPP, and/or species diversity will differ between experimental plots and control plots.

Prediction of null hypothesis: Soil moisture, NPP, and species diversity will not differ between experimental plots and control plots.

Results:



Conclusion: Altering variability in rainfall has dramatic effects on soil moisture (data not shown), NPP, and species diversity.

FIGURE 50.28 Experimental Increases in Rainfall Variability Change Species Composition in Temperate Grasslands.

To test how increased variation in climate will affect a temperate grassland ecosystem, researchers set up the experiment described in **Figure 50.28**. The goal was to keep the average annual rainfall unchanged during the growing season, but increase variability. The biologists increased the severity of storms by capturing rain that fell over study plots during some storms and then applying that water to the same plots during later storms.

The results from the first four years of the experiment are striking: Average soil moisture and overall NPP declined in the experimental plots, compared with similar plots where rainfall was not manipulated. Overall species diversity is increasing in the high-variation plots, however, because the grass that produces most of the biomass at this site is doing poorly in the experimental plots—opening up room for other species to grow. The experiment is ongoing, however, because it is possible that long-term changes will differ from short-term changes, due to continued alterations in the species present.

Experiments like this are documenting that climate change causes dramatic alterations in the composition and distribution of biomes. Your world is changing.

Check Your Understanding

If you understand that...

- Global climate patterns are dictated by differential heating of Earth's surface, Hadley cells, and seasonality. These general patterns are modified at a regional scale by the presence of mountains and oceans.

You should be able to...

Predict how the biome where you live will change over the course of your lifetime.

50.5 Biogeography: Why Are Organisms Found Where They Are?

Understanding why organisms are found where they are is one of ecology's most basic tasks. It is a fundamental aspect of predicting the consequences of climate change, and is required for designing nature preserves in a rational and effective way.

The study of how organisms are distributed geographically is called **biogeography**. You were introduced to this subject in Chapter 26, which analyzed how continental drift has contributed to the current distributions of ostriches and their relatives. Biogeography will come up repeatedly in this unit as well: Chapter 53 analyzes general patterns in how species numbers vary around the world, and Chapter 54 presents data showing that the geographic ranges of many species are changing rapidly in response to global warming. Here, let's focus on how interactions with the abiotic and biotic environments affect where a particular species is able to live.

The most fundamental observation about the **range**, or geographic distribution, of species is simple: No one species can survive the full range of environmental conditions present on Earth. *Thermus aquaticus* cells thrive in hot springs with temperatures above 70°C. These archaea can live in this environment because they have enzymes that do not denature at

Copyright © 2010 Pearson Education, Inc. All rights reserved. Legal Notice | Privacy Policy | Permissions | Feedback

near-boiling temperatures. The same cells would die instantly, however, if they were transplanted to the frigid waters near polar ice. But vast numbers of other archaea are present in cold seawater. These cells have enzymes that can work efficiently at near-freezing temperatures. No organism thrives in both hot springs and cold ocean water, however. This observation is explained by the phenomenon called fitness trade-offs, introduced in Chapters 24 and 41: No enzyme can function well in both extremely high temperatures and extremely low temperatures.

Because of fitness trade-offs, organisms tend to be adapted to a limited set of physical conditions. Although some species have much broader geographic ranges than other species do—humans and the bacteria that live in and on them may have the widest distribution of any species at present—no organism can live everywhere.

To understand a species' distribution thoroughly, though, it is essential to examine historical and biotic factors in addition to the physical conditions present. For example, the temperature and moisture regimes of large areas of southern California, in North America, are almost identical to those found in the Mediterranean region of Europe and north Africa. Both regions are considered part of the same biome. But even though the physical conditions at these sites are extremely similar, the species present are almost completely different. Why?

The Role of History

To explain why certain species occur in a particular region while others don't, the first factor to consider is history—specifically, the history of dispersal. **Dispersal** refers to the movement of an individual from the place of its birth, hatching, or origin to the location where it lives and breeds as an adult. If a particular species is missing from an area, a physical barrier to dispersal—such as a river, a glacier, a mountain range, or an ocean—may be present. For example, the plant species found along North America's southwest coast are different from those found in the Mediterranean because the Pacific and Atlantic Oceans are effective barriers against the dispersal of seeds.

In many cases, human activity circumvents physical barriers to dispersal. For example, public health officials closely monitor annual flu outbreaks in south China—where most new strains originate—because they recognize that new strains disperse all over the planet in a matter of weeks or even days, via the respiratory passages of airplane passengers. Prior to the invention of air travel, disease epidemics in humans were much more likely to be confined to relatively small geographic areas.

Similarly, humans have transported thousands of seeds, birds, insects, and other species across physical barriers to new locations—sometimes purposefully and sometimes by accident. One accidental introduction has had disastrous consequences for the arid shrublands and grasslands of the western United States. In 1889 a native plant of Eurasia called cheatgrass was accidentally introduced to western North America in a shipment of crop seeds. Cheatgrass is an annual plant with seeds that germinate over winter, so that plants grow and set seed in early spring. As a result, cheatgrass seedlings get a "jump" on many North American plant species, which initiate growth later. Early growth allows cheatgrass to use more of the available water and nutrients. Within 30 years, cheatgrass had taken over tens of thousands of square miles of habitat (**Figure 50.29**).

If an **exotic** species —one that is not native—is introduced into a new area, spreads rapidly, and eliminates native species, it is said to be an **invasive species**. In North America alone, dozens of invasive species have had devastating effects on native plants and animals. Examples include kudzu, purple loosestrife, reed canary grass, garlic mustard, Russian thistle (also known as tumbleweed), European starlings, African honeybees, and zebra mussels. Similar lists could be compiled for other regions of the world.

Regarding the distribution of organisms, the story of invasive species is straightforward: They and other introduced species did not exist in certain parts of the world until recently, simply because they had never been dispersed there. But data show that only about 10 percent of the species introduced to an area actually become common, and a smaller percentage than that increases in population enough to be considered invasive. Why is it that some species introduced into an area do not thrive? Conversely, why are invasives so successful?

Biotic Factors

The distribution of a species is often limited by biotic factors—meaning interactions with other organisms. As an example, recall the data presented in Chapter 26 on the current and former

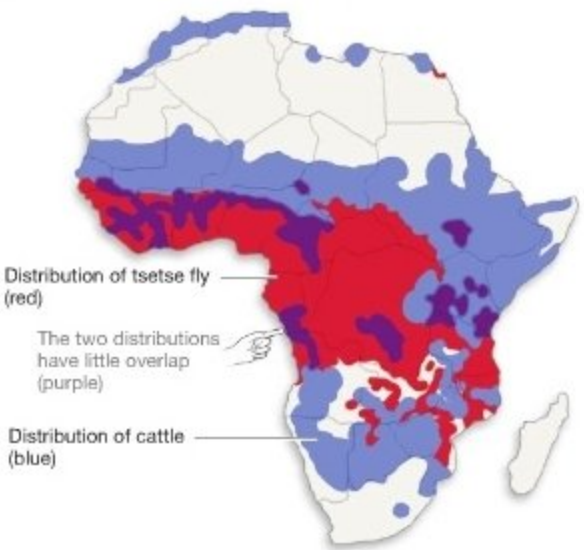
FIGURE 50.29 Cheatgrass Has Invaded Extensive Areas of North America.

Copyright © 2010 Pearson Education, Inc. All rights reserved. Legal Notice | Privacy Policy | Permissions | Feedback

distributions of hermit warblers and Townsend's warblers along the Pacific coast of North America. Both hermit warblers and Townsend's warblers live in evergreen forests. Experiments have shown that male Townsend's warblers directly attack male hermit warblers and evict them from breeding territories, and historical data indicate that the geographic range of Townsend's warblers has been expanding steadily at the expense of hermit warblers. The results support the hypothesis that a biotic factor—competition with another species—is limiting the range of hermit warblers.

Competition is not the only biotic factor to consider, however. In Africa, the range of domestic cattle is limited by the distribution of tsetse (pronounced *TSEE-tsee*) flies. Tsetse flies transmit a parasite that causes the disease trypanosomiasis, which is fatal in cattle (**Figure 50.30a**). Similarly, most of the songbirds native to Hawaii are limited to alpine habitats—above the range of the mosquitoes that transmit avian malaria. And the moth pictured in **Figure 50.30b** lays its eggs only in the flowers of yucca plants. As a result, this species does not exist outside the range of yucca plants.

(a) Distribution of cattle is limited by distribution of tsetse flies.



(b) Yucca moth distribution is limited by yucca plant distribution.

FIGURE 50.30 Distributions Can Be Limited by Biotic Factors. **(a)** Because tsetse flies carry a disease that is fatal to cattle, tsetse flies and cattle rarely coexist. **(b)** Because yucca moths lay their eggs only in the flowers of yucca plants, the moths cannot live where yucca plants are absent.

Abiotic Factors

In many cases, introduced species may not become established in a region because of abiotic factors—particularly temperature and moisture. An area may simply be too cold or too dry for an organism to survive. For example, even though the invasive plant kudzu grows prolifically throughout the southeastern United States, it is killed when the soil freezes to a depth of a foot or more. As a result, it has not expanded its range farther north and west.

It is often difficult to separate the effects of biotic and abiotic factors on a species' range, however. To drive this point home, consider how cheatgrass became established in North America. Cheatgrass does not grow in wet grasslands because it does not compete well against the tall species that thrive there. But it has been able to invade two important types of biomes in North America: dry temperate grasslands and the arid, shrub-dominated habitats known as sage-steppe. In each case, the reasons for the success of cheatgrass were different.

Cheatgrass has been able to invade sage-steppe habitats because it is not affected by fire. Fire is an abiotic factor that can kill the shrubs that dominate sage-steppe (**Figure 50.31**). In fact, because cheatgrass grows in dense beds and dies back in

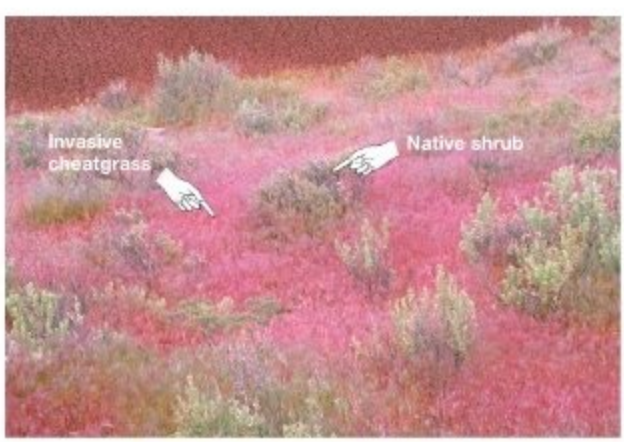


FIGURE 50.31 Sage-Steppe Is an Arid Biome Dominated by Shrubs. Large areas of western North America are covered with sage-steppe vegetation.

QUESTION If cheatgrass were not present, what would happen if a fire started here?

yright © 2010 Pearson Education, Inc. All rights reserved. Legal Notice | Privacy Policy | Permissions | Feedback

early spring, it actually leads to an increase in the frequency and intensity of wildfires. Normally, fires are rare in sage-steppe biomes, because plants are widely spaced. This distribution usually prevents fires from spreading and affecting a large area. But when this biome begins to dry in late summer, beds of dead cheatgrass offer a continuous, extremely flammable source of fuel. If a fire does come through, it does not affect the cheatgrass for two reasons: (1) Cheatgrass is an annual, so there is no living tissue exposed once the growing season is over, and (2) cheatgrass seeds sprout readily in soils that have been depleted of organic matter by fire. Because sagebrush and other shrubs are perennials, their tissues are heavily damaged or killed by hot fires. By promoting the frequency and intensity of fire in sage-steppe biomes, the presence of cheatgrass creates an environment that favors the spread of cheatgrass.

How has this species been able to invade dry grassland biomes? Prior to the arrival of cheatgrass, grasslands in arid areas of the American West were dominated by the types of bunchgrasses shown in **Figure 50.32**. Bunchgrasses do not form a continuous sod; instead, they grow in compact bunches. The spaces between these bunches are occupied by what biologists call "black-soil crust." This material is a community of soil-dwelling cyanobacteria, archaea, and other microorganisms that grow when moisture is available. Many of these species also fix nitrogen (see Chapter 38). The nitrogen becomes available to the surrounding plants when the microbial cells die and decompose.

When European settlers arrived and began grazing cattle in this biome, however, both the black soils and bunchgrasses were affected. Cattle grazed on the bunchgrasses until the grasses died, and their hooves compacted and disrupted the black soils. Neither component of the ecosystem was allowed to recover, in part because intensive grazing continued and in part because cheatgrass arrived. Cheatgrass shades out black-soil crust organisms. When black-soil crust is gone, the amount of nitrogen available to bunchgrasses is reduced. Cheatgrass also competes successfully with bunchgrasses for water and nutrients, because it completes its growth early in the spring—before the native bunchgrasses have broken dormancy and begun to grow. And as in sage-steppe habitats, the expansion of cheatgrass increased the frequency and severity of fires, which further degraded the integrity of black-soil crust communities.

To summarize, changes in abiotic and biotic factors allowed cheatgrass to invade native biomes in North America and thrive as an invasive species. Currently, managing cheatgrass is the major problem facing conservation biologists and rangeland managers in the western United States.

Although the story of cheatgrass is particularly dramatic, it is important to remember that the range of every species on Earth is limited by a combination of historical, abiotic, and biotic factors. The range of a particular species depends on dispersal ability, the capacity to survive climatic conditions, and the ability to find food and avoid being eaten. Climate and other abiotic factors were the focus of this chapter; the next several chapters focus on the biotic aspects of ecology. How do interactions among organisms of the same species and interactions among different species affect geographic range and population size?

FIGURE 50.32 Arid Grasslands Feature Bunchgrasses and Black-Soil Crust. As their name implies, bunchgrasses grow in compact bunches instead of forming a sod. The black-soil crust that forms between bunchgrasses is composed of cyanobacteria, archaea, and other microscopic organisms that add organic matter and nutrients to the soil.

QUESTION Suggest a hypothesis to explain why grasses with the bunching growth habitat tend to be found in dry habitats, as compared to grasses that form sods.

Chapter Review

SUMMARY OF KEY CONCEPTS

Ecology focuses on how organisms interact with their environment. Because its goal is to understand the distribution and abundance of organisms, ecology provides a scientific foundation for the conservation of species and natural areas.

Biologists study ecology at four main levels: (1) organisms, (2) populations, (3) communities, and (4) ecosystems. The goal of organismal biology is to understand how individuals respond to stimuli from the environment, including members of their own species and other species. Population ecology focuses on how and why populations grow or decline. Community ecology is the study of how two or more species interact, and ecosystem ecology analyzes interactions between communities of organisms and their abiotic environment—particularly the flow of energy and nutrients. In efforts to preserve endangered species and communities, conservation biologists apply analytical methods and results from all four levels.

You should be able to explain how data from ecology's four levels would inform efforts to preserve an endangered species such as polar bears, pandas, tigers, or blue whales.

Physical structure—particularly water depth—is the primary factor that limits the distribution and abundance of aquatic species. Climate—specifically, both the average value and annual variation in temperature and in moisture—is the primary factor that limits the distribution and abundance of terrestrial species.

Water depth is a crucial factor in aquatic ecosystems because the wavelengths of sunlight that are required for photosynthesis do not penetrate water efficiently. Thus, only certain zones in a lake or ocean can support photosynthesis, and organisms in other aquatic zones must depend on food that rains out of the sunlit areas near the surface.

Distinct climatic regimes are associated with distinct types of terrestrial vegetation, or biomes. Biomes represent the major types of environments available to terrestrial organisms. Because photosynthesis is most efficient when temperatures are warm and water supplies are ample, the productivity and degree of seasonality in biomes varies with temperature and moisture.

You should be able to design a man-made stream and lake system that would maximize the diversity of aquatic ecosystems present. You should also be able to comment on how increased temperatures alone (not considering changes in precipitation) might affect the biomes described in Figures 50.11 through 50.16.

Climate varies with latitude, elevation, and other factors. Climate is changing rapidly around the globe.

An array of abiotic factors affect organisms, including the chemistry of water in aquatic habitats; the nature of soils in terrestrial habitats; and climate, which is a combination of temperature, moisture, sunlight, and wind. Climate varies around the globe because sunlight is distributed asymmetrically, with equatorial regions receiving on average more solar radiation than do regions toward the poles. Hadley cells create bands of wet and dry habitats, and the tilt of Earth's axis causes seasonality in the amount of sunlight that non-equatorial regions receive. The presence of mountains can create local areas of wet or dry habitats, and proximity to an ocean moderates temperatures in nearby terrestrial habitats. Global warming is causing temperature profiles and precipitation patterns to change in ecosystems throughout the planet.

You should be able to explain how climate would be expected to vary around the Earth if the planet were cylindrical and spun on an axis that was at a right angle to the Sun.

MB **Web Animation** at www.masteringbio.com
Tropical Atmospheric Circulation

In addition to abiotic aspects of the environment such as physical structure and climate, a species' distribution is constrained by historical and biotic factors.

The range, or geographic distribution, of a particular species depends on dispersal ability, the capacity to survive climatic conditions, and the ability to find food and avoid being eaten. For each species, a unique combination of historical, abiotic factors, and biotic factors dictates where individuals live and the size of the population.

You should be able to describe conditions that would maximize the likelihood that an introduced species becomes invasive.

QUESTIONS

Test Your Knowledge

1. What is a rain shadow?
   a. the part of a mountain that receives prevailing winds and heavy rain
   b. the region beyond a mountain range that receives dry air masses
   c. the region along the equator where precipitation is abundant
   d. the region near 30°N and 30°S latitude that receives hot, dry air masses

2. A region receives less than 5 cm (2 in.) of precipitation annually and has temperatures that never drop below freezing. Which type of biome is present?
   a. subtropical desert
   b. temperate grassland
   c. boreal forest
   d. arctic tundra

yright © 2010 Pearson Education, Inc. All rights reserved. Legal Notice | Privacy Policy | Permissions | Feedback

3. What is the predominant type of vegetation in a tropical wet forest?
   a. shrubs and bunchgrasses
   b. herbs, grasses, and vines
   c. broad-leaved deciduous trees
   d. broad-leaved evergreen trees
4. The littoral zone of a lake is most similar to which of the following environments?
   a. oceanic zone
   b. intertidal zone
   c. neritic zone
   d. marsh
5. Typically, where are oxygen levels highest and nutrient levels lowest in a stream?
   a. near its source
   b. near its mouth, or end
   c. where it flows through a swamp or marsh
   d. where it forms an estuary
6. Which of the following is most important in the success of an invasive species?
   a. historical factors
   b. abiotic factors
   c. biotic factors
   d. Historical, abiotic, and biotic factors are equally important in limiting invasive species.

Test Your Knowledge answers: 1. b; 2. a; 3. d; 4. b; 5. a; 6. c

Test Your Understanding

Answers are available at www.masteringbio.com

1. Name the four main levels of study in ecology. Write a question about the ecology of humans, trout, or oak trees that is relevant to each level.
2. In June, does the Northern Hemisphere receive more or less solar radiation than the equator does? Explain your answer.
3. Diagram the Hadley cell that exists between the equator and 30° latitude south. Indicate the direction of air flow, regions where air is warming or cooling, and regions where air is gaining or losing moisture. Use your diagram to explain why the Australian Outback is a subtropical desert.
4. Contrast the productivities of the intertidal, neritic, and oceanic zones of marine environments. Explain why large differences in productivity exist.
5. Compare and contrast the biomes found at increasing elevation on a mountain with the biomes found at increasing latitude in Figure 50.9.
6. Explain why productivity is much lower in bogs than it is in marshes or lakes that receive the same amount of solar radiation.

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Mars has an even more pronounced tilt than Earth does. Does Mars experience seasons? Why or why not?
2. Mountaintops are closer to the Sun than the surrounding area is. Why are mountaintops cold?
3. The southwest corners of some Caribbean islands are extremely dry, even though other areas of the islands receive substantial rainfall. Explain this observation. Base your answer on a hypothesis (one that you propose) about the direction of the prevailing winds in this region of the world.
4. Edinburgh, Scotland, and Moscow, Russia, are at the same latitude, yet these two cities have very different climates—Moscow has much colder winters. Explain why.

www.masteringbio.com is also your resource for • Answers to text, table, and figure caption questions and exercises • Answers to *Check Your Understanding* boxes • Online study guides and quizzes • Additional study tools including the *E-Book for Biological Science* 3rd ed., textbook art, animations, and videos.

Behavior

51

Peregrine falcons hunt ducks and other large birds.

KEY CONCEPTS

- After describing a behavior, biologists seek to explain both its proximate and ultimate causes—meaning, how it happens at the genetic and physiological levels and how it affects the individual's fitness.
- In a single species, behavior may range from highly stereotyped, invariable responses to highly flexible, conditional responses and from unlearned to learned responses.
- The types of learning that individuals do, the way they communicate, and the way they orient and navigate all correlate closely with their habitat and with the challenges they face in trying to survive and reproduce.
- When individuals behave altruistically, they are usually helping close relatives or individuals that help them in return.

To biologists, **behavior** is action—specifically, the response to a stimulus. Pond-dwelling bacteria swim toward drops of blood that fall into the water. Time-lapse movies of growing sunflowers document the steady movement of their flowering heads throughout the day, as they turn to face the shifting Sun. Filaments of the fungus *Arthrobotrys* form loops, then release a molecule that attracts roundworms. When a roundworm touches one of these loops, the fungal filaments swell—ensnaring the worm. *Arthrobotrys* cells then proceed to grow into the worm's body and digest it.

Among animals, action may be frequent and even spectacular. Peregrine falcons reach speeds of up to 320 km/hr (200 mph) when they dive in pursuit of ducks or other flying prey. Some Arctic terns migrate over 32,000 km (20,000 miles) each year. Deep inside a hive, in complete darkness, honeybees communicate the position and nature of food sources a mile away.

Ecology is the study of how organisms interact with their physical and biological environments, and behavioral biology is the study of how organisms respond to particular stimuli from those environments. What does an *Anolis* lizard do when it gets too hot? How does that same individual respond when a member of the same species approaches it? Or when a house cat approaches?

Although all organisms respond in some way to signals from their environment, most behavioral research is performed on vertebrates, arthropods, or molluscs. With their sophisticated nervous systems and skeletal-muscular systems, these animals can sense, process, and respond rapidly to a wide array of environmental stimuli.

Although most behavioral studies start by describing what animals do in response to a particular stimulus, the eventual goal is to explain the proximate and ultimate causes of behavior.

Proximate, or mechanistic, **causation** explains *how* actions occur in terms of the neurological, hormonal, and skeletal-muscular mechanisms involved. **Ultimate**, or evolutionary, **causation** explains *why* actions occur—based on their evolutionary consequences and history. Is a particular behavior adaptive, meaning that it increases an individual's fitness? If so, how does it help individuals produce offspring in a particular environment?

To illustrate the proximate and ultimate levels of causation, consider the spiny lobster shown in **Figure 51.1**. These animals spend the day hiding in cracks or holes in coral reefs. At night they emerge and wander away from the reef in search of clams, mussels, crabs, or other sources of food. Before dawn, they return to one of several dens they use on a regular basis. How do they find their way back? This question is proximate in nature—it asks how an individual does what it does. Although research is continuing, recent experiments have provided strong support for the hypothesis that spiny lobsters have receptors in their brains that detect changes in Earth's magnetic field, and that they navigate by using information on how the orientation and strength of the field changes as they move about. At the ultimate level of causation, biologists want to know why the behavior occurs. The leading hypothesis to explain homing behavior is that the ability to navigate allows spiny lobsters to search for food over a wide area under cover of darkness, then return to a safe refuge before sharks and other large predators that hunt by sight can find them.

It is important to recognize that efforts to explain behavior at the proximate and ultimate levels are complementary. To understand what an organism is doing, biologists want to know how the behavior happens and why. Accomplishing this task requires them to draw on techniques and data from genetics, physiology, and evolutionary biology. But even though behavioral biologists work at the interface of many fields, their work is essentially ecological in nature. Questions about behavior are almost always aimed at understanding how individuals cope with changing physical conditions or how they interact with individuals of their own or other species—in short, how they interact with their environment.

The goals of this chapter are to explore some key topics in behavioral biology and illustrate the spirit of the field. To begin, let's consider one way to categorize and organize the enormous variety of behavioral responses observed in animals.

51.1 Types of Behavior: An Overview

Some types of behavior are performed nearly the same way every time. When people yawn, the action is so similar that every instance takes about 6 seconds. Other types of behavior are highly flexible. When people smile, the action is variable. The same person may smile in dozens of ways, and different people tend to have their own individual style and frequency of smiling. In addition, some types of behavior are readily modified by learning, while other types of behavior are not. Formally, **learning** is defined as a change in behavior that results from a specific experience in the life of an individual. Human infants learn their native language through imitation and trial and error, but they begin to yawn and smile before they have a chance to learn these actions from their parents.

Figure 51.2 offers one way of summarizing these general observations about behavior. Notice that the graph has two axes.

FIGURE 51.1 Spiny Lobsters Can Find Their Way Back to Their Home Burrow. Spiny lobsters wander widely in search of food at night, then return to their hiding places in coral reefs before dawn.

QUESTION Compared to other lobsters, spiny lobsters have extremely long antennae for their body size. Generate a hypothesis to explain why. (Your hypothesis will be at the ultimate level of causation.)

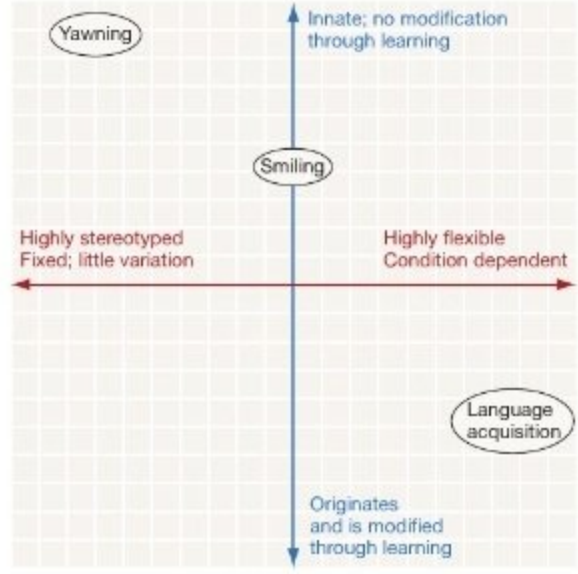

FIGURE 51.2 Behavioral Traits Vary in Flexibility and Dependence on Learning. These axes represent one way to organize the diversity of behavioral traits. Each type of behavior observed in a species could be plotted at a particular point on the graph.

The horizontal axis maps how flexible a behavior is in terms of its expression within and between individuals of the same species. This axis forms a continuum ranging from fixed, invariant, behaviors (often referred to as stereotyped behaviors) to highly flexible and variable responses. The vertical axis plots how much learning is involved in the nature of the response. This axis ranges from behaviors that require little or no learning for normal expression to responses that are highly dependent on learning. In humans, yawning would map in the upper left-hand corner of this graph. Language acquisition would be plotted in the lower right-hand corner.

When researchers first began to explore animal behavior experimentally, they focused on responses that are highly stereotyped and largely unlearned. This general research strategy is common in biological science. When biologists start to analyze a question—ranging from how DNA is transcribed to how plasma membranes work—they start by studying the simplest possible system. Once simple systems are understood, investigators can delve into more complex situations and questions. Behavioral biology started the same way. Early work focused on inflexible behavioral responses—those that map to the upper left-hand corner of the graph in Figure 51.2. Let's look at some conclusions from these pioneering studies of stereotyped responses, then consider examples of work on more flexible types of behavior.

Innate Behavior

Highly inflexible behavior patterns are called **fixed action patterns**, or **FAPs**. FAPs are stereotyped—meaning that they are performed in the same way every time—and are usually triggered by simple stimuli called **releasers** or **sign stimuli**. As an example, consider what happens in a darkened environment when a kangaroo rat hears the sound of a rattlesnake's rattle, or when a person hears a piercing scream. In both cases, a simple sign stimulus releases a FAP—a rapid jumping movement backward, away from the direction of the stimulus. In both cases, the FAP may result in survival. But kangaroo rats and humans don't learn to do this jump-back response, and it is performed in virtually the same way in response to the same stimulus. FAPs are examples of what biologists call **innate behavior**—behavior that is inherited and shows little variation based on learning or the individual's condition. (**Box 51.1** explores the role of genetics in behavior in more detail.)

It is common to observe innate behavior in response to (1) situations that have a high impact on fitness and demand a

BOX 51.1 A Closer Look at Behavior Genetics

Biologists explore the genetic bases of behavior to understand the proximate mechanisms responsible for specific behavioral traits. Are certain alleles associated with certain types of behavior? If so, how do the products of these alleles change what an individual does in response to certain stimuli?

To explore how biologists are answering these questions, consider the first gene shown to affect feeding behavior. When Marla Sokolowski was working as an undergraduate research assistant, she noticed that some of the fruit-fly larvae she was studying tended to move after feeding at a particular location, while others tended to stay put. By rearing these "rovers" and "sitters" to adulthood, breeding them, and studying the offspring, she was able to determine that the trait is inherited. Using information from the *Drosophila melanogaster* genome sequence (see Chapter 20) and genetic mapping techniques introduced in Chapter 19, Sokolowski found and cloned the gene responsible for the rover-sitter difference. She named it *foraging* (*for*).

Follow-up work showed that the protein product of *for* is involved in a signal transduction cascade (see Chapters 8 and 47)—meaning it is involved in the response to a signal. Rovers and sitters behave differently because they have different alleles of the *for* gene. The difference in behavior is apparent only in the presence of food, however.

By altering population density experimentally and documenting the reproductive success of rovers and sitters, Sokolowski has shown that the rover allele is favored when population density is high, but that the sitter allele reaches high frequency in low-density populations. These results are exciting because they link a proximate mechanism with an ultimate outcome—in this case, the presence of certain alleles is responsible for a difference in fitness in specific types of habitats. Genes that are homologous to *for* have now been found in honeybees and the roundworm *Caenorhabditis elegans*. Currently, researchers are focused on finding out which signaling pathway uses the *for* gene product and why different alleles lead to different types of feeding behavior.

Although the *for* gene presents a compelling story, biologists recognize that it is rare for behavioral traits to be so heavily affected by a single gene product. In reality, most aspects of behavior are influenced by the action of many genes. (Think of the number of genes that are likely to be involved in forming the human brain and thus in aspects of human personality and decision making.) To use a term that was introduced in Chapter 13, most behavioral traits are polygenic. Instead of representing discrete states such as roving and sitting, polygenic traits exhibit quantitative variation—meaning that individuals differ by degree and that many different phenotypes are observed when the population is considered as a whole.

reflex-like, unlearned response, or (2) situations where learning is not possible. Web-weaving in spiders and nest-building in birds are largely innate, because offspring have little or no opportunity to watch adults perform these behaviors and learn from them. In addition, the quality of a web or a nest has a high impact on fitness in spiders and birds—individuals need to get it right the first time.

Conditional Strategies and Decision Making

Although all species studied to date show some degree of innate behavior, it is much more common for an individual's behavior to change in response to learning and to show flexibility in response to changing environmental conditions. Animals are not stimulus-response machines. Instead, they take in information from the environment and, based on that information, make decisions about what to do. Animals make choices.

It is generally assumed that animals do not make conscious decisions. In most cases, though, biologists know relatively little about the proximate mechanisms involved in flexible responses and decision making. Fortunately, flexibility in behavior is well understood at the ultimate level. The guiding principle here is what biologists call cost-benefit analysis. Animals appear to take in information about their environment and weigh the costs and benefits of responding in various ways. Costs and benefits are measured in terms of their impact on fitness—the ability to produce offspring. As the following three examples show, individuals usually choose the option that maximizes their fitness.

What Decisions Do White-Fronted Bee-Eaters Make When Foraging? Given a choice, what should an animal eat? Biologists answered this question by assuming that individuals should forage in a way that maximizes the amount of usable energy they take in, given the costs of finding and ingesting their food and the risk of being eaten while they're at it. This claim—that animals should maximize their feeding efficiency—is called **optimal foraging**.

To test whether optimal foraging actually occurs, a researcher began studying feeding behavior in a bird called the white-fronted bee-eater (**Figure 51.3a**). Mated pairs of this species dig tunnels in riverbanks and raise their young inside. Appropriate riverbanks are rare, so many pairs build tunnels in the same location, forming a colony. To feed their young, pairs have to fly away from the colony, capture insects, and bring the prey back to the nest. Each pair defends a specific area where only they find food.

The key observation here is that some individuals forage a few meters from the colony, while some have to look for food hundreds of meters away. It takes only a few seconds to make a round trip to the closest feeding territories versus several minutes to the farthest territories. Thus, the fitness cost of each feeding trip varies widely among individuals.

(a) White-fronted bee-eaters are native to East Africa.

Birds fly from their nesting colony to a foraging area, which might be close to the colony or far away

(b) Foraging behavior depends on distance traveled.

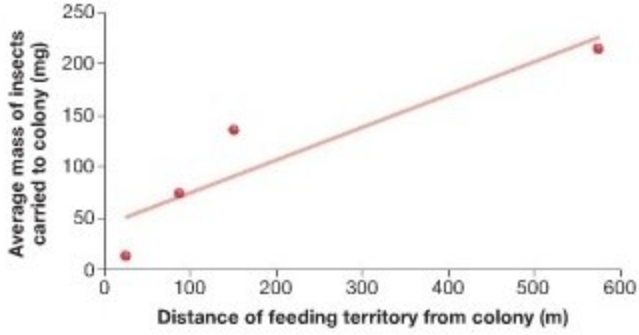

FIGURE 51.3 White-Fronted Bee-Eaters Vary Their Foraging Behavior Depending on Conditions.

If optimal foraging occurs, how do individuals maximize their benefits, given the cost they have to pay in time and energy? Individuals that have to find food far from the colony stay away longer on each trip. And as the data in **Figure 51.3b** show, individuals foraging far from the colony bring back a much larger mass of insects on each trip, on average, than do individuals that fly a short distance each time.

White-fronted bee-eaters appear to make decisions that maximize the energy they deliver to their offspring, given their costs in finding food. This behavior is highly flexible and condition dependent. If the same individual had a territory close to the colony instead of far away, it would make different decisions. Its behavior would change, but in each case it would be acting in a way that maximizes its fitness.

How Do Female Barn Swallows Choose Mates? Given a choice, who should an individual choose for a mate? Chapter 25 presented data indicating that females are usually the gender that is pickiest about mate choice, and that females choose males that contribute good alleles and/or resources to their offspring.

To see this type of decision making in action, consider an experiment on mate choice by female barn swallows native to Denmark. Although both male and female barn swallows help to build the nest and feed the young, the species exhibits a significant amount of sexual dimorphism—males are slightly

FIGURE 51.4 Barn Swallows Are Sexually Dimorphic.

larger and more brightly colored, and their outer tail feathers are about 15 percent longer than the same feathers in females (**Figure 51.4**). Research on other bird species has shown that individuals with particularly long tails, bright colors, and energetic courtship displays are usually the healthiest and best fed in the population (see Chapter 25). Recent work has shown that barn swallows with particularly long tails are more efficient in flight and thus more successful in finding food. If a female barn swallow chooses to mate with a long-tailed male, then she should be picking an individual that will pass high-fitness alleles on to her offspring *and* be able to help her rear them efficiently.

A researcher tested this prediction by altering tail length experimentally—in this case, by cutting off tail feathers and re-gluing them. The operation is painless and does not appear to affect flying ability. As the "Experimental Setup" section of **Figure 51.5** shows, the biologist caught a large series of males and randomly assigned them to one of four groups: shortened tails, "sham-operated" unchanged tails, untouched tails, and elongated tails. When he documented how long it took males in each group to find a mate, a strong trend emerged: Long-tailed males mated earliest—meaning that females preferred

Experiment

Question: Does tail length in barn swallows affect female choice of mates?

Hypothesis: Females prefer to mate with the longest-tailed males.

Null hypothesis: Tail length in males has no influence on female choice of mates.

Experimental setup:

Capture many males at the same site and randomly assign them to 1 of 4 groups:

Short tail: Outermost tail feathers cut

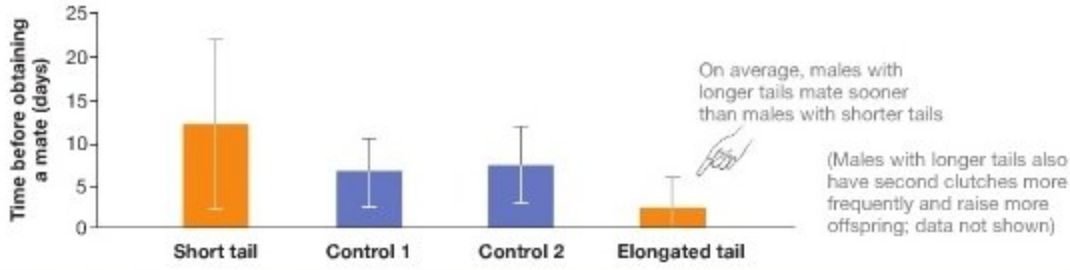
Control 1: Outermost tail feathers cut and glued back in place

Control 2: Males caught and handled, but no change in tail feathers

Elongated tail: Outermost feathers cut and elongated with feathers from other males, glued in place

Release males and document which males are first to mate, have a second nest that season, and raise the most offspring.

Results:



Conclusion: Females prefer to mate with long-tailed males.

FIGURE 51.5 Barn Swallow Females Prefer to Mate with Long-Tailed Males.

● **QUESTION** Why did the investigator bother to artificially lengthen and shorten tails? Why didn't he just record natural variation in tail length and observe mating success?

● **QUESTION** Why did he employ two controls?

them. This finding is important because pairs that nest early have time to complete a second nest later in the season and thus produce the most offspring.

Data on mate choice in barn swallows reinforce a central theme of this chapter: Animals make decisions in a way that maximizes their fitness.

Why Do Some Bluehead Wrasses Undergo a Sex Change? Many species of coral-reef fish have a distinctive mating system. Males defend territories that contain nesting sites and feeding areas. A group of females live inside the boundaries of this territory. When these females lay eggs, the male fertilizes the eggs. Thus, a single male monopolizes all the matings in that territory. Invariably, this male is the largest individual in the group. This is logical because the male guards the territory, and because fights between fish are usually won by the biggest contestant.

When the territory-holding male dies, however, something unusual happens. The largest female in the group changes sex. Her reproductive organs change from egg production to sperm production, and her coloration changes (**Figure 51.6**). She becomes the dominant male and begins fertilizing all of the eggs laid in the territory.

Why does she do this? An idea called the size-advantage hypothesis states that if a group of fish are living in a territory dominated by a single male, and if that male dies, then females should switch from female to male if their body size is very large. The hypothesis is based on the observation that fish have indeterminate growth—meaning they continue growing throughout their lives.

To understand the logic behind the size-advantage hypothesis, suppose that a small female fish can lay 10 eggs a year but a large female of the same species can lay 20 eggs a year. If six small females and two large females live in a harem, the male that owns the territory fertilizes 100 eggs each year. If the male dies, the largest female can increase the number of offspring she produces each year from 20 to 80 by changing sex and taking over the role of dominant male. The switch is costly in terms of time and energy, but the benefit is large. There is no fitness advantage for smaller females to switch sex, though, because they would be defeated in fights and have 0 offspring per year instead of 10.

Like foraging in white-fronted bee-eaters, sex change in bluehead wrasses is flexible and condition dependent. If conditions don't change, females remain female. If conditions change, the same individual will stay female if she is small but become a male if she is large. In many cases animals have alleles that make a wide range of behavior possible; what an individual actually does is based on decisions that change, depending on conditions.

What other types of factors lead to flexible behavior? In many species, learning is crucial. Chapter 45 showed that at the proximate level, learning occurs because individual neurons and connections between neurons are modified in response to experience. For example, recall that in the sea slug *Aplysia*, the production of the neurotransmitter serotonin changes in response to experience. Changes in serotonin release lead to changes in the behavior of sea slugs in response to attacks by predators. Learning is usually based on changes in neurons.

Learning is a fundamentally important phenomenon in animal behavior. Let's take a closer look at learning from both proximate and ultimate perspectives. How does the process occur, and why?

FIGURE 51.6 Many Species of Coral-Reef Fish Can Change Sex, Depending on Conditions. Bluehead wrasses: a group of females surround a male. Bluehead wrasses start life as females but can change sex and become male.

Check Your Understanding

If you understand that...

- Within a given species, behavioral traits may range from highly stereotyped to highly flexible and from innate to learned.
- Fixed action patterns (FAPs) are highly stereotyped, innate responses released by simple stimuli.
- Foraging, mate choice, and sex change are examples of flexible decision-making. Animals usually make decisions that maximize their fitness, given their current environmental conditions.

You should be able to...

1) Think of an example of a FAP and a condition-dependent behavior in a species that you are familiar with.
2) Pose hypotheses to explain why each type of behavior you just listed is adaptive.

51.2 Learning

Learning occurs when behavior changes in response to specific life experiences. Learning is particularly important in species that have large brains and a lifestyle dominated by complex social interactions—including humans, dolphins, chimps, and crows. In species such as these, FAPs and other types of inflexible, stereotyped behaviors are relatively rare. Instead, each individual is capable of a wide range of behavior. What an individual actually does is condition dependent or learned.

An enormous amount of research has been done on learning. This section touches on only a few highlights, to provide examples of what is known and illustrate how biologists go about studying it.

Simple Types of Learning: Classical Conditioning and Imprinting

Learning can be simple. For example, dogs salivate in response to the sight or smell of food. Ivan Pavlov discovered that if he rang a bell each time food was presented to a dog, the dog would learn to associate the sound of the bell with food. When stimulated by a bell in the absence of food, the dogs Pavlov was training would begin to salivate. This type of learning is called classical conditioning. In **classical conditioning**, individuals are trained by experience to give the same response to more than one stimulus—even a stimulus that has nothing to do with the normal response.

Another type of simple learning takes place in newly hatched ducks, geese, and certain other species of birds. Upon hatching, ducklings and goslings adopt as their mother the first moving thing they see. This type of learning is called **imprinting**. In nature, the "thing" that creates the imprint is the mother duck or goose. But Konrad Lorenz found that if he incubated eggs artificially until they hatched, he could be the first thing that the offspring saw. In response, young greylag geese would imprint on whatever boots he was wearing at the time (**Figure 51.7**). In contrast, mallard ducklings would imprint on him only if he crawled on all fours and quacked continuously.

Why does imprinting occur? At the ultimate level of causation, the leading hypothesis is that offspring must quickly learn to recognize and respond to their mother in order to survive. This explanation is most relevant to species that nest on the ground, such as ducks and geese. Ducklings and goslings are easy prey for foxes, raccoons, and other predators, so mother ducks and geese lead their offspring away from the nest to the safety of nearby water almost immediately. In these bird species, the ability to recognize a moving object and follow it immediately should increase the fitness of offspring.

Lorenz was also able to establish that imprinting occurs only in the early life of the animal, during a short interval called the **critical period** or **sensitive period**. In addition, his research showed that imprinting lasts for life and may establish not only the identity of the offspring's mother but also its species identity.

FIGURE 51.7 Imprinting Occurs in Some Species of Birds and Lasts for Life. Goslings imprint on the first moving object they see—in this case, researcher Konrad Lorenz's boots.

The key characteristics of imprinting—that it is fast and irreversible and occurs during a critical period—are not typical of most types of learning. Yet recent research has shown that imprinting and human language acquisition share some common characteristics. You may have personal experience with how quickly children learn a foreign language relative to adults. This observation suggests that there might be something like a critical period for language learning. The commonplace observation that babies learn the language of their parents is also important. The babbling noises that babies make are thought to be imitations of words and sounds uttered by their parents. Children who are born deaf cannot hear these sounds. Learning a spoken language may be almost impossible for these individuals, even with intensive training later in life. In contrast, people who become deaf as adults experience relatively slight changes in their speech. These data suggest that auditory feedback is important during the learning process and that language acquisition should be presented as shifted to the left in the graph depicted in Figure 51.2. Let's explore the topic of language learning further by considering research on how birds learn to sing.

More Complex Types of Learning: Birdsong

Birds sing to attract mates and to mark territories where they find food and raise offspring. In most cases, bird songs are unique to each species. Do young birds learn their species-specific song or suite of songs from their parents, or are songs innate? To answer these questions, biologists perform experiments to control the sound stimuli that birds hear over the course of their lives. The experimental protocols involve taking eggs from the nest, hatching them, and rearing individuals in the laboratory in a controlled auditory environment.

The results of these experiments show that, depending on the species, song-learning behavior falls at various locations on the learning continuum in Figure 51.2. For example, if young chickens or phoebes—birds that have simple vocalizations—are raised in isolation from other members of their species and never hear their species-specific calls, they still produce the correct vocalizations as adults. Song-learning behavior is innate in these species and may be highly stereotyped.

In contrast, white-crowned sparrows that are raised in isolation do not sing a normal song unless they hear a tape recording of their species-specific song during the early months of life. In this species—which sings a complex song—singing is learned during a critical period. Yet if researchers play the song of a song sparrow or other closely related species during the critical period for language acquisition, white-crowned sparrow chicks do not learn it. Instead they learn an abnormal song differing from that of their own species and from that of the alien introduced species. In this species, the ability to learn songs is restricted to songs of their own species (**Figure 51.8**).

In addition, the critical period for song learning in white-crowned sparrows is augmented by practice that occurs when the individual is older. White-crowned sparrows don't begin to sing until they are almost one year old, during the spring. Beginning singers produce a disorganized warbling called sub-song. With practice, this sub-song becomes more and more organized and progressively closer to adult song. Eventually an adult song develops and is "crystallized," meaning that it remains unchanged for the rest of the individual's life. For this improvement to occur, though, the individual must hear itself sing. Individuals that are prevented from hearing their own practice never sing a normal song. Yet if the same individual is deafened after it has developed adult song, it continues to sing a perfectly normal song. These data suggest that individuals have two critical periods for song learning during their lives: one as a nestling, when they must hear the song of their own species, and a second as a 1-year-old, when they must hear themselves practice.

To summarize, singing in white-crowned sparrows is heavily influenced by learning. But in this species, learning is constrained to certain periods of life and occurs only in response to certain types of stimuli.

If chickens are at one end of the learning continuum and if white-crowned sparrows are in the middle, then species such as mynahs, mockingbirds, lyrebirds, and some types of parrots occupy the other end. Individuals of these species continue to learn new songs throughout their lives by imitating sounds in their environment. They have relatively few age-related or species-specific limitations on song learning. "Polly-wanna-cracker" is not a species-specific call in parrots, and the ability to use this call does not depend on hearing it during a critical period early in life.

One of the great challenges that remains for research on song learning is to explain why so much variation exists in song-learning ability and in the size of song repertoires. Why is it adaptive for chickens to make a few innate calls while mynahs sing dozens of learned songs? Research continues.

Can Animals Think?

Research on classical conditioning, imprinting, and song learning has some important take-home messages: Several types of learning exist, and the ability to learn varies widely among species. It is clear that simple types of learning are widespread in animals and that at least some species can learn a great deal by imitation and practice. But can organisms other than humans think?

Cognition is defined as the recognition and manipulation of facts about the world, combined with the ability to form concepts and gain insights. Unlike the results of classical conditioning, imprinting, and song learning, the results of cognition

FIGURE 51.8 White-Crowned Sparrows Have a Critical Period for Song Learning Early in Life. To sing a normal song, white-crowned sparrows have to hear the song of their own species while they are chicks. They also must hear themselves practice their own song when they begin singing at age 1 year.

cannot be observed directly. Instead, to infer that animals are thinking, researchers must design experimental situations that require animals to manipulate facts or information and demonstrate an ability to form novel associations or insights. As an example of work on animal cognition, consider recent experiments on tool use by New Caledonian crows.

New Caledonian crows routinely make and use tools to find food in the wild. Each of these tools is held in the beak and used to remove insect larvae (grubs) or other types of food from plant stems or from crevices (**Figure 51.9a**). Biologists have documented that the crows manufacture the following general types of tools:

- Straight or curved sticks are broken off and cleaned before use. Several other bird species—including one of the Galápagos finches introduced in Chapter 41—are known to modify sticks or plant stems to "fish" for insects. Chimpanzees also make these types of tools. Recent laboratory experiments have shown that when New Caledonian crows are presented with an array of straight sticks along with a piece of food in a clear plastic tube, the crows select a stick whose width or length is appropriate for the tube's width and the food's distance from the end of the tube. The crows then insert the stick into the tube to fish out the food.
- Hooks are made by breaking complex leaves into pieces (**Figure 51.9b**).
- Spearing tools are constructed from a complex series of cuts and rips, made with the beak, along the edge of leaves from pandanus plants (**Figure 51.9c**).

FIGURE 51.9 New Caledonian Crows Make and Use Several Types of Tools.

These observations support the hypothesis that crows can think. More specifically, crows appear to understand facts about the size and shape of raw materials and the location of food. Crows recognize that if they choose or manipulate materials in a certain way, they can use the resulting structure as a tool to acquire the food. The idea is that natural selection has favored the evolution of cognition in this species, because crows with the ability to manufacture and manipulate tools have higher fitness than do crows that lack this ability.

As **Figure 51.10** shows, the crows-can-think hypothesis was supported by recent experiments with two New Caledonian crows in captivity. The experimental setup consisted of a small bucket, containing food, in the bottom of a clear tube that was open at the top, with the handle of the bucket pointing up. In an initial experiment, a male crow and a female crow were given a choice of straight or bent wires to use in retrieving the food from the inside of the tube. The goal of the experiment was to test the hypothesis that the crows can distinguish the two shapes and associate the bent shape with the ability to lift the bucket and acquire the food. During the fifth trial with the apparatus and the choice of two wires, the male happened to remove the hooked wire from the area. Apparently in response, the female picked up the straight wire in her beak, bent it, and successfully used it to lift the bucket and obtain the food.

To confirm the validity of this observation, the researchers gave the pair a straight wire and let them use it until they either successfully retrieved the food or dropped the wire into the tube and were unable to retrieve it. Over the course of 17 trials, the male or female dropped the wire into the tube and was unable to retrieve it 7 times. Once the male was able to lift the bucket out and obtain the food using only the unmodified, straight wire. But 9 times, the female bent the straight wire and used it successfully to obtain the food.

These observations are nothing short of astonishing. They imply that the female was able to associate the shape of a wire

Experiment

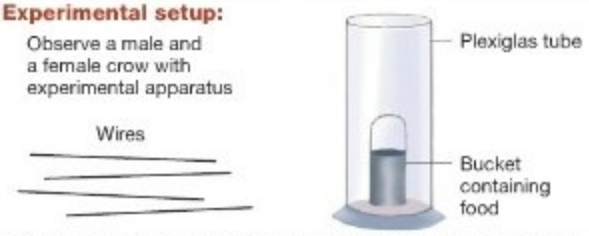
Question: Can crows think?

Hypothesis: Crows can use tools to solve problems.

Null hypothesis: Crows cannot use tools to solve problems.

Experimental setup:

Observe a male and a female crow with experimental apparatus

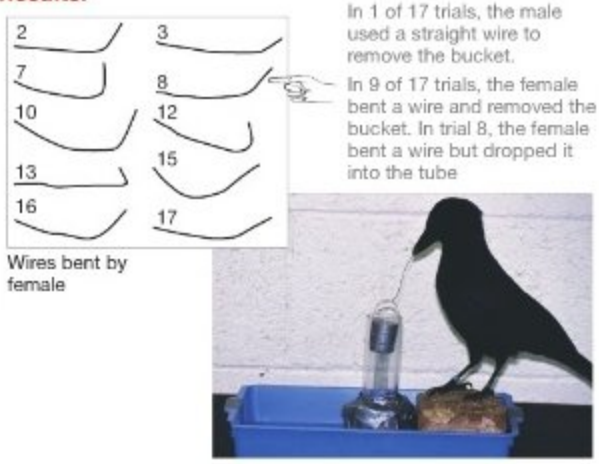


NOTE: These individuals had earlier been given a choice of straight or hooked wires to use in obtaining the bucket of food.

Prediction: Crows will figure out how to use the wire as a tool to remove the bucket from the tube.

Prediction of null hypothesis: Crows will not figure out how to remove the bucket from the tube.

Results:



Conclusion: Female crows can use tools to solve problems. Female crows can also make tools from unfamiliar materials to solve problems.

FIGURE 51.10 Experimental Evidence that New Caledonian Crows Understand How to Make Tools. Prior to these experiments, the crows involved had never seen the experimental apparatus or wires of the type available to them. Bending of materials to form hooks has not been observed in the wild.

with the ability to lift the bucket successfully, and that she also had the insight to understand that exerting a force on the wire would bend it into the shape required to be successful. In more colloquial terms, she appeared to understand what sort of tool she needed and how to make one. She had no model to imitate when she made her hooks, however, and she had had no prior experience with bending wires. Instead, she appeared to be thinking.

What Is the Adaptive Significance of Learning?

Biologists view learning as an adaptation that allows individuals to change their behavior in response to a changing and unpredictable environment. Under this hypothesis, the ability to learn varies among species because some species live in environments that are much more unpredictable than others.

In addition, the type of learning that occurs in a given species is correlated with the type of environmental unpredictability it encounters. Norway rats, for example are extremely adept at learning to navigate mazes (**Figure 51.11**). These animals live in sewers, the walls of homes, or other locations where the ability to learn travel routes is essential for survival. Norway rats are also exceptionally good at learning to avoid foods that contain poisons. In nature they feed on a wide variety of fruits, seeds, and insects. The availability of these foods changes with the season, and many potential food items are actually toxic. Thus, it is logical to observe that rats will taste only small quantities of novel foods and that they quickly learn to avoid any foods that induce illness.

Scrub jays, in contrast, are not particularly adept at negotiating mazes or learning to avoid foods. Instead they are proficient at remembering where they have cached (stored) seeds. In this species, spatial learning and a good memory are essential for survival. In addition, scrub jays learn how to prevent theft. This species lives in social groups, and it is not unusual for some members of the group to steal food that was cached by other jays in their group. Experiments have shown that if an individual that has stolen food in the past caches food while being watched by other jays, the individual will come back later, by itself, and move the stored food to a new location.

FIGURE 51.11 Different Species Are Adept at Different Types of Learning. There is often a strong correlation between the type of learning that occurs in a particular species and the problems the species must solve to survive and reproduce.

QUESTION Domestic dogs have been trained by people for thousands of years. Domestic dogs are adept at learning via classical conditioning. What is the relationship between these observations?

To summarize, the ability to learn and the type of learning that occurs vary within and among species. Learning is an adaptation that helps organisms cope with challenges from their environment.

Check Your Understanding

If you understand that...

- The same species of animal may learn in a variety of ways, ranging from simple forms such as imprinting and classical conditioning to imitation to cognition.
- It is common to observe that an individual is capable of learning only certain types of things—such as its species-specific song—only at certain times in its life.

You should be able to...

1) Define learning and give examples of at least two distinct types of learning.
2) Discuss the adaptive value of cognition.
3) Offer a hypothesis to explain why cognition appears to be rare among animals.

51.3 How Animals Act: Hormonal and Neural Control

Most behavior is modified at least slightly by some type of learning, and most animals have behavioral responses that range from highly stereotyped to highly flexible. In many cases, the adaptive value of learning various types of behavior has been documented. But we have yet to explore a question about proximate causation in detail. To understand how biologists go about addressing questions at the proximate level, consider the following: When behavior is flexible and condition dependent, it means that an individual has the potential to behave in a variety of ways. How are changes in behavior implemented and controlled? To answer this question, let's explore how lizards reproduce and how moths escape from bats.

Sexual Activity in *Anolis* Lizards

Anolis carolinensis lives in the woodlands of the southeastern United States. After spending the winter under a log or rock, males emerge in January and establish breeding territories (**Figure 51.12a**). Females become active a month later, and the breeding season begins in April. By May, females are laying an egg every 10–14 days. By the time the breeding season is complete three months later, the eggs produced by a female will total twice her body mass. **Figure 51.12b** maps this series of events, along with the corresponding changes observed in the male and female reproductive systems.

What causes these dramatic seasonal changes in behavior? The proximate answer is sex hormones—testosterone in males and estradiol in females. Testosterone is produced in the testes of males, and estradiol in the ovaries of females. The evidence for effects of these hormones is direct. Testosterone injections induce sexual behavior in castrated males, while estradiol injections induce sexual activity in females whose ovaries have been removed.

This result leaves some key questions unanswered, however. *Anolis* lizards are most successful if they reproduce early in the spring. In springtime their food supplies are increasing, and snakes and other predators are not yet hunting lizards to feed their own young. If testosterone and estradiol levels induced sexual activity in *Anolis* lizards at the wrong time of year, it would be a disaster for the individuals involved. In addition, it is critical for all *Anolis* individuals in a population to start their sexual activity at the same time, so that females can find males that are ready to breed, and vice versa. What environmental cues trigger the production of sex hormones in early spring? How do male and female *Anolis* synchronize their sexual behavior so that they are ready to produce gametes at the same time?

(a) Courtship display of a male *Anolis* lizard

(b) Changes in sexual organs through the year

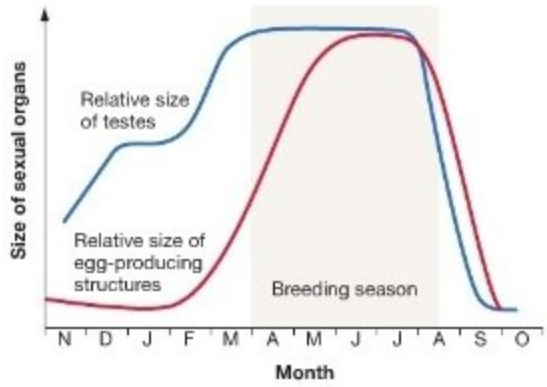


FIGURE 51.12 Sexual Behavior in *Anolis* Lizards.

To answer these questions, a biologist brought a large group of sexually inactive adult lizards into the laboratory during the winter and divided them into five treatment groups. The physical environment was exactly the same in all treatments. Each individual received identical food, and in all treatments high "daytime" temperatures were followed by slightly lower "nighttime" settings. The biologist also continued to monitor the condition of lizards that remained in natural habitats nearby.

To test the hypothesis that changes in day length signal the arrival of spring and trigger initial changes in sex hormones, the biologist exposed the five treatment groups in the laboratory to artificial lighting that simulated the long days and short nights of spring. To test the hypothesis that social interactions among individuals are responsible for synchronizing sexual behavior, the social setting was varied among treatment groups: (1) single isolated females; (2) groups of females only; (3) pairs of lizards: single females, each with a single male; (4) single females, each with a group of castrated (nonbreeding) males; or (5) single females, each with a group of uncastrated (breeding) males.

Each week, the researcher examined the ovaries of females in each group. He also monitored the ovaries of females in nearby natural habitats, since those females were not exposed to springlike conditions. As **Figure 51.13** shows, the differences in the animals' reproductive systems were dramatic. Females that were exposed to springlike conditions began producing eggs; females in the field that were not exposed to springlike conditions did not. But in addition, females that were exposed to breeding males began producing eggs much earlier than did the females placed in the other treatment groups. These results support the hypothesis that two types of stimulation are necessary to produce the hormonal changes that lead to sexual behavior. Females need to experience springlike light and temperatures *and* exposure to breeding males.

What aspect of male behavior causes the difference in female egg production? When males court females, they bob up and down and extend a brightly colored patch of skin called a dewlap. To test the hypothesis that this visual stimulation triggers changes in estradiol production, the investigator repeated the previous experiment but added a twist: He placed some females with males that had intact dewlaps, and other females with males whose dewlaps had been surgically removed. The result? Females grouped with dewlap-less males were slow to produce eggs—just as slow, in fact, as the females in the first experiment that had been grouped with castrated males. These latter females had not been courted at all. The result suggests that the dewlap is a key visual signal. The experiments succeeded in identifying the environmental cues that trigger hormone production and the onset of sexual behavior.

Escape Behavior in Noctuid Moths

Many bats hunt night-flying insects. To find insects in the dark, the bats emit high-pitched pulses of sound and listen for the echo. This process, called **echolocation**, is remarkably acute. If you toss a small stone into the air, a foraging bat will pursue it but then turn away at the last instant. Bats are able to tell the difference between the echos from a stone and an insect.

As **Figure 51.14** shows, bats emit a relatively slow series of pulsed sound when they are searching for prey, switch to a faster series when they are approaching a flying insect, and finish with an extremely rapid sequence as they close in. In this way they get progressively detailed information about the prey's location. The "shouting" involved in echolocation is

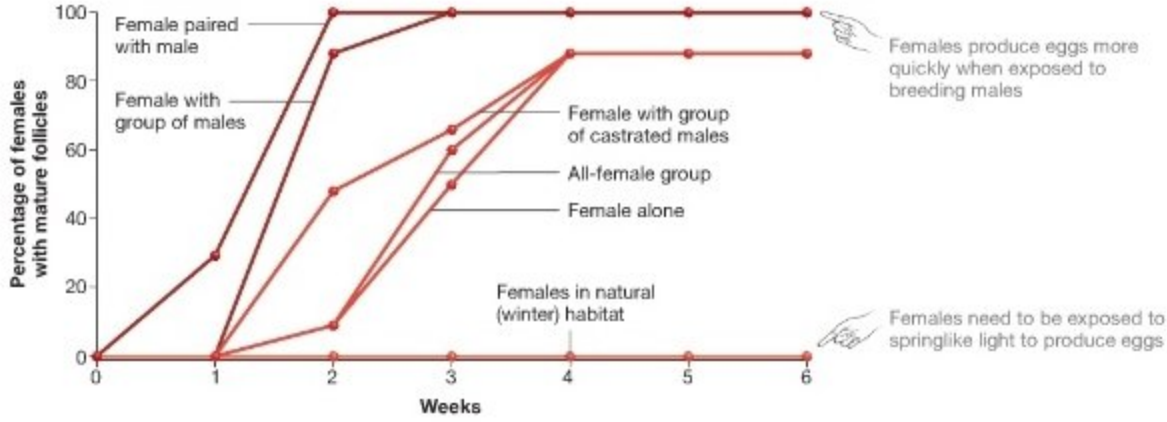

FIGURE 51.13 Exposure to Springlike Conditions and Breeding Males Stimulates Female Lizards to Produce Eggs. The percentage of female lizards with mature follicles, plotted over time. Five treatment groups were exposed to springlike light and temperature; data are also plotted for females left in a natural (winter) habitat. Each data point represents the average value for a group of 6–10 females.

QUESTION Some critics contend that the females that remained outside do not represent a legitimate control in this experiment. What conditions would represent a better control?

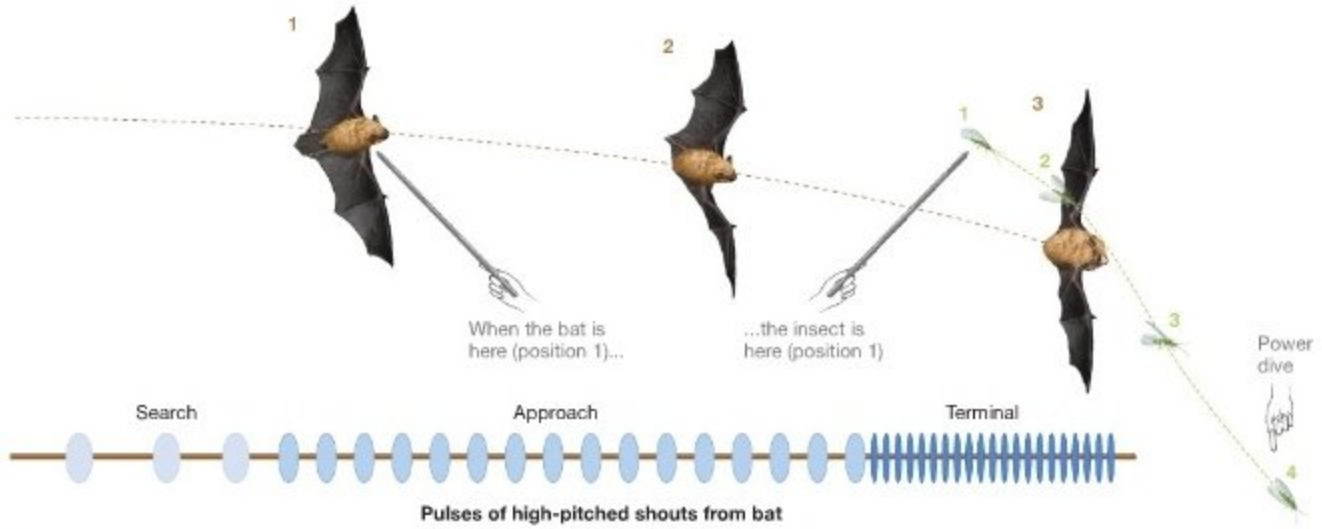

FIGURE 51.14 Bats Hunt By Echolocation. This drawing shows how the pulses of high-pitched sounds change as a bat locates and closes in on a flying insect. To read this diagram, put one finger on the bat at its position 1 and another finger on the insect's position 1. Then change your fingers to the bat's and insect's position 2, then position 3, noting how the bat's calls change as the positions change.

QUESTION Did the bat catch the insect?

energetically expensive, so it is reasonable to observe that bats switch to rapid, high-cost sound production only when it is likely to pay off in a kill.

Humans can't hear the sounds that bats make, but moths and other insects that are preyed on by bats can. When a noctuid moth hears a bat in the distance, it turns and flies away. But if the bat is very close, the moth makes a power dive—it drops from the air like a stone. The adaptive significance of the power-dive behavior is obvious. But at the proximate level, how do moths detect and avoid bats?

Kenneth Roeder did pioneering work on this question. He showed that on either side of their bodies, moths have ears consisting of a tympanic membrane attached to two sensory neurons. When the membrane vibrates in response to bat sounds, the sensory neurons generate action potentials (see Chapter 46). One of the neurons is sensitive to high-pitched sounds of low to moderate loudness, while the other sends action potentials only in response to high-pitched sounds of high intensity. Roeder hypothesized that when the sensory neurons send an extremely rapid sequence of action potentials to the moth brain in response to increasingly loud sounds from an onrushing bat, the moth brain responds by shutting down the neurons that control the flight muscles. The result is chaotic flight or a power dive—desperate behavior that might save the moth's life. In this case, researchers have identified and characterized the neurons responsible for a particularly dramatic example of behavior.

Although a great deal remains to be learned about the hormonal and neural basis for behavior, biologists are making good progress. As techniques advance for measuring hormone concentrations as well as for finding and recording action potentials from individual neurons, the proximate basis for complex behaviors should become increasingly well understood.

51.4 Communication

The song of a bird, the bobbing dewlap of a male *Anolis carolinensis*, and the sentences in this text all have the same overall goal: communication. In biology, **communication** is defined as any process in which a signal from one individual modifies the behavior of a recipient individual. A **signal** is any information-containing behavior. Communication is a crucial component of animal behavior, because it creates a stimulus that elicits a response.

By definition, communication is a social process. For communication to occur, it is not enough that a signal is sent; the signal must be received and acted on. A lizard's bobbing dewlap does not qualify as communication unless another individual sees it and responds to the message. In addition, some biologists maintain that for an event to qualify as communication, the signal that is sent must be intended as a signal. According to these investigators, predicting a person's behavior by watching their body language does not qualify as communication. Similarly, if students unintentionally fall asleep in class and the instructor changes his behavior to wake them up, the exchange does not qualify as communication.

Modes of Communication

The information that organisms communicate may be encoded and delivered in a variety of ways. Communication can be

acoustic, as in the song of crickets or birds. It can be visual, as in the color patterns of birds or fish. It can be olfactory, as in scent marking by mice and wolves. It can be tactile, as in communication in some spiders.

One of the most general observations about communication is that the type of signal used by an organism correlates with its habitat. For example, light is quickly dispelled in aquatic habitats, but sound is not. Based on this observation, it is logical to observe that humpback whales rely on songs for long-distance communication. In some cases, humpback whale songs can travel hundreds of kilometers. Groups of whales use acoustic communication to keep together as they move from summer feeding areas to winter breeding grounds, and individual males sing to attract mates and warn rivals. Correlations between habitat and mode of communication are also observed in visual, olfactory, and tactile communication. Animals that are active during the day and that live in open or treeless habitats tend to rely on visual communication during courtship and territorial displays. Bats, wolves, and other animals that are active at night communicate via sound or scent; ants and termites that live underground rely on olfactory and tactile communication.

It is also common to observe several modes of communication being used in conjunction. For example, male red-winged blackbirds establish a breeding territory in the spring by giving a display that combines auditory and visual signals. The birds' display is based on revealing the bright red patches of feathers near their shoulders and giving a loud call. To test the hypothesis that both components of the display are important, researchers have manipulated both acoustic and visual elements. In one experiment, biologists used a speaker to play recordings of red-winged blackbird songs in existing territories (**Figure 51.15a**). In response, the territory-owning males flew toward the speaker and appeared to hunt for it. In a second experiment, researchers made a crude model of a male red-winged blackbird by sewing red patches on a black sock stuffed with rags. When the model was placed in existing territories, territory owners approached the model and inspected it (**Figure 51.15b**). But if the model was presented along with a recorded blackbird song, the resident males attacked the model (**Figure 51.15c**). These experiments support the hypothesis that both auditory and visual information are important in territorial displays of red-winged blackbirds. More specifically, the data indicate that while each type of stimulus alone induces a response, the combination of both types of stimuli provokes a much more powerful change in behavior.

Each mode of communication has advantages and disadvantages. Although acoustic communication can be extremely effective in some habitats, songs and calls are short lived. A red-winged blackbird's red feathers remain in place for at least 6 months, but each call lasts less than 3 seconds. Thus, calls and songs have to be repeated to be effective. Frequent repetition of calls and songs requires a large expenditure of time and energy. In addition, acoustic communication has been shown to attract predators. It is no surprise that when a hawk or falcon approaches a marsh inhabited by red-winged blackbirds, things get very quiet. Communication systems have been honed by natural selection to maximize their benefits and minimize their costs.

FIGURE 51.15 Experimental Evidence that Visual and Auditory Stimuli Are Important in Territorial Behavior.
Territory-owning red-winged blackbirds react differently to **(a)** auditory stimuli, **(b)** visual stimuli, and **(c)** auditory plus visual stimuli. Territory owners inspect each stimulus presented in (a) and (b) but attack the combination of the two in (c).

EXERCISE Researchers have clipped the red feathers from male red-winged blackbirds and released the birds into territories. Predict how territory owners respond to these individuals.

Research on animal communication has gone far beyond describing types of communication and documenting correlations between modes of communication and habitat characteristics, however. To appreciate the array of questions that biologists ask about communication and how they go about answering them, let's consider two research programs on animal signaling—one classical and one more recent. The classical work revealed a remarkable form of communication in honeybees; the more recent work has focused on the question of how and why signalers lie.

A Case History: The Honeybee Dance

Honeybees are highly social animals that live in hives. Inside the hive, a queen bee lays eggs that are cared for by individuals called workers. Besides caring for young and building and maintaining the hive, workers obtain food for themselves and other members of the colony by gathering nectar and pollen from flowering plants.

Biologists noticed that bees appear to recruit to food sources, meaning that if a new source is discovered by one or a few individuals, many more bees begin showing up over time. This observation inspired the hypothesis that successful food-finders have some way of communicating the location of food to other individuals. Karl von Frisch suspected that successful food-finders communicate information about food sources when they interact with other workers inside the hive. Because beehives are completely dark, von Frisch hypothesized that communication was tactile in nature.

In the 1930s Von Frisch began studying bee communication by observing bees that built hives inside the glass-walled chambers he had constructed. He found that if he placed a feeder containing sugar water near one of these observation hives, a few of the workers began moving in a circular pattern on the vertical, interior walls of the hive. Von Frisch called these movements the "round dance" (**Figure 51.16a**). Other bee workers appeared to follow the progress of the dance by touching the displaying individual as it danced, and to respond by flying away from the hive in search of the food source.

To investigate the function of these movements further, von Frisch placed feeders containing sugar water at progressively greater distances from the hive. Using this technique, he was able to get bees to visit feeders at a distance of several kilometers from the hive. By catching bees at the feeders and dabbing them with paint, he could individually mark successful food-finders. Follow-up observations at the hive confirmed that marked foragers danced when they returned to the hive. Follow-up observations at the feeders confirmed that marked foragers returned with greater and greater numbers of unmarked bees. To explain these data, von Frisch proposed that the round dance contained information about the location of food and that workers got information from the dance by touching the dancer and following the dancer's movements.

When von Frisch placed feeders at longer distances from the hive, however, he found that successful food-finders no longer did the round dance. Instead, they performed a new type of display. He named these movements the "waggle dance," because they combined circular movements like those of the round dance with short, straight runs (**Figure 51.16b**). During these runs, the dancer vigorously moved her abdomen from side to side.

These observations supported the hypothesis that both the round dance and waggle dance communicated information about food sources. But a key observation allowed von Frisch to push this result further. He noticed that the orientation of the waggle part of the dance varied and that the variation correlated with the direction of the food source from the hive. In addition, he observed that the length of the straight, "waggling" run was

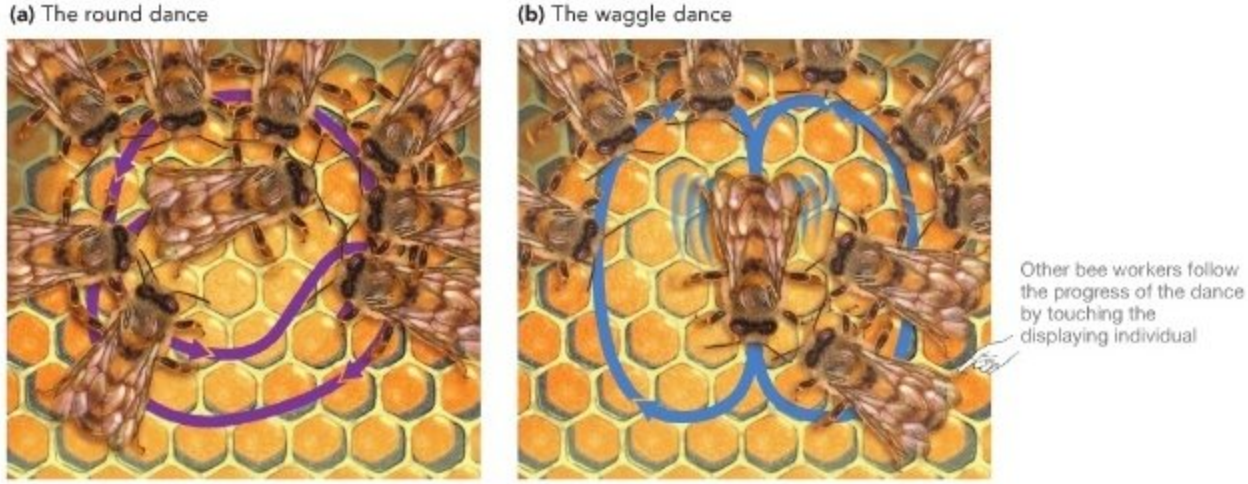

FIGURE 51.16 Honeybees Perform Two Types of Dances. (a) During the round dance, successful food-finders move in a circle. **(b)** During the waggle dance, successful foragers move in a circle but then make straight runs through the circle. During the straight part of the dance, the dancer waggles her abdomen.

proportional to the distance the foragers had to fly to reach the feeder. By varying the location of the food source and observing the orientation of the waggle dance given by marked workers, von Frisch was able to confirm that dancing bees were communicating the position of the food relative to the current position of the Sun. For example, if he placed food directly away from the Sun's current position, marked bees would give the waggle portion of their dance directly downward (**Figure 51.17a**). But if the food was 90 degrees to the right of the Sun, bees would waggle 90 degrees to the right of vertical (**Figure 51.17b**).

Based on these experiments, von Frisch concluded that the difference between the round dance and the waggle dance was a matter of distance. The round dance is used to indicate the presence of food within 80 to 100 m of the hive. The waggle dance is used to indicate the direction and distance to food that is over 100 m from the hive.

These results are nothing short of astonishing. Honeybees do not have large brains, yet they are capable of symbolic language. What's more, they are able to interpret the angle of the waggle dance performed on a vertical surface and to respond by flying horizontally along the corresponding angle. Further work has confirmed that the dance language of bees includes several modes of communication. In addition to the tactile information in the movements themselves, bees make sounds during the dance and give off scents that indicate the nature of the food source.

When Is Communication Honest or Deceitful?

As far as is known, honeybees are always honest. Stated another way, honeybee dances consistently "tell the truth" about the location of food sources. This observation is logical, because the honeybees that occupy a hive are closely related and cooperate closely in the rearing of offspring. As a result, it is advantageous for an individual to convey information accurately. If a food-finder provided inaccurate or misleading information to its hivemates, fewer offspring would be reared and thus the food-finder's fitness would be reduced.

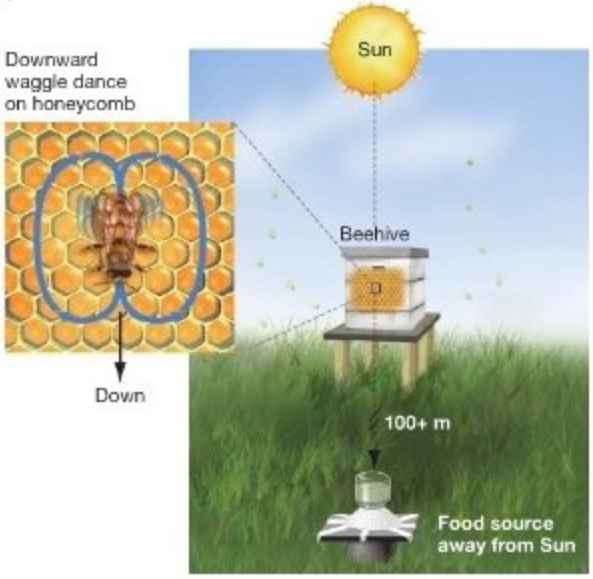
In many cases, however, natural selection has favored the evolution of deceitful communication, or what is commonly called lying. Recent research on deceitful communication has highlighted just how complex interactions between signalers and receivers can be. A few examples will help drive this point home.

Deceiving Individuals of Another Species

Figure 51.18 illustrates a few of the hundreds of examples of deceitful communication that have been documented among members of different species. Many of the best-studied instances involve predation:

- The anglerfish in Figure 51.18a has an appendage that dangles near its mouth and looks remarkably like a minnow. If another fish approaches this "lure" and attempts to eat it, the anglerfish attacks.

(a) Straight runs down the wall of the hive indicate that food is opposite the direction of the Sun.



(b) Straight runs to the right indicate that food is 90° to the right of the Sun.

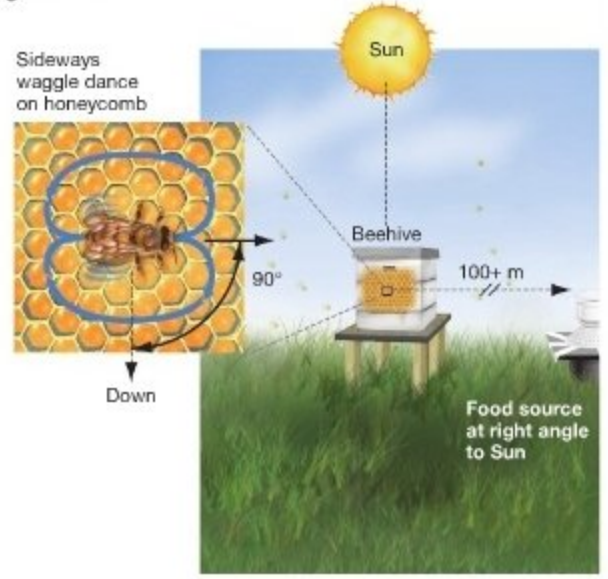


FIGURE 51.17 The Direction of the Waggle Dance Indicates the Location of Food Relative to the Sun. Waggle dances are done only when the food is at least 100 m from the hive.

EXERCISE The length of the straight run in the waggle dance indicates the relative distance of the food. Diagram a waggle dance that indicates food in the direction of the Sun and twice as far away as the food sources indicated by the dances drawn here.

(a) Anglerfish use a "lure" to attract prey.

(b) Female *Photuris* fireflies flash the courtship signal of another species, then eat males that respond.

(c) This butterfly looks like a bad-tasting species but actually tastes good.

FIGURE 51.18 Deceitful Communication Is Common in Nature.

- Male and female fireflies flash a species-specific signal to each other during courtship. Predatory *Photuris* fireflies can mimic the pattern of flashes given by females of several other species. A *Photuris* female attracts a male of different species with the appropriate set of flashes, and then attacks and eats him (Figure 51.18b).
- The butterfly shown in Figure 51.18c is highly palatable to birds and other predators. It is rarely attacked, though, because it strongly resembles butterfly species that contain toxins and are highly unpalatable to predators. This phenomenon, known as mimicry, is discussed in more detail in Chapter 53.

In each of these examples, individuals increase their fitness by providing inaccurate or misleading information to members of a different species. Deceitful communication is also known in plants, where it functions in pollination. For example, several orchid species have flowers that look and smell like female wasps and that accomplish pollination by "fooling" male wasps into attempting copulation.

Deceiving Individuals of the Same Species In some cases, natural selection has favored the evolution of traits or actions that deceive members of an organism's own species. When mantis shrimps molt, for example, they lack any external covering and cannot use their large claws. Thus, they are unable to defend the cavities where they live. But if another mantis shrimp approaches with the intent of evicting the individual and taking over the cavity, the molting individual bluffs. It raises its claws in the normal aggressive display and may even lunge at the intruder.

Perhaps the best-studied type of deceit in nonhuman animals, however, involves the mating system of bluegill sunfish. Male bluegills set up nesting territories in the shallow water along lake edges, fertilize the eggs laid in their nests, care for the developing embryos by fanning them with oxygen-rich water, and protect newly hatched offspring from large predators. Some males cheat on this system, however, by mimicking females. To understand how this happens, examine the female, normal male, and female-mimic male in **Figure 51.19**. Female mimic males look like females but have well-developed testes

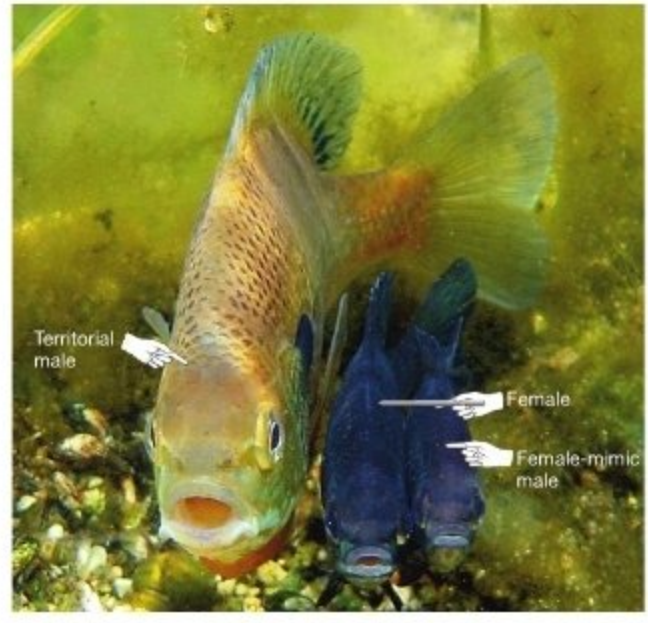

FIGURE 51.19 In Bluegill Sunfish, Some Males Look and Act Like Females. Female-mimic males have fully functional testes and produce large numbers of sperm.

and produce large volumes of sperm. Mimics also act like females during courtship movements with territory-owning males. They even adopt the usual egg-laying posture. Then when normal females approach the nest and begin courtship, the female-mimic males join in. The territory-owning male tolerates the mimic, apparently thinking that he is successfully courting two females at the same time. But when the actual female begins to lay eggs, the mimic responds by releasing sperm and fertilizing some of them, and then darting away. In this way, the female-mimic male fathers offspring but does not help care for them.

When Does Deception Work? In analyzing deceitful communication in bluegill sunfish and other species, researchers point out that in most cases, lying works only when it is relatively rare. The logic behind this hypothesis is that if deceit becomes extremely common, then natural selection will strongly favor individuals that can detect and avoid or punish liars. But if liars are rare, then natural selection will favor individuals that are occasionally fooled but are more commonly rewarded by responding to signals in a normal way. In mantis shrimps, for example, molting occurs only once or twice a year. Thus, the vast majority of contests over hiding places involve individuals that have an intact exoskeleton and claws that qualify as a deadly weapon. As a result, intruders usually benefit by interpreting threat displays as honest and responding to the stimulus by retreating. If molting were frequent and bluffing behavior common, then intruders would benefit by challenging territory owners, which are likely to be defenseless. Research on deceit and honesty in communication has been extraordinarily productive and continues at a rapid pace.

Check Your Understanding

If you understand that...

- Communication is an exchange of information between individuals.
- In most instances, the mode of communication that animals use maximizes the probability that the information will be transferred efficiently.
- Communication can be honest or deceitful, depending on the intent of the signaler.

You should be able to...

1) Explain the adaptive significance of different modes of communication (e.g. auditory, tactile, visual) and give examples of each.
2) Explain why natural selection favors individuals that can detect deceitful communication and either avoid liars or punish them.

51.5 Migration and Navigation

In response to many stimuli, organisms move. Ants follow odor trails; bees fly toward food sources. A movement that results in a change of position, like the flight paths of hunting bats, escaping moths, and foraging bees, is called **orientation**. The simplest type of orientation is termed **taxis**, and it involves positioning the body, or part of the body, toward or away from a stimulus. A moth attracted to a porch light is an example of a positive **phototaxis**—orientation toward light. A female cricket approaching a calling male is an example of a positive **phonotaxis**—orientation toward sound. A person who retreats from the sound of a siren blaring is an example of negative phonotaxis.

Orienting movements cover fairly short distances. But in some cases, bats and other species travel thousands of miles in search of places to feed and breed. Why?

Why Do Animals Move with a Change of Seasons?

In ecology, **migration** is defined as the long-distance movement of a population associated with a change of seasons. A few examples will bring home the simple point that migratory movements can be spectacular in their extent and the navigation challenge they pose:

- Arctic terns nest along the Atlantic coast of North America in warm months, fly south along the coast of Africa to wintering grounds off Antarctica, and then fly back north along the eastern coast of South America. Chicks follow their parents south but make the return trip on their own. The journey totals over 32,000 km (20,000 miles).
- Many of the monarch butterflies native to North America spend the winter in the mountains of central Mexico or southwest California. Tagged individuals are known to have flown over 3000 km (1870 miles) to get to a wintering area. In spring, monarchs begin the return trip north. They do not live to complete the trip, however. Instead, mating takes place along the way, and females lay eggs en route. Although adults die on the journey, offspring continue to head north. After several generational cycles of reproduction and death in the original habitats in northern North America have passed, individuals again migrate south to overwinter. Instead of a single generation making the entire migratory cycle, then, the round trip takes several generations.
- Salmon that hatch in rivers along the Pacific Coast of North America and northern Asia migrate to the ocean when they are a few months to several years old, depending on the species. After spending several years feeding and growing in the North Pacific Ocean, they return to the stream where they hatched. There they mate and die.

In most cases, it is relatively straightforward to generate hypotheses for why migration exists at the ultimate level. Arctic

terns feed on fish that are available in different parts of the world at different seasons. Thus, individuals that migrate achieve higher reproductive success than do individuals that do not migrate. Monarch butterflies may achieve higher reproductive success by migrating to wintering areas and new breeding areas than by trying to overwinter in northern North America. Salmon eggs and young are safer and thrive better in freshwater habitats than they do in the ocean, but adult salmon can find much more food in saltwater habitats than in freshwater.

At the proximate level, however, explaining migratory movements is often extremely difficult. How do all of these animals find their way? What cues guide them on these immense journeys? The surprising answer is that in many or even most cases, biologists don't really know.

How Do Animals Find Their Way?

To organize research into how animals find their way during migratory movements, biologists distinguish three categories of navigation: (1) **Piloting** is the use of familiar landmarks, (2) **compass orientation** is movement that is oriented in a specific direction, and (3) **true navigation** is the ability to locate a specific place on Earth's surface. A thought experiment will help you understand these categories. Suppose you grew up on the shores of Lake Superior and were transported to the middle of this enormous lake. Because you were blindfolded and made to spin in place en route, you are disoriented and have no idea where you are. But you are given a magnetic compass. The compass tells you where north, south, east, and west are. Unfortunately this information will not help you find home, because you have no idea where you are in relation to home. You are stuck because you have no mechanism of true navigation. Now suppose that a helicopter flying overhead drops you a map. The map has an X marking your current position and an H marking your home. The map also has a scale and a compass symbol. From this information, you determine that home is 100 miles to the west. The map has solved your navigational problem. The compass has solved your orientation problem. Now that you know you live to the west, you can use the compass to find west and paddle home. As you approach the shore, you recognize familiar landmarks. Piloting gets you home.

Organisms other than humans do not have magnetic compasses or printed maps. How do they navigate? Although biologists know little about the nature of a map sense in animals, piloting and compass orientation are increasingly well understood.

Piloting A substantial amount of data suggests that at least some migratory animals use piloting to find their way. In some species of migratory birds and mammals, offspring follow their parents south in the fall and north in the spring. Young appear to memorize the route. Piloting even plays a role in species with more sophisticated navigational abilities. Homing pigeons, for example, can find their way home even when they are released in strange terrain a long distance away. But if these birds are equipped with frosted spectacles so that they see the world as a foggy haze, they return to within a mile or so of their home but do not actually find it. Based on these experiments, researchers have concluded that homing pigeons use piloting to navigate the final stages of a journey home.

Compass Orientation How do animals perform compass orientation? To date, most research on compass orientation has been done on migratory birds. To determine where north is, these animals appear to use the Sun during the day and the stars at night. Let's consider each type of compass orientation separately, because they work differently.

The Sun is difficult to use as a compass reference, because its position changes during the day. It rises in the east, is due south at noon (in the Northern Hemisphere), and sets in the west. To use the Sun as a compass reference, then, an animal must have an internal clock that defines morning, noon, and evening. Fortunately, most animals have such a clock. The **circadian clock** that exists in organisms maintains a 24-hour rhythm of chemical activity. The clock is set by the light–dark transitions of day and night. It tells individuals enough about the time of day that they can use the Sun's position to find magnetic north.

The situation is actually simpler on clear nights, because migratory birds in the Northern Hemisphere can use the North Star to find magnetic north and select a direction for migration. But what if the weather is cloudy and neither the Sun nor stars are visible? Under these conditions, migratory birds appear to orient using Earth's magnetic field. Exactly how they detect magnetism is under debate. One hypothesis contends that the birds can detect magnetism by their visual system, through an unknown molecular mechanism. An alternative hypothesis maintains that individuals have small particles of magnetic iron—the mineral called magnetite—in their bodies. Changes in the positions of magnetic particles, in response to Earth's magnetic field, could then be detected and provide reliable information for compass orientation.

Although research on mechanisms of compass orientation continues, one important point is clear: Birds and perhaps other organisms have multiple mechanisms of finding a compass direction. At least some species can use a Sun compass, a star compass, and a magnetic compass. Which system they use depends on the weather and other circumstances.

Homing Behavior in Digger Wasps

51.6 The Evolution of Self-Sacrificing Behavior

The types of behavior reviewed thus far—including FAPs, learned behaviors, honest and deceitful communication, and migration—all have a key common element: They help

individuals respond to environmental stimuli in a way that increases their fitness. There is a type of behavior that appears to contradict this pattern, however: altruism. **Altruism** is behavior that has a fitness cost to the individual exhibiting the behavior and a fitness benefit to the recipient of the behavior. It is the formal term for self-sacrificing behavior. Altruism decreases an individual's ability to produce offspring but helps others produce more offspring.

The existence of altruistic behavior appears to be paradoxical, because if certain alleles make an individual more likely to be altruistic, those alleles should be selected against. Why does it occur?

Kin Selection

Even though it is not possible for behavior to evolve for the good of the species, self-sacrificing behavior does occur in nature. For example, black-tailed prairie dogs perform a behavior called alarm calling (**Figure 51.20**). These burrowing mammals live in large communities, called towns, throughout the Great Plains region of North America. When a badger, coyote, hawk, or other predator approaches a town, some prairie dogs give alarm calls that alert other prairie dogs to run to mounds and scan for the threat. Giving these calls is risky. In several species of ground squirrels and prairie dogs, researchers have shown that alarm-callers draw attention to themselves by calling and are in much greater danger of being attacked than non-callers are.

How can natural selection favor the evolution of self-sacrificing behavior? William Hamilton answered this question by creating a mathematical model to assess how an allele that contributes to altruistic behavior could increase in frequency in a population. To model the fate of altruistic alleles, Hamilton represented the fitness cost of the altruistic act to the actor as C and the fitness benefit to the recipient as B. Both C and B are measured in units of offspring produced. His model showed that the allele could spread if

$$Br > C$$

where r is the coefficient of relatedness. The **coefficient of relatedness** is a measure of how closely the actor and beneficiary are related. Specifically, r measures the fraction of alleles in the actor and beneficiary that are identical by descent—that is, inherited from the same ancestor (see **Box 51.2**).

This result is called **Hamilton's rule**. It is important because it shows that individuals can pass their alleles on to the next generation not only by having their own offspring but also by helping close relatives produce more offspring. Stated another way, an altruist might produce slightly fewer offspring because of the sacrifices the individual makes to help others. But if those sacrifices help close relatives produce many more offspring than the relatives could produce on their own, then copies of the altruist's alleles will increase in frequency.

According to Hamilton's rule, if the fitness benefits of altruistic behavior are high for the recipients, if the recipients are close relatives, and if the fitness costs to the altruist are low, then alleles associated with altruistic behavior will be favored by natural selection and will spread throughout the population. The keys are that (1) close relatives are very likely to have copies of the altruistic allele, and (2) help from close relatives allows these relatives to produce more offspring than they could produce without help. Biologists use the term **kin selection** to refer to natural selection that acts through benefits to relatives. ● If you understand this concept, you should be able to give an example of a species for which kin selection should be important, and explain why. You should also be able to explain whether kin selection can occur in plants.

Does Hamilton's rule work? Do animals really favor relatives when they act altruistically? To test the kin-selection hypothesis, a researcher studied which of the inhabitants of a black-tailed prairie dog town were most likely to give alarm calls. Within a large prairie dog town, individuals live in small groups called coteries that share the same underground burrow. Members of each coterie defend a territory inside the town. By tagging offspring that were born over several generations, the researcher identified the genetic relationships among individuals in the town. More specifically, the researcher determined, within each coterie, to which of the following three categories each prairie dog belonged: (1) an individual with no close genetic relatives in its coterie; (2) an individual with no offspring in the coterie but at least one sibling, cousin, uncle, aunt, niece, or nephew; and (3) an individual with at least one offspring or grandoffspring in the coterie.

FIGURE 51.20 Black-Tailed Prairie Dogs Are Highly Social. Prairie dogs live with their immediate and extended family within large groups called towns. The individual with the upright posture has spotted an intruder and may give an alarm call.

BOX 51.2 Calculating the Coefficient of Relatedness

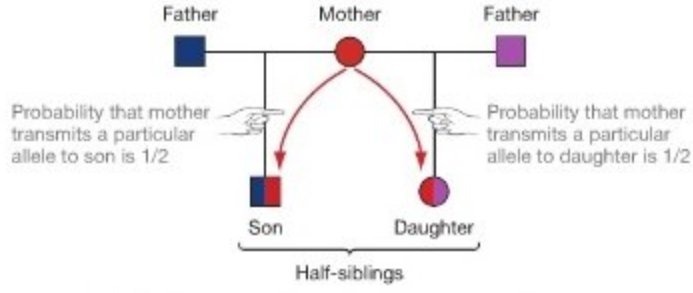
The coefficient of relatedness, *r*, varies between 0.0 and 1.0. If two individuals have no identical alleles that were inherited from the same ancestor, then their *r* value is 0.0. Because every allele in pairs of identical twins is identical, their coefficient of relatedness is 1.0.

What about other relationships? **Figure 51.21a** shows how *r* is calculated between half-siblings. (To review what the boxes, circles, and lines in a pedigree mean, see Figure 13.21.) Half-siblings share one parent. Thus, *r* represents the probability that half-siblings share alleles as a result of inheriting alleles from their common parent. It is critical to realize that in each parent-to-offspring link of descent, the probability of any particular allele being transmitted is 1/2. This is so because meiosis distributes alleles from the parent's diploid genome to their haploid gametes randomly. Thus, half the gametes produced by a parent get one of the alleles present at each gene, and half the gametes produced get the other allele. Half-siblings are connected by two such parent-to-offspring links. The overall probability of two half-siblings sharing the same allele by descent is $1/2 \times 1/2 = 1/4$ (To review rules for combining probabilities, see **BioSkills 9**.)

To think about this calculation in another way, focus on the red arrows in Figure 51.21a. The left arrow represents the probability that the mother transmits a particular allele to her son. The right arrow represents the probability that the mother transmits the same allele to her daughter. Both probabilities are 1/2. Thus, the probability that the mother transmitted the same allele to both her son and daughter is $1/2 \times 1/2 = 1/4$.

Figure 51.21b shows how *r* is calculated between full siblings. The challenge here is to calculate the probability of two individuals sharing the same allele as a result of inheriting it through their mother or through their father. The probability that full siblings share alleles as a result of inheriting them from one parent is 1/4. Thus, the probability that full siblings share alleles inherited from either their mother or their father is $1/4 + 1/4 = 1/2$. (To review rules for combining probabilities, see BioSkills 9.) ● If you understand how to calculate *r*, you should be able to draw a pedigree with 3 generations and calculate *r* between any 2 individuals on the diagram.

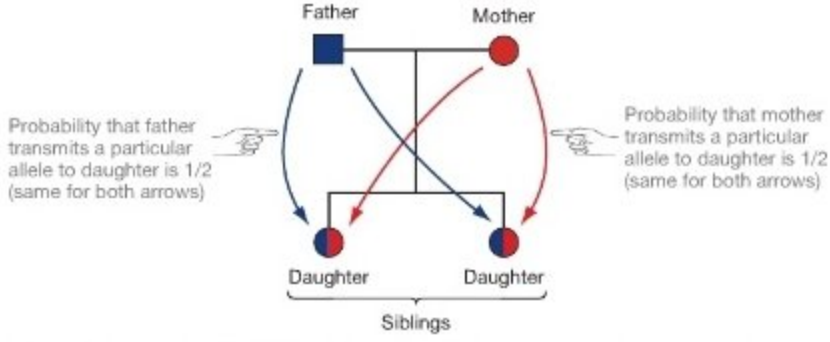
(a) What is the *r* between half-siblings?



What is the probability that half-siblings inherit the same allele from their common parent?

Answer: *r* between half-siblings = $1/2 \times 1/2 = 1/4$

(b) What is the *r* between full siblings?



What is the probability that full siblings inherit the same allele from their father or their mother?

Answer: Probability that they inherit same allele from father = $1/2 \times 1/2 = 1/4$
Probability that they inherit same allele from mother = $1/2 \times 1/2 = 1/4$
Overall probability that they inherit the same allele = $1/4 + 1/4 = 1/2$
r between full siblings = 1/2

FIGURE 51.21 The Coefficient of Relatedness Is Calculated from Information in Pedigrees.

● **QUESTION** According to Hamilton's rule, who should help each other more: half-siblings or full siblings?

● **QUESTION** What is the *r* between first cousins?

The kin-selection hypothesis predicts that individuals who do not have close genetic relatives nearby will rarely give an alarm call. To evaluate this prediction, the biologist recorded the identity of callers during 698 experiments. In these studies, a stuffed badger was dragged through the colony on a sled. Were prairie dogs with close relatives nearby more likely to call, or did kinship have nothing to do with the probability of alarm calling? The data in **Figure 51.22** illustrate that black-tailed prairie dogs are much more likely to call if they live in a coterie that includes close relatives. This same pattern—of preferentially dispensing help to kin—has been observed in many other species of social mammals and birds. Most cases of self-sacrificing behavior that have been analyzed to date are consistent with Hamilton's rule and are hypothesized to be the result of kin selection.

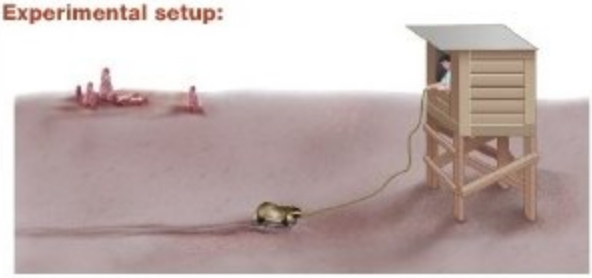
Experiment

Question: Do black-tailed prairie dogs prefer to help relatives when they give an alarm call?

Kin-selection hypothesis: Individuals give an alarm call only when close relatives are near.

Null hypothesis: The presence of relatives has no influence on the probability of alarm calling.

Experimental setup:

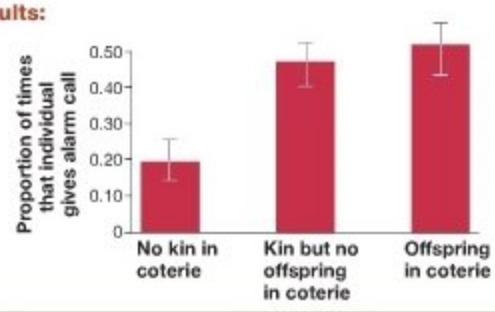


1. Determine relationships among individuals in prairie dog coterie.
2. Drag stuffed badger across territory of coterie.
3. From observation tower, record which members of coterie give an alarm call.
4. Repeat experiment 698 times. Each individual prairie dog coterie is tested 6-9 times over 3-year period.

Prediction of kin-selection hypothesis: Individuals in coteries that contain a close genetic relative are more likely to give an alarm call than are individuals in coteries that do not contain a close genetic relative.

Prediction of null hypothesis: The presence of relatives in coteries will not influence the probability of alarm calling.

Results:



Conclusion: Alarm calling usually benefits relatives.

FIGURE 51.22 Experimental Evidence that Black-Tailed Prairie Dogs Are More Likely to Give Alarm Calls If Relatives Are Nearby.

Reciprocal Altruism

During long-term studies of highly social animals, such as lions, chimpanzees, and vampire bats, biologists have observed nonrelatives helping each other. Chimps and other primates, for example, occasionally spend considerable time grooming unrelated members of their social group—cleaning their fur and removing ticks and other parasites from their skin. In vampire bats, individuals that have been successful in finding food are known to regurgitate blood meals to non-kin that have not been successful and that are in danger of starving.

How can self-sacrificing behavior like this evolve if kin selection is not acting? The leading hypothesis to explain altruism among nonrelatives is called **reciprocal altruism**, which is an exchange of fitness benefits that are separated in time. Data that have been collected so far support the reciprocal-altruism hypothesis in at least some instances. Among vervet monkeys, for example, individuals are most likely to groom unrelated individuals that have groomed or helped them in the past. Similarly, vampire bats are most likely to donate blood meals to non-kin that have previously shared food with them. Reciprocal altruism is also widely invoked as an explanation for the helpful and cooperative behavior commonly observed among unrelated humans.

To summarize, altruistic behavior increases the fitness of individuals by favoring kin or by increasing the likelihood of receiving help in the future from non-kin. Altruism is a flexible, condition-dependent behavior that occurs in a surprisingly wide array of species that live in social groups.

Check Your Understanding

If you understand that...

- Hamilton's rule states that alleles for altruistic behavior increase in frequency if the fitness cost of the behavior for the actor is low, the fitness benefit to the recipient is high, and the actor and recipient are closely related.
- Reciprocal altruism is based on an exchange of fitness benefits, separated in time.

You should be able to...

1) Use Hamilton's rule to describe situations in which a black-tailed prairie dog is likely and unlikely to give an alarm call.
2) Explain why reciprocal altruism has been observed only in species where individuals have good memories and live in small, long-lived social groups.

Chapter Review

SUMMARY OF KEY CONCEPTS

After describing a behavior, biologists seek to explain both its proximate and ultimate causes—meaning how it happens at the genetic and physiological levels and how it affects the individual's fitness.

At the proximate level, experiments and observations focus on understanding how specific gene products, neuron activity, and hormonal signals cause behavior. At the ultimate level, researchers seek to understand the adaptive significance of behavior, or how it enables individuals to survive and reproduce. By combining proximate and ultimate viewpoints and studying the genetic basis of behavior, biologists can seek a comprehensive understanding of how and why animals do what they do.

You should be able to give an explanation at the proximate and ultimate levels for biological phenomena other than behavior—for example, cellular respiration, meiosis, water transport in plants, or the action potential in animal neurons.

In a single species, behavior may range from highly stereotyped, invariable responses to highly flexible, conditional responses and from unlearned to learned responses.

FAPs are examples of highly stereotyped, unlearned behaviors that are released by extremely simple stimuli. Language acquisition and tool making are examples of behavior that are highly dependent on learning, cognition, and the environmental conditions experienced by an individual. Most of the behavior observed in animals is condition dependent, meaning an individual has the genetic, neuronal, and hormonal mechanisms in place for behaving in a variety of ways, and the actual behavior observed depends on environmental conditions. Foraging in white-fronted bee-eaters, mate choice in barn swallow, sex change in coral-reef fish, and the onset of sexual behavior in *Anolis* lizards are examples of flexible, condition-dependent behaviors triggered by changing environmental stimuli.

You should be able to explain why migration in some birds is considered condition dependent, based on the observation that some species do not migrate if people supply food in feeders.

The types of learning that individuals do, the way they communicate, and the way they orient and navigate all correlate closely with their habitat and with the challenges they face in trying to survive and reproduce.

Animals usually behave in a way that increases their ability to survive and reproduce in their current environment. Deceitful communication can be adaptive—as when anglerfish fool prey into attacking a "lure" attached to the anglerfish's face or when molting mantis shrimps try to bluff their way into retaining ownership of a hiding place.

You should be able to predict the consequences for deceitful communication in bluegill sunfish if most large, territory-owning males were fished out of a lake.

MB **Web Animation** at www.masteringbio.com
Homing Behavior in Digger Wasps

When individuals behave altruistically, they are usually helping close relatives or individuals that help them in return.

Although it is common to observe self-sacrificing behavior in animals, most altruistic behavior is directed toward close relatives. When this is the case, alleles that lead to self-sacrificing can increase in frequency due to kin selection. In addition, some animals that live in close-knit social groups engage in reciprocal altruism—meaning they exchange help over time.

You should be able to describe the characteristics of a species for which altruistic behavior is expected to be extremely common.

QUESTIONS

Test Your Knowledge

1. What do proximate explanations of behavior focus on?
   a. how displays and other types of behavior have changed through time, or evolved
   b. the functional aspect of a behavior, or its "adaptive significance"
   c. genetic, neurological, and hormonal mechanisms of behavior
   d. psychological interpretations of behavior—especially motivation
2. What evidence suggests that there is a critical period for song learning in some bird species?
   a. In mynahs and mockingbirds, individuals continue to sing new songs throughout their lives.
   b. Individuals do not learn to sing normally unless they are allowed to hear themselves practice.
   c. Individuals that never hear their species-specific song can still sing normally as adults.
   d. Birds that are deafened soon after hatching never sing normally, but birds that are deafened several months after hatching sing normally.
3. What is the difference between orienting behavior and piloting?
   a. Orienting movements are fast responses to visual or auditory stimuli; piloting is finding the way using landmarks.
   b. Orienting is the ability to follow a compass during navigation; piloting is the ability to use map information during navigation.
   c. Orienting is used during long-distance movements such as migration; piloting is used in short-distance movements involved in homing.
   d. Orienting is the ability to use a Sun or star compass; piloting is the ability to use a magnetic compass.
4. Which of the following statements about the waggle dance of the honeybee is not correct?
   a. The length of a waggling run is proportional to the distance from the hive to a food source.
   b. Sounds and scents produced by the dancer provide information about the nature of the food source.

c. The dancer uses no elements of the round dance.
d. The orientation of the waggling run provides information about the direction of the food from the hive, relative to the Sun's position.

5. Why are biologists convinced that the sex hormone testosterone is required for normal sexual activity in male *Anolis* lizards?
   a. Male *Anolis* lizards with larger testes court females more vigorously than do males with smaller testes.
   b. The testosterone molecule is not found in female *Anolis* lizards.
   c. Male *Anolis* lizards whose gonads had been removed did not develop dewlaps.
   d. Male *Anolis* lizards whose gonads had been removed did not court females.

6. What does Hamilton's rule specify?
   a. why animals do things "for the good of the species"
   b. why reciprocal altruism can lead to fitness gains for unrelated individuals
   c. how alleles that favor self-sacrificing acts increase in frequency via kin selection
   d. the conditions under which more complex behaviors evolve from simpler behaviors

Test Your Knowledge answers: 1. c; 2. d; 3. a; 4. c; 5. d; 6. c

Test Your Understanding

Answers are available at www.masteringbio.com

1. Make a graph like that in Figure 51.2, with axes that plot the degree to which a particular behavior is modified by learning and the degree to which behavior is stereotyped and inflexible. Plot the following behaviors on the graph: tool use in New Caledonian crows; exploration of mazes by rats; singing by chickens, by white-crowned sparrows, and by mynahs; and blushing in humans.
2. Discuss the proximate and ultimate causes of the following behaviors: (a) homing behavior by spiny lobsters, (b) sexual behavior by *Anolis* lizards, and (c) the "jump-back" response of kangaroo rats.
3. Propose a hypothesis to explain the adaptive significance of tool use in New Caledonian crows. Recall that a female crow bent an unfamiliar material into a hooked tool. Explain why this observation supports the hypothesis that individuals of this species can think.
4. What environmental stimuli cause changes in hormone levels that lead to egg laying in *Anolis* lizards? Based on the data presented on sexual behavior in *Anolis*, propose a hypothesis to explain the proximate basis of sex switching in coral-reef fish.
5. For an animal to navigate, it must have a "map" and a "compass." Explain why both types of information are needed. Describe three types of compasses that have been identified in migratory or homing species.
6. Compare and contrast kin selection and reciprocal altruism. Be sure to identify the conditions under which self-sacrificing behavior is expected to evolve under kin selection versus reciprocal altruism.

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Mated pairs of cranes give territorial displays called unison calls. Cranes that are raised in isolation from other cranes give unison calls normally, and the display is performed the same way every time. Your friend argues that the unison call of cranes is a FAP, because it is stereotyped and not influenced by learning. Another friend argues that it is a condition-dependent behavior, because only mated pairs do it and because the tendency to give unison calls varies among pairs and with time of year. (Some pairs are more aggressive than others and give unison calls more frequently in territorial contexts.) Who's right?
2. Most tropical habitats are highly seasonal. But instead of alternating warm and cold seasons, there are alternating wet and dry seasons. Most animal species breed during the wet months. If you were studying a species of *Anolis* native to the tropics, what environmental cue would you simulate in the lab to bring them into breeding condition? How would you simulate this cue? Further, think about the sensory organs that lizards use to receive this cue. Are they the same as or different than the receptors that *Anolis carolinensis* uses to recognize that spring has arrived in the southeastern United States?
3. What is the significance of the observation that the product of the *for* gene in fruit flies is involved in a signal transduction pathway? Propose a hypothesis to explain why fruit-fly larvae with the rover genotype and phenotype have higher fitness when population density is high and individuals are crowded.
4. A biologist once remarked that he'd be willing to lay down his life to save two brothers or eight cousins. Explain what he meant. Based on the theory of kin selection and reciprocal altruism, predict the conditions under which people are expected to be nice to one another.

Population Ecology

52

A flock of white pelicans swimming in a channel of the Mississippi River. This chapter explores how and why growth rates in populations change through time.

KEY CONCEPTS

- Life tables summarize how likely it is that individuals of each age class in a population will survive and reproduce.
- The growth rate of a population can be calculated from life-table data or from the direct observation of changes in population size over time.
- Researchers observe a wide variety of patterns when they track changes in population size over time, ranging from no growth, to regular cycles, to continued growth independent of population size.
- Data from population ecology studies help biologists evaluate prospects for endangered species and design effective management strategies.

If you asked a biologist to name two of the most pressing global issues facing your generation, she might say global warming and extinction of species. If you were asked to name two of the most pressing issues facing the region where you live, you might say traffic and the price of housing. All four of these problems have a common cause: recent and dramatic increases in the size of the human population.

A **population** is a group of individuals of the same species that live in the same area at the same time. In both ecology and evolutionary biology, populations are the basic unit of analysis. Evolutionary biologists study how the characteristics of populations change through time; ecologists study how populations interact with their environment. Increasingly, ecologists are studying how species are being affected by growing human populations.

Population ecology is the study of how and why the number of individuals in a population changes over time. Biologists also analyze changes in the ages of individuals in a population, the proportion of males to females, and geographic distribution. With the explosion of human populations across the globe, the massive destruction of natural habitats, and the resulting threats to species throughout the tree of life, population ecology has become a vital field in biological science. The mathematical and analytical tools introduced in this chapter help biologists predict changes in population size and design management strategies to save threatened species.

Biologists ask a wide array of questions in population ecology. How are individuals distributed in space? How old are they, and how likely are they to reproduce or die? Is the population growing, declining, or staying the same through time, and why?

To answer these questions, let's consider some of the basic tools that biologists use to study populations, then follow up with examples of how biologists study changes in the population

size of humans and other species over time. The chapter concludes by asking how all of these elements fit together in efforts to limit human population growth and save endangered species.

52.1 Demography

The number of individuals that are present in a population depends on four processes: birth, death, immigration, and emigration. Populations grow due to births—here meaning any form of reproduction—and **immigration**, which occurs when individuals enter a population by moving from another population. Populations decline due to deaths and **emigration**, which occurs when individuals leave a population to join another population. Analyzing birth rates, death rates, immigration rates, and emigration rates is fundamental to **demography**: the study of factors that determine the size and structure of populations through time.

To make detailed predictions about the future of a population, however, biologists must understand the makeup of the population in more detail. If a population consists primarily of young individuals with a high survival rate and reproductive rate, the population size should increase over time. But if a population comprises chiefly old individuals with low reproductive rates and low survival rates, then it is almost certain to decline over time. To predict the future of a population, biologists need to know how many individuals of each age are alive, how likely individuals of different ages are to survive to the following year, how many offspring are produced by females of different ages, and how many individuals of different ages immigrate and emigrate each **generation**—the average time between a mother's first offspring and her daughter's first offspring.

Demographic data provide an important tool for biologists charged with designing management programs for endangered species. To understand the nature of these data and how they are used in conservation programs, let's examine a classical tool for describing the demography of a population.

Life Tables

Formal demographic analyses of populations are based on a type of data set called a life table. A **life table** summarizes the probability that an individual will survive and reproduce in any given year over the course of its lifetime. Life tables were invented almost 2000 years ago; in ancient Rome they were used to predict food needs. In modern times, life tables have been the domain of life-insurance companies, which have a strong financial interest in predicting the likelihood of a person dying at a given age. More recently, biologists have employed life tables to study the demographics of endangered species and other nonhuman populations.

To understand how researchers use life tables, consider the lizard *Lacerta vivipara* (**Figure 52.1**). *L. vivipara* is a common resident of open, grassy habitats in western Europe.

FIGURE 52.1 *Lacerta vivipara* Are Native to Europe. Translated literally, *vivipara* means "live birth." Females in most populations bear live young, though females in *L. vivipara* populations from northern Spain and southwest France lay eggs.

As their name suggests, most populations of the species are ovoviviparous (see Chapter 32) and give birth to live young. Researchers set out to estimate the life table of a low-elevation population in the Netherlands, with the goal of comparing the results to data that other researchers had collected from *L. vivipara* populations in the mountains of Austria and France and in lowland habitats in Britain and Belgium. The researchers wanted to know whether populations that live in different environments vary in basic demographic features.

To complete the study, the researchers visited their study site daily during the seven months that these lizards are active during the year. Each day the researchers captured and marked as many individuals as possible. Because this program of daily monitoring continued for seven years, the biologists were able to document the number of young produced by each female in each year of her life. If a marked individual was not recaptured in a subsequent year, they assumed that it had died sometime during the previous year. These data allowed researchers to calculate the number of individuals that survived each year in each particular age group and how many offspring each female produced. What did the data reveal?

Survivorship **Survivorship** is a key component of a life table and is defined as the proportion of offspring produced that survive, on average, to a particular age. For example, suppose 1000 *L. vivipara* are born in a particular year. These individuals represent a **cohort**—a group of the same age that can be followed through time. How many individuals would survive to age 1, age 2, age 3, and so on?

As **Table 52.1** shows, the biologists calculated that in the population living in the Netherlands, survivorship from birth to age 1 was 0.424. If 1000 females were born in a particular year in this population, on average 424 would still be alive one year later. Survivorship from birth to age 2 was 0.308, meaning an average of 308 female lizards would survive for two years.

TABLE 52.1 **Life Table for *Lacerta vivipara* in the Netherlands**

Year	Number Alive	Survivorship	Fecundity	Survivorship × Fecundity = Average Number of Offspring Produced per Female Born
0	1000	1.000	0.00	0.00
1	424	0.424	0.08	0.03
2	308	0.308	2.94	0.91
3	158	0.158	4.13	0.65
4	57	0.057	4.88	0.28
5	10	0.010	6.50	0.07
6	7	0.007	6.50	0.05
7	2	0.002	6.50	0.01

Data are from H. Strijbosch and R.C.M. Creemers, 1988. Comparative population demography of sympatric populations of *Lacerta vivipara* and *Lacerta agilis*. *Oecologia* 76: 20–26.

To recognize general patterns in survivorship and make comparisons among populations or species, biologists plot the logarithm of the number of survivors versus age. The resulting graph is called a **survivorship curve**. Studies on a wide variety of species indicate that three general types of survivorship curves exist (**Figure 52.2a**). Humans have what biologists call a type I survivorship curve. In this pattern, survivorship throughout life is high, and most individuals approach the species' maximum life span. Songbirds, in contrast, experience relatively constant mortality throughout their lives once they have left the nest, resulting in a type II survivorship curve. Many plants have type III curves due to extremely high death rates for seeds and seedlings. **Figure 52.2b** provides a graph for you to plot survivorship of *L. vivipara*.

Survivorship curves are important in conservation work, because they pinpoint the stage of life when endangered species have particularly low survivorship. Biologists can then put measures into place to protect individuals during that period. For example, when they are very young, trees or herbaceous plants can be protected from drought by germinating them in a nursery and from predation by putting a wire cage over seedlings.

Fecundity The number of female offspring produced by each female in the population is termed **fecundity**. (In most cases, biologists keep track only of females when calculating life-table data, because only females produce offspring.) Researchers documented the reproductive output of the same *L. vivipara* lizard females year after year and thus were able to calculate a quantity called **age-specific fecundity**, which is defined as the average number of female offspring produced by a female in age class x. An **age class** is a group of individuals of a specific age—for instance, all female lizards between 4 and 5 years old. As **Box 52.1** shows, data on survivorship and fecundity allow researchers to calculate the growth rate of a population. How do data on survivorship and fecundity in the Netherlands populations compare with populations in different types of habitats?

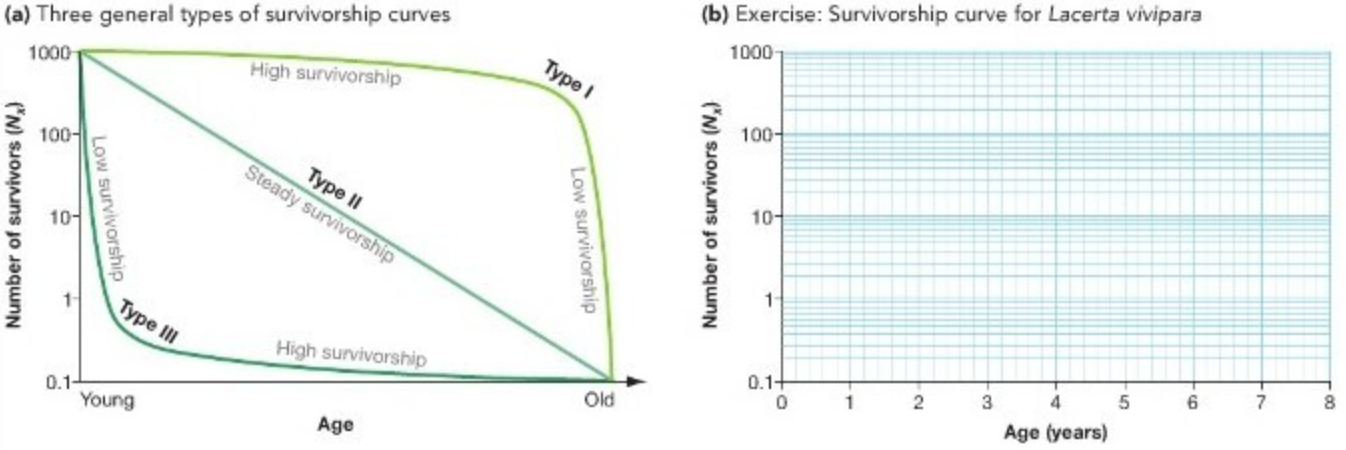

FIGURE 52.2 Survivorship Curves Identify When Mortality Rates Are Low, Steady, or High.

EXERCISE Fill in the graph in part **(b)** with data on survivorship of *Lacerta vivipara* given in Table 52.1. Compare the shape of the curve to the generalized graphs in part (a).

BOX 52.1 Using Life Tables to Calculate Population Growth Rates

If immigration and emigration are ignored, the data in a life table can be used to calculate a population's growth rate. This is logical, because survivorship and fecundity are ways to express death rates and birth rates—the other two factors influencing population size. To see how a population's growth rate can be estimated from life-table data, let's look at each component in a life table more carefully.

Survivorship is symbolized as l_x, where x represents the age class being considered. Survivorship for age class x is calculated by dividing the number of individuals in that age class (N_x) by the number of individuals that existed as offspring (N_0):

$$l_x = \frac{N_x}{N_0} \qquad \textbf{(Eq. 52.1)}$$

Age-specific fecundity is symbolized m_x, where x again represents the age class being considered. Age-specific fecundity is calculated as the total number of offspring produced by females of a particular age, divided by the total number of females of that age class present. It represents the average number of offspring produced by a female of age x.

Documenting age-specific survivorship and fecundity allows researchers to calculate the net reproductive rate, R_0, of a population:

$$R_0 = \sum_{i=0}^{x} l_x m_x \qquad \textbf{(Eq. 52.2)}$$

The **net reproductive rate** represents the growth rate of a population per generation. The logic behind the equation for R_0 is that the growth rate of a population per generation equals the average number of female offspring that each female produces over the course of her lifetime. A female's average lifetime reproduction, in turn, is a function of survivorship and fecundity at each age class. In Table 52.1, R_0 is the sum of the survivorship × fecundity values in the right column.

If R_0 is greater than 1, then the population is increasing in size. If R_0 is less than 1, then the population is declining. ● If you understand these concepts, you should be able to use the data in Table 52.1 to calculate R_0 in the Netherlands population of *L. vivipara*;[1] state how many female offspring an average *L. vivipara* female produces over the course of her lifetime,[2] and describe whether the population is growing, stable, or declining.[3] Answers are given below.

[1] $R_0 = 2.0$; [2] 2.00; [3] The population is growing rapidly.

The Role of Life History

The life-table data in Table 52.1 are interesting because they contrast with results from other populations of *L. vivipara*. For example, notice that almost no 1-year-old female *L. vivipara* lizards in the Netherlands reproduces. But in Brittany, France, 50 percent of 1-year-old female lizards reproduce. Both situations contrast sharply with data on females in the mountains of Austria. In populations that live at high elevation, females do not begin breeding until they are 4 years old. In addition, most females in the Austrian population live much longer than do individuals in either lowland population—in the Netherlands or France. When the three sites are compared, it is clear that fecundity is high but survivorship is low in Brittany. In contrast, fecundity is low but survivorship is high in Austria. The population in the Netherlands is intermediate in both characteristics.

Why isn't it possible for *L. vivipara* females to have both high fecundity and high survival? Biologists answer this question using the concept of **fitness trade-offs** (see Chapters 24 and 41). Fitness trade-offs occur because every individual has a restricted amount of time and energy at its disposal—meaning that its resources are limited. If a female lizard devotes a great deal of energy to feeding a large number of offspring as they develop, it is not possible for her to devote that same energy to her immune system, growth, nutrient stores, or other traits that increase survival. (Ask yourself whether a woman who has 10 children would be expected to live a longer or shorter time than a woman who has 2.) A female can maximize fecundity, maximize survival, or strike a balance between the two. An organism's **life history** consists of how an individual allocates resources to growth, reproduction, and activities or structures that are related to survival.

Life history trade-offs are universal. To drive this point home, **Figure 52.3** graphs the average number of eggs laid—a measure of fecundity—in 10 species of birds versus the probability that a female of that species survives to the following year. There are no points in the upper right corner of the graph because it is not possible to have high fecundity and high survivorship. There are no points in the lower left corner of the graph because species with low survivorship and low fecundity have low population growth and go extinct.

In almost all cases, biologists find that life history is shaped by natural selection in a way that maximizes an individual's fitness in its environment. For example, Chapter 41 provided experimental evidence that there is a fitness trade-off between egg size and egg number in side-blotched lizards, and that females in the study population strike a balance in egg size and number that is optimum for their habitat.

To make sense of the life-history data from *L. vivipara* populations, biologist contend that females who live a long time but mature late and have few offspring each year have high fitness in cold, high-elevation habitats. In contrast, females who have short lives but mature early and have large numbers of offspring each year do better in warm, low-elevation habitats. ● If you understand the concept of fitness trade-offs, you

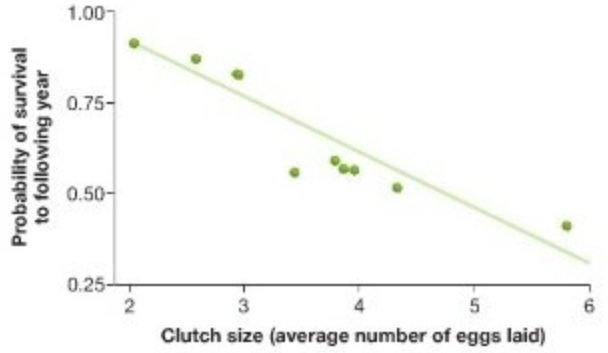

FIGURE 52.3 There Is a Trade-off between Survival and Reproduction. Graph of survivorship versus fecundity. Each data point represents a different species of bird. A statistical analysis called regression was used to create a "line of best fit" to these data points.

QUESTION To study survival-reproduction trade-offs within species of birds, researchers randomly add or subtract eggs to clutches. Predict what happens to survivorship in females that rear additional versus a reduced number of young.

FIGURE 52.4 Life-History Traits Form a Continuum. Every organism can be placed somewhere on this life-history continuum. The placement of a species is most meaningful when it is considered relative to closely related species.

EXERCISE Place *Arabidopsis thaliana* and the coconut palm on the continuum. For plants, list the types of traits you would expect to see on the left, middle, and right of the continuum. Include growth habit (herbaceous, shrub, or tree) as well as relative disease- and predator-fighting ability, seed size, seed number, body size, and investment in roots versus shoots.

should be able to (1) predict how survivorship and fecundity should compare in *L. vivipara* in the warmest part of their range (southwest France and northern Spain), and (2) comment on why females in these populations lay many eggs instead of giving birth to a few live young.

In general, organisms with high fecundity tend to grow quickly, reach sexual maturity at a young age, and produce many small eggs or seeds. The mustard plant *Arabidopsis thaliana*, for example, germinates and grows to sexual maturity in just 4 to 6 weeks. In this species, individuals usually live only a few months but may produce as many as 10,000 tiny seeds. In contrast, organisms with high survivorship tend to grow slowly and invest resources in traits that reduce damage from enemies and increase their own ability to compete for water, sunlight, or food. A coconut palm, for example, may take a decade to reach sexual maturity but live 60–70 years and produce offspring each year. Coconut palms invest resources in making stout stems that allow them to grow tall, a relatively extensive root system, large fruits (coconuts), molecules that make herbivores sick, and enzymes that reduce infections from disease-causing fungi. These traits increase the survivorship of both seedlings and adults but decrease fecundity.

An *Arabidopsis thaliana* plant and a coconut palm represent two ends of a broad continuum of life-history characteristics (**Figure 52.4**). Even within the species *L. vivipara*, analyses of life tables have shown that there is considerable variation in life-history traits.

Research has also documented that within populations, life-history traits can change if conditions change. For example, suppose that a series of wet years produced an abundance of food for lizards. Females might survive better in response, or they might begin breeding at an earlier age or produce more offspring at a particular age. Such changes might directly affect a population's growth rate. How do biologists analyze growth rates in populations? And what factors make growth rates increase or decrease?

52.2 Population Growth

The most fundamental questions that biologists ask about populations involve growth or decline in numbers of individuals. For conservationists, analyzing and predicting changes in population size is fundamental to managing threatened species.

Recall that four processes affect a population's size: Births and immigration add individuals to the population; deaths and emigration remove them. It follows that a population's overall growth rate is a function of birth rates, death rates, immigration rates, and emigration rates. In this section we consider only the impact of births and deaths on population growth; Section 52.4 includes an analysis of the movement of individuals into and out of populations.

A population's growth rate is the change in the number of individuals in the population (ΔN) per unit time (Δt). If no immigration or emigration is occurring, then the growth rate is equal to the number of individuals (N) in the population times the difference between the birth rate per individual (b) and death rate per individual (d). The difference between the birth rate and death rate per individual is called the **per-capita rate of increase** and is symbolized r. (*Per capita* means "for each individual.") If the per-capita birth rate is greater than the per-capita death rate, then r is positive and the population is growing. But if the per-capita death rate begins to exceed the per-capita birth rate, then r becomes negative and the population declines. Within populations, r varies through time and can be positive, negative, or 0.

When conditions are optimal for a particular species—meaning birth rates per individual are as high as possible and death

rates per individual are as low as possible—then r reaches a maximal value called the **intrinsic rate of increase,** r_{max}. When this occurs, a population's growth rate is expressed as

$$\Delta N/\Delta t = r_{max}N$$

In species such as *Arabidopsis* and fruit flies, which breed at a young age and produce many offspring each year, r_{max} is high. In contrast, r_{max} is low in species such as giant pandas and coconut palms, which take years to mature and produce few offspring each year. Stated another way, r_{max} is a function of a species' life-history traits.

A species with a certain life history has a characteristic r_{max} that does not change. But at any specific time, each population of that species has an instantaneous growth rate, or per-capita rate of increase, symbolized by r. The instantaneous growth rate of a population at a particular time is likely to be much lower than r_{max}. A population's r is also likely to be different from r values of other populations of the same species, and to change over time.

Exponential Growth

The graphs in **Figure 52.5** plot changes in population size for various values of r, under the condition known as exponential growth. **Exponential population growth** occurs when r does not change over time. The key point about exponential growth is that the growth rate does not depend on the number of individuals in the population. Biologists say that this type of population growth is **density independent.**

It's important to emphasize that exponential growth adds an increasing number of individuals as the total number of individuals, N, gets larger. As an extreme example, an r of 0.02 per year in a population of 1 billion adds over 20 million individuals per year. The same growth rate in a population of 100 adds just over 2 individuals per year. Even if r is constant, the number of individuals added to a population is a function of N.

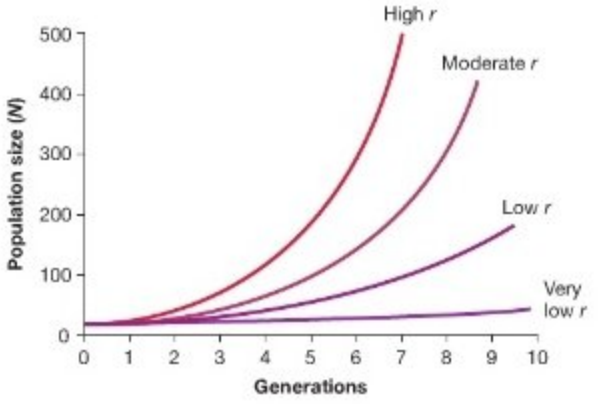

FIGURE 52.5 Exponential Growth Is Independent of Population Size. When the per-capita growth rate r does not change over time, exponential growth occurs. Population size may increase slowly or rapidly, depending on the size of r.

QUESTION Consider a species on the left-hand side of the life-history continuum in Figure 52.4 (high fecundity, low survivorship) versus a species on the right-hand side (low fecundity, high survivorship). Under ideal conditions, which species has higher r? Explain your reasoning.

In nature, exponential growth is observed when a few individuals found a new population in a new habitat or when a population has been devastated by a storm or some other type of catastrophe and then begins to recover, starting with a few surviving individuals. But it is not possible for exponential growth to continue indefinitely. If *Arabidopsis* populations grew exponentially for a long period of time, they would eventually fill all available breeding habitat. When **population density**—the number of individuals per unit area—gets very high, we would expect the population's per-capita birth rate to decrease and the per-capita death rate to increase, causing r to decline. Stated another way, growth in the natural world is most often **density dependent.**

Logistic Growth

To analyze what happens when growth is density dependent, biologists use a parameter called carrying capacity. **Carrying capacity, *K*,** is defined as the maximum number of individuals in a population that can be supported in a particular habitat over a sustained period of time. The carrying capacity of a habitat depends on a large number of factors: food, space, water, soil quality, resting or nesting sites, and the intensity of disease and predation. Carrying capacity can change from year to year, depending on conditions.

If a population of size N is below the carrying capacity K, then the population should continue to grow. More specifically, a population's growth rate should be proportional to $(K - N)/K$:

$$\frac{\Delta N}{\Delta t} = r_{max}N\left(\frac{K-N}{K}\right)$$

This expression is called the logistic growth equation. In the expression $(K - N)/K$, the numerator defines the number of additional individuals that can be accommodated in a habitat with carrying capacity K; dividing $K - N$ by K turns this number of individuals into a proportion. Thus, $(K - N)/K$ describes the proportion of "unused resources and space" in the habitat. It can be thought of as the environment's resistance to growth. When N is small, then $(K - N)/K$ is large and the growth rate should be high. But as N gets larger, $(K - N)/K$ gets smaller. When N is at carrying capacity, then $(K - N)/K$ is equal to 0 and growth stops. Thus, as a population approaches a habitat's carrying capacity, its growth rate should slow.

The logistic growth equation describes **logistic population growth,** or changes in growth rate that occur as a function of population size. Just as exponential growth is density independent, logistic growth is density dependent. **Box 52.2** explores population growth models and how they are applied in more detail.

BOX 52.2 Developing and Applying Population Growth Equations: A Closer Look

To explore how biologists model changes in population size in more detail, let's consider data on whooping cranes, which are large, wetland-breeding birds native to North America (**Figure 52.6**). Whooping cranes may live more than 20 years in the wild, but it is common for females to be six or seven years old before they breed for the first time. Female cranes lay just two eggs per year and usually rear just one chick. Based on these life-history characteristics, we would expect the growth rate of whooping crane populations to be extremely low.

Conservationists monitor this species closely, because hunting and habitat destruction reduced the total number of individuals in the world to about 20 in the mid-1940s. Since then, intensive conservation efforts have resulted in a current total population of about 518. That number includes a group of 237 individuals that breeds in Wood Buffalo National Park in the Northwest Territories of Canada.

In addition to the Wood Buffalo population, two new populations of cranes have been established recently by releasing offspring raised in captivity. One of these groups lives near the Atlantic coast of Florida year-round; the other group migrates from breeding areas in northern Wisconsin to wintering areas along Florida's Gulf coast.

FIGURE 52.6 Whooping Cranes Have Been the Focus of Intensive Conservation Efforts.

According to the biologists who are managing whooping crane recovery, the species will no longer be considered endangered when the two newly established populations have at least 25 breeding pairs—meaning there would be about 125 individuals in each—and when neither population needs to be supplemented with captive-bred young in order to be self-sustaining. How long will this take?

Discrete Growth

Whooping cranes breed once per year, so the simplest way to express a crane population's growth rate is to compare the number of individuals at the start of one breeding season to the number at the start of the following year's breeding season.

When populations breed during discrete seasons, their growth rate can be calculated as for whooping cranes. To create a general expression for how populations grow over a discrete time interval, biologists use N to symbolize population size. N_0 is the population size at time zero (the starting point), and N_1 the population size one breeding interval later. In equation form, the growth rate is given as

$$N_1 = N_0\lambda \qquad \textbf{(Eq. 52.3)}$$

The parameter λ (lambda) is called the **finite rate of increase**. (In mathematics, a *finite rate* refers to an observed rate over a given period of time. A *parameter* is a variable or constant term that affects the shape of a function but does not affect its general nature.) The current total at Wood Buffalo is 237. Suppose that biologists count 248 cranes on the breeding grounds next year. The population growth rate could be calculated as 248/237 = 1.046 = λ. Stated another way, the population will have grown at the rate of 4.6 percent per year. Rearranging the expression in Equation 52.3 gives

$$N_1 = N_0\lambda \qquad \textbf{(Eq. 52.4)}$$

Stated more generally, the size of the population at the end of time t will be given by

$$N_t = N_0\lambda^t \qquad \textbf{(Eq. 52.5)}$$

This equation summarizes how populations grow when breeding takes place seasonally. The size of the population at time t is equal to the starting size, times the finite rate of increase multiplied by itself t times. In a sense, λ works like the interest rate at a bank. For species that breed once per year, the "interest" on the population is compounded annually. A savings account with a 5 percent annual interest rate increases by a factor of 1.05 per year. If a population is growing, then its λ is greater than one. The population is stable when λ is 1.0 and declining when λ is less than 1.0.

If a population's age structure is stable, meaning that the proportion of females in each age class is not changing over time, then its finite rate of increase also has a simple relationship to its net reproductive rate: $\lambda = R_0/g$, where g is the generation time. In essence, dividing the net reproductive rate by generation time transforms it into a discrete rate.

Continuous Growth

The parameters λ and r—the finite rate of increase and the per-capita growth rate—have a simple mathematical relationship. The best way to understand their relationship is to recall that λ expresses a population's growth rate over a discrete interval of time. In contrast, r gives the population's per-capita growth rate at any particular instant. This is why r is also called the instantaneous rate of increase. The relationship between the two parameters is given by

$$\lambda = e^r \qquad \textbf{(Eq. 52.6)}$$

where e is the base of the natural logarithm, or about 2.72. (For help with using logarithms, see **BioSkills 5**. Also, note that the relationship between any finite rate and any instantaneous rate is given by finite rate = $e^{\text{instantaneous rate}}$.)

(Continued on next page)

(continued)

Substituting Equation 52.6 into Equation 52.5 gives

$$N_t = N_0 e^{rt} \qquad \textbf{(Eq. 52.7)}$$

This expression summarizes how populations grow when they breed continuously, as do humans and bacteria, instead of at defined intervals. For species that breed continuously, the "interest" on the population is compounded continuously. When the growth rates λ and r are equivalent, however, the differences between discrete and continuous growth are negligible.

Because r represents the growth rate at any given time, and because r and λ are so closely related, biologists routinely calculate r for species that breed seasonally. In the whooping crane example, $\lambda = 1.046 = e^r$. To solve for r, take the natural logarithm of both sides. (**BioSkills 5** explains how to do this on your calculator.) In this case, $r = 0.045$.

The instantaneous rate of increase, r, is also directly related to the net reproductive rate, R_0, introduced in Box 52.1. In most cases, r is calculated as $\ln R_0/g$, where g is the generation time. Thus, r can be calculated from life-table data. It is a more useful measure of growth rate than R_0, because r is independent of generation time.

To summarize, biologists have developed several ways of calculating and expressing a population's growth rate. Growth rate expressed as λ has the advantage of being easy to understand, and R_0 has the advantage of being calculated directly from life-table data. Although r is slightly more difficult conceptually, it is the most useful expression for growth rate, because it is independent of generation time and is relevant for species that breed either seasonally or continuously.

Applying the Models

To get a better feel for r and for Equation 52.7, consider the following series of questions about whooping cranes. The key to answering these questions is to realize that Equation 52.7 has just four parameters. Given three of these parameters, you can calculate the fourth. ● If you understand this concept, you should be able to solve the following four problems:

1. If 20 individuals were alive in 1941 and 518 existed in 2007, what is r? Here $N_t = 518$, $N_0 = 20$, and $t = 66$ years. Substitute these values into Equation 52.7 and solve for r. Then check your answer at the end of this box.[1]
2. In the most recent report issued by the biologists working on the Wood Buffalo crane recovery program, it is estimated that the flock should be able to sustain an r of 0.046 for the foreseeable future. If the flock currently contains 237 individuals, how long will it take that population to double? Here $N_0 = 237$ and $N_t = 2 \times 237 = 474$. In this case, you solve Equation 52.7 for t. Then check your answer.[2]
3. In 2002 a pair of birds in the flock that lives in Florida year-round successfully raised offspring (nine years after the first cranes were introduced there). In 2003 another pair of cranes in this population bred successfully. If the number of breeding pairs continues to double each year, how long will it take to reach the goal of 25 breeding pairs? (Note that $\lambda = 2.0$ if a population is doubling each year.) Given that $N_0 = 2$ and $N_t = 25$, solve for t again, and check your answer.[3]
4. The whooping crane flock that migrates between Wisconsin and Florida was founded in 2001. If its development is like that of the resident flock in Florida, the first successful breeding attempt will occur in 2010—nine years after the initial introduction. Suppose that the instantaneous growth rate for the number of breeding pairs in this population will be 0.05. In what year will the breeding population reach 25 pairs? This is the year that whooping cranes should come off the endangered species list. Here $N_0 = 1$, $N_t = 25$, and $r = 0.05$. Solve for t, and add this number of years to 2010; then check your answer.[4]

[1] $r = 0.049$; [2] $t = 15$ years; [3] $t = 3.64$ years; [4] 2074

Figure 52.7a illustrates density-dependent growth for a hypothetical population. Notice that the graph has three sections. Initially, growth is exponential—meaning that r is constant. With time, N increases to the point where competition for resources or other density-dependent factors begins to occur. As a result, the growth rate begins to decline and eventually reaches 0. When the population is at the habitat's carrying capacity, the graph of population size versus time is flat.

Figure 52.7b shows data on logistic growth from laboratory populations of two species of protists in the group called ciliates (see Chapter 29): *Paramecium aurelia* and *P. caudatum*. In this experiment, an investigator placed 20 individuals from one of the *Paramecium* species into 5 mL of a solution. He created many replicates of these 5-mL environments for each species separately. He kept conditions as constant as possible in each replicate by adding the same number of bacterial cells every day for food, washing the solution every second day to remove wastes, and maintaining the pH at 8.0. As the graphs show, both species exhibited logistic growth in this environment. The carrying capacity differed in the two species, however. The maximum density of *P. aurelia* averaged 448 individuals per mL, but that for *P. caudatum* averaged just 128 individuals per mL.

In both of the *Paramecium* species in this experiment, exponential growth could be sustained for only about 5 days. Exponential growth is almost always short lived. When population size increases, a population's growth rate has to decline. Why? What factors cause growth rates to change?

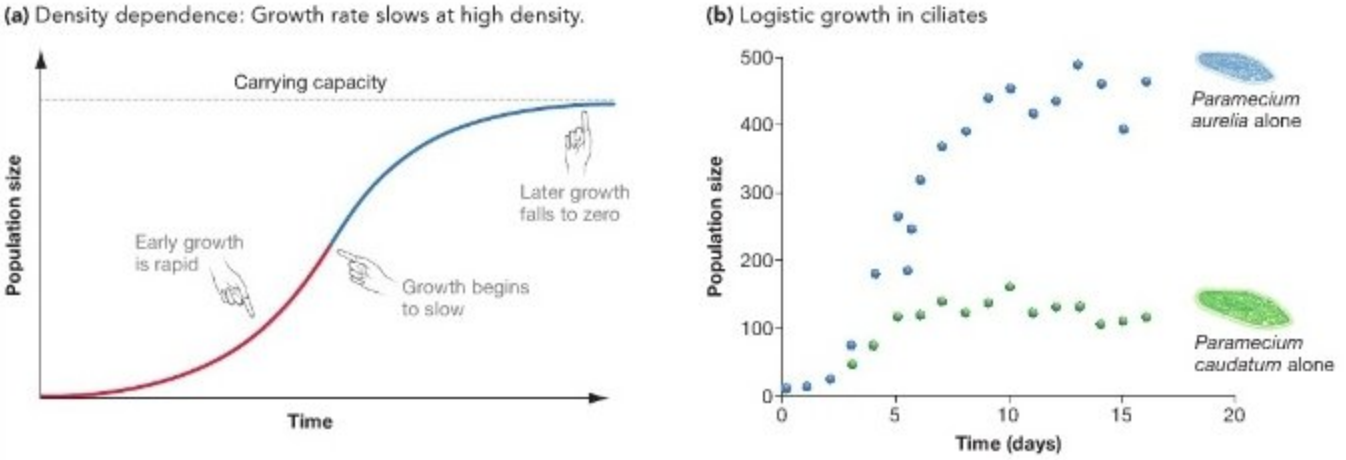

FIGURE 52.7 Logistic Growth Is Dependent on Population Size. **(a)** Hypothetical curve illustrating the pattern predicted by the logistic growth equation. This pattern often occurs when a small number of individuals colonizes an unoccupied habitat. Initially, r is high because competition for resources is low to nonexistent. Carrying capacity depends on the quality of the habitat and can vary over time. **(b)** Data from laboratory experiments with two species of *Paramecium*.

EXERCISE In part (b), draw dashed horizontal lines indicating the carrying capacity for each species.

What Limits Growth Rates and Population Sizes?

Population sizes change as a result of two general types of factors: (1) density-independent and (2) density-dependent factors. Density-independent factors alter birth rates and death rates irrespective of the number of individuals in the population. Density-independent changes are usually triggered by changes in the abiotic environment—variation in weather patterns or catastrophic events such as cold snaps, hurricanes, volcanic eruptions, or drought. In contrast, density-dependent factors are usually biotic and change in intensity as a function of population size. For example, predation rates on deer may increase when deer population sizes are high, or competition for food and starvation may become more common. When trees are crowded, they have less water, nutrients, and sunlight at their disposal and make fewer seeds. Death rates may increase and birth rates decrease when populations are at high density.

To get a better understanding of how biologists study the density-dependent factors that affect population size, consider the data in **Figure 52.8**:

- The graph in Figure 52.8a presents results of an experimental study of a coral-reef fish called the bridled goby. Each data point represents an identical artificial reef, constructed by a researcher from the rubble of real coral reefs. The initial density, plotted along the horizontal axis, is the number of marked bridled gobies that were released on each artificial reef at the start of the experiment. The proportion surviving, plotted on the vertical axis, is the number of these introduced individuals that were still living at that reef 2.5 months later. This graph shows a strong density-dependent relationship in survivorship.
- The graph in Figure 52.8b is from a long-term study of song sparrows on Mandarte Island, British Columbia. Each data point represents a different year. The density of females, plotted along the horizontal axis, is the number of females that bred on the island; the clutch size, plotted on the vertical axis, is the average number of eggs laid by each female. This graph indicates a strong density-dependent relationship in fecundity.

Density-dependent changes in survivorship and fecundity cause logistic population growth. In this way, density-dependent factors define a particular habitat's carrying capacity. If gobies get crowded, they die or emigrate. If song sparrows are crowded, the average number of eggs and offspring that they produce declines.

It's important to recognize that K varies among species and populations, however, and that this variation affects both growth rates and population sizes. K varies because for any particular species, some habitats are better than other habitats due to differences in food availability, predator abundance, and other density-dependent factors. Stated another way, K varies in space. It also varies with time, as conditions in some years are better than in others. In addition, the same region may have a very different carrying capacity for different species. The same area will tend to support many more individuals of a small-bodied species than of a large-bodied species, simply because large individuals demand more space and resources. These simple observations help explain the variation in total population size that exists among species and among populations of the same species.

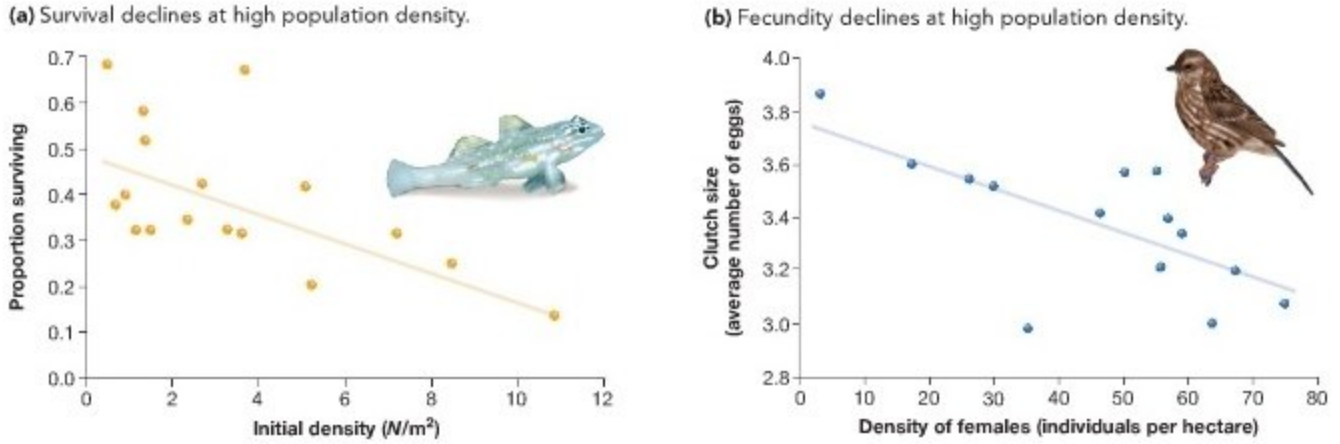

FIGURE 52.8 Density-Dependent Growth Results from Changes in Survivorship and Fecundity. (a) When bridled gobies are introduced at different population densities to artificial reefs, survivorship is highest at low density. **(b)** In the song sparrow population on Mandarte Island, there is a strong negative correlation between population density in a particular year and the average number of eggs (clutch size) produced by females.

QUESTION When song sparrow populations are at high density and extra food is provided to females experimentally, average clutch size is much higher than expected from the data in part (b). Based on these data, state a hypothesis to explain why average clutch size declines at high density.

Check Your Understanding

If you understand that...

- Populations grow exponentially unless slowed by density dependence.
- Density-dependent factors that influence population growth rates include predation, disease, and competition for resources such as food and sunlight.

You should be able to...

1) Propose a density-dependent factor that limits growth in *Paramecium aurelia* and design an experiment to test this hypothesis.
2) Propose a hypothesis to explain why the carrying capacity for *P. caudatum* in Figure 52.7b is so much lower than the carrying capacity for *P. aurelia* and design an experiment to test this hypothesis.

Modeling Population Growth

52.3 Population Dynamics

The tools introduced in the previous two sections provide a foundation for exploring how biologists study **population dynamics**—changes in populations through time. Research on population dynamics has uncovered a wide array of patterns in natural populations in addition to exponential and logistic growth.

As an initial example of how population sizes change through time, consider data on the longest-running experiment in the history of biological science: the Park Grass study in Rothamsted, United Kingdom. In 1856 researchers established a series of 0.1–0.2-ha (about 1/3-acre) plots in a hay meadow that had uniform soil characteristics and vegetation. Since then, some of the plots have received regular fertilizer treatments or lime (a mix of calcium and magnesium oxides), and some have been left untreated as controls. Each year researchers recorded which plant species were present in each plot, as an index of population size.

The weather was the same in all plots, the fertilizing and liming regimes were constant in treated plots, and presumably all plots were exposed to the same predators and diseases. Even so, several dramatic changes in population size have taken place. When the data from 1920 to 1979 were analyzed for the control plots, four major patterns emerged among the 43 species present. Ten of the species showed a clear spike in abundance, followed by a decline over the course of the 60-year period (**Figure 52.9a**). Seven species increased in abundance and then reached a plateau (**Figure 52.9b**). Five species declined steadily, and 21 showed no discernible change (**Figure 52.9c**).

In several cases, patterns of change over time appeared to correlate with life-history traits. For example, species that maintained a constant population size throughout the 60-year interval have longer life spans and a lower r_{max} than do other species at the site. To interpret this observation, biologists suggest that these species allocate more energy and resources to competitive ability than to reproduction. As a result, these species are able to maintain abundance over a longer period. In contrast, species that spiked and declined or that increased and maintained high abundance had a higher r_{max}, an earlier age at first reproduction, and shorter life spans than did species

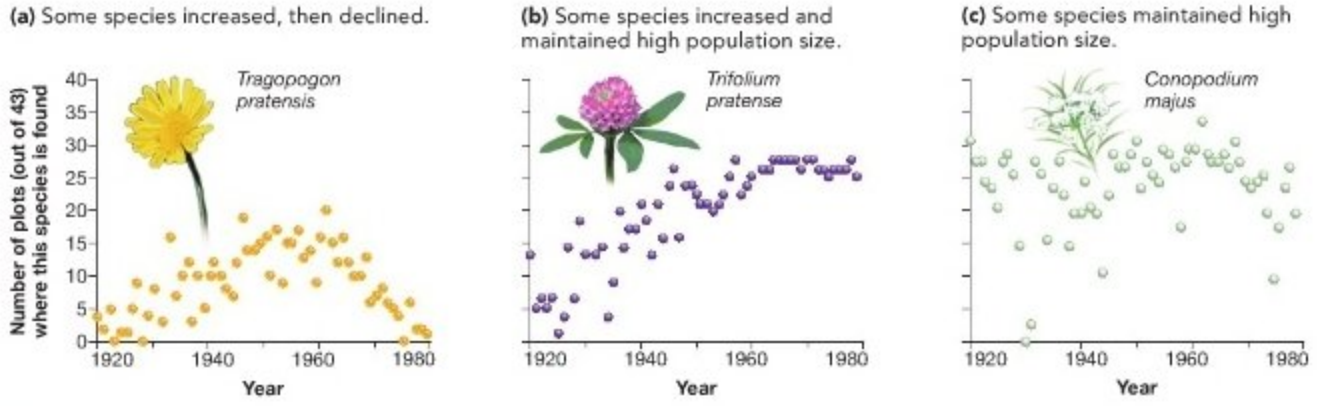

FIGURE 52.9 Distinct Patterns of Long-Term Changes in the Populations of Meadow Species. Graphs showing some of the distinct patterns in population dynamics from 1920 to 1979 among species in the Park Grass experiment, which began in 1856.

that maintained a constant population size. Researchers are still working on the question of why some of these species remained constant over time and why others declined.

How Do Metapopulations Change through Time?

If you browse through an identification guide for trees or birds or butterflies, you'll likely find range maps indicating that most species occupy a broad area. In reality, however, the habitat preferences of many species are restricted, and individuals occupy only isolated patches within that broad area. The meadows occupied by Glanville fritillaries—an endangered species of butterfly native to the Åland islands off the coast of Finland (**Figure 52.10**)—are a well-studied example of this pattern.

If individuals from a species occupy many small patches of habitat, so that they form many independent populations, they are said to represent a **metapopulation**, or population of populations. Glanville fritillaries exist naturally as metapopulations. But because humans are reducing large, contiguous areas of forest and grasslands to isolated patches or reserves, more and more species are being forced into a metapopulation structure.

Recent research on Glanville fritillaries by Ilkka Hanski and colleagues illustrates the consequences of metapopulation structure for endangered species. The work began with a survey of meadow habitats on the islands. Because fritillary caterpillars feed on just two types of host plant, *Plantago lanceolata* and *Veronica spicata*, the team was able to pinpoint potential butterfly habitats. They estimated the fritillary population size within each patch by counting the number of larval webs in each. Of the 1502 meadows that contained the host plants, 536 had Glanville fritillaries. The patches ranged from 6 m^2 to 3 ha in area. Most had only a single breeding pair of adults and one larval group, but the largest population contained hundreds of pairs of breeding adults and 3450 larvae.

FIGURE 52.10 Glanville Fritillaries Live in Patches of Meadow. The Glanville fritillary is extinct in much of its former range; it is now found only on the Åland islands near Finland.

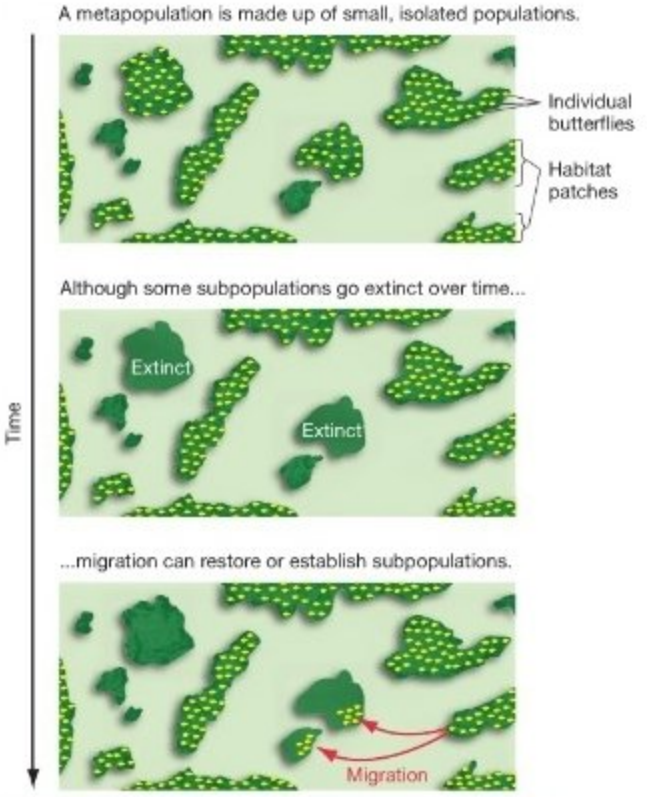

FIGURE 52.11 Metapopulation Dynamics Depend on Extinction and Recolonization. The overall population size of a metapopulation stays relatively stable even if subpopulations go extinct. These populations may be restored by migration, or unoccupied habitats might be colonized.

Figure 52.11 illustrates how a metapopulation like this is expected to change over the years. Given enough time, each population within the larger metapopulation is expected to go extinct. The cause could be a catastrophe, such as a storm or an oil spill; it could also be a disease outbreak or a sudden influx of predators. Migration from nearby populations can reestablish populations in these empty habitat fragments, however. In this way, there is a balance between extinction and recolonization. Even though subpopulations blink on and off over time, the overall population is maintained at a stable number of individuals.

Does this metapopulation model correctly describe the population dynamics of fritillaries? To answer this question, Hanski's group conducted a mark-recapture study. (**Box 52.3** on page 1188 provides details on how a mark-recapture study is done.) Of the 1731 butterflies that the biologists marked and released, 741 were recaptured over the course of the summer study period. Of the recaptured individuals, 9 percent were found in a previously unoccupied patch. This migration rate is high enough to suggest that patches where a population has gone extinct will eventually be recolonized. Hanski and co-workers repeated the survey two years after their initial census. Just as the metapopulation model predicts, some populations had gone extinct and others had been created. On average, butterflies were lost from 200 patches each year; 114 unoccupied patches were colonized and newly occupied each year. The overall population size was relatively stable even though constituent populations came and went.

To summarize, the history and future of a metapopulation is driven by the birth and death of populations, just as the dynamics of a single population are driven by the birth and death of individuals. As the final section in this chapter will show, these dynamics have important implications for saving endangered species.

Why Do Some Populations Cycle?

One of the most striking patterns in population dynamics has also been one of the most difficult to understand. **Population cycles** are regular fluctuations in size that some animal populations exhibit. **Figure 52.12** shows a classic case of population cycling: snowshoe hare and lynx populations in northern Canada. Snowshoe hares are herbivores and are the primary prey of lynx.

Most hypotheses to explain population cycles hinge on some sort of density-dependent factor. The idea is that predation, disease, or food shortages intensify dramatically at high population density and cause population numbers to crash. It has been extremely difficult, however, to document a causal

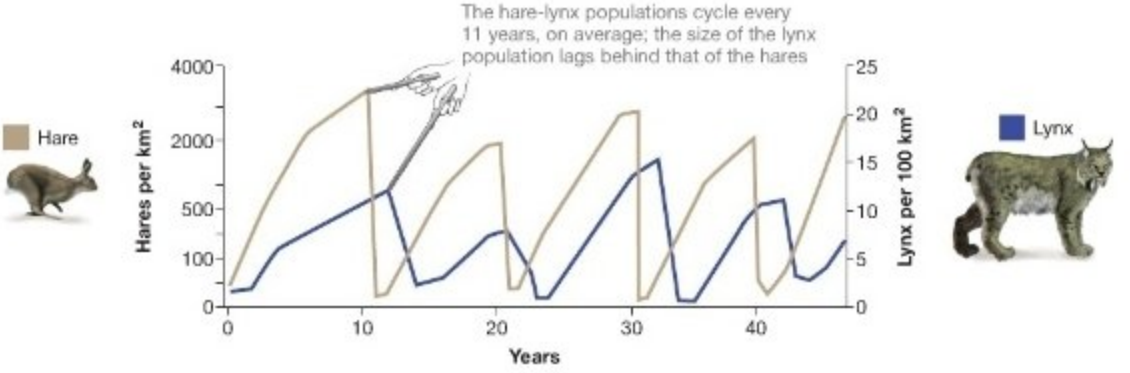

FIGURE 52.12 Hare and Lynx Populations Cycle in Synchrony. To make it easier to read, the left-hand vertical axis, which indicates hare density, is not linear.

relationship between population cycles and factors such as predation intensity, disease outbreaks, or food availability.

Although the hare-lynx cycle was documented in the early 1900s, it was not well understood. Two hypotheses were proposed to explain these population dynamics:

1. Hares use up all their food when their populations reach high density and starve; in response, lynx also starve.
2. Lynx populations reach high density in response to increases in hare density. At high density, lynx eat so many hares that the prey population crashes.

Stated another way, either hares control lynx population size or lynx control hare population size.

To test these hypotheses rigorously, researchers set up a series of 1-km^2 study plots in boreal forest habitats that were as identical as possible (**Figure 52.13**). Three plots were left as unmanipulated controls. One plot was ringed with an electrified fence with a mesh that excluded lynx but allowed hares to pass freely. Two plots received additional food for hares year-round. One plot had a predator-exclusion fence and was also supplemented with food for hares year-round. The biologists then monitored the size of the hare and lynx populations over an 11-year period, or enough time for a complete cycle in the two populations.

As the data in Figure 52.13 show, plots with predators excluded showed higher hare populations at the peak of the cycle than did control plots. This result supports the hypothesis that

Experiment

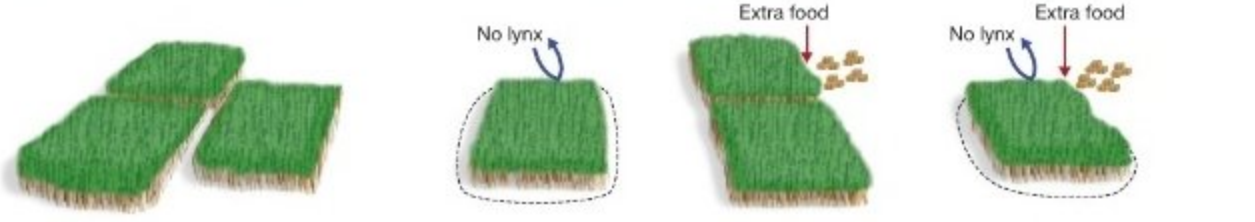
Question: What factors control the hare-lynx population cycle?

Hypothesis: Predation, food availability, or a combination of those two factors controls the hare-lynx cycle.

Null hypothesis: The hare-lynx cycle isn't driven by predation, food availability, or a combination of those two factors.

Experimental setup:

Document hare population in seven study plots (similar boreal forest habitats, each 1 km^2) over 11 years (duration of one cycle).



3 plots: Unmanipulated controls

1 plot: Electrified fence excludes lynx but allows free access by hares.

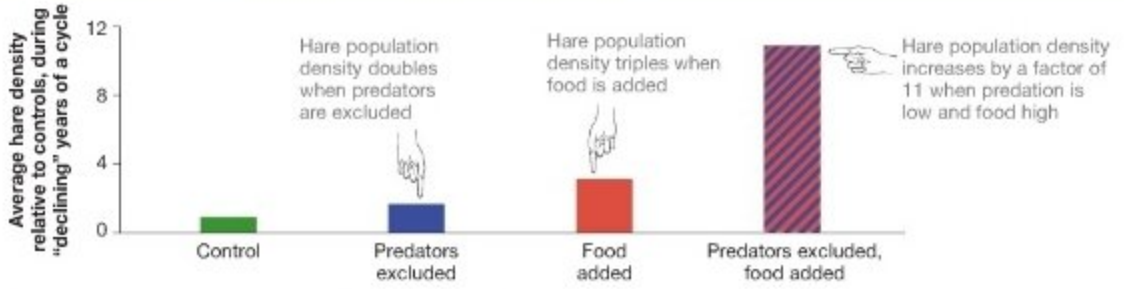
2 plots: Supply extra food for hares.

1 plot: Electrified fence excludes lynx but allows free access by hares; supply extra food for hares.

Prediction: Hare populations in at least one type of manipulated plot will be higher than the average population in control plots.

Prediction of null hypothesis: Hare populations in all of the plots will be the same.

Results:



Conclusion: Hare populations are limited by both predation and food availability. When predation and food limitation occur together, they have a greater effect than either factor does independently.

FIGURE 52.13 Experimental Evidence that Predation and Food Availability Drive the Hare-Lynx Cycle.

QUESTION State a hypothesis to explain why lack of predation and increased food, in combination, have such a large effect on hare population size.

predation by lynx reduces hare populations. Plots with supplemental food had even higher peak populations, however, and the plot with supplemental food and predators excluded had a hare population over 16 times as large as the average in control plots.

These data support the hypotheses that hare populations are limited by availability of food as well as by predation, and that food availability and predation intensity interact—meaning the combined effect of food and predation is much larger than their impact in isolation. Research continues to figure out why this is so. In the meantime, the study illustrates the power of a well-designed experiment to solve long-standing controversies in biology.

How Does Age Structure Affect Population Growth?

As the life-table data presented in Section 52.1 showed, age has a dramatic effect on the probability that an individual will reproduce and survive to the following year. But the previous analysis of life-table data left out a critical point about the ages of individuals in a population: A population's **age structure**—meaning the proportion of individuals that are at each possible age—has a dramatic influence on the population's growth over time. To see how changes in age structure can affect population dynamics, let's consider two case histories for which biologists have documented changes in age structure—one example concerns a flowering plant, and the other focuses on our own species.

Age Structure in a Woodland Herb The common primrose, pictured in **Figure 52.14a**, grows in the woodlands of Western Europe. Primroses grow on the forest floor and can germinate, mature, and produce offspring only in the relatively high-light environment created when a tall tree falls and opens a gap in the forest canopy. These sunny spaces are short lived, however, because mature trees and saplings in and around the gap grow and fill the space. As they do, light levels in the gap decline and the environment becomes increasingly unsuitable for herbs such as primrose.

Biologists recently set out to document how primrose populations respond to this ephemeral woodland environment. The researchers hypothesized that populations in new gaps and populations in large gaps—meaning those with the highest light availability—would experience high rates of reproduction and an age structure characterized by large numbers of juveniles. The researchers also hypothesized that as light levels declined in a particular gap due to the growth of surrounding trees, primrose reproduction would decline. As a result, the age structure of populations in older gaps should be characterized by a large proportion of individuals in adult stages, with fewer juveniles.

To test these hypotheses, the investigators selected eight common primrose populations growing in a range of light levels, from high to low. The team established 1-m^2 study plots inside each gap and studied approximately 350 individuals per population. Each individual was assigned to one of five ages: seedlings, juveniles, or adults in one of three size classes. As **Figure 52.14b** shows, the data supported the hypothesis that in gaps with high light levels, populations have a larger proportion of juveniles than do gaps with low light levels. In addition, the proportion of juvenile individuals declined over time in all gaps as light levels declined. These data have three important messages about the dynamics of primrose populations:

1. Populations that are dominated by juveniles should experience rapid growth. Population size should then decline with time, however, due to a density-independent factor: shading by trees.

(a) Common primroses live in sunlit gaps in forests.

(b) Age structure of primrose population varies with age of gap.

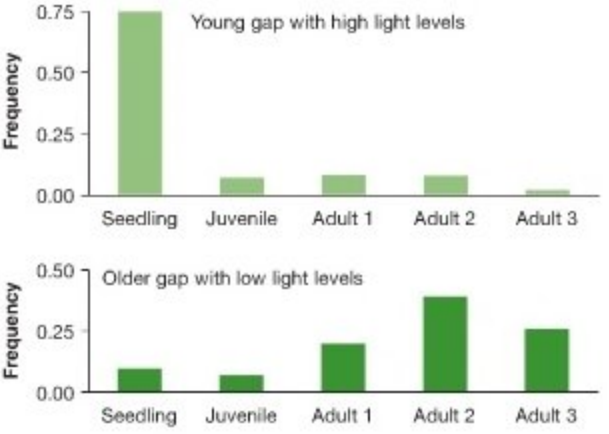


FIGURE 52.14 The Age Structure of Common Primrose Populations Changes over Time. In the graphs, "Adult 1," "Adult 2," and "Adult 3" individuals are of increasingly large size and thus age.

EXERCISE Create a third graph showing the age distribution of a gap that has completely filled in and closed, meaning that light levels are now as low as they were before the gap existed.

2. The long-term trajectory of the overall primrose population in an area may depend primarily on the frequency and severity of windstorms that knock down trees and create sunlit gaps. If so, it means that the dynamics of primrose populations are governed by an abiotic, density-independent factor.

3. In a large tract of forest, the primrose population will consist of a large number of subpopulations, each found in canopy gaps. Some of these subpopulations are likely to be very small, and each subpopulation will arise, grow, and then go extinct over time. Recall that biologists say that a group of small, isolated populations such as this represents a metapopulation, a population of populations. Primroses have metapopulation structure.

Age Structure in Human Populations As another example of how age structure affects population dynamics, consider humans. In countries where industrial and technological development occurred many decades ago, survivorship has been high and fecundity low for several decades. As a result, these populations are not growing quickly. When researchers create a graph with horizontal bars representing the numbers of males and females of each age group for such a population, an age pyramid like that in **Figure 52.15a** results. The most striking pattern in these data is that there are similar numbers of people in most age classes. The evenness occurs because the same number of infants are being born each year and because most survive to old age. In this way, analyzing an age pyramid can give biologists important information about a population's history.

Studying age distributions can also help researchers predict a population's future. For example, the populations of developed nations are not expected to grow especially quickly, because only modest numbers of individuals will reach reproductive age in the near future. The white lines and lighter bars in Figure 52.15a show the projected age structure of a developed nation (Sweden) in 2050. Modest changes in the age distribution have occurred since 2000 because survivorship has increased while fecundity has remained the same. The projections highlight a major public policy concern in countries such as this: how to care for an increasingly aged population.

In contrast, the age distribution is bottom-heavy in less-developed nations. As **Figure 52.15b** shows, these populations are dominated by the very young. This type of age distribution occurs when populations have undergone rapid growth—with more children being born than exist in older age classes. Due to dramatic improvements in health care, most people in the younger age classes now survive to reproductive age.

For Figure 52.15b, the projected age distribution in 2050 in Honduras is based on continued high survivorship and a pattern that has occurred repeatedly around the world: When infant mortality drops in a country, fecundity rates begin to decline within a generation or two. The white lines and light bars in Figure 52.15b are relatively even for ages 0–55—meaning that rapid growth has stopped—because fecundity is expected to be relatively low and survivorship high. The projected data also illustrate a major public policy concern in less-developed countries—providing education and jobs for an enormous group of young people who will be reaching adulthood during your lifetime.

The data in Figure 52.15b make another important point: Because of recent and rapid growth in developing countries, overall population size will increase dramatically in these nations over the course of your lifetime. A large part of the increase will be due to increased survivorship. But the number

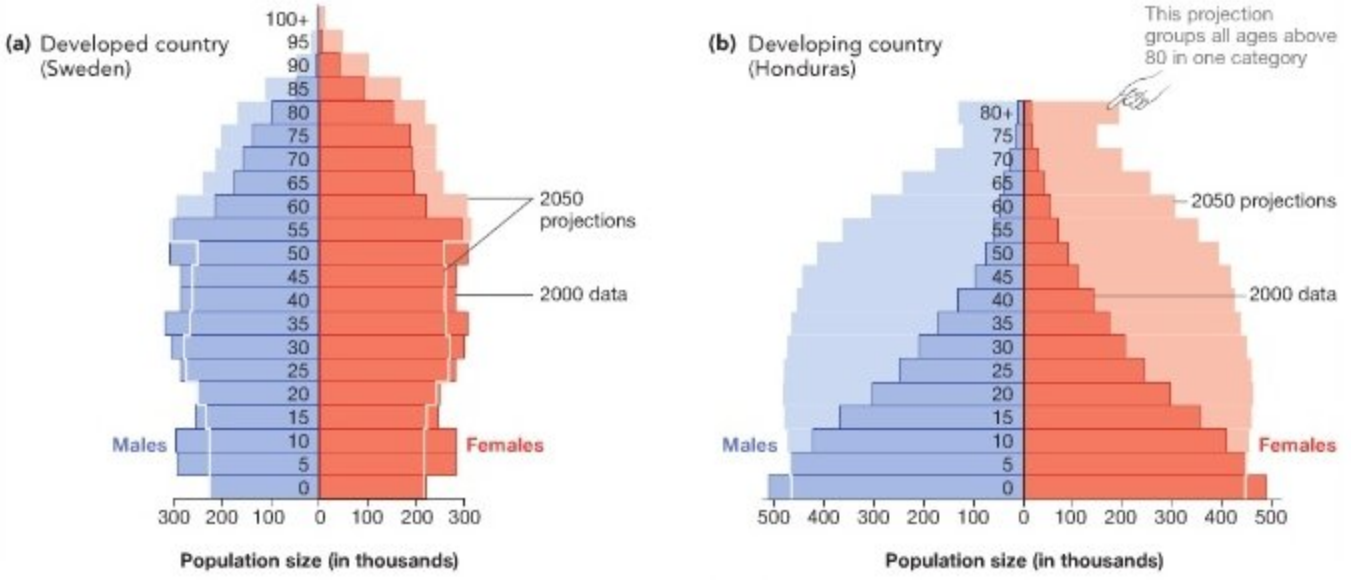

FIGURE 52.15 The Age Structure of Human Populations Varies Dramatically. Age distributions showing the number of males and females in 5-year age increments from 0 to 100.

BOX 52.3 Mark-Recapture Studies

To estimate the population size of sedentary (largely immobile) organisms, researchers sample appropriate habitats by counting the individuals that occur along transects or inside rectangular plots—called quadrats—set up at random locations in the habitat. These counts can be extrapolated to the entire habitat area to estimate the total population size. In addition, they can be compared to later censuses to document trends over time.

In contrast, estimating the total population size of organisms that are mobile and that do not congregate into herds or flocks or schools is much more of a challenge. In species such as the Glanville fritillary, the population inside sample quadrats or along transects changes constantly as individuals move in and out. Further, it can be difficult to track whether a particular individual has already been counted.

If individuals can be captured and then tagged in some way, however, the total population size of a mobile species can be estimated by using an approach called mark-recapture. To begin a mark-recapture study, researchers catch individuals and mark them with leg bands, ear tags, or some other method of identification. After the marked individuals are released, they are allowed to mix with the unmarked animals in the population for a period of time. Then a second trapping effort is conducted, and the percentage of marked individuals that were captured is recorded.

To estimate the total population from these data, researchers make a key assumption: The percentage of marked and recaptured individuals is equal to the percentage of marked individuals in the entire population. This assumption should be valid when no bias exists regarding which individuals are caught in each sample attempt. It is important that individuals do not learn to avoid traps after being caught once and that they do not emigrate or die as a result of being trapped.

The relationship between marked and unmarked individuals can be concisely expressed algebraically:

$$\frac{m_2}{n_2} = \frac{n_1}{N}$$

In this equation, m_2 is the number of marked animals in the second sample (the recapture), n_2 is the total number of animals (marked and unmarked) in the second sample, n_1 is the number of marked animals in the first sample, and N is the total population size. Having measured m_2, n_2, and n_1, the researcher can estimate N. If you understand how to estimate population size in a mark-recapture study, you should be able to do so in this example: Suppose researchers marked 255 animals and later were able to trap a total of 162 individuals in the population, of which 78 were marked. What is the estimate for total population size? Solve for N and check your answer.[1]

$0\varepsilon\varsigma = N_1$

of offspring being born each year is also expected to stay high, even though fecundity is predicted to decline significantly. This result seems paradoxical but is based on a key observation: There are now so many young women in these populations that the overall number of births will stay high even though the average number of children per female is much less than it was a generation ago. To capture this point, biologists say that these populations have momentum or inertia. Combined with high survivorship, population pyramids like these make continuing increases in overall population size inevitable.

As these examples show, understanding age structure is a key component of analyzing population dynamics in humans and other species. Now let's take a more detailed look at recent and projected changes in the world population of humans.

Analyzing Change in the Growth Rate of Human Populations

Studies on changes in whooping crane and the Park Grass populations over 60-year periods have been extraordinarily valuable. But six decades turns out to be short in comparison to data available on human population dynamics.

Archeological and anthropological data have been used to estimate the size of human populations over the past 250 years (**Figure 52.16**). Although the shape of the curve is superficially similar to the examples of exponential growth in Figure 52.5, the growth rate for humans has actually increased over time since 1750, leading to a steeply rising curve.

It is difficult to overemphasize just how dramatically the human population has increased over the past 250 years. **Table 52.2** presents data that will allow you to calculate how long it has taken this population to add each billion people, and to determine how many times the population has doubled—from a starting point in the year A.D. 1420—and how many years the

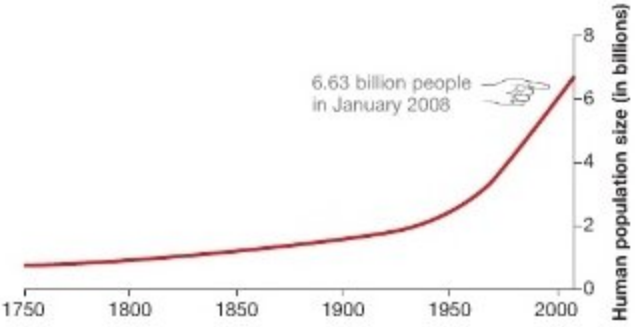

FIGURE 52.16 The Human Population Has Been Growing Rapidly. Graph based on estimates from historical and census data.

TABLE 52.2 **Milestones in Human Population Growth**

Date	Human Population (in hundreds of millions)

1720	750
1800	1000
1875	1500
1927	2000
1961	3000
1974	4000
1987	5000
1999	6000
Number of years required to add 1 billion people:	
Number of years required to double population:	

EXERCISE Using the data provided, fill in the correct number of years in the blank cells in the table. To calculate the time required for the human population to reach 1 billion, assume that *Homo sapiens* originated 150,000 years ago.

population took to double each time. To put your calculations on doubling time in perspective, consider that until your grandparents' generation, no individual had lived long enough to see the human population double. But many members of the generation born in the early 1920s have lived to see the population *triple*. And to drive home the impact of continued population doubling, consider the following: If you were given a penny on January 1, then $0.02 on January 2, $0.04 on January 3, and so on, you would be handed $10,737,418 on January 31.

As this book goes to press, the world population is estimated at 6.6 billion. About 77 million additional people—equivalent to the current population of Egypt, or more than double the state of California—are being added each year.

It is not possible to overstate the consequences of recent and current increases in human population. In addition to being the primary cause of the habitat losses and species extinctions analyzed in Chapter 55, overpopulation is linked by researchers to declines in living standards, mass movements of people, political instability, and acute shortages of water, fuel, and other basic resources in many parts of the world.

The one encouraging trend in the data is that the growth rate of the human population has already peaked and begun to decline. The highest growth rates occurred between 1965 and 1970, when populations increased at an average of 2.04 percent per year. Between 1990 and 1995, the overall growth rate in human populations averaged 1.46 percent per year; the current growth rate is 1.2 percent annually. In humans, r may be undergoing the first long-term decline in history. The question is: Will the human population stabilize or begin to decline in time to prevent global—and potentially irreversible—damage?

Will Human Population Size Peak in Your Lifetime? The United Nations Population Division makes regular projections for how human population size will change between now and 2050. For most readers of this book, these projections describe what the world will look like as you reach your early 60s.

The UN projections are based on four scenarios, which hinge on different values for fertility rates—the average number of children that each woman has during her lifetime. Currently, the worldwide average is 2.7. This represents an enormous reduction from the fertility rates during the 1950s, which averaged 5.0 children per woman. **Figure 52.17** shows how total population size is expected to change by 2050 if average fertility continues to decline and averages 2.5 (high), 2.1 (medium), or 1.7 (low) children per woman. The middle number, 2.1, **replacement rate**, where each woman produces exactly enough offspring to replace herself and her offspring's father. When this fertility rate is sustained for a generation, $r = 0$ and there is **zero population growth** (**ZPG**).

A glance at Figure 52.17 should convince you that the four scenarios are starkly different. If average fertility around the world stays at its present level, world population will be closing in on 12 billion about the time you might consider retiring. This is close to double the current population. To realize what this might mean, imagine what traffic or home prices in your city would be like if double the number of people were using the roads and needing housing.

The "high-fertility" projection assumes that fertility rates continue to drop but average 2.5 children per woman over this interval. This model predicts that world population in 2050 will reach nearly 11 billion—a 75 percent increase over today's population—with no signs of peaking. The low-fertility projection, in contrast, predicts that the total human population in 2050 will be about 7.4 billion and will already have peaked.

The graphs make an important point: The future of the human population hinges on fertility rates—on how many children each of the women living today decides to have. Those decisions, in turn, depend on a wide array of factors,

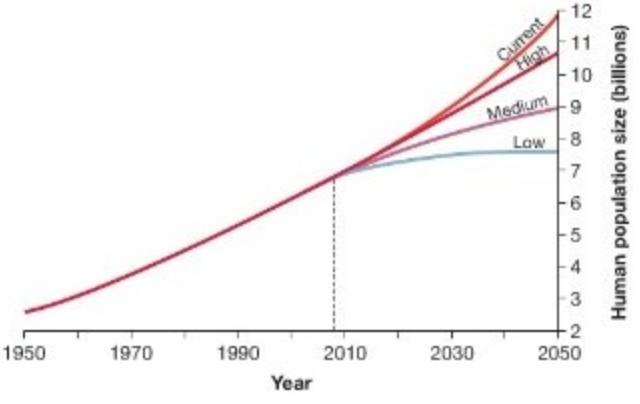

FIGURE 52.17 Projections for Human Population Growth to 2050. The "Current," "High," "Medium," and "Low" labels refer to fertility rates.

including how free women are to choose their family size and how much access women have to education. When women are allowed to become educated, they tend to delay when they start having children and have a smaller overall family size. Access to education and reliable birth control methods (see Chapter 48), in addition to overall economic development, access to quality health care, and other issues—including the course of the AIDS epidemic (see Chapter 35)—will all play a large role in determining how world population changes over your lifetime.

To summarize, humans may be approaching the end of a period of rapid growth that lasted well over 500 years. How quickly growth rates decline and how large the population can eventually become will be decided primarily by changes in fertility rates.

Check Your Understanding

If you understand that...

- Biologists use observational data—such as the life history of species in the Park Grass experiment—or experiments—such as manipulating food and predation in snowshoe hare populations—to text hypotheses about changes in the size of populations over time.
- In many cases, understanding population dynamics depends on understanding changes in a population's age structure.

You should be able to...

1) Explain why the age structure of human populations differs between developed and developing nations.
2) Explain why changes in fertility rates have such a dramatic impact on projections for the total human population in 2050.

Human Population Growth and Regulation

52.4 How Can Population Ecology Help Endangered Species?

Conservationists draw heavily on concepts and techniques from population ecology when designing programs to save species threatened with extinction. As habitat destruction and invasive species push species throughout the world into decline, the study of population growth rates and population dynamics has taken on an increasingly applied tone.

To illustrate one of the ways that biologists apply the theory and results introduced in this chapter, let's analyze how an understanding of life-table data and geographic structure can help direct conservation action.

Using Life-Table Data to Make Population Projections

Demographic data such as age-specific survivorship and fecundity are important for saving endangered species and for other applied problems. To understand why, suppose that you were in charge of reintroducing a population of lizards to a nature reserve, and that research conducted when this species occupied the site previously documented the survivorship and fecundity data. Your initial plan is to take 1000 newly hatched females from a captive breeding center and release them into the habitat. Is this population likely to become established and grow, or will you need to keep introducing offspring that have been raised in captivity?

To answer this question, you need to use the life-table data in **Figure 52.18a** and calculate (1) how many adults will survive to each age class each year and (2) how many offspring will be produced by each adult age class each year over the course of several years. **Figure 52.18b** starts these calculations for you. The fate of the original 1000 females is indicated in red. In the second year, just 330 of these individuals have survived; 40 are left as 3-year-olds.

How many offspring did this generation produce? As just stated, 330 of the original 1000 females remain after one year. As the first purple number in Figure 52.18b indicates, these survivors have an average of 3.0 female offspring apiece, so they contribute 990 new juveniles to the population. In the second year, the 200 females that are left have an average of 4.0 female offspring each and contribute 800 juveniles. In their third year, the 40 surviving females average 5.0 offspring and contribute 200 juveniles.

Figure 52.18c extends the calculations by showing what happens as the offspring of the original females begin to breed. Their offspring are shown in green. By adding subsequent generations and continuing the analysis, you should be able to predict whether the population will stay the same, decline, or increase over time. In this way, life-table data can be used to predict the future of populations.

Part of the value of a population projection based on life-table data—like the one begun in Figure 52.18—is that it allows biologists to alter values for survivorship and fecundity at particular ages and assess the consequences. For example, suppose that a predatory snake began preying on juvenile lizards. According to the model in Figure 52.18, what would be the impact of a change in juvenile mortality rate? Analyses like this allow biologists to determine which aspects of survivorship and fecundity are especially sensitive for particular species. The studies done to date support some general conclusions:

- Whooping cranes, sea turtles, spotted owls, and many other endangered species have high juvenile mortality, low adult mortality, and low fecundity. In these species, the fate of a population is extremely sensitive to increases in adult mortality. Based on this insight, conservationists have

(a) Life table

Age (x)	Survivorship (l_x)	Fecundity (m_x)
0 (birth)	----	0.0
1	0.33	3.0
2	0.2	4.0
3	0.04	5.0

(b) Fate of first-generation females

Year	0 (newborns)	1-year-olds	2-year-olds	3-year-olds	Total population size (N)
1st	1000 (just introduced)				1000
2nd	990 (= 330 × 3.0)	330 (= 1000 × 0.33)			1320 (= 990 + 330)
3rd	800 (= 200 × 4.0)		200 (= 1000 × 0.20)		
4th	200 (= 40 × 5.0)			40 (= 1000 × 0.04)	
5th					

(c) Fate of first- and second-generation females

Year	0 (newborns)	1-year-olds	2-year-olds	3-year-olds	Total population size (sum across all rows)
1st	1000				1000
2nd	990	330			1320
3rd	800 + 981 (981 = 327 × 3.0)	327 (= 990 × 0.33)	200		2308 (= 800 + 981 + 327 + 200)
4th	200 + 792 (792 = 198 × 4.0)		198 (= 990 × 0.20)	40	
5th	195 (195 = 39 × 5.0)			39 (= 990 × 0.04)	

FIGURE 52.18 Life-Table Data Can Be Used to Project the Future of a Population. (a) Life table providing age-specific survivorship and fecundity for a hypothetical population of lizards. **(b)** Predicted fate of 1000 one-year-old females introduced into a habitat just before the breeding season. The number of individuals in this cohort is shown in red; the number of offspring they produce each year is indicated in purple. **(c)** Extension of the data in part (b), indicating how many of the offspring produced by the original females in their first year survived in subsequent years, shown in purple, and how many offspring they produced in each subsequent year, shown in green.

EXERCISE Assume that all 4-year-old females die after producing three young. Fill in the 4th and 5th years in the table.

recently begun an intensive campaign to reduce the loss of adult female sea turtles in fishing nets. Previously, most conservation action had focused on protecting eggs and nesting sites.

- In humans and other species with high survivorship in most age classes, rates of population growth are extremely sensitive to changes in age-specific fecundity. Because of this, programs to control human population growth focus on two issues: lowering fertility rates through the use of birth control, and delaying the age of first reproduction by improving women's access to education.

In some or even most cases, however, the population projections made from life-table data may be too simplistic to be useful. For example, conservationists may need to expand the basic demographic models to account for occasional disturbances such as fires or storms or disease outbreaks. And what about species where overall population dynamics are dictated by a metapopulation structure?

Preserving Metapopulations

Decades of work have convinced biologists that the conclusions about metapopulation dynamics introduced in the previous section are correct, and that an increasing number of species are being forced into a metapopulation structure. Habitat destruction caused by suburbanization and other human activities leaves small populations isolated in pockets of intact habitat.

Work on Glanville fritillaries and other species has shown that a small, isolated population—even one within a nature preserve—is unlikely to survive over the long term. In Glanville fritillaries, data collected by Hanski's group have identified the attributes of subpopulations that are most likely to persist: They are large, occupy larger geographical areas, and are closer to neighboring populations (and hence more likely to be colonized). The data also indicate that fritillary populations with low genetic diversity—probably due to inbreeding—are more likely to go extinct than are populations of the same size that have higher genetic diversity.

Results like these have important messages for conservation biologists:

- Areas that are being protected for threatened species should be substantial enough in area to maintain large populations that are unlikely to go extinct in the near future.
- When it is not possible to preserve large tracts of land, an alternative is to establish systems of smaller tracts that are connected by corridors of habitat, so that migration between patches is possible.
- If the species that is threatened exists as a metapopulation, it is crucial to preserve at least some patches of unoccupied habitat to provide future homes for immigrants. If a population is lost from a preserve, the habitat should continue to be protected so it can be colonized in the future.

These results also have a more general message: Although traditional population growth models such as the expressions for exponential and logistic growth are simple and elegant, the factors they ignore—immigration and emigration—are crucial to understanding the dynamics of most populations. Because metapopulation structure is common, biologists must use more sophisticated models to predict the fates of populations.

Population Viability Analysis

A **population viability analysis**, or **PVA**, is a model that estimates the likelihood that a population will avoid extinction for a given time period. In most cases, a PVA attempts to combine basic demographic models for a species with data on geographic structure and the rate and severity of habitat disturbance. Typically, a population is considered viable if the analysis predicts that it has a 95 percent probability of surviving for at least 100 years. Natural resource managers are currently using PVA to assess the effects of logging, suburbanization, and other land management practices on sensitive species and to evaluate the merits of alternative recovery plans for endangered species.

A recent study—conducted on an endangered marsupial called Leadbeater's possum—illustrates the value of a carefully constructed PVA. Leadbeater's possum (**Figure 52.19a**) inhabits old-growth forests in southeastern Australia and relies on dead trees for nest sites. The goal of the PVA was to assess the effects that logging these habitats might have on the viability of the species. The question was, if logging reduced the ability of possums to migrate to new habitats, what would the impact on the population be?

(a) Leadbeater's possum

(b) Population viability analysis (PVA)

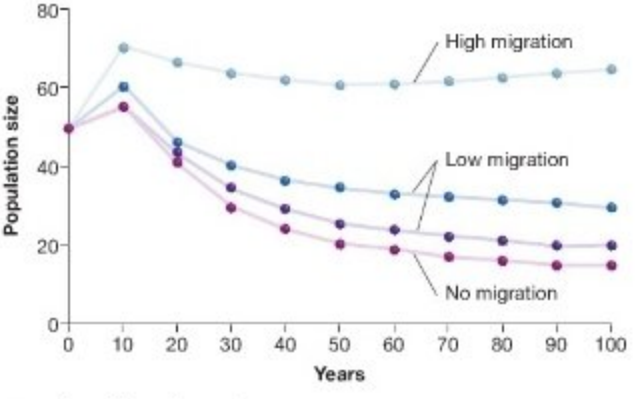

FIGURE 52.19 A PVA Can Predict the Consequences of Habitat Loss and Fragmentation. (a) Leadbeater's possum, a marsupial that breeds in old-growth forests of southeast Australia. **(b)** Results of a PVA: the fate of possum populations for four different rates of migration among habitat patches. The rates range from a case in which patches are isolated and no migration occurs to a case in which 5 percent of the individuals migrate each year. The no-migration scenario simulates what might happen if extensive deforestation occurred and created isolated patches of old-growth forest.

Life-table data are difficult to obtain for Leadbeater's possum, because this species is rare, lives in trees, and is active at night. Enough data were available from field studies, however, to allow for an estimate of age-specific survival and average fecundity per female per year. Biologists used these data to make population projections while varying the spatial configuration of habitat patches. The analysis allowed the researchers to assess the impact of migration and to simulate the effects of logging, fires, storms, and other disturbances.

Figure 52.19b illustrates the researchers' results. Each data point represents a population in a particular year. The four curves describe the changes in population size predicted to occur over time, based on different assumptions about the migration rates between groups of possums in patches of old-growth forest. When migration is high, the overall population size is predicted to stabilize at approximately 65 individuals. When no migration among fragments occurs, the final population size is predicted to be fewer than 20 individuals. Based on these results, the biologists concluded that extensive timber harvesting would pose a serious threat to the species. The PVA showed that reducing the size and number of remaining old-growth fragments would reduce the possibility for migration and lead to rapid population declines.

Like all analyses based on simulations, though, a PVA makes many assumptions about future events and is only as accurate as the data entered into it. In particular, the usefulness of PVAs has been challenged because data on age-specific fecundity and survivorship and other basic demographic information are lacking or poorly documented in many endangered species.

A group of biologists recently defended the approach, however, by analyzing 21 long-term studies that have been completed on threatened populations of animals. To do their analysis, the researchers split each of the 21 data sets in two. Data from the first half of each study was used to run a PVA on each of the 21 species. After comparing the predictions of the PVAs to the actual data from the second half of each study, the researchers found that the correspondence was extremely close. This result strengthens confidence in PVA as a good predictive method for land managers.

Chapter Review

SUMMARY OF KEY CONCEPTS

A population is a group of individuals of the same species that occupy the same area at the same time. Population ecology is the study of how and why the number of individuals in a population changes over time. Population size changes in response to changes in birth, death, immigration, and emigration rates. Biologists use a variety of mathematical and analytical tools to study population ecology.

Life tables summarize how likely it is that individuals of each age class in a population will survive and reproduce.

Life tables are a basic tool in demography—the study of patterns in births and deaths in populations. When life tables of different species or populations are compared, it is clear that individuals have distinct ways of allocating energy and resources to activities that promote survival versus activities that promote reproduction. Because the resources available to an individual are always limited, any increase in allocation of resources to survival and competitive ability necessitates a decrease in the resources allocated to reproduction. This trade-off between survival and reproduction is the most fundamental aspect of a species' life history.

You should be able to explain why a life table is relevant only to a particular population at a particular time, and predict how the first life tables—constructed in ancient Rome—differ from the current life table for the same population.

The growth rate of a population can be calculated from life-table data or from directly observing changes in population size over time.

One of the most basic characteristics of a population is its growth rate. Exponential growth occurs when the per-capita growth rate, r, does not change over time. Eventually, however, growing populations approach the carrying capacity of their environment. When this happens, logistic growth occurs.

Laboratory and field studies have confirmed the existence of exponential and logistic growth in species ranging from whooping cranes to *Paramecium*. Field research has documented that as population density increases, survivorship and fecundity may decrease—leading to increased death rates and lowered birth rates and thus a reduction in growth rate. Density dependence in population growth is due to competition for resources, disease, predation, or other factors that increase in intensity when population size is high.

You should be able to draw a logistic growth curve for a hypothetical human population, describe how r changes along its length, and suggest factors responsible for each change in r.

Modeling Population Growth

A wide variety of patterns are observed when researchers track changes in population size over time, ranging from no growth, to regular cycles, to continued growth independent of population size.

Experiments have shown that density-dependent factors drive the regular population cycles observed in certain species. In the case of snowshoe hare and lynx populations, both predator-prey interactions and food availability affect these species' synchronized population cycles.

Changes in population size through time may occur due to changes in the age structure of populations—specifically the number of individuals in various age classes. A population with few juveniles and many adults past reproductive age, like the human populations of developed nations, may be declining or stable in size. In contrast, a population with a large proportion of juveniles is likely to increase rapidly in size. Human populations in the developing nations currently have this type of age distribution.

The total human population has been increasing rapidly since about 1750 and is currently over 6.6 billion. In countries where survivorship has increased due to medical advances, fecundity has decreased. Based on various scenarios for average female fertility, the total human population in 2050 is expected to be between 7 and 11 billion.

You should be able to explain why human populations are projected to continue rapid growth, even though fertility rates are declining.

Web Animation at www.masteringbio.com
Human Population Growth and Regulation

Data from population ecology studies help biologists evaluate prospects for endangered species and design effective management strategies.

Human activities are isolating populations into metapopulations occupying small, fragmented habitats. The dynamics of a metapopulation are driven by the birth and death of populations, just as the dynamics of a population are driven by the birth and death of individuals. Migration among habitat patches is essential for the stability of a metapopulation, so conservationists are trying to preserve unoccupied patches of habitat and establish corridors that link habitat fragments.

Demographic data are the basis of population projections that are fundamental to population viability analysis, or PVA. Most PVAs attempt to model the effects that different management strategies might have on populations of endangered species. A PVA estimates the probability that a population will persist for a certain number of years under a prescribed set of demographic and habitat conditions.

You should be able to explain why a small, isolated population is virtually doomed to extinction, but why population size may be stable in a species consisting of a large number of small, isolated populations.

QUESTIONS

Test Your Knowledge

1. What is the defining feature of exponential growth?
   a. The population is growing very quickly.
   b. The growth rate is constant.
   c. The growth rate increases rapidly over time.
   d. The growth rate is very high.
2. What four factors define population growth?
   a. age-specific birth rates, age-specific death rates, age structure, and metapopulation structure
   b. survivorship, age-specific mortality, fecundity, death rate
   c. mark-recapture, census, quadrat sampling, transects
   d. births, deaths, immigration, emigration
3. In what populations does exponential growth tend to occur?
   a. in populations that colonize new habitats
   b. in populations that experience intense competition
   c. in populations that experience high rates of predation
   d. in metapopulations
4. Which of the following is *not* a reason that population growth declines as population size approaches the carrying capacity?
   a. Climate becomes unfavorable.
   b. Competition for resources increases.
   c. Predation rates increase.
   d. Disease rates increase.
5. If most individuals in a population are young, why is the population likely to grow rapidly in the future?
   a. Death rates will be low.
   b. The population has a skewed age distribution.
   c. Immigration and emigration can be ignored.
   d. Many individuals will begin to reproduce soon.
6. Why have population biologists become particularly interested in the dynamics of metapopulations?
   a. because humans exist as a metapopulation
   b. because whooping cranes exist as a metapopulation
   c. because many populations are becoming restricted to small islands of habitat
   d. because metapopulations explain why populations occupying large, contiguous areas are vulnerable to extinction

Test Your Knowledge answers: 1. b; 2. d; 3. a; 4. a; 5. d; 6. c

Test Your Understanding

Answers are available at www.masteringbio.com

1. Explain Equations 52.3 and 52.5 in words.
2. Draw type I, II, and III survivorship curves on a graph with labeled axes. Explain why the growth rate of species with a type I survivorship curve depends primarily on fertility rates. Explain why the growth rate of species with a type III survivorship curve is extremely sensitive to changes in adult survivorship.
3. Offer a hypothesis to explain why humans have undergone near-exponential growth for over 500 years. Why can't exponential growth continue indefinitely? Describe two documented examples of density-dependent factors that influence population growth in natural populations.
4. Compare and contrast the dynamics of a population that resides in a large contiguous habitat to the dynamics of a metapopulation. Be sure to consider density-dependent and density-independent factors on birth rates and death rates, and the importance of immigration and emigration. Assume that the total amount of area occupied is the same in both populations.
5. Make a rough sketch of the age distribution in developing versus developed countries, and explain the significance of the differences. How is AIDS, which is a sexually transmitted disease, affecting the age distribution in countries hard hit by the epidemic?
6. Compare the pros and cons of using R_0, λ, and r to express growth rates. What is the difference between r (the per-capita rate of increase) and r_{max} (the maximum or intrinsic growth rate)?

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. When wild plant and animal populations are logged, fished, or hunted, only the oldest or largest individuals tend to be taken. What impact does harvesting have on a population's age structure? How might harvesting affect the population's life-table and growth rate?
2. Design a system of nature preserves for an endangered species of beetle whose larvae feed on only one species of sunflower. The sunflowers tend to be found in small patches that are scattered throughout dry grassland habitats. Explain the rationale behind your proposal.
3. The population of the United States is projected to increase dramatically over the next 50 years, even though fertility rates are only slightly above replacement level and the age distribution is largely stable. How is this possible?
4. In most species the sex ratio is at or near 1.00, meaning that there is an approximately equal number of males and females. In China, however, there is a strong preference for male children. According to the 2000 census there, the sex ratio of newborns is almost 1.17, meaning that close to 117 boys are born for every 100 girls. Based on these data, researchers project that there will soon be about 50 million more men than women of marriageable age in China. Discuss how this skewed sex ratio might affect the population growth rate in China.

53 Community Ecology

KEY CONCEPTS

- Interactions among species, such as competition and consumption, have two main outcomes: (1) They affect the distribution and abundance of the interacting species, and (2) they are agents of natural selection and thus affect the evolution of the interacting species. The nature of interactions between species frequently changes over time.
- The assemblage of species found in a biological community changes over time and is primarily a function of climate and chance historical events.
- Species diversity is high in the tropics and lower toward the poles. The mechanism responsible for this pattern is still being investigated.

This chapter explores how species that live in coral reefs and other communities interact with each other, and how communities change over time.

Chapter 52 focused on the dynamics of populations—how and why they grow or decline and how they change over time and through space. That chapter considered each population as an isolated entity. But in reality, populations of different species form complex assemblages called communities. A biological **community** consists of interacting species, usually living within a defined area.

The concept of a biological community was introduced in Chapter 50. Each of the biomes analyzed in that chapter represents a broad grouping of plant communities. The goal of that chapter was to describe the general characteristics of selected biomes and analyze broad correlations between a region's climate and the type of biome present.

The task in this chapter is to analyze the dynamics of biological communities—how they develop and change over time. Biologists want to know how communities work. How do species inside communities interact with each other, and what are the long-term consequences? What happens to communities when they are disturbed by fires or flood, and why is the number of species higher in some areas than others? Let's delve in.

53.1 Species Interactions

The species in a community interact almost constantly. Members of different species eat one another, pollinate each other, exchange nutrients, compete for resources, and provide habitats for each other. As a result, the fate of a particular population may be tightly linked to the other species that share its habitat.

To study species interactions, biologists focus on analyzing the effects on the fitness of the individuals involved. Recall

from Chapter 24 that **fitness** is defined as the ability to survive and produce offspring. Does the relationship between two species provide a fitness benefit to members of one species (a + interaction) but hurt members of the other species (a − interaction)? Or does the association have no effect on the fitness of a participant (a "0" interaction)? Three broad categories of interaction are analyzed in this chapter: the −/− relationship known as competition, the +/− interactions called consumption and parasitism, and the +/+ association termed mutualism. A fourth category of interaction, **commensalism**, is defined as a +/0 association. An example is the birds that follow moving army ants in the tropics. As the ants march along the forest floor, they hunt insects and small vertebrates. As they do, birds follow and pick off prey species that fly or jump up out of the way of the ants (**Figure 53.1**). The birds are commensals that benefit from the association (+) but have no measurable impact on the ants (0).

In addition to introducing the array of tools that biologists use to study competition, consumption, and mutualism, this section focuses on three key themes:

1. Species interactions may affect the distribution and abundance of a particular species. Recall from Chapter 52 that most of the density-dependent factors that produce logistic growth are based on species interactions—predation, disease, or competition for space and resources. In addition, changes in species interactions often explain short-term changes in population size and distribution.

2. Species act as agents of natural selection when they interact. Deer are fast and agile in response to natural selection exerted by their major predators, wolves and cougars. The speed and agility of deer, in turn, promote natural selection that favors wolves and cougars that are fast and that have superior eyesight and senses of smell. To capture this point, biologists say that species interactions resemble an arms race. In humans, an arms race is said to occur when one nation develops a new weapon, which prompts a rival country to develop a defensive weapon, which pushes the original country to manufacture an even more powerful weapon, and so on. In biology, a coevolutionary arms race occurs between predators and prey, parasites and hosts, and other types of interacting species. "Coevolutionary" indicates that species influence each others' evolution, leading to reciprocal adaptation. In this way, changes in species interactions lead to long-term changes in the characteristics of populations, a phenomenon called **coevolution**, in addition to having short-term impacts on population size.

3. The outcome of interactions among species is dynamic and conditional. Consider the relationship between army ants and birds that follow them, which is usually commensal. If bird attacks start to force other insects into the path of the ants, then both ants and birds benefit and the relationship becomes mutualistic. But if birds begin to steal prey that would otherwise be taken by ants, then the relationship becomes parasitic. The outcome of the interaction may depend on the number and types of prey, birds, and ants present and may change over time.

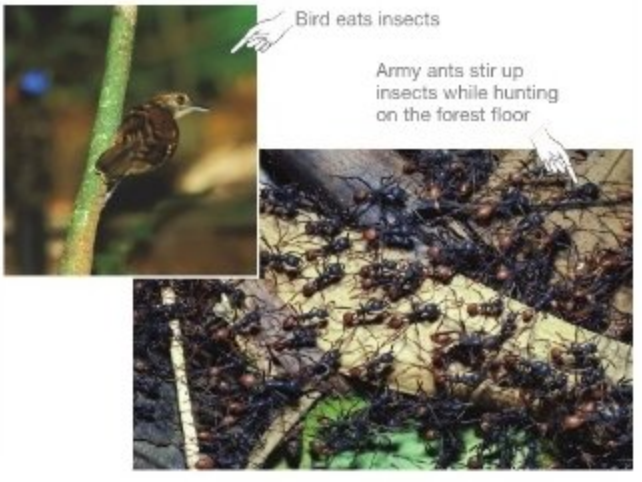

FIGURE 53.1 Commensals Gain a Fitness Advantage but Don't Affect the Species They Depend On. Birds that associate with army ants are commensals. They have no measurable fitness effect on the ants but gain from the association by capturing insects that try to fly or climb out of the way of the ants.

Competition

Competition is a −/− interaction that occurs when different individuals use the same resources and when those resources are limiting—meaning that lack of access to those resources prevents individuals from surviving better and having more offspring.

Ever since ecological studies began, researchers have focused on competition as an important interaction within and between species. The attention is justified in part by the central place that competition holds in the theory of evolution by natural selection. Darwin pointed out that individuals within a population compete for the resources that are required for growth and reproduction. Further, some individuals are more successful in this competition and leave more offspring than others do. If the traits that lead to success are heritable, then the frequency of alleles in the population changes and evolution by natural selection occurs.

Competition that occurs between members of the same species is called **intraspecific** (literally, "within species") **competition**. In addition to creating opportunities for natural selection to occur, intraspecific competition for space, sunlight, food, and other resources intensifies as a population's density increases. As a result, intraspecific competition is a major cause of density-dependent growth (see Chapter 52).

(a) Consumptive competition

These trees are competing for water and nutrients.

(b) Preemptive competition

Space preempted by these barnacles is unavailable to competitors.

(c) Overgrowth competition

The large fern has overgrown other individuals and is shading them.

(d) Chemical competition

Few plants are growing under these *Salvia* shrubs.

(e) Territorial competition

Grizzly bears drive off black bears.

(f) Encounter competition

Spotted hyenas and vultures fight over a kill.

FIGURE 53.2 Many Types of Competition Exist.

Interspecific ("between species") **competition** occurs when individuals from different species use the same limiting resources. As **Figure 53.2** shows, the mechanisms involved vary widely.

1. *Consumptive competition* occurs when two species consume the same resources (Figure 53.2a).
2. *Preemptive competition* exists when one species makes space unavailable to other species (Figure 53.2b).
3. *Overgrowth competition* happens when one species grows above another (Figure 53.2c).
4. *Chemical competition* takes place when one species produces toxins that negatively affect another species (Figure 53.2d).
5. *Territorial competition* arises when a mobile species protects its feeding or breeding territory against other species (Figure 53.2e).
6. *Encounter competition* occurs when two species interfere directly for access to specific resources (Figure 53.2f).

Using the Niche Concept to Analyze Competition Early work on competition focused on the concept of the niche. A **niche** can be thought of as the range of resources that the species is able to use or the range of conditions it can tolerate. G. Evelyn Hutchinson proposed that a species' niche could be envisioned by plotting these habitat requirements along a series of axes. **Figure 53.3a**, for example, represents one niche axis for a hypothetical species. In this case, the habitat requirement plotted is the size of seeds eaten by members of this population, which might be a function of mouth or tooth size. Other niche axes could represent other types of foods used or the temperatures, humidity, and other environmental conditions tolerated by the species.

Interspecific competition occurs when the niches of two species overlap. The two species plotted in **Figure 53.3b**, for example, compete for seeds of intermediate size. When competition occurs, each individual will get fewer seeds on average and fitness will decline. This is why competition is considered a $-/-$ interaction.

What Happens When One Species Is a Better Competitor? G. F. Gause claimed it is not possible for species with the same niche to coexist. This hypothesis is called the **competitive exclusion principle**, and it was inspired by a series of experiments Gause did with similar species of the unicellular pond-dweller *Paramecium*. When Gause placed small populations of *P. caudatum* and *P. aurelia* in separate laboratory cultures, both species exhibited logistic growth (see Chapter 52). But Gause showed that when the two species are put in the same

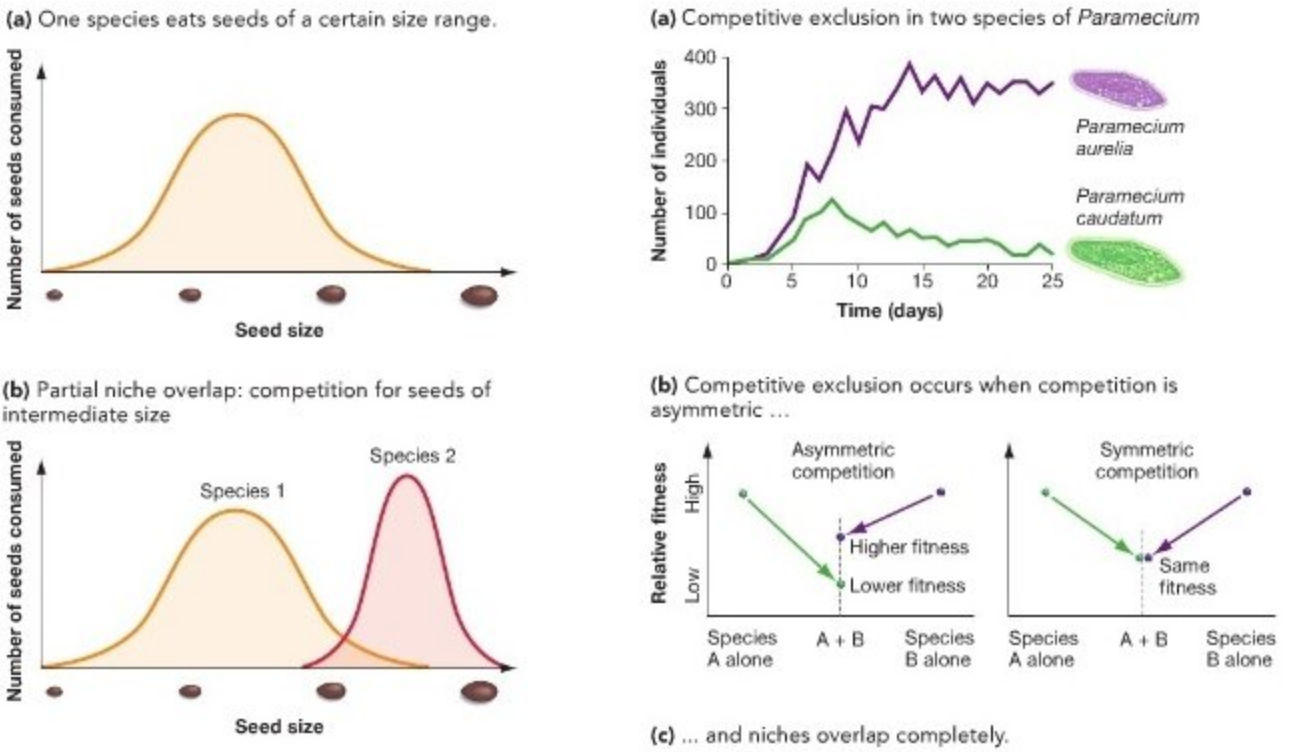

FIGURE 53.3 Niche Overlap Leads to Competition. (a) Graph describing one aspect of a species' fundamental niche, meaning the range of resources that it can use or range of conditions it can tolerate. **(b)** Competition occurs when the niches of different species overlap. In this case, both species use seeds of intermediate size.

EXERCISE Mark the horizontal axis to indicate the range of seed sizes where competition occurs.

culture together, only the *P. aurelia* population exhibits a logistic growth pattern. *P. caudatum*, in contrast, is driven to extinction (**Figure 53.4a**).

Gause's result is a product of asymmetric competition. When **asymmetric competition** occurs, one species suffers a much greater fitness decline than the other species does (**Figure 53.4b**). Under **symmetric competition**, however, each of the interacting species experiences a roughly equal decrease in fitness.

If asymmetric competition occurs and the two species have completely overlapping niches, as diagrammed in **Figure 53.4c**, then the stronger competitor is likely to drive the weaker competitor to extinction. But if the niches do not overlap completely, then the species that is the weaker competitor should be able to retreat to an area of non-overlap. In cases like this, an important distinction arises between a species' **fundamental niche**, which is the combination of resources or areas used or conditions tolerated in the absence of competitors, and its **realized niche**, which is the portion of resources or areas used or conditions tolerated when competition occurs (**Figure 53.4d**).

FIGURE 53.4 Niche Overlap Leads to Competitive Exclusion or Restricted Habitat Use. (a–c) If two species have completely overlapping niches, there is no refuge for the weaker competitor. It may be driven to extinction. **(d)** A realized niche is a subset of a species' fundamental niche.

In Gause's laboratory cultures, competition between *P. aurelia* and *P. caudatum* was asymmetric and competitive exclusion occurred. How can researchers study competition in the field, under natural conditions?

Experimental Studies of Competition Joseph Connell began a classic study of competition in the late 1950s, after observing an interesting pattern in an intertidal rocky shore in Scotland. He noticed that there were two species of barnacles with distinctive distributions. Barnacle larvae are mobile, but adults live attached to rocks. The adults of one species, *Chthamalus stellatus*, occurred in an upper intertidal zone, while the adults of the other species, *Semibalanus balanoides* (formerly named *Balanus balanoides*), were restricted to a lower intertidal zone (**Figure 53.5**). The upper intertidal zone is a more severe environment for barnacles, because it is exposed to the air for longer periods at low tide each day. The young of both species were found together in the lower intertidal zone, however.

To explain these observations, Connell hypothesized that adult *Chthamalus* were competitively excluded from the lower intertidal zone. The alternative hypothesis is that adult *Chthamalus* are absent from the lower intertidal zone because they do not thrive in the physical conditions there.

Connell tested these hypotheses by performing the experiment shown in **Figure 53.6**. He began by removing a number of rocks that had been colonized by *Chthamalus* from the upper intertidal zone and transplanting them into the lower intertidal zone. He screwed the rocks into place and allowed *Semibalanus* larvae to colonize them. Once the spring colonization period was over, Connell divided each rock into two groups. In one half, he removed all *Semibalanus* that were in contact with or next to a *Chthamalus*.

This experimental design allowed Connell to document *Chthamalus* survival in the absence of competition with *Semibalanus* and compare it with survival during competition. This is a common experimental strategy in competition studies: One of the competitors is removed, and the response by the remaining species is observed.

Connell's results support the hypothesis of competitive exclusion. In the unmodified areas, *Semibalanus* killed many of the young *Chthamalus* by growing against them and lifting them off the substrate. As the graph in Figure 53.6 shows, *Chthamalus* survival was much higher when all of the *Semibalanus* were removed.

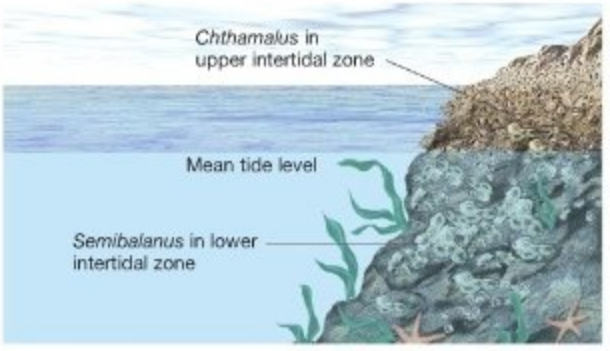

FIGURE 53.5 Barnacle Species Are Distributed in Distinct Zones. In natural habitats, adult *Chthamalus* and *Semibalanus* barnacles do not coexist.

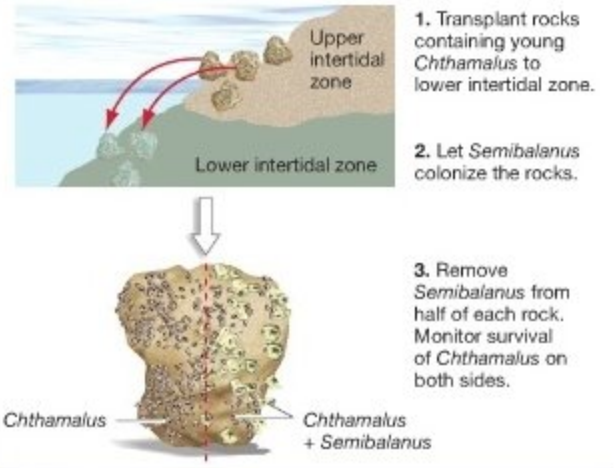
Experiment

Question: Why is the distribution of adult *Chthamalus* restricted to the upper intertidal zone?

Hypothesis: Adult *Chthamalus* are competitively excluded from the lower intertidal zone.

Alternative hypothesis: Adult *Chthamalus* do not thrive in the physical conditions of the lower intertidal zone.

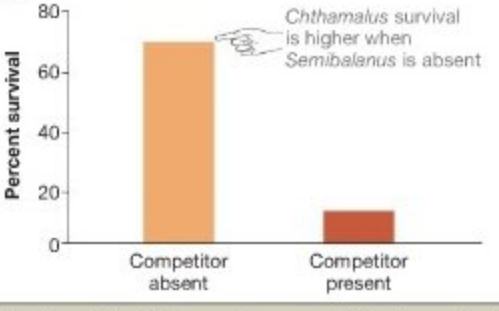
Experimental setup:



Prediction: *Chthamalus* will survive better in the absence of *Semibalanus*.

Prediction of alternative hypothesis: *Chthamalus* survival will be low and the same in the presence or absence of *Semibalanus*.

Results:



Conclusion: *Semibalanus* is competitively excluding *Chthamalus* from the lower intertidal zone.

FIGURE 53.6 Experimental Evidence for Competitive Exclusion.

QUESTION Why was it important to carry out both treatments on the same rock? Why not use separate rocks?

QUESTION Connell also did the reciprocal removal experiment—removing *Chthamalus* from experimental rocks. Predict the outcome of this experiment.

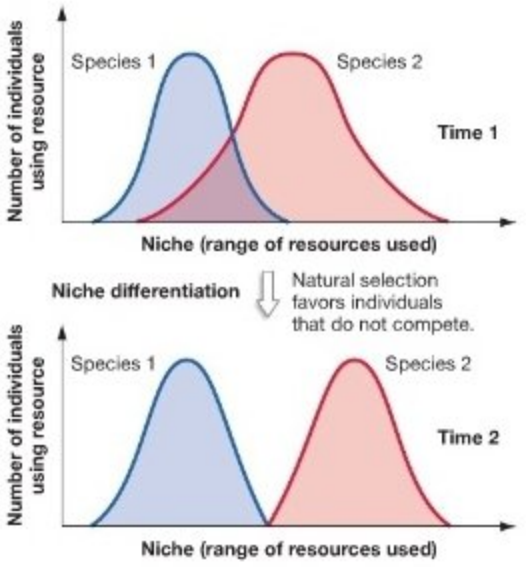


FIGURE 53.7 Over Time, Competition Can Lead to Niche Differentiation.

QUESTION Biologists call the outcome of this process resource partitioning. Explain why.

Mechanisms of Coexistence: Fitness Trade-offs and Niche Differentiation Why haven't *Semibalanus* and other superior competitors taken over the world? Biologists answer this question by invoking the concept of fitness trade-offs (see Chapter 24). The key here is that the ability to compete for a particular resource—like space on rocks or edible seeds of a certain size—is only one aspect of an organism's niche. If individuals are extremely good at competing for a particular resource, then they are probably less good at enduring drought conditions, warding off disease, or preventing predation.

In the case of *Semibalanus* and *Chthalamus* growing in the intertidal, the fitness trade-off is rapid growth and success in competing for space versus the ability to endure the harsh physical conditions of the upper intertidal. *Semibalanus* are fast-growing and large; *Chthalamus* grow slowly but can survive long exposures to the air and to intense sun and heat. Neither species can do both things well. Fitness trade-offs limit the ability of superior competitors to spread.

It's also important to realize that because competition is a −/− interaction, there is strong natural selection on both species to avoid it. **Figure 53.7** shows the predicted outcome: An evolutionary change in traits reduces the amount of niche overlap, and thus the amount of competition. This change in resource use is called **niche differentiation** or resource partitioning; the change in species' traits is called **character displacement**. The fundamental idea is that competition exerts natural selection, and that the characteristics of species change in a way that reduces competition.

Peter and Rosemary Grant recently documented character displacement occurring in Galápagos finches. You might recall, from Chapter 24, that the Grants observed dramatic increases in average beak size and body size of a *Geospiza fortis* population during a drought in 1977. The changes occurred because the major food source available during the drought was fruits from a plant called *Tribulus cistoides*, and because only the largest-beaked individuals were able to crack these fruits and eat the seeds inside. In 1982, however, individuals from a species called *Geospiza magnirostris* arrived on the island and began breeding. *G. magnirostris* are about twice the size of *G. fortis* and use *T. cistoides* fruits as their primary food source (**Figure 53.8**).

A severe drought recurred in 2003 and 2004; most finches died of starvation. When the Grants measured the surviving *G. fortis* they made a remarkable observation: In contrast to the 1977 drought, only the *smallest*-beaked individuals survived. Data on feeding behavior indicated that *G. magnirostris* were outcompeting *G. fortis* for *T. cistoides* fruits. Only *G. fortis* that could eat extremely small seeds efficiently could survive.

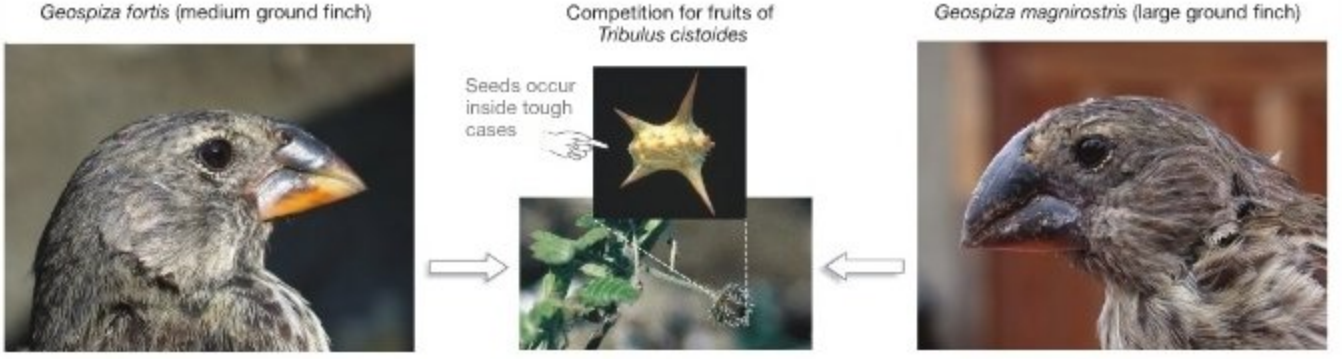

FIGURE 53.8 A Natural Experiment in Niche Differentiation. During drought years, *Geospiza fortis* have to compete for *Tribulus cistoides* fruits with *Geospiza magnirostris* if they are present.

Under similar environmental conditions, then, the presence of competition altered the course of evolution. This is a dramatic example of character displacement. Large ground finches and medium ground finches are partitioning a resource to avoid competition.

Consumption

Consumption occurs when one organism eats another. There are three major types of consumption:

1. **Herbivory** takes place when **herbivores** ("plant-eaters") consume plant tissues. Bark beetles mine cambium; cicadas suck sap; caterpillars chew leaves.
2. **Parasitism** occurs when a **parasite** consumes relatively small amounts of tissue or nutrients from another individual, called the **host**. Parasitism often occurs over a long period of time. It is not necessarily fatal, and parasites are usually small relative to their host. An array of worms and unicellular protists parasitizes humans; ticks parasitize cattle and other large mammals. Not all parasitism involves consumption, however—social parasites in birds and insects lay their eggs in other species' nests and induce them to raise the young.
3. **Predation** occurs when a predator kills and consumes all or most of another individual. The consumed individual is called the prey. Woodpeckers eat bark beetles; finches eat seeds; ladybird beetles devour aphids; wasps kill caterpillars.

To illustrate how biologists analyze the impact of consumption, let's consider a series of questions about predators, herbivores, parasites, and their victims.

How Do Prey Defend Themselves? With respect to fitness, predation is costly for the prey species and beneficial for the predator. Prey individuals do not passively give up their lives to increase the fitness of their predators, however. Instead, prey may hide or run, fly, or swim away when they sense the presence of a predator. Analyses have shown that many species find safety in numbers—schooling and flocking behavior is an effective way to reduce the risk of predation, in part because predators become confused when they dive or swim into a mass of prey. Other prey species sequester or spray toxins or employ weaponry such as sharp spines or kicking hooves. The traits just listed are called **standing** or **constitutive defenses**, because they are always present (**Figure 53.9a**).

Some of the best-studied constitutive defenses involve the phenomenon called mimicry. **Mimicry** occurs when one species closely resembles another species. **Figure 53.9b** illustrates two major types of mimicry. The wasp on the far left is brightly colored and dangerous, because of its stinger. It looks like other dangerous insects—particularly other wasps and bees. When harmful prey species resemble each other, **Müllerian mimicry** is said to occur. To explain the existence of **Müllerian** mimics, biologists propose that the existence of similar-looking dangerous prey in the same habitat increases the likelihood that predators will learn to avoid them. In this way, Müllerian mimicry

(a) Constitutive defenses of animals vary.

Camouflage: blending into the background

Schooling: safety in numbers

Weaponry: fighting back

(b) Mimicry can protect both dangerous and harmless species.

FIGURE 53.9 Constitutive Defenses Are Always Present. (a) Prey have an array of adaptations to reduce the likelihood of predation. **(b)** Müllerian mimicry occurs among dangerous prey species; Batesian mimicry occurs between a dangerous prey species and harmless prey species.

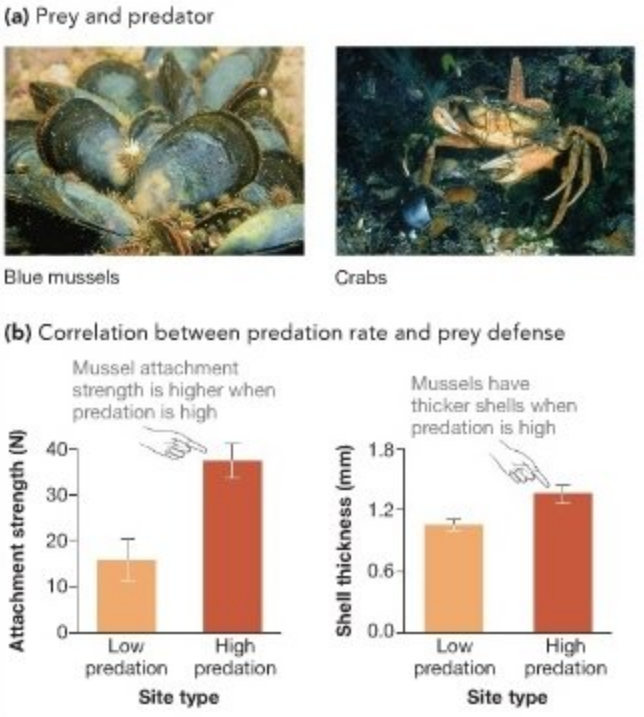

FIGURE 53.10 Inducible Defenses Are Produced Only when Prey Are Threatened. (a) In shallow-water environments in Maine, blue mussels (left) are preyed on by crabs (right). **(b)** To measure how strongly mussels are attached to the substrate, researchers drilled a hole in their shells and measured the force, in newtons (N), required to pull them off. They also measured how large mussel shells were relative to an individual's size by dividing shell weight by soft-tissue weight.

should reduce the likelihood of dangerous individuals being attacked. But wasps also act as a model for harmless species of moth, beetle, and fly that resemble wasps. To explain these mimics, biologists propose that predators avoid the harmless mimics because they mistake them for a dangerous wasp. This resemblance is known as **Batesian mimicry**.

The key point here is that prey have adaptations that reduce their likelihood of becoming victims. These adaptations are responses to natural selection exerted by predators. Constitutive defenses are expensive, however, in terms of the energy and resources that must be devoted to producing and maintaining them. Based on this observation, it should not be surprising to learn that many prey species have **inducible defenses**—meaning defensive traits that are produced only in response to the presence of a predator. Induced defenses then decline if predators leave the habitat. Inducible defenses are efficient energetically, but they are slow—it takes time to produce them.

To see how inducible defenses work, consider recent research on the blue mussels that live in an estuary along the coast of Maine (**Figure 53.10a**). Biologists had documented that predation on mussels by crabs was high in an area of the estuary with relatively slow tidal currents (a "low-flow" area) but low in an area of the estuary with relatively rapid tidal currents (a "high-flow" area). The researchers hypothesized that if blue mussels possess inducible defenses, then heavily defended prey individuals should occur in the low-flow area, where predation pressure is higher, but not in the high-flow area, where water movement reduces the number of crabs present.

To evaluate this hypothesis, the biologists measured mussel shell characteristics in the two areas. They found that mussels in the high-predation area were more strongly attached to their base or substrate and had thicker shells than did mussels in the low-predation area (**Figure 53.10b**). These traits make the mussels more difficult to remove from the substrate and harder to crush and so function as effective antipredator defenses.

The data in Figure 53.10b are correlational in nature, however, so they are open to interpretation. A critic of the inducible defense explanation could offer a reasonable alternative hypothesis—for example, that only constitutive defenses exist and that crabs have eliminated weakly attached mussels with thin shells from the low-flow areas. The observed differences could also be due to differences in light, temperature, or other abiotic factors that might affect mussel traits but have nothing to do with predation.

To test the inducible-defense hypothesis more rigorously, biologists carried out the experiment diagrammed in **Figure 53.11**. The tank on the left allowed the researchers to measure shell growth in mussels that were "downstream" from crabs. As predicted by the induced-defense hypothesis, the mussels exposed to a crab in this way developed significantly tougher shells than did mussels that were not exposed to a crab. These results suggest that, even without direct contact, mussels can sense the presence of crabs and increase their investment in defenses. In a similar experiment, the investigators compared mussels that were exposed to water running through broken mussel shells versus intact but empty mussel shells. They recorded a significant increase in shell thickness in the tank downstream from the broken shells. This result supports the hypothesis that mussels can detect the presence of predators from molecules released by broken shells.

Results like these underscore several themes of this section: Species interactions are dynamic and result in coevolution—in this case, adaptations and counteradaptations in an evolutionary arms race between predators and prey.

Are Animal Predators Efficient Enough to Reduce Prey Populations? Research on animal defense systems supports the hypothesis that species interactions have a strong impact on the evolution of predator and prey populations. Can predators also affect the short-term distribution and abundance of prey populations? Prey are typically smaller than predators, have larger litter or clutch sizes, and tend to begin reproduction at a younger age. As a result, they have a much larger intrinsic growth rate, r_{max}—that is, the maximum growth rate that a population can achieve under ideal

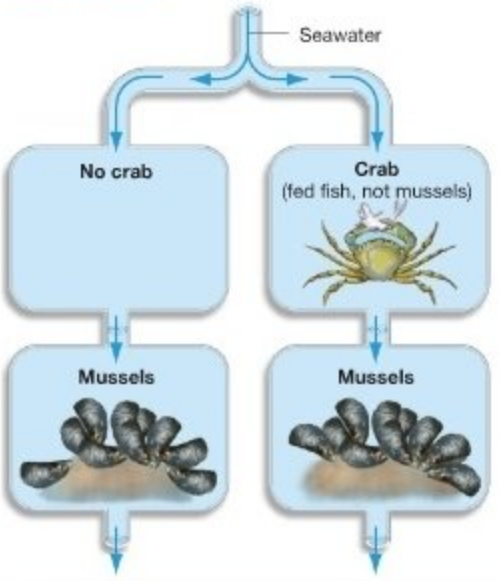
Experiment

Question: Are mussel defenses induced by the presence of crabs?

Hypothesis: Mussels increase investment in defense in the presence of crabs.

Null hypothesis: Mussels do not increase investment in defense in the presence of crabs.

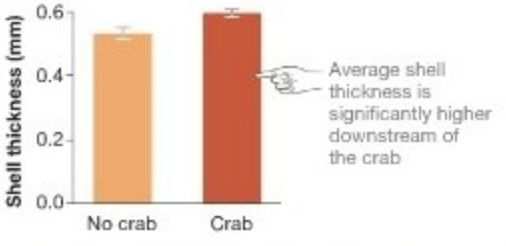
Experimental setup:



Prediction: Mussels downstream of the crab tank will have thicker shells than mussels downstream of the empty tank.

Prediction of null hypothesis: Mussels in the two tanks will have shells of equal thickness.

Results:



Conclusion: Mussels increase investment in defense when they detect crabs. Shell thickness is an inducible defense.

FIGURE 53.11 Experimental Evidence for Inducible Defenses.

QUESTION Why did the researchers feed the crabs fish instead of mussels?

conditions (see Chapter 52). If prey reproduce rapidly and are also well defended, it is not clear whether predators should be able to kill enough of them to reduce the prey population significantly—particularly if predators tend to take old or sick members of a population.

In several cases, data from predator-removal programs—in which wolves, cougars, coyotes, or other predators are actively killed by human hunters—support the hypothesis that predators actually do reduce the size of prey populations. For example, a wolf control program in Alaska during the 1970s decreased predator abundance to 55–80 percent below pre-control density. Concurrently, the population of moose, on which wolves prey, tripled. This observation suggests that wolf predators had reduced this moose population far below the number that could be supported by the available space and food.

Other types of experiments have also supported the hypothesis that predators play a role in density-dependent growth of prey populations. Recall from Chapter 52 that some populations go through regular cycles and that the regular population cycles of snowshoe hare and lynx appears to be driven, at least in part, by density-dependent increases in predation. Taken together, the data available to date indicate that in many instances, predators are efficient enough to reduce prey populations.

Why Don't Herbivores Eat Everything—Why Is the World Green? If predators affect the size of populations in prey that can run or fly or swim away, then consumers should have a devastating impact on plants and on mussels, anemones, sponges, and other sessile (nonmoving) animals.

In some cases, this prediction turns out to be correct. For example, consider the results of a recent **meta-analysis**—a study of studies, meaning an analysis of a large number of data sets on a particular question. Biologists who compiled the results of more than 100 studies on herbivory found that the median percentage of mass removed from aquatic algae by herbivores was 79 percent. Herbivores eat the vast majority of algal food available in aquatic biomes. The figure dropped to just 30 percent for aquatic plants, however, and only 18 percent for terrestrial plants.

Why don't herbivores don't eat more of the food available on land? Stated another way, why is the world green? Biologists routinely consider three possible answers to this question. Herbivores could be kept in check by predation or disease; plant tissues could offer poor or incomplete nutrition; or plants could defend themselves effectively against attack:

1. The **top-down control hypothesis** states that herbivore populations are limited by predation and disease. The "top-down" name is inspired by the food chains introduced in Chapter 30 and explored in detail in Chapter 54. It's appropriate because predators and parasites remove herbivores that eat plants. In a recent test of this idea, researchers monitored herbivory on islands created by a 1986 dam project in Venezuela. On some small islands in the new lake, predators disappeared. There are now many more herbivores on these islands than on similar sites nearby where predators were present, and a much higher percentage of primary production is being eaten. Predator-free islands, for example, had

just 25 percent of the small trees found on similar islands that contained predators.

2. The **poor-nutrition hypothesis** contends that plants are a poor food source in terms of the nutrients they provide for herbivores. More specifically, plant tissues have less than 10 percent of the nitrogen found in animal tissues, by weight. If the growth and reproduction of herbivores are limited by the availability of nitrogen, then their populations will be low and the impact of herbivory relatively slight. Herbivores could eat more plant material to gain nitrogen, but at a cost—they would be exposed to predation and expend energy processing the food. To evaluate the poor-nutrition hypothesis, a recent meta-analysis examined 185 studies of how insect herbivores had responded when the nitrogen concentration of plants was increased experimentally via fertilization. In over half of the cases, herbivores showed a significant increase in growth rate or reproduction when the plants that they feed on were fertilized. Based on this result, the researchers concluded that nitrogen limitation is an important factor in a large fraction of plant-herbivore interactions.

3. The **plant-defense hypothesis** holds that plants defend themselves effectively enough to limit herbivory. Most plant tissues are defended by weapons such as thorns, prickles, or hairs, or by potent poisons such as nicotine, caffeine, and cocaine. In addition, no animal species can, without help from protists or bacteria, digest cellulose or lignin, which are components of wood. Manufacturing defensive compounds seems like the perfect solution to the problem of herbivory. In practice, however, plants face a complex challenge in defending themselves. Consider data on interactions between cottonwood trees and two of their herbivores: beavers and leaf beetles. Cottonwoods resprout after they are cut down by a beaver (**Figure 53.12a**), and resprouted trees contain high concentrations of a defensive compound that deters further attack by beavers (**Figure 53.12b**). This is an induced defense. But larvae of a particular leaf beetle species eat this defensive compound readily. In fact, the larvae store enough of it in their bodies to act as a defensive compound against their own major predator—ants. The data in **Figure 53.12c** show that larvae that grow on resprouted cottonwood trees survive longer than do larvae that grow on normal cottonwoods when the larvae are placed on an ant mound. This is an example of an indirect effect in species interactions. The response by cottonwoods to herbivory by beavers benefits another herbivore—leaf beetles. The net result is that there is no perfect, one-size-fits-all defensive strategy. Natural selection should favor plants that evolve an ever-changing suite of compounds to deter the ever-changing array of herbivores they face.

Taken together, the data reviewed here suggest that there is no single answer to the question of why herbivores don't eat a greater fraction of the available plant food. All three of the hypotheses we have examined are correct. Top-down control, nitrogen limitation, and effective defense are all important factors in limiting the impact of herbivory, although the particular mix of factors will vary from plant species to plant species and from habitat to habitat.

Adaptation and Arms Races Over the long term, how do species that interact via consumption affect each other's evolution? When predators and prey or herbivores and plants interact over time, coevolutionary arms races result: Consumers evolve traits that increase their efficiency; in response, prey

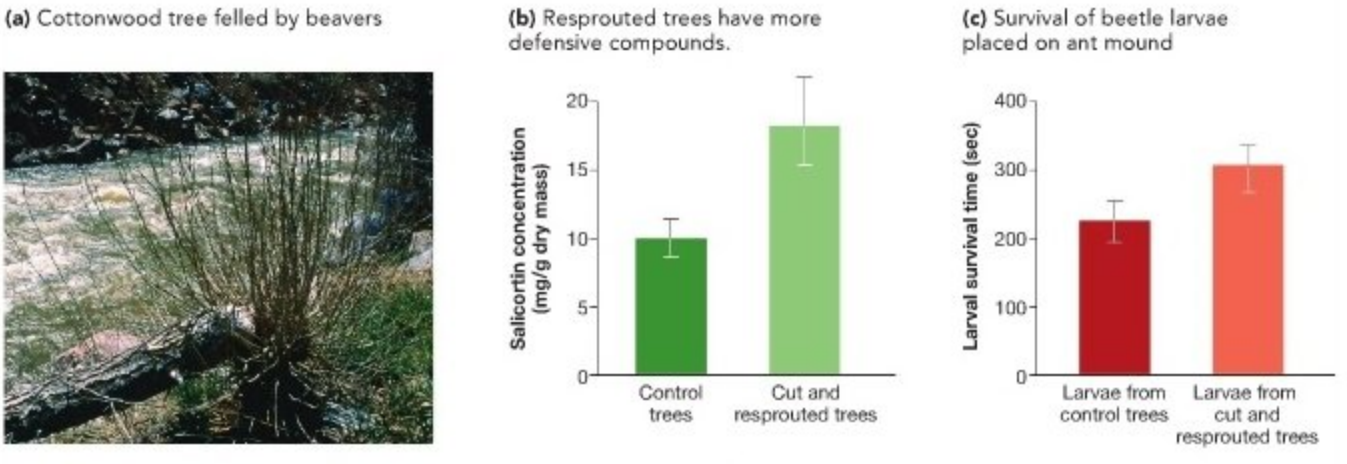


FIGURE 53.12 Defensive Compounds in Cottonwood Trees Discourage Beavers but Favor Beetles.

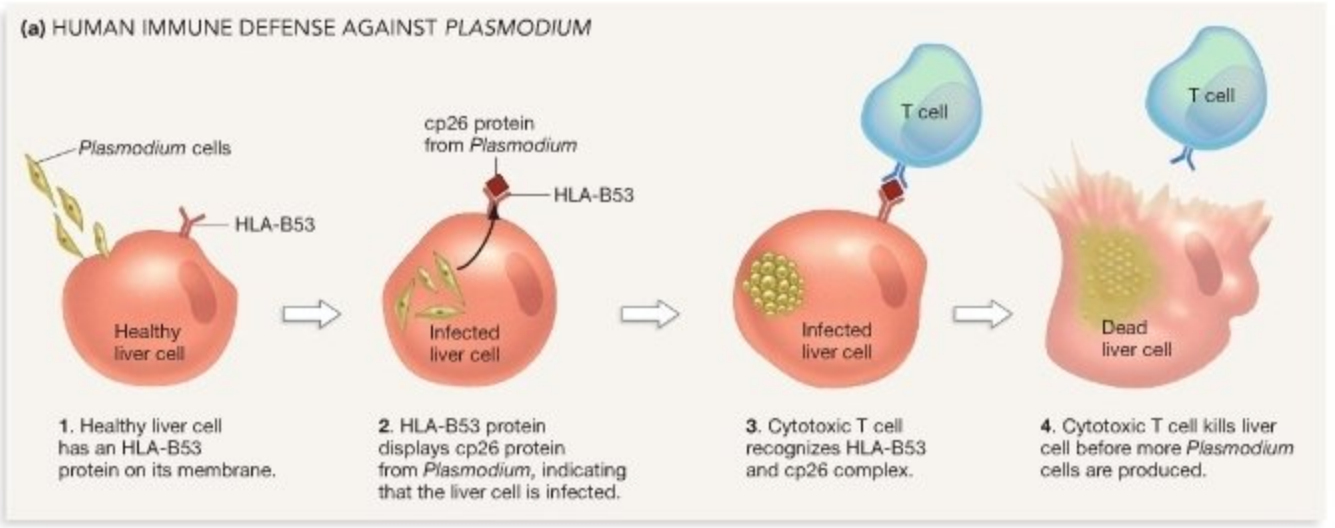
QUESTION Beetle larvae survive better on resprouted versus control trees, so they should damage resprouted trees more. If natural selection has maximized cottonwood fitness, do beavers or beetle larvae present the greater overall threat to them?



evolve traits that make them unpalatable or elusive, which leads to selection on consumers for traits that counter the prey adaptation, and so on.

To see a coevolutionary arms race in action, consider interactions between humans and the most serious of all human parasites—species in the genus *Plasmodium*. Recall from Chapter 29 that *Plasmodium* are unicellular protists that cause malaria in a wide array of vertebrates. Malaria kills at least a million people a year, most of them preschool-age children. Recent data suggest that humans and the causative agent of malaria—four species in the genus *Plasmodium*—are locked in a coevolutionary arms race.

Plasmodium has several distinct cell types, each of which infects liver, red blood cell, or other types of cells in mosquitoes or humans (see Chapter 29). Natural selection favors alleles that allow *Plasmodium* cells to infect their hosts efficiently and multiply inside. Cells in the human immune system do not sit passively by as *Plasmodium* destroys liver cells and red blood cells. Instead, immune system cells (introduced in Chapter 49) seek out and destroy *Plasmodium* cells. Natural selection favors alleles that allow mosquitoes and humans to resist infection.

In West Africa, for example, there is a strong association between an allele called *HLA-B53* and protection against malaria. In liver cells that are infected by *Plasmodium*, HLA-B53 proteins on the surface of the liver cell display a parasite protein called cp26 (**Figure 53.13a**). The display is a signal that immune system cells can read. It means "I'm an infected cell. Kill me before they kill all of us." Immune system cells destroy the liver cell before the parasite cells inside can multiply. In this way, people who have at least one copy of the *HLA-B53* allele are better able to beat back malarial infections. People who have the *HLA-B53* allele appear to be winning the arms race against malaria.

(b) *Plasmodium* strains have different versions of the cp protein.

Plasmodium strain	Infection rate	Interpretation
cp26	Low	HLA-B53 binds to these proteins. Immune response is effective.
cp29	Low	
cp26 and cp29 strains together	High	Immune response fails when these strains infect the same person.
cp27	High	HLA-B53 does not bind to these proteins. Immune response is not as effective.
cp28	Average	

FIGURE 53.13 Interactions between the Human Immune System and *Plasmodium*. (a) If HLA-B53 binds to a particular *Plasmodium* protein, then infected cells are recognized and destroyed. **(b)** Some strains of *Plasmodium* appear to avoid detection by the immune system better than others do. Also, certain strains defeat the immune response if they infect the same person at the same time.

Follow-up research has shown that the arms race is far from won, however. *Plasmodium* populations in West Africa now have a variety of alleles for the protein recognized by HLA-B53. Some of these variants bind to HLA-B53 and trigger an immune response in the host, but others escape detection. Furthermore, many people in West Africa are infected with several different strains of *Plasmodium*, some of which are better at evading the immune system response. In some cases, the recognition step by HLA-B53 breaks down when certain strains are found together (**Figure 53.13b**). To make sense of these observations, researchers suggest that natural selection has favored the evolution of *Plasmodium* strains with weapons that counter HLA-B53.

An arms race continues to rage between *Plasmodium* and humans. Certain human proteins act as antimalarial weapons. But as predicted by coevolutionary theory, *Plasmodium* has evolved effective responses and continues to evolve.

Life Cycle of a Malaria Parasite

Can Parasites Manipulate Their Hosts? To thrive, parasites do not just have to invade tissues and grow while evading defensive responses by their host. They also have to be transmitted to new hosts. To a parasite, an uninfected host represents uncolonized habitat, teeming with resources. What have biologists learned about how parasites are transmitted to new hosts?

To answer this question, consider species of land snails that are parasitized by flatworms—specifically, by flukes in the genus *Leucochloridium*. Researchers who studied this association discovered something unusual. When the flukes have matured and are ready to be transmitted to their next host, a bird, they burrow into the snail's tentacles and wriggle. In addition, infected snails become attracted to light, even though uninfected snails avoid sunlit areas and prefer dark, shady environments (**Figure 53.14**). When infected snails move out of the shade into the open and glide about with wriggling tentacles, they are more easily spotted and consumed by birds. To interpret these observations, biologists suggest that the worms manipulate the behavior of the snail, and that the change in snail behavior makes the parasite more likely to be transmitted to a new host.

Studies of how parasites are transmitted to new hosts reinforce a general message: Extensive coevolution occurs among species that interact via consumption. Experiments on mutualistic interactions carry the same message.

FIGURE 53.14 A Parasite That Manipulates Host Behavior.
The behavior of snails that are infected with flukes in the genus *Leucochloridium* is dramatically different from the behavior of uninfected snails.

EXERCISE Design an experiment to test the hypothesis that infected snails are more likely than uninfected snails to be eaten by birds.

Mutualism

Mutualisms are +/+ interactions that involve a wide variety of organisms and rewards. Many species of bees, for example, visit flowers to harvest nectar and pollen. Bees benefit because nectar is used as a food source for adult bees and the pollen is fed to larvae. Flowering plants also benefit because, in the process of visiting flowers, foraging bees carry pollen from one plant to another and accomplish pollination. Chapters 30 and 40 detailed some of the adaptations found in flowering plants that increase the efficiency of pollination. Other chapters highlighted an array of other mutualisms:

- One of the most important of all mutualisms occurs between fungi and plant roots. Chapter 31 reviewed experimental evidence indicating that fungi receive sugars and other carbon-containing compounds in exchange for nitrogen or phosphorus needed by the plant partner.
- Arguably the most critical of all mutualisms involves bacteria that fix nitrogen and certain species of plants. As Chapters 28 and 38 pointed out, the partnership is based on host plants providing sugars and protection and the bacteria supplying nitrogen in return.
- Chapter 32 cited mutualisms between (1) rancher ants and the aphids that the ants protect in exchange for sugar-rich honeydew, and (2) farmer ants and the fungi that they cultivate for food.

Figure 53.15 illustrates some other interesting mutualisms. Figure 53.15a shows ants in the genus *Crematogaster*, which live in acacia trees native to Africa and the New World tropics. The ants live in bulbs at the base of acacia thorns and feed on small structures that grow from tree branches. These ants protect the tree by attacking and biting herbivores and by cutting vegetation from the ground below the host tree. Figure 53.15b illustrates cleaner shrimp in action. These shrimp pick external parasites from the jaws and gills of fish. In this mutualism, one species receives dinner while the other obtains medical attention.

As these examples show, the rewards from mutualistic interactions range from the transportation of gametes to food, housing, medical help, and protection. It is important to note, however, that even though mutualisms benefit both species, the interaction does not involve individuals from different species being altruistic or "nice" to each other. Expanding on a point that Charles Darwin introduced in 1862, Judith Bronstein described mutualisms as "a kind of reciprocal parasitism; that is, each partner is out to do the best it can by obtaining what it needs from its mutualist at the lowest possible cost to itself." Her point is that the benefits received in a mutualism are a by-product of each individual pursuing its own self-interest, by maximizing its ability to survive and reproduce.

(a) Mutualism between ants and acacia trees

(b) Mutualism between cleaner shrimp and fish

FIGURE 53.15 Mutualisms Take Many Forms. (a) In certain species of acacia tree, ants in the genus *Crematogaster* live in large bulbs at the base of spines and attack herbivores that threaten the tree. The ants eat nutrient-rich tissue produced at the tips of leaves or on branches. **(b)** Cleaner shrimp remove and eat parasites that take up residence on the gills of fish.

QUESTION What is the cost of these associations to the acacia tree, the *Crematogaster* the cleaner shrimp, and the host fish?

In this light, it is not surprising that some species "cheat" on mutualistic systems. For example, deceit pollination occurs when certain species of plants produce a showy flower but no nectar reward. Pollinators have to be deceived to make a visit and carry out pollination. Evolutionary studies show that deceit pollinators evolved from ancestral species that did provide a reward. Over time, a +/+ interaction evolved into a +/− interaction.

A recent experimental study of mutualism provides another good example of the dynamic nature of these interactions. This study focused on ants and treehoppers. Ants are insects that live in colonies; treehoppers are small, herbivorous insects that feed by sucking sugar out of the phloem of plants. Treehoppers excrete the sugary solution honeydew from their posteriors. The honeydew, in turn, is harvested for food by ants.

It is clear that ants benefit from this association. But do the treehoppers? Biologists hypothesized that the ants might protect the treehoppers from their major predator, jumping spiders. These spiders feed heavily on juvenile treehoppers.

To test the hypothesis that ants protect treehoppers, the researchers studied ant-treehopper interactions over a three-year period. As **Figure 53.16** shows, the researchers marked out a 1000-m^2 study plot. Each year they removed the ants from one group of the treehopper host plants inside the plot but left the others alone to serve as a control. Then they compared the growth and survival of treehoppers on plants with and without ants. Recall that this is a common research strategy for studying species interactions. To assess the fitness costs or benefits of the interaction, researchers remove one of the participants experimentally and document the effect on the other

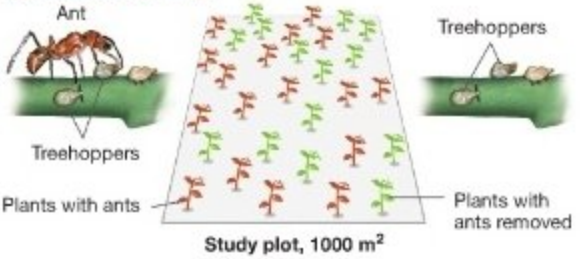
Experiment

Question: Is the relationship between ants and treehoppers mutualistic?

Hypothesis: Ants harvest food from treehoppers. In return, they protect treehoppers from jumping spiders.

Null hypothesis: Ants harvest food from treehoppers but are not beneficial to treehopper survival.

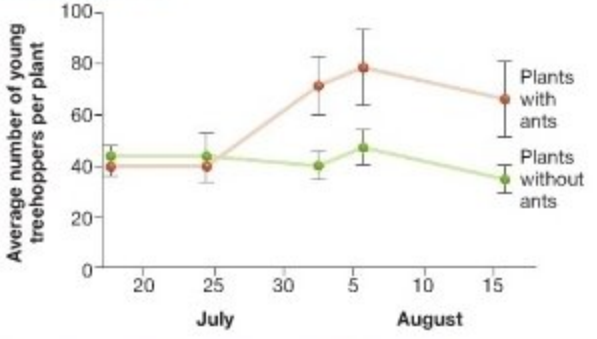
Experimental setup:



Prediction: Treehopper reproduction will be higher when ants are present than when ants are absent.

Prediction of null hypothesis: There will be no difference in the number of young treehoppers on the plants.

Results (Year 1):



Conclusion: Treehoppers benefit from the interaction with ants.

FIGURE 53.16 Experimental Evidence that the Treehopper-Ant Interaction Is Mutualistic.

SUMMARY TABLE **53.1 Species Interactions**

Type of Interaction	Fitness Effects	Short-Term Impact: Distribution and Abundance	Long-Term Impact: Coevolution
Competition	− / −	Reduces population size of both species; if competition is asymmetric, competitive exclusion reduces range of one species.	Niche differentiation via selection to reduce competition
Consumption	+ / −	Impact on prey population depends on prey density and effectiveness of defenses.	Strong selection on prey for effective defense; strong selection on consumer for traits that overcome defenses
Parasitism	+ / −	Impact on host population depends on parasite density and effectiveness of defenses.	Strong selection on host for effective defense; strong selection on parasite for traits that overcome defenses
Mutualism	+ / +	Population size and range of both species are dependent on each other.	Strong selection on both species to maximize fitness benefits and minimize fitness costs of relationship
Commensalism	+ / 0	Population size and range of commensal may depend on size and distribution of host.	Strong selection on commensal to increase fitness benefits in relationship; no selection on host

participant's survival and reproduction, compared with the survival and reproduction of control individuals that experience a normal interaction.

In both the first and third years of the study, the number of treehopper young on host plants increased in the treatment with ants but showed a significant decline in the treatment with no ants. This result supports the hypothesis that treehoppers benefit from the interaction with ants because the ants protect the treehoppers from predation by jumping spiders.

In the second year of the study, however, the researchers found a very different pattern. There was no difference in offspring survival, adult survival, or overall population size between treehopper populations with ants and those without ants. Why? The researchers were able to answer this question because they also measured the abundance of spiders that prey on treehoppers in each of the three years. Their census data showed that in the second year of the study, spider populations were very low.

Based on these results, the investigators concluded that the benefits of the ant-treehopper interaction depend entirely on predator abundance. Treehoppers benefit from their interaction with ants in years when predators are abundant but are unaffected in years when predators are scarce. If producing honeydew is costly to treehoppers, then the +/+ mutualism changes to a +/− interaction when spiders are rare.

Mutualism is like parasitism, competition, and other types of species interactions in an important respect: The outcome of the interaction depends on current conditions. Because the costs and benefits of species interactions are fluid, an interaction between the same two species may range from parasitism to mutualism to competition. **Table 53.1** summarizes the fitness effects, short-term impacts on population size, and long-term evolutionary aspects of species interactions.

Check Your Understanding

If you understand that...

- Natural selection favors the evolution of traits that decrease competition, resulting in changes in a species' niche over time.
- Consumers may reduce the population size of the species on which they feed and often exert strong natural selection for effective defense mechanisms.
- Mutualisms benefit the species involved and can lead to highly coevolved associations, such as mycorrhizal fungi and symbiotic nitrogen-fixing bacteria.

You should be able to...

1) Explain what a coevolutionary arms race is and give an example.
2) Give specific examples of how competition, consumption, and mutualism each affect population size and long-term evolution.

53.2 Community Structure

Biologists have made important progress in understanding the nature of species interactions and their consequences. In terms of understanding the structure and function of biological communities, however, research on species interactions has a limitation: It usually focuses on just two species at a time. But biological communities contain many thousands of species. To understand how communities work, biologists broaden the scope of research and explore how combinations of many species interact.

The question that biologists initially asked about communities concerned structure: Do biological communities have a

tightly prescribed organization and composition, or are they merely loose assemblages of species? If communities are highly structured entities, then their makeup should be predictable. For example, if a community is destroyed by a disturbance and then allowed to recover, the diversity and abundance of species at that site should be identical when recovery is complete. But if communities can be made up of many different combinations of species, depending on which arrive earlier or later, then community composition will be difficult to predict. The diversity and abundance of species found in a region would vary substantially before a disturbance and after recovery.

How Predictable Are Communities?

Beginning with a paper published in 1936, Frederick Clements promoted the view that biological communities are stable, integrated, and orderly entities with a highly predictable composition. His hypothesis was that species interactions are so extensive and coevolution is so important that the groups of species called communities have become highly integrated and interdependent units in nature. Stated another way, the species within a community cannot live without each other.

To drive his idea home, Clements likened the development of a plant community to the development of an individual organism. He argued that communities develop by passing through a series of predictable stages dictated by extensive interactions among species and that this development culminates in a stable final stage known as a **climax community**. According to Clements, the nature of the climax community is determined by the area's climate and does not change over time. Further, he held that if a fire or other disturbance destroys the climax community, it will reconstitute itself by repeating its predictable developmental stages.

Henry Gleason, in contrast, contended that the community found in a particular area is neither stable nor predictable. He claimed that plant and animal communities are ephemeral associations of species that just happen to share similar climatic requirements. According to Gleason, it is largely a matter of chance whether a similar community develops in the same area after a disturbance occurs. Gleason downplayed the role of biotic factors, such as species interactions, in structuring communities. To him, abiotic factors and history—for example, which seeds and juvenile animals happened to arrive after a disturbance—were the key elements in determining which species are found at a particular location.

Which viewpoint is more accurate? Let's consider observational and experimental data.

Mapping Current and Past Species' Distributions If communities are predictable assemblages, then the ranges of species that make up a particular community should be congruent. Stated another way, the same group of species should almost always be found growing together.

When biologists began documenting the ranges of tree species along elevational gradients, however, they found that species came and went independently of each other. As you go up a mountain, for example, you might find white oak trees growing with hickories and chestnuts. As you continue to gain elevation, chestnuts might disappear but white oaks and hickories remain. Farther upslope, hickories might drop out of the species mix while white pines and red pines start to appear.

Data on the historical composition of plant communities supported these observations. Studies of fossil pollen documented that the distribution of plant species and communities at specific locations throughout North America has changed radically since the end of the last ice age about 11,000 years ago. An important pattern emerged from these data: Species do not come and go in the fossil record in tightly integrated units. Instead, the ranges of individual species tended to change independently of one another. For example, at a study site in Mirror Lake, New Hampshire, the percentage of pollen present from pines and oaks rose and fell in tandem over the past 14,000 years—just as predicted for a tightly integrated, pine-oak forest community. In contrast, the percentage of pollen from spruce, fir, cedar, beech, and most other tree species changed independently of each other. In general, studies of fossil pollen suggest that the composition of most plant communities has been dynamic and contingent on historical events, rather than static.

Experimental Tests To explore the predictability of community structure experimentally, biologists constructed 12 identical ponds (**Figure 53.17**). They filled the ponds at the same time with water that contained enough chlorine to kill any preexisting organisms. If community structure is predictable, then each pond should develop the same community of species once the chlorine vaporized and made the water habitable. If community structure is unpredictable, then each pond should develop a different community.

To test these predictions, the researchers sampled water from the ponds repeatedly for one year. They measured temperature, chemical makeup, and other physical characteristics of the water and recorded the diversity and abundance of each planktonic species by examining the samples under the microscope. They found a total of 61 species in all of the ponds but discovered that individual ponds each had only 31 to 39 species. This observation is important. Each pond contained just half to two-thirds of the total number of species that lived in the experimental area and that were available for colonization. A number of species occurred in most or all of the 12 ponds, but each pond had a unique species assemblage. Why?

To explain their results, the researchers contended that some species are particularly good at dispersing and are likely to colonize all or most of the available habitats. Other species disperse more slowly and tend to reach only one or a few of the

Experiment

Question: Are communities predictable or unpredictable?

Communities-are-predictable hypothesis: The group of species present at a particular site is highly predictable.

Communities-are-unpredictable hypothesis: The group of species present at a particular site is highly unpredictable.

Experimental setup:

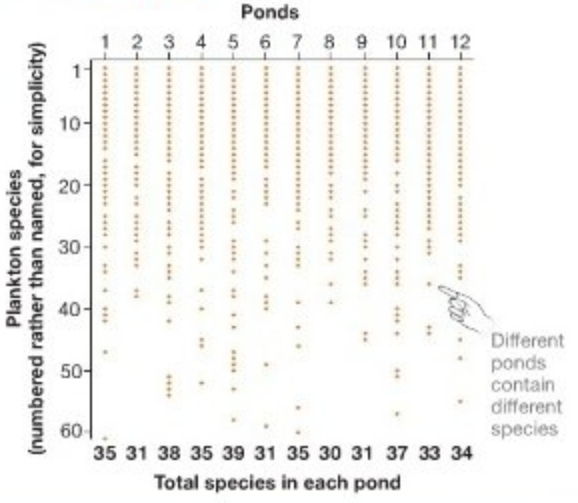
1. Construct 12 identical ponds. Fill at the same time and sterilize water so that there are no preexisting organisms.

2. Examine water samples from each pond. Identify each plankton species present in each sample.

Communities-are-predictable prediction: Identical plankton communities will develop in all 12 ponds.

Communities-are-unpredictable prediction: Different plankton communities will develop in different ponds.

Results (after 1 year):



Conclusion: Although about half of the species present appear in all or most ponds, each pond has a unique composition. Both hypotheses are partially correct.

FIGURE 53.17 Experimental Evidence that Identical Communities Do Not Develop in Identical Habitats.

QUESTION How many species are found in all 12 ponds?

available habitats. Further, the investigators proposed that the arrival of certain competitors or predators early in the colonization process greatly affects which species are able to invade successfully later. As a result, the specific details of community assembly and composition are somewhat contingent and difficult to predict. At least to some degree, communities are a product of chance and history.

The overall message of research on community structure is that Clements's position was too extreme and that Gleason's view is closer to being correct. Although both biotic interactions and climate are important in determining which species exist at a certain site, chance and history also play a large role.

How Do Keystone Species Structure Communities?

Even though communities are not predictable assemblages dictated by obligatory species interactions, the presence of certain consumers can have an enormous impact on the species present. Experiments have shown that, in some cases, the structure of an entire community can change dramatically if a single species of predator or herbivore is removed from a community or added to it.

As an example of this research, consider an experiment that Robert Paine conducted in intertidal habitats of the Pacific Northwest of North America. In this environment, the sea star *Pisaster ochraceous* is an important predator (**Figure 53.18a**). When Paine removed *Pisaster* from experimental areas, what had been diverse communities of algae and invertebrates became overgrown with solid stands of the California mussel *Mytilus californianus* (**Figure 53.18b**). Although *M. californianus* is a dominant competitor, its populations had been held in

(a) Predator: *Pisaster ochraceous*

(b) Prey: *Mytilus californianus*

FIGURE 53.18 A Keystone Predator and Its Prey

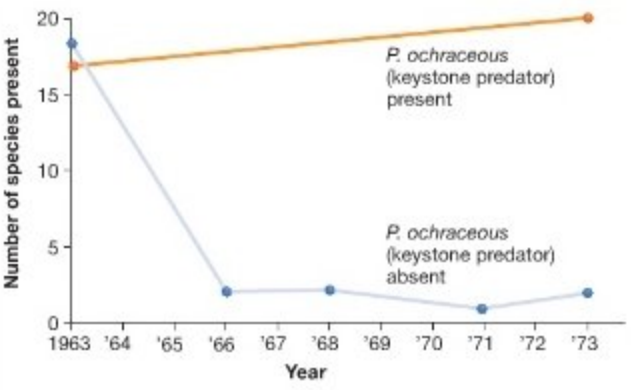


FIGURE 53.19 Keystone Predation Alters Community Structure in a Rocky Intertidal Habitat. Each data point represents the average number of species present in several study plots.

check by sea-star predation. When this predator was gone, the species richness and structural complexity of the habitat changed radically (**Figure 53.19**).

To capture the effect that a predator such as *Pisaster* can have on a community, Paine coined the term "keystone species." A **keystone species** has a much greater impact on the surrounding species than its abundance and total biomass would suggest. For example, wolves were introduced to the Greater Yellowstone Ecosystem of western North America in 1995. Although their population has grown to only about 150 individuals, their presence has led to far-reaching changes in plant and animal communities. Wolves feed on elk and do not tolerate the presence of coyotes. As elk declined, populations of favorite elk foods like aspen, willow, and cottonwood have increased, triggering an increase in beavers, which compete with elk for these plants. As coyotes declined, mouse populations increased and led to larger populations of hawks.

Sea stars, wolves, and other keystone species vary in abundance in space or over time. As a result, the composition and structure of their communities vary. Communities are ever-changing entities whose composition is difficult to predict.

53.3 Community Dynamics

Once biologists had a basic understanding of how species interact and how communities are structured, they turned to questions about how communities change through time. Like cells, individuals, and species, communities can be described in one word: dynamic.

Disturbance and Change in Ecological Communities

Community composition and structure may change radically in response to changes in abiotic and biotic conditions. Biologists have become particularly interested in how communities respond to disturbance. A **disturbance** is any event that removes some individuals or biomass from a community. (Recall from Chapter 50 that biomass is the total mass of living organisms.)

Forest fires, windstorms, floods, the fall of a large canopy tree, disease epidemics, and short-term explosions in herbivore numbers all qualify as disturbances. These events are important because they alter light levels, nutrients, unoccupied space, or some other aspect of resource availability.

Biologists have come to realize that the impact of disturbance is a function of three factors: (1) the type of disturbance, (2) its frequency, and (3) its severity—for example, the speed and duration of a flood, or the intensity of heat during a fire. Most communities experience a characteristic type of disturbance, and in most cases, disturbances occur with a predictable frequency and severity. To capture this point, biologists refer to a community's **disturbance regime**. For example, fires kill all or most of the existing trees in a boreal forest every 100 to 300 years, on average. In contrast, numerous small-scale tree falls, usually caused by windstorms, occur in temperate and tropical forests every few years.

How Do Researchers Determine a Community's Disturbance Regime? Ecologists use two strategies to determine a community's natural pattern of disturbance. The first approach is based on inferring long-term patterns from data obtained in a short-term analysis. For example, an observational study might document that 1 percent of all boreal forest on Earth burns in a given year. Assuming that fires occur randomly, researchers project that any particular piece of boreal forest has a 1 in 100 chance of burning each year. According to this reasoning, fires will recur in that particular area every 100 years, on average.

This extrapolation approach is straightforward to implement, but it has important drawbacks. In boreal forests, for example, fires do not occur randomly in either space or time. They are more likely in some areas than in others, and they tend to occur in particularly dry years. Unless sampling is extensive, it is difficult to avoid errors caused by extrapolating from particularly disturbance-prone or disturbance-free areas or years.

The second approach to determining disturbance regimes is based on reconstructing the history of a particular site. Flooding frequency, for example, can be estimated by analyzing sediments, because floods deposit distinctive groups of sediment particles. Researchers estimate the frequency and impact of storms by finding wind-killed trees and determining their date of death. (Investigators do so by comparing patterns in the growth rings of the dead trees with those of living individuals nearby; see Chapter 36.) The disturbances that have been most extensively studied using historical techniques, however, are forest fires.

Forest fires often leave a layer of burned organic matter and charcoal on the surface of the ground. As a result, researchers can dig a soil pit, find charcoal layers, and use radioisotope

dating to establish when the fires occurred. It is also possible to date the death of trees killed by fire by comparing their growth rings with those of living trees. Further, trees that are not killed by fire are often scarred. When a fire burns close enough to kill a patch of cambium tissue, a scar forms. These fire scars occur most often at the tree's base, where dead leaves and twigs accumulate and furnish fuel. Fire scars can be dated by analyzing growth rings.

Why Is It Important to Understand Disturbance Regimes?

To appreciate why biologists are so interested in understanding disturbance regimes, consider a recent study on the fire history of giant sequoia groves in California (**Figure 53.20a**). Giant sequoias grow in small, isolated groves on the western side of the Sierra Nevada range. Individuals live more than a thousand years, and many have been scarred repeatedly by fires. A biologist obtained samples of cross sections through the bases of 90 giant sequoias in five different groves. As **Figure 53.20b** shows, the cross sections contained numerous rings that had been scarred by fire. To determine the date of each disturbance, the researcher counted tree rings back from the present. He found that, in most of the groves, 10 to 53 fires had occurred each century for the past 1530 to 2000 years (**Figure 53.20c**). The data indicated that each tree had been burned an average of 64 times.

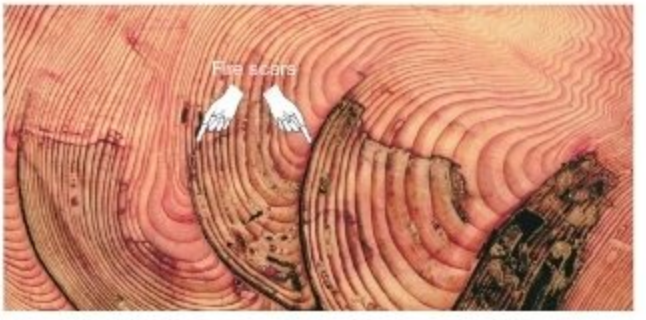
This study established that fires are extremely frequent in the community examined. Because not enough time would pass for large amounts of fuel to accumulate between fires, they were probably of low severity. Partly because of this work, the biologists responsible for managing sequoia groves now set controlled fires or let low-intensity natural fires burn instead of suppressing them immediately. Similarly, studies of disturbance regimes along the Colorado River in southwestern North America inspired land managers to release a huge pulse of water from the reservoirs behind dams on the waterway recently. The flood that resulted was designed to mimic a natural disturbance. According to follow-up studies, the artificial flood appears to have benefited the plant and animal communities downstream.

Succession: The Development of Communities after Disturbance

Severe disturbances remove all or most of the organisms from an area. The recovery that follows is called **succession**. The name was inspired by the observation that certain species succeed others over time. **Primary succession** occurs when a disturbance removes the soil and its organisms as well as organisms that live above the surface. Glaciers, floods, volcanic eruptions, and landslides often initiate primary succession. **Secondary succession** occurs when a disturbance removes some or all of the organisms from an area but leaves the soil intact. Fire and logging are examples of disturbances that initiate secondary succession.

(a) Giant sequoias after a fire

(b) Fire scars in the growth rings



(c) Reconstructing history from fire scars

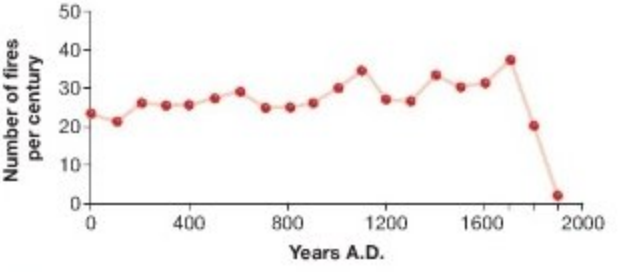


FIGURE 53.20 History of Disturbance in a Fire-Prone Community. Because trees form one ring (light band/dark band) every year, researchers can count the rings to determine how often fires have occurred during the last 2000 years.

QUESTION About how many fires occurred during the last century?

As **Figure 53.21** shows, a sequence of plant communities develops as succession proceeds. Early successional communities are dominated by species that are short lived and small and that disperse their seeds over long distances. Late successional communities are dominated by species that tend to be long lived, large, and good competitors for resources such as light and nutrients. The specific sequence of species that appears over time is called a successional pathway. What determines the pattern and rate of species replacement during succession at a particular time and place?

Theoretical Considerations Biologists focus on three factors to predict the outcome of succession in a community: (1) the particular traits of the species involved, (2) how species interact, and (3) historical and environmental circumstances such as the size of the area involved and weather conditions. Before going on to consider a detailed case history, we need to explore these factors in more detail.

Species traits, such as dispersal capability and the ability to withstand extreme dryness, are particularly important early in succession. As common sense would predict, recently disturbed sites tend to be colonized by plants and animals with good dispersal ability. When these organisms arrive, however, they often have to endure harsh environmental conditions. These **pioneering species** tend to have "weedy" life histories. (A **weed** is a plant that is adapted for growth in disturbed soils.) Early successional species devote most of their energy to reproduction and little to competitive ability. They have small seeds, rapid growth, and a short life span, and they begin reproducing at an early age. As a result, they have a high reproductive rate. But in addition, they can tolerate severe abiotic conditions, such as high light levels, poor nutrient availability, and drying.

Once colonization is under way, the course of succession tends to depend less on how species cope with aspects of the abiotic environment and more on how they interact with other species. This change occurs because plants that grow early in succession change abiotic conditions in a way that makes the conditions less severe. Because plants provide shade, they reduce temperatures and increase humidity. Their dead bodies also add organic material and nutrients to the soil. As abiotic conditions improve, biotic interactions become more important.

During succession, existing species can have one of three effects on subsequent species: (1) facilitation, (2) tolerance, or (3) inhibition. **Facilitation** takes place when the presence of an early arriving species makes conditions more favorable for the arrival of certain later species by providing shade or nutrients. **Tolerance** means that existing species do not affect the probability that subsequent species will become established. **Inhibition** occurs when the presence of one species inhibits the establishment of another. For example, a plant species that requires high light levels to germinate may be inhibited late in

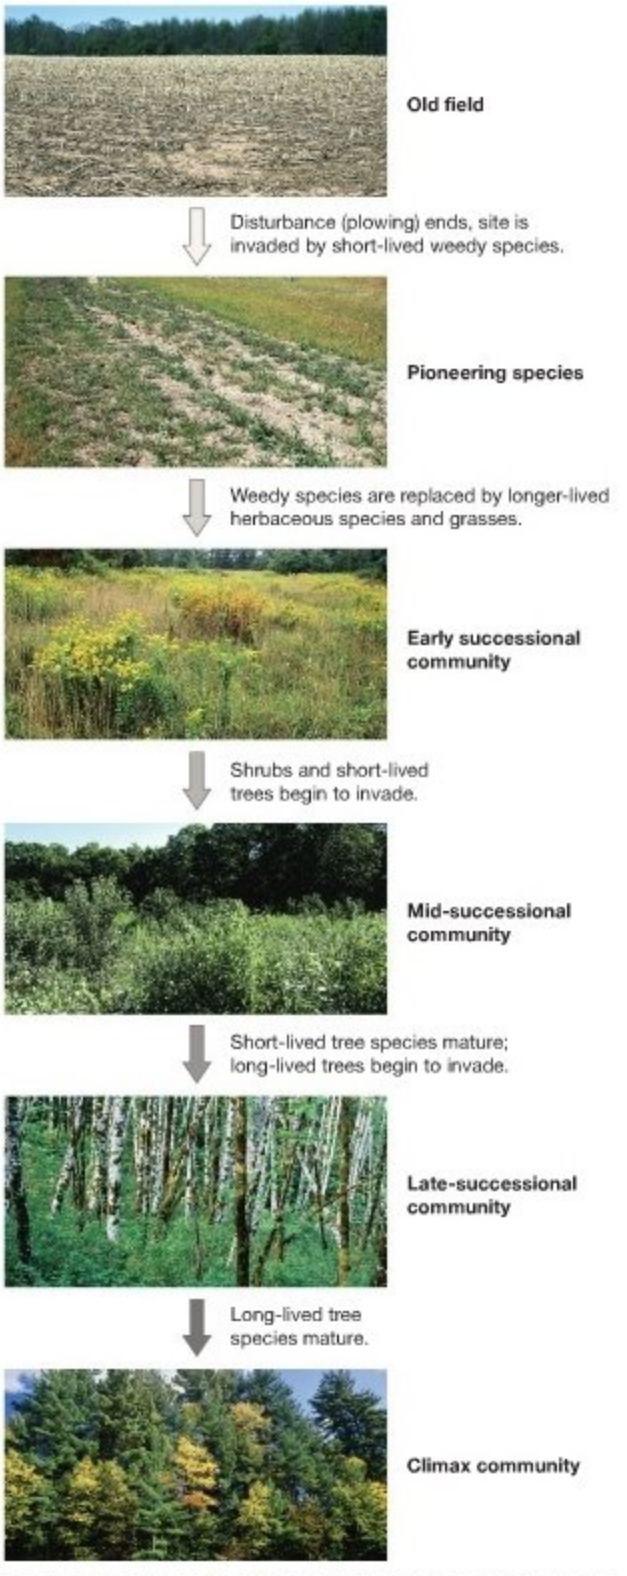

FIGURE 53.21 Succession in Midlatitude Temperate Forests. Sequence of photos showing how succession leads to the development of a temperate forest from a disturbed state (in this case, an abandoned agricultural field).

succession by the presence of mature trees that prevent sunlight from reaching the forest floor.

In addition to species traits and species interactions, the pattern and rate of succession depend on the historical and environmental context in which they occur. For example, researchers found that the communities that developed after forest fires disturbed Yellowstone National Park in 1988 depended on the size of the burned patch and how hot the fire had been at that location. Succession is also affected by the particular weather or climate conditions that occur during the process. Variation in weather and climate causes different successional pathways to occur in the same place at different times.

Analyzing species traits, species interactions, and the historical/environmental context provides a useful structure for understanding why particular successional pathways occur. To see this theoretical framework in action, let's examine data on the course of primary succession that has occurred in Glacier Bay, Alaska.

A Case History: Glacier Bay, Alaska An extraordinarily rapid and extensive glacial recession is occurring at Glacier Bay (**Figure 53.22**, bottom). In just 200 years, glaciers that once filled the bay have retreated approximately 100 km, exposing extensive tracts of barren glacial sediments to colonization. Because of this event, Glacier Bay has become an important site for studying succession.

The top of Figure 53.22 shows the plant communities found in the area. The oldest sites are dense forests of Sitka spruce and western hemlock. Areas that have been deglaciated for about 100 years are inhabited by scattered spruce trees and dense thickets of a shrub called Sitka alder. Sites that have been deglaciated for 45 to 80 years are also covered with dense alder thickets, but the emergent trees are primarily cottonwood. Locations that have been ice free for 20 years or less do not have a continuous plant cover. Instead, they host scattered individuals of willow and a small shrub called *Dryas*.

These observations inspired a hypothesis for the pattern of succession in Glacier Bay: With time, the youngest communities of *Dryas* and willow succeed to alder thickets, which subsequently become dense spruce-hemlock forests. Stated another way, there is a single successional pathway throughout the bay. A recent study has challenged this hypothesis, however. Researchers who reconstructed the history of each community by studying tree rings found that three distinct successional pathways have occurred (**Figure 53.23**): (1) In the lower part of the bay, soon after the ice retreated, Sitka spruce began growing and quickly formed dense forests. Western hemlock arrived after spruce and is now common in the understory. (2) At middle-aged sites in the upper part of the bay, alder thickets were dominant for several decades, and spruce is just beginning to become common. These forests will probably never be as dense as the ones in the lower bay, however, and there is no sign that western hemlock has begun to establish itself. (3) In contrast, the youngest sites in the uppermost part of the bay may be following a third pathway. Alder thickets became dominant fairly early, but spruce trees are scarce. Instead, cottonwood trees are abundant.

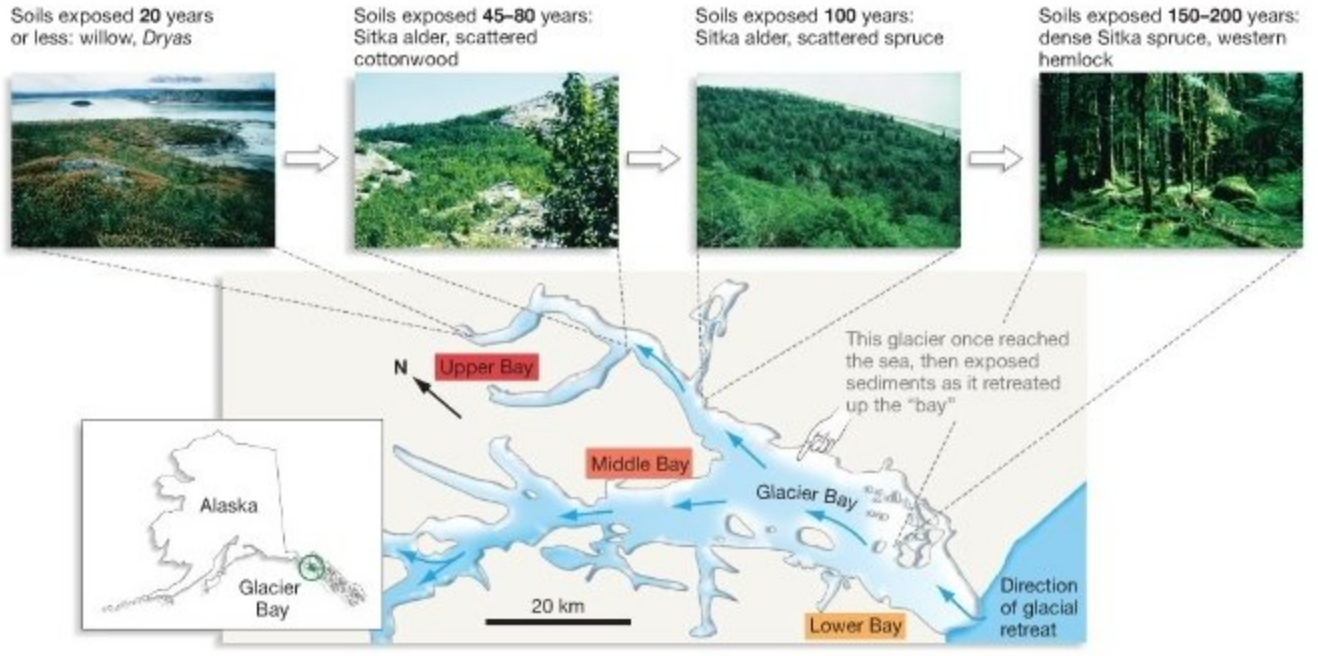

FIGURE 53.22 Evidence That a Single Successional Pathway Occurs in Glacier Bay.

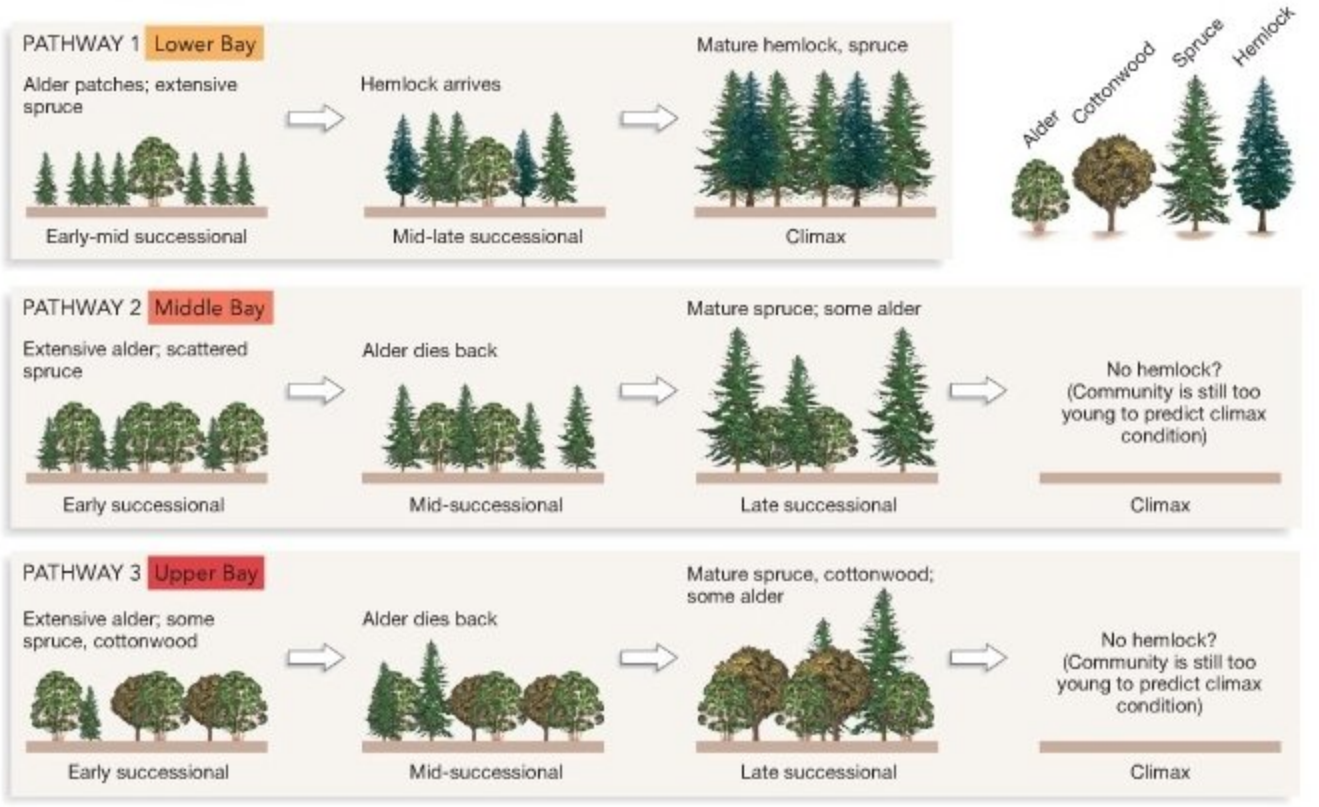

FIGURE 53.23 Evidence for Multiple Successional Pathways in Glacier Bay.

QUESTION Suppose that a forest fire wiped out all of the plant communities throughout Glacier Bay. Would you predict that the successional pathways described here would reoccur?

These data present a challenge: How do species traits, species interactions, and dispersal patterns interact to generate the three observed successional pathways?

Species traits may be especially important in explaining certain details about the successional pathways. Western hemlock, for example, is abundant at older sites but largely absent from young ones. This is logical, because its seeds germinate and grow only in soils containing a substantial amount of organic matter and because the young trees can tolerate deep shade but not bright sunlight. Western hemlock's intolerance of early successional conditions explains why none of the three pathways began with colonization by this species.

Species interactions have been important in all three pathways. For example, research has shown that alder facilitates the growth of Sitka spruce. The facilitating effect occurs because symbiotic bacteria that live inside nodules on the roots of alder convert atmospheric nitrogen (N_2) to nitrogen-containing molecules that alder use to build proteins and nucleic acids. When alder leaves fall and decay or roots die, the nitrogen becomes available to spruce. Although spruce trees are capable of invading and growing without the presence of alder, they grow faster when alder stands have added nitrogen to the soil.

Competition is another important species interaction. For example, shading by alder reduces the growth of spruce until spruce trees are tall enough to protrude above the alder thicket. Once the spruce trees breach the alder canopy, however, alder dies out, because it is unable to compete with spruce trees for light.

Historical and environmental context also clearly influences succession at Glacier Bay. For example, geologists have found evidence that the ice was more than 1100 m thick in the upper part of Glacier Bay during the mid-1700s. Because forests grow to an elevation of only 700 m or 800 m in this part of Alaska, the glacier eliminated all of the existing forests. In the lower part of the bay, however, the ice was substantially thinner. As a result, some forests remained on the mountain slopes beyond the ice. As the glacier retreated from these areas, the forests on the slopes provided a source of spruce and hemlock seeds and set a dramatically different successional pathway in motion. In this way, environmental context—in this case, distance to existing forests—helped determine how the community developed.

To summarize, successional pathways are determined by an array of factors. These factors include the adaptations that certain species have to their abiotic environment, interactions among species, and the history of the site. Species traits and species interactions tend to make succession predictable, while history and chance events contribute a degree of unpredictability to succession.

Check Your Understanding

If you understand that...

- Disturbance is a normal part of communities.
- The impact of a disturbance depends on its type, frequency, and severity.
- After a disturbance occurs, a succession of species and communities replaces the individuals that were lost.
- The exact sequence of species observed is a function of their traits, their interactions, and the history of the site.

You should be able to...

Primary Succession

53.4 Species Richness in Ecological Communities

The diversity of species present is a key feature of biological communities, and it can be quantified in two ways. **Species richness** is a simple count of how many species are present in a given community. **Species diversity**, in contrast, is a weighted measure that incorporates a species' relative abundance as well as its presence or absence (see **Box 53.1**). But at scales above relatively small study plots, it is rare to have data on relative abundance. As a result, ecologists sometimes use species richness and species diversity interchangeably. To introduce research on richness and diversity, let's focus on a simple question. Why are some communities more species rich than others?

Predicting Species Richness: The Theory of Island Biogeography

When researchers first began counting how many species are present in various areas, a strong pattern emerged: Larger patches of habitat contain more species than do smaller patches of habitat. The observation is logical because large areas should contain more types of niches and thus support higher numbers of species. But early work on species richness highlighted another pattern—one that was harder to explain. Islands in the ocean have smaller numbers of species than do areas of the same size on continents.

Robert MacArthur and Edward O. Wilson tackled this question by assuming that speciation occurs so slowly that the number of species present on an island is a product of just two events: immigration and extinction. The rates of both of these processes, they contended, should vary with the number of species present on an island. Immigration rates should decline as the number of species on the island increases, because individuals that arrive are more likely to represent a species that is already present. But extinction rates should increase as species richness increases, because niche overlap and competition for resources will be more intense. The result is an equilibrium—a balance between the arrival of new species and the extinction of existing ones (**Figure 53.24a**). If species richness changes due to a hurricane or fire or some other disturbance, then continued immigration and extinction should restore the equilibrium value.

MacArthur and Wilson also realized that immigration and extinction rates should vary as a function of island size and how far the island was to a continent or other source of immigrants. Immigration rates should be higher on large islands that are close to mainlands, because immigrants are more likely to find large islands that are close to shore than small ones that are far

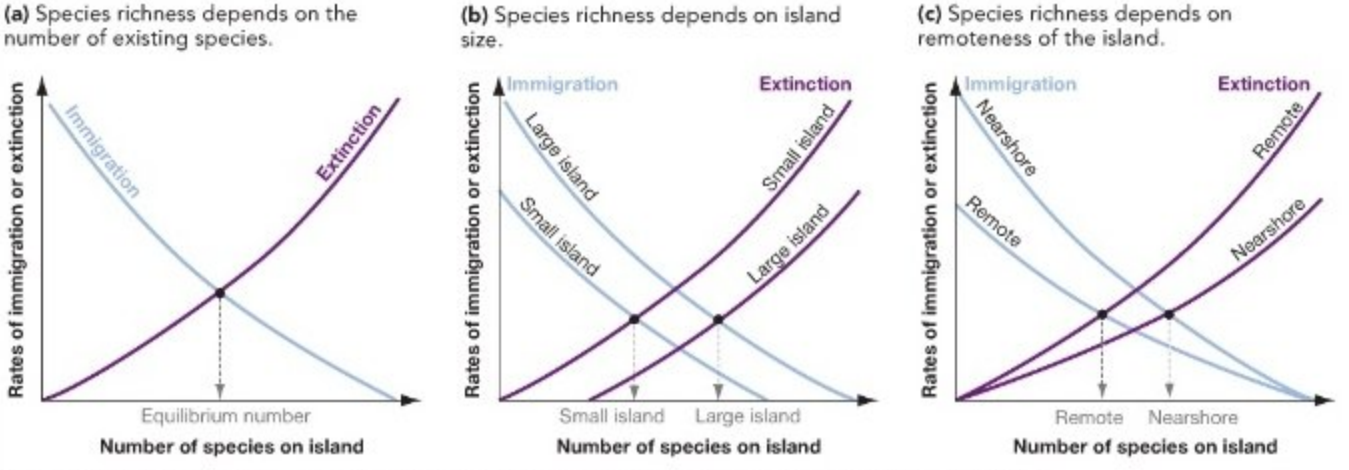

FIGURE 53.24 Species Richness Varies as a Function of Island Characteristics. If species richness on islands is dictated only by immigration and extinction rates, then species richness will vary as a function of (a) number of existing species, (b) island size, and (c) remoteness of the island from large landmasses.

QUESTION Suppose that the mainland habitats closest to an island were wiped out by suburbanization. How would this affect the curves in part (c)?

BOX 53.1 Measuring Species Diversity

To measure species diversity, a biologist could simply count the number of species present in a community. The problem is that simple counts provide an incomplete picture of diversity. The relative abundance of species is also an important component of diversity. To grasp this point, consider the composition of the three hypothetical communities shown in **Figure 53.25.** These communities are nearly identical in species composition but differ greatly in the relative abundance of each species.

These data can be used to compare two measures of species diversity. Species richness is simply the number of species found in a community. In this case, communities 1 and 2 have equal species richness and community 3 is lower in richness by one species. It is important to note, however, that communities 2 and 3 have similar relative abundances of each species, or what biologists call high *evenness*. Community 1, in contrast, is highly uneven. Fifty-five percent of the individuals in community 1 belong to species A, and other species are relatively rare. An uneven community has lower effective diversity than its species richness would indicate.

To take evenness into account, other diversity indices have been developed. A simple example is the Shannon index, given by the following equation:

$$H' = -\sum_{i=1}^{S} p_i \ln p_i$$

In this equation, p_i is the proportion of individuals in the community that belong to species *i*. The index is summed over all of the species in the study. The Shannon index for the three hypothetical communities is shown at the bottom of Figure 53.25.

FIGURE 53.25 Species Diversity Can Be Quantified.

In each case, the index is calculated by (1) computing the proportion of individuals in each community that belong to each species, (2) taking the natural logarithm of each of these proportions (see **BioSkills 5** for an introduction to logarithms), (3) multiplying each natural logarithm times the proportion for each species, and (4) summing the total across the six species in the community. ● If you understand the equation, you should be able to do these calculations and get the same result given in the figure. Notice that while communities 1 and 2 have the same species richness, community 2 has higher diversity because of its greater evenness. Community 3 has lower species richness than community 1 but higher diversity.

● If you understand how to use and interpret the Shannon index, you should be able to calculate species richness and the Shannon diversity index for 3 communities that "double" Communities 1–3 in Figure 53.25. For example, one of the three new communities should be identical to Community 1, except that there are 2 species with 10 individuals present like species "A", 2 species with 1 individual present like species "B", 2 species with 1 individual present like species "C", 2 species with 3 individuals present like species "D", and so on. There are a total of 12 species in each community. ● You should also be able to compare and contrast your results with the richness and diversity values given in the figure.

from shore. Extinction rates should be highest on small islands that are far from shore, because fewer resources are available to support large populations and because fewer individuals arrive to keep the population going. As a result, species richness should be higher on larger islands than smaller islands (**Figure 53.24b**), and on nearshore islands versus remote islands (**Figure 53.24c**).

This model, called the theory of island biogeography, is important for several reasons:

- It is relevant to a wide variety of island-like habitats such as alpine meadows, lakes and ponds, and caves.
- It made specific predictions that could be tested. For example, researchers have measured species richness on tiny islands, removed all of the species present, and then measured whether the same number of species recolonized the island and reached an equilibrium number. Predictions about immigration and extinction rates have also been measured by observing islands over time.
- It is relevant to the metapopulation dynamics introduced in Chapter 52 and can help inform decisions about the design of natural preserves. In general, the most-species rich reserves should be ones that are (1) relatively large, and (2) located close to other relatively large habitat areas.

Global Patterns in Species Richness

Biologists have long understood that large habitat areas tend to be species-rich, and the theory of island biography has been

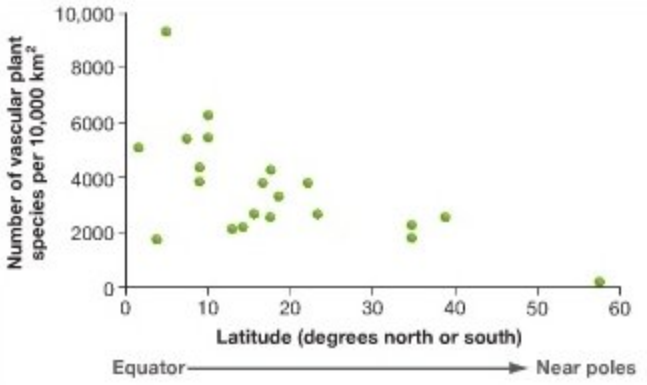

FIGURE 53.26 There Is a Strong Latitudinal Gradient in Species Diversity. One example of a latitudinal gradient in species diversity.

successful in framing thinking about how species richness should vary among island-like habitats. But researchers have had a much more difficult time explaining what may be the most striking pattern in species richness.

Biologists who began cataloguing the flora and fauna of the tropics in the mid-1800s quickly recognized that these habitats contain many more species than do temperate or subarctic environments. Data compiled in the intervening years have confirmed the existence of a strong latitudinal gradient in species diversity—for communities as a whole as well as for many taxonomic groups. In birds, mammals, fish, reptiles, many aquatic and terrestrial invertebrates, orchids, and trees, for example, species diversity declines as latitude increases (**Figure 53.26**). Although this pattern is not universal—a number of marine groups, as well as shorebirds, show a positive relationship between latitude and diversity—it is widespread. Why does it occur?

To explain why species diversity might decline with increasing latitude, biologists have to consider two fundamental principles. First, the causal mechanism must be abiotic, because latitude is a physical phenomenon produced by Earth's shape. The explanation must be a physical factor that varies predictably with latitude and that could produce changes in species diversity. Second, the species diversity of a particular area is the sum of four processes: speciation, extinction, immigration (colonization), and emigration (dispersal). Thus, the latitudinal gradient must be caused by an abiotic factor that affects the rate of speciation, extinction, immigration, or emigration in a way that would lead to more species in the tropics and fewer near the poles.

Over 30 hypotheses have been proposed to explain the latitudinal gradient. One of these maintains that high productivity in the tropics promotes high diversity by increasing speciation rates and decreasing extinction rates. (Recall from Chapter 50 that productivity is the total amount of photosynthesis per unit area per year.) The idea is that increased biomass production supports more herbivores and thus more predators and parasites and scavengers. In addition, speciation rates should increase when niche differentiation occurs within populations of herbivores, predators, parasites, and scavengers. Although this high-productivity hypothesis is supported by the global-scale correlation between productivity and diversity, experimental studies challenge it. For example, researchers who add fertilizer to aquatic or terrestrial communities routinely observe significant increases in productivity but decreases in diversity.

In light of results such as these, researchers have concluded that productivity alone is probably not a sufficient explanation for the higher species diversity in the tropics. Research continues, however, and investigators have recently begun to focus on an abiotic factor that is correlated with productivity: temperature. Biologists who analyzed data on gastropods and other marine invertebrates have documented a strong correlation between the temperature of marine waters and species diversity. This observation has inspired the energy hypothesis: High temperatures increase species diversity by increasing productivity and the likelihood that organisms can tolerate the physical conditions in a region.

A third hypothesis is that tropical regions have had more time for speciation to occur than other regions have. Temperate and arctic latitudes were repeatedly scoured by ice sheets over the last 2 million years, but tropical regions were not. Recent data suggest, however, that tropical forests were dramatically reduced in size by widespread drying trends during the ice ages. Existing forests may be much younger than originally thought. If so, then the contrast in the age of northern and southern habitats may not be enough to explain the dramatic difference in species diversity.

A fourth hypothesis was inspired by the observation that species diversity is much higher in mid-successional communities than in pioneer or mature communities. The **intermediate disturbance hypothesis** holds that regions with a moderate type, frequency, and severity of disturbance should have high species richness and diversity. The logic here is that, with intermediate levels of disturbance, communities will contain pioneering species as well as species better adapted to late-successional conditions. For example, recent studies have confirmed that tree falls and canopy gaps occur regularly in tropical forests and that fires occur in these biomes occasionally. As yet, however, there are no convincing data showing that intermediate levels of disturbance are more likely to occur in the tropics than they are at higher latitudes.

Each of the factors discussed here may influence diversity, but no single one offers a convincing explanation for the global diversity gradient. Although the high temperatures present in the tropics seem to have an especially important role in promoting species richness, there is no simple answer to the question of why the tropics are so much more species rich than temperate and high-latitude habitats.

Chapter Review

SUMMARY OF KEY CONCEPTS

Interactions among species, such as competition and consumption, have two main outcomes: (1) They affect the distribution and abundance of the interacting species, and (2) they are agents of natural selection and thus affect the evolution of the interacting species. The nature of interactions between species frequently changes over time.

A community is an assemblage of interacting species.

To categorize the different types of interactions that occur among species, biologists consider whether each participant experiences a net fitness cost or benefit from the interaction. These costs and benefits depend on the conditions that prevail at a particular time and place and may change through time.

Competition is a −/− interaction that occurs when the niches of two species overlap—meaning they use the same resources. Competition may result in the complete exclusion of one species. It may also result in niche differentiation, in which competing species evolve traits that allow them to exploit different resources or live in different areas.

Consumption is a +/− interaction that occurs when consumers eat prey, which resist through standing defenses or inducible defenses. Predators are efficient enough to reduce the size of many prey populations. Levels of herbivory are relatively low in terrestrial ecosystems, however, because predation and disease limit herbivore populations, because plants provide little nitrogen, and because many plants contain toxic compounds or other types of defenses. Parasites generally spend all or part of their life cycle in or on their host (or hosts) and usually have traits that allow them to escape host defenses. In turn, hosts have evolved counteradaptations that help fight off parasites.

Mutualism is a +/+ interaction that provides participating individuals with food, shelter, transport of gametes, or defense against predators. For each species involved, the costs and benefits of a mutualism may vary over time and from place to place.

You should be able to give an example of how competition can evolve into commensalism, and how a mutualistic relationship can evolve into a parasitic one.

MB **Web Animation** at www.masteringbio.com
Life Cycle of a Malaria Parasite

The assemblage of species found in a biological community changes over time and is primarily a function of climate and chance historical events.

Ecologists have debated whether communities are fixed, predictable entities or simply places where the distributions of various species overlap. Historical and experimental evidence support the view that communities are dynamic rather than static and that their composition is neither entirely predictable nor stable over time.

In addition to climate, the composition of a community is influenced by disturbance. In extreme cases, disturbance may remove all organisms and all soil from a large area. Each community has a characteristic disturbance regime—meaning a type, severity, and frequency of disturbance that it experiences. Three types of factors influence the pattern of succession that occurs after a disturbance. First, the historical and environmental context of the site affects which species are available to join the resulting communities. The dispersal ability of different species also affects their availability. Second, the physiological traits of any given species influence the kinds of abiotic environmental conditions it can tolerate and dictate when it can successfully join a community. Third, interactions among species influence if and when a species appears during succession.

You should be able to to explain why climate makes the three successional pathways documented in Glacier Bay similar, and why chance historical events make them different.

MB **Web Animation** at www.masteringbio.com
Primary Succession

Species diversity is high in the tropics and lower toward the poles. The mechanism responsible for this pattern is still being investigated.

One of the most widely studied patterns in community ecology is the latitudinal gradient in species diversity. Within most specific taxonomic groups and within communities as a whole, species diversity declines from the equator to the poles. Recent research suggests that the high species richness observed in the tropics results from a combination of factors—the most important of which may be high temperatures that increase productivity and provide relatively benign abiotic conditions.

You should be able to suggest a hypothesis to explain an exception to the latitudinal gradient rule—specifically, that most species of shorebirds live at high latitudes, not the tropics. (Note that many shorebird species nest near the abundant lakes found in arctic tundra).

QUESTIONS

Test Your Knowledge

1. What is competitive exclusion?
   a. the evolution of traits that reduce niche overlap and competition
   b. interactions that allow species to occupy their fundamental niche
   c. the degree to which the niches of two species overlap
   d. the claim that species with the same niche cannot coexist

2. What is niche differentiation?
   a. the evolution of traits that reduce niche overlap and competition
   b. interactions that allow species to occupy their fundamental niche
   c. the degree to which the niches of two species overlap
   d. the claim that species with the same niche cannot coexist

3. Why is the phrase "coevolutionary arms race" an appropriate way to characterize the long-term effects of species interactions?
   a. Both plants and animals have evolved weapons for defense that are so effective that many plants are not eaten and predators cannot reduce prey populations to extinction.
   b. Adaptations that give one species a fitness advantage in an interaction are likely to be countered by adaptations in the other species that eliminate this advantage.
   c. In all species interactions except for mutualism, at least one species loses (suffers decreased fitness).
   d. Even mutualistic interactions can become parasitic if conditions change. As a result, interacting species are always "at war."
4. Why are inducible defenses advantageous?
   a. They are always present—thus, an individual is always able to defend itself.
   b. They make it impossible for a consumer to launch surprise attacks.
   c. They result from a coevolutionary arms race.
   d. They make efficient use of resources, because they are produced only when needed.
5. Which of the following is *not* correlated with species diversity?
   a. latitude
   b. productivity
   c. longitude
   d. island size
6. What is net primary productivity?
   a. an individual's lifetime reproductive success (lifetime fitness)
   b. an individual's average annual reproductive success
   c. the total amount of photosynthesis that occurs in an area of a given size per year
   d. the amount of energy that is stored in standing biomass per year

Test Your Knowledge answers: 1. d; 2. a; 3. b; 4. d; 5. c; 6. d

Test Your Understanding

Answers are available at www.masteringbio.com

1. The text claims that species interactions are conditional and dynamic. Do you agree with this statement? Why or why not? Cite specific examples to support your answer.
2. State three hypotheses that have been proposed to explain the low level of herbivory in terrestrial plant communities. Are these hypotheses mutually exclusive? (In other words, can more than one be correct?) Explain why or why not.
3. Biologists have tested the hypotheses that communities are highly predictable versus highly unpredictable. State the predictions that these hypotheses make with respect to (a) the presence and impact of keystone species, (b) changes in the distribution of the species in a particular community over time, and (c) the communities that should develop at sites where abiotic conditions are identical. Which hypothesis appears to be more accurate?
4. What is a disturbance? List five examples of disturbance. Compare and contrast their effects. For each type of disturbance, compare and contrast the consequences of high-frequency and low-frequency disturbances and high and low severity of disturbances.
5. Summarize the life-history attributes of early successional versus late successional species. Why are these attributes considered adaptations?
6. Describe the latitudinal gradient in species diversity that exists for most taxonomic groups. Discuss the pros and cons of one hypothesis to explain this pattern.

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Some insects harvest nectar by chewing through the wall of the structure that holds the nectar As a result, they obtain a nectar reward, but pollination does not occur. Suppose that you observed a certain bee species obtaining nectar in this way from a particular orchid species. Over time, how might you expect the characteristics of the orchid population to change in response to this bee behavior?
2. Using this chapter's information on fire regimes in giant sequoia groves, propose a management plan for Sequoia National Park. Explain the logic behind your plan.
3. Suppose that a two-acre lawn on your college's campus is allowed to undergo succession. Describe how species traits, species interactions, and the site's history might affect the community that develops.
4. Design an experiment to test the hypothesis that increasing species richness increases a community's productivity and ability to resist disturbance and recover from disturbance.

54 Ecosystems

KEY CONCEPTS

- An ecosystem has four components: (1) the abiotic environment, (2) primary producers, (3) consumers, and (4) decomposers. These components are linked by the movement of energy and nutrients.
- The productivity of terrestrial ecosystems is limited by warmth and moisture, while nutrient availability is the key constraint in aquatic ecosystems. As energy flows from producers to consumers and decomposers, much of it is lost.
- To analyze nutrient cycles, biologists focus on the nature of the reservoirs where elements reside and on how quickly elements move between reservoirs.
- Humans are causing large, global changes in the abiotic environment. The burning of fossil fuels has led to rapid global warming. Extensive fertilization is increasing productivity and causing pollution.

The Qori Kalis glacier in the Andes Mountains of Peru in the year 2006. In 1978 the glacier extended past the edge of the lake in the lower left-hand corner of this photograph. Global warming is causing dramatic reductions in the size of glaciers and ice fields in many locations throughout the world.

An **ecosystem** consists of the organisms that live in an area together with their physical, or abiotic, environment. With the explosive growth of human populations, dramatic changes are occurring in both the biotic and abiotic components of ecosystems around the globe. Extinctions and other effects on the biotic elements of ecosystems are explored in Chapter 55; this chapter analyzes changes in the chemical and physical characteristics of the environment. Human impacts on the abiotic environment include global warming, acid rain, a hole in the atmosphere's ozone layer, and nitrate pollution (see Chapter 28). Ecosystem studies are taking a prominent place in biological science.

How does an ecosystem differ from a community? In most cases, ecosystems are composed of multiple communities along with their chemical and physical environments. For example, biologists who study lakes recognize a number of communities within a lake. There are distinct communities of interacting species along the lake bottom, at the surface, and in the shallow water of the littoral zone. Those different communities are studied as a unit called the lake ecosystem, because energy and matter flow among them.

Adjacent ecosystems—such as a river, a lake, and the surrounding forest—can be distinguished because their energy and nutrient flows are self-contained. Occasionally, though, energy and nutrients can also be transferred between ecosystems. This happens when nutrients dissolved in rainwater run off of agricultural ecosystems into nearby streams, or when an eagle kills a fish and carries it into a forest ecosystem.

This chapter introduces ecosystem studies with a look at how energy flows among the components of an ecosystem; it continues by exploring how carbon, nitrogen, and other key elements cycle through organisms, sediments, the oceans, and the atmosphere; and it ends by analyzing how humans are affecting the abiotic environment. Ecosystem ecology has taken on an increasingly applied focus, because humans are adding massive amounts of energy to ecosystems, disrupting nutrient cycles, and changing the chemistry of lakes, oceans, and the atmosphere. Understanding ecosystem ecology is fundamental to managing the future of our planet.

54.1 Energy Flow and Trophic Structure

If you imagine that an ecosystem is like an economy, then energy is its currency. Ecosystems have four components: (1) the abiotic environment, (2) primary producers, (3) consumers, and (4) decomposers. The four components are linked by a flow of energy (**Figure 54.1**).

A **primary producer** is an **autotroph** (literally, "self-feeder")—meaning, an organism that can synthesize its own food from inorganic sources. In most ecosystems, primary producers use solar energy to manufacture their own food via photosynthesis. But in some ecosystems, such as deep-sea hydrothermal vents and iron-rich rocks deep below Earth's surface, bacteria use the chemical energy contained in inorganic compounds such as hydrogen (H_2), methane (CH_4), or hydrogen sulfide (H_2S) to make food (see Chapter 28).

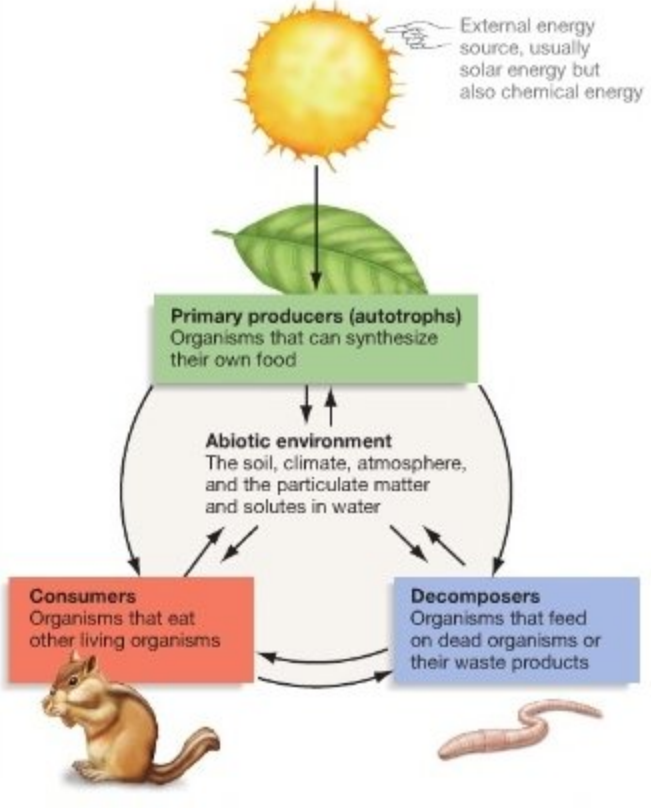

FIGURE 54.1 The Four Components of an Ecosystem Interact. The arrows represent energy. A similar diagram could be drawn to represent the flow of nutrients.

Primary producers form the basis of ecosystems because they transform the energy in sunlight or inorganic compounds into the chemical energy stored in sugars. Primary producers use this chemical energy in two ways: Most supports maintenance or respiratory costs, but some makes growth and reproduction possible. The energy that is invested in new tissue is called **net primary productivity** (**NPP**).

Net primary productivity represents the amount of energy that is available to the second and third components of an ecosystem: consumers and decomposers. **Consumers** eat living organisms. **Herbivores** are consumers that eat plants; **carnivores** are consumers that eat animals. **Decomposers**, or **detritivores**, obtain energy by feeding on the dead remains of other organisms or waste products.

The fourth and final component of an ecosystem is the abiotic environment, which includes soil, climate, the atmosphere, the Sun, and the particulate matter and solutes in water. The four components are linked because energy moves from the Sun or inorganic compounds to consumers, decomposers, and the abiotic environment.

Understanding NPP is a primary focus of ecosystem ecology because it dictates the amount of energy available to consumers and decomposers, and because global warming is altering NPP worldwide. Let's consider two of the most fundamental questions about net primary productivity: How does it vary among the world's ecosystems, and what happens to it?

Global Patterns in Productivity

Figure 54.2 summarizes data on NPP from around the globe. A quick look at the color key should convince you that the terrestrial ecosystems with highest productivity are located in the wet tropics. Notice that, with the exception of the world's major deserts, NPP on land declines from the equator toward the poles. Productivity patterns in marine ecosystems are different, however. Marine productivity is highest along coastlines, and it can be as high near the poles as it is in tropics. The oceanic zones, introduced in Chapter 50, have extremely low NPP. Typically, a square meter of open ocean produces a maximum of 35 g (1.2 oz) of organic matter each year. In terms of productivity per m^2, the open ocean is a desert.

Figure 54.3 presents the NPP data a different way—organized by biome instead of by geography. Figure 54.3a provides data on average NPP per square meter per year for each

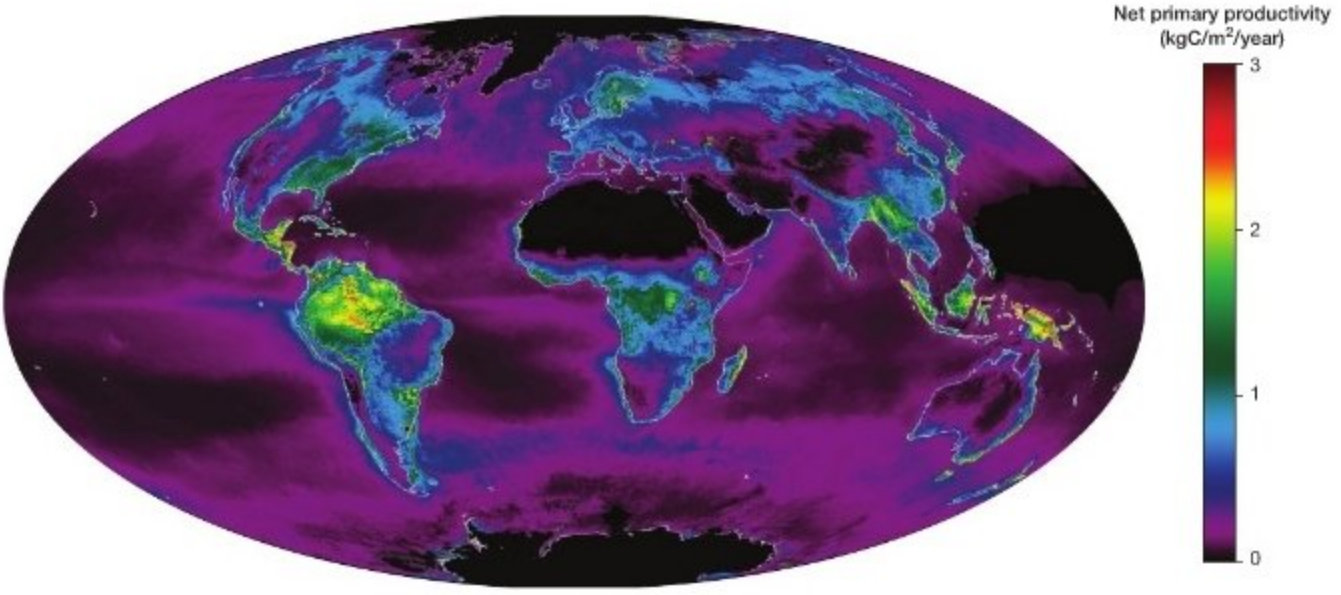

FIGURE 54.2 Net Primary Productivity Varies among Regions. The terrestrial ecosystems with the highest primary productivity are found in the tropics, where warm temperatures and high moisture encourage high rates of photosynthesis. Tundras and deserts have the lowest productivity. The highest productivity in the oceans occurs in nutrient-rich coastal areas.

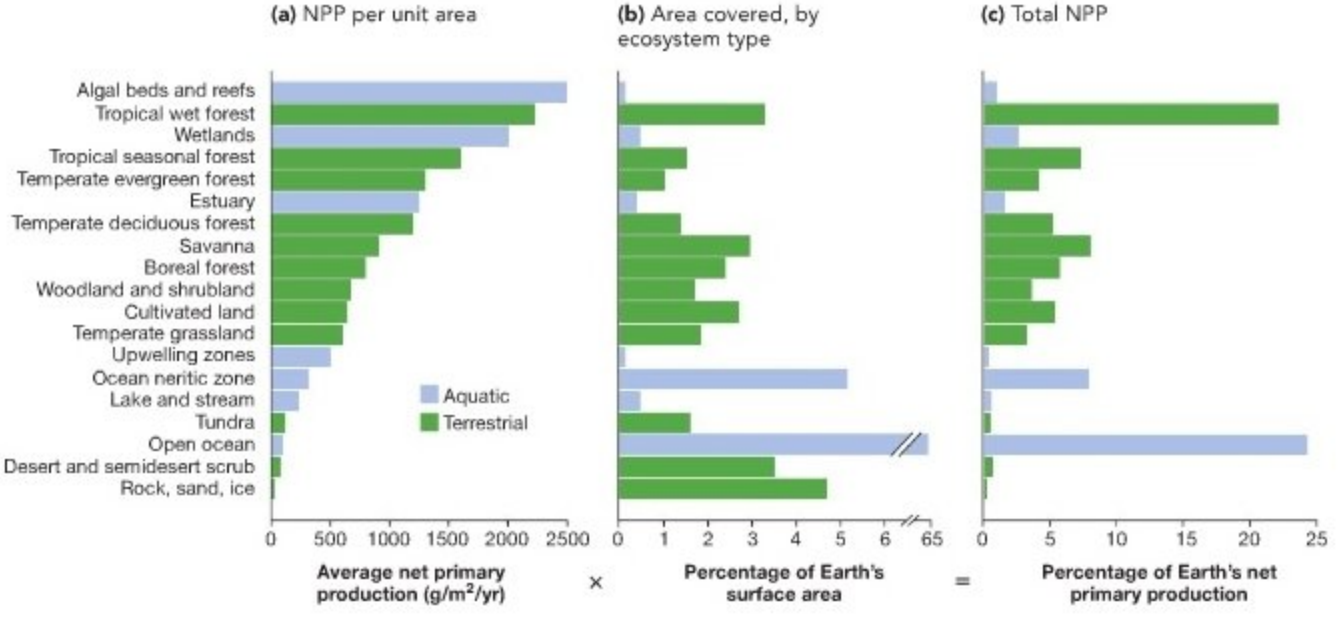

FIGURE 54.3 Net Primary Productivity Varies among Ecosystems. **(a)** Among biomes, average annual NPP per square meter varies by over three orders of magnitude. **(b)** Most of Earth's surface is covered by open ocean. The most common terrestrial habitat consists of unvegetated rock, sand, or ice. **(c)** Even though it has a low NPP per square meter, the open ocean is so vast that it is responsible for over 25 percent of Earth's total NPP.

EXERCISE Using information in Chapter 50, explain the patterns in part (a).

biome; Figure 54.3b documents the total area that is covered by each type of ecosystem; and Figure 54.3c presents the percentage of the world's total productivity—the result of multiplying the data in part (a) by the data in part (b). Note that tropical wet forests and tropical seasonal forests, which have a dry season, cover less than 5 percent of Earth's surface but together account for over 30 percent of total NPP. Among aquatic ecosystems, the most productive habitats are algal beds and coral reefs, wetlands, and estuaries. Most of the total NPP provided by aquatic ecosystems derives from the open ocean, however. Even though NPP per square meter is low in these regions, the open ocean is so extensive that its total production is high.

These patterns raise an interesting question: What limits NPP in terrestrial and marine ecosystems? The short answer is that productivity is limited by any factor that limits the rate of photosynthesis—specifically, temperature and the availabilities of water, sunlight, and nutrients. Different limiting factors prevail in different environments, however. Let's take a closer look.

What Limits Productivity? The data in Figure 54.2 and Figure 54.3 document that terrestrial productivity is lowest in deserts and arctic regions. This observation suggests that the overall productivity of terrestrial ecosystems is limited by a combination of temperature and availability of water and sunlight.

To explain why the productivity of marine habitats is so much higher along coastlines than in deepwater regions, biologists focus on nutrient limitation. As Chapter 50 pointed out, the neritic and intertidal zones along coasts receive nutrients from two major sources: (1) rivers that carry and deposit nutrients from terrestrial ecosystems, and (2) nearshore ocean currents that bring nutrients from the cold, deep water of the oceanic zone back up to the surface. Both of these sources are absent in the surface waters of the open ocean. In addition, nutrients found in organisms near the surface of the open ocean—where sunlight is abundant—constantly fall to dark, deeper waters in the form of dead cells and are lost.

Analyses have confirmed that trace elements such as zinc, iron, and magnesium are particularly rare in the open ocean. These atoms are important because they are required as enzyme cofactors. Iron, for example, is essential to the proteins that are involved in electron transport chains (see Chapters 9 and 10). On the basis of these observations, biologists have proposed that the productivity of open-ocean ecosystems could be increased dramatically by fertilizing them with iron. The results of one iron-fertilization experiment are shown in **Figure 54.4**. The data show large increases in the concentration of chlorophyll *a* in surface waters over a two-week interval. Consistent with this result, recent research on ocean waters that are naturally enriched by nearby iron-containing rocks indicates that these regions have exceptionally high NPP. Results like these provide strong support for the hypothesis that NPP in marine ecosystems is limited primarily by the availability of nutrients and that iron is particularly important in the open ocean.

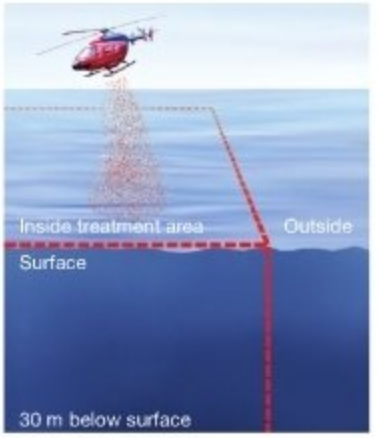
Experiment

Question: Is net primary productivity (NPP) in the open ocean limited by nutrients?

Hypothesis: NPP in the open ocean is limited by availability of iron.

Null hypothesis: NPP in the open ocean is not limited by availability of iron.

Experimental setup:



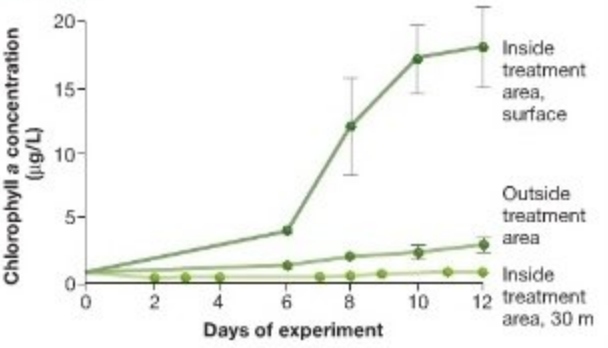
1. Add 350 kg iron (as $FeSO_4$) to a treatment area—a patch of ocean 8 km × 10 km.

2. Take water samples for a two-week period outside and inside the treatment area, at surface and at a depth of 30 m, and record amount of chlorophyll *a* present (as indicator of NPP).

Prediction: Amount of chlorophyll *a* near the surface inside the treatment area will increase relative to amounts outside the treatment area or at 30 m below the surface.

Prediction of null hypothesis: Amount of chlorophyll *a* will be the same in all measurements.

Results:



Conclusion: NPP in the open ocean is limited by the scarcity of nutrients—specifically, iron.

FIGURE 54.4 Fertilization with Iron Increases NPP in the Open Ocean.

QUESTION Most of the increased chlorophyll *a* was present in a single species of diatom (see Chapter 29). What happens to the biomass present in diatoms after they die?

How Does Energy Flow through an Ecosystem?

What happens to NPP? Net primary productivity results in **biomass**—organic material that non-photosynthetic organisms can eat. In every terrestrial and marine environment in the world, the chemical energy in primary producers eventually moves to one of two types of organisms: primary consumers or primary decomposers.

A **primary consumer** is an herbivore—an organism that eats plants or algae or other photosynthetic cells. As Chapter 53 pointed out, however, only a small percentage of all plant tissue is consumed by herbivores. Tissues that are not consumed eventually die. In forest ecosystems, for example, dead animals and dead plant tissues ("plant litter") are collectively known as **detritus**. Detritus is consumed by a variety of **primary decomposers**, including bacteria, archaea, and fungi.

Trophic Levels, Food Chains, and Food Webs Biomass represents chemical energy. Every time an herbivore eats a leaf or a fungus absorbs molecules from decaying wood, chemical energy flows from primary producers to primary consumers and decomposers. To describe these energy flows, biologists identify distinct feeding levels in an ecosystem. Organisms that obtain their energy from the same type of source are said to occupy the same **trophic** ("feeding") **level**.

A **food chain** connects the trophic levels in a particular ecosystem. In doing so, it describes how energy moves from one trophic level to another. As **Figure 54.5** shows, primary consumers are a key link in what biologists call the **grazing food chain**: the collection of organisms that eat plants, along with the organisms that eat herbivores. Consumers that eat herbivores are called **secondary consumers**. Organisms at the top trophic level in a food chain are not killed and eaten by any other organisms but enter the **decomposer food chain** when they die—along with biomass from dead primary producers and other consumers. A decomposer food chain starts with primary decomposers and includes primary consumers that usually specialize in eating primary decomposers. At higher trophic levels, though, the grazing and decomposer food chains merge. For example, the robin in Figure 54.5 functions as a secondary consumer in the grazing food chain and a tertiary consumer in the decomposer food chain.

In addition to feeding at several trophic levels, most organisms eat more than one type of food. As a result, food chains are almost always embedded in more complex **food webs**. The food web shown in **Figure 54.6** is a more complete description of the trophic relationships among the organisms in an ecosystem.

Food webs are a compact way of summarizing energy flows and documenting the complex trophic interactions that occur in communities. The keystone species introduced in Chapter 53, for example, are usually at the top of food chains and food webs. Removing or adding them has dramatic effects on a wide array of species at lower trophic levels. ● If you understand this concept, you should be able to predict how removing the top predator in Figure 54.5 would affect each of the other species in the food web.

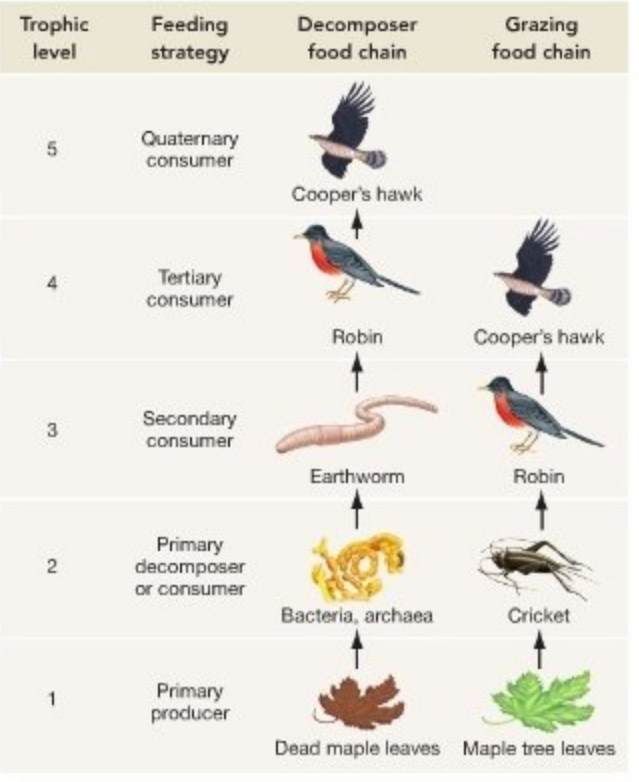


FIGURE 54.5 Trophic Levels Identify Steps in Energy Transfer. Examples from a temperate-forest ecosystem are shown; many other species exist at each level in this ecosystem.

● **EXERCISE** Label the "top predator" in these food chains—a species that is not eaten by any other species.

Why Is Energy Lost at Each Trophic Level? All ecosystems share a characteristic pattern: The total biomass produced each year declines from lower trophic levels up to the higher levels. Although biomass production at each trophic level varies widely among ecosystems, the data in **Figure 54.7** are representative. The most striking observation is that biomass production at upper trophic levels is often only 10 percent of the production at the next lowest level.

To understand why this pattern occurs, consider the interface between primary producers and primary consumers. Much of the NPP produced each year is unavailable to herbivores, because it resides in indigestible substances such as the lignin in wood or because it is protected by noxious defensive compounds. NPP that is not eaten by an herbivore enters the decomposer food web. Even if the material is ingested by an herbivore,

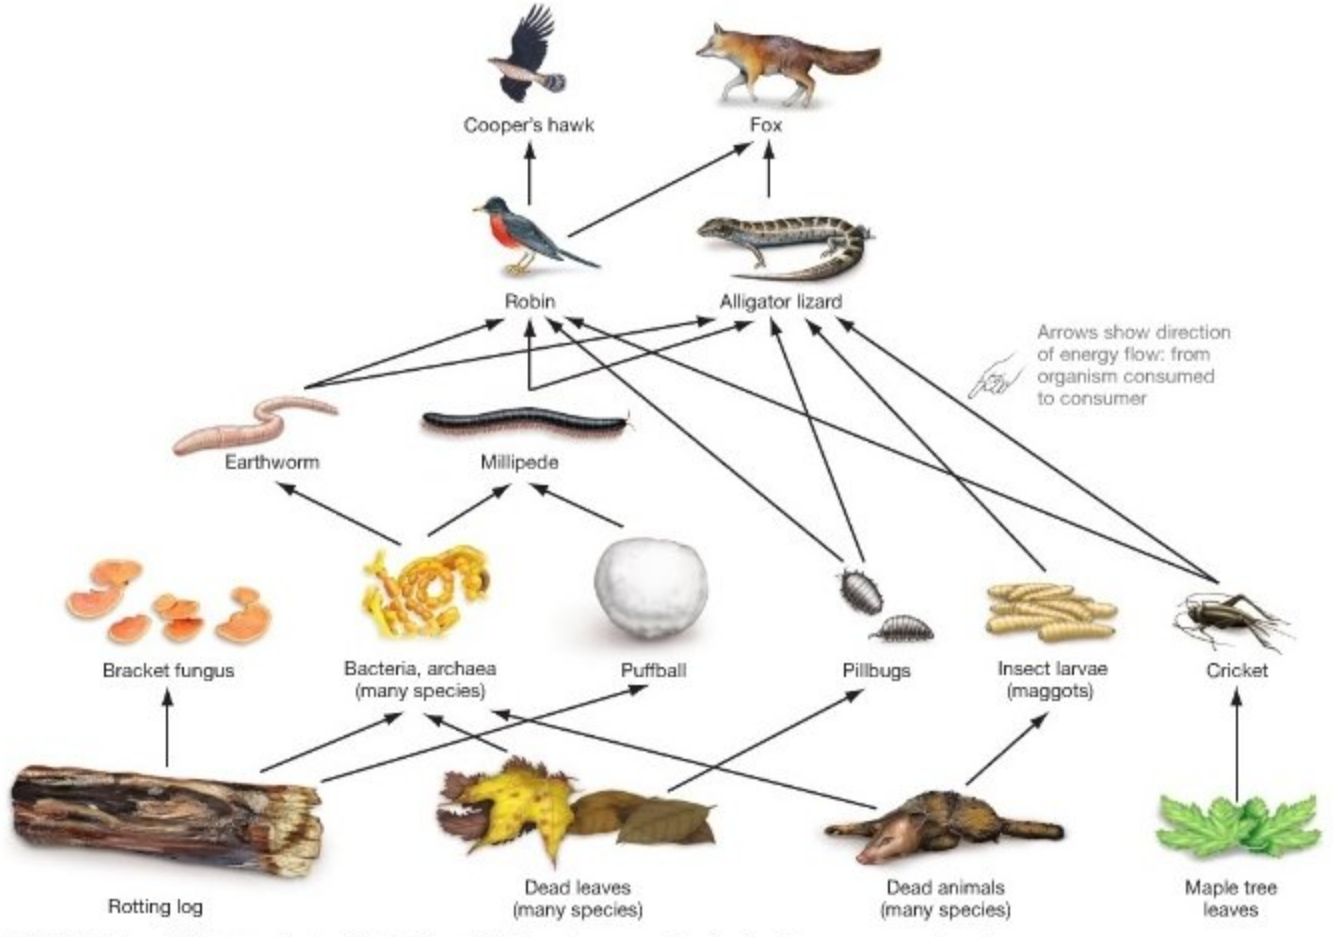

FIGURE 54.6 Food Webs Describe Trophic Relationships in an Ecosystem. Food webs offer a more comprehensive analysis of feeding relationships than food chains do. This food web shows only a fraction of the total feeding relationships and species of a temperate deciduous forest. More complete food webs include species in the grazing food chain, along with data on the average amount of energy transferred between each link in the web.

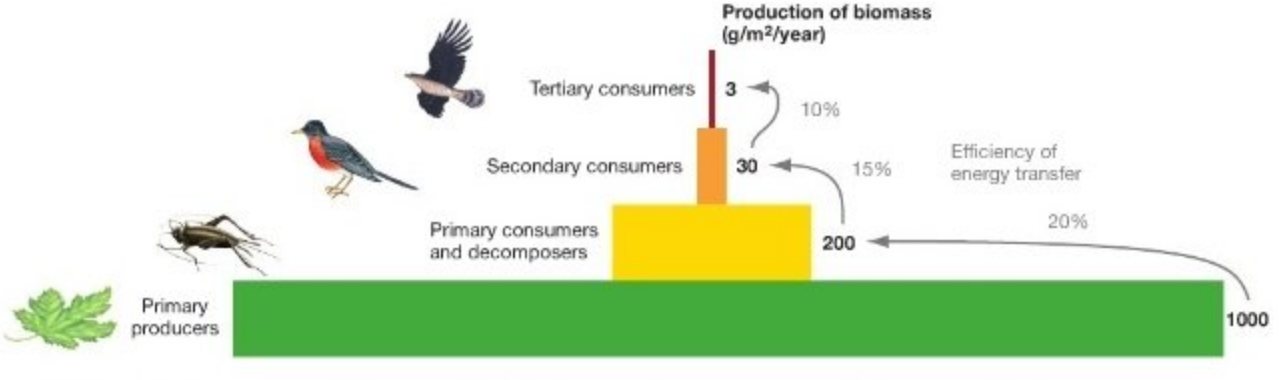

FIGURE 54.7 Productivity Declines at Higher Trophic Levels. In all ecosystems, annual production of biomass is highest at the lowest (bottom) trophic level and declines at higher levels. This pattern is the pyramid of productivity.

most of the energy stored in the chemical bonds of carbon compounds is lost as heat as it is metabolized or used to keep the consumer alive—not to grow or reproduce. At the next higher trophic level, many herbivores are never consumed by secondary consumers, because these herbivores defend themselves effectively and die of other causes. Of the energy that is successfully ingested by secondary consumers, some is again lost as heat or used up in efforts to stay alive and capture prey.

The general point here is simple: The amount of biomass produced at the second trophic level must be less than productivity at the first trophic level; productivity at the third trophic level must be less than that at the second. This pattern holds true for the entire food chain and produces a pyramid of productivity. Production of biomass is highest at the lowest trophic level. ● If you understand this concept, you should be able to explain why keystone species have relatively low biomass. You should also be able to explain why biologists consider vegetarian diets in humans much more efficient than diets that include large quantities of meat.

What Limits the Length of Food Chains? It is interesting to note that none of the food chains, food webs, or trophic structures presented in this chapter thus far have more than four or five trophic levels. When a biologist reviewed the characteristics of food chains that had been documented by researchers working in a wide variety of ecosystems, he found that the maximum number of links ranged from 1 to 6. Each link joins two trophic levels. In this study, terrestrial and lake ecosystems had 3.7 links per food chain, on average, while streams had an average of 3.2 links. Why don't ecosystems have 8 or 9 or 10 trophic levels? Why does the overall average number of levels seem to be about 3.5? Several competing hypotheses have been offered to explain this observation. Let's consider three:

- *Hypothesis 1: Energy Transfer* As energy is transferred up a food chain, a large fraction of that energy is lost. By the time energy reaches the top trophic level, there may not be enough left to support an additional suite of consumers. Suppose that the efficiency of energy transfer between each pair of trophic levels is 10 percent. If the initial trophic level in a hypothetical ecosystem produces 10,000 kcal per day, then the second, third, and fourth levels will produce 1000, 100, and 10 kcal per day, respectively. Can any organism obtain enough energy to survive at a fifth trophic level?

  The hypothesis that food-chain length is limited by productivity leads to a strong prediction: There should be more trophic levels in ecosystems with higher productivity or higher efficiency of energy transfer than in ecosystems with lower productivity or lower efficiency of energy transfer. When a researcher analyzed data on the productivity of four aquatic and four terrestrial ecosystems, however, he found that low-productivity ecosystems were as likely to contain four trophic levels as high-productivity ones were. To date, research has not supported the prediction that the most productive ecosystems have the longest food chains.

- *Hypothesis 2: Stability* Stuart Pimm proposed an alternative hypothesis to the energy-transfer explanation for why food chains are short. His idea was that long food chains are easily disrupted by droughts, floods, or other disturbances and thus tend to be eliminated. Using mathematical models, he demonstrated that long food chains took longer to return to their previous state following a disturbance than did short food chains. He then proposed that long food chains are unlikely to persist in a variable environment.

  Pimm's hypothesis also predicts that the length of food chains should increase with the stability of the environment. A biologist tested this prediction by comparing the animal communities that develop inside tree holes in Australia and Great Britain. After water accumulates in depressions or in the holes in tree branches or roots, leaf litter from the trees falls in and forms the basis of a food web. The researcher found that tree-hole communities in Australia and Great Britain were similar in many respects, except that annual leaf fall was much more variable in the British communities than in the Australian ones. As predicted by the stability hypothesis, the British ecosystems had only two trophic levels while Australian habitats supported three.

  Other researchers have challenged the assumptions behind Pimm's theoretical analysis, however, and support for the stability hypothesis remains tentative. Experimental and observational tests of this hypothesis are continuing.

- *Hypothesis 3: Environmental Complexity* Biologists have also hypothesized that food-chain length is a function of an ecosystem's physical structure. Specifically, researchers have proposed that tundra, grasslands, lake and sea bottoms, streambeds, and intertidal zones offer a largely flat, or two-dimensional, surface to the organisms living there. In contrast, forests and open-water environments in lakes and rivers offer three-dimensional volumes. This hypothesis predicts that three-dimensional ecosystems should have longer food chains than two-dimensional sites do.

  To test this hypothesis, researchers examined 113 publications that described food chains in a wide variety of aquatic and terrestrial environments. These data supported the prediction that food webs are significantly longer in three-dimensional ecosystems. As a result, the investigators concluded that dimensionality does influence food-web structure. As yet, however, no one knows why. The mechanism for this pattern remains to be determined.

To summarize, there is unlikely to be a single, simple answer to the question of what limits food-chain length. Inefficiencies of energy transfer, environmental stability, and environmental complexity may all influence the number of

trophic levels that can be supported in a given ecosystem. Multiple causation is not unusual in biological science. In genetics, for example, gene expression is rarely triggered by a single regulatory site in DNA and just one regulatory protein. Instead, the amount and timing of gene expression result from interactions among dozens of regulatory DNA sequences and proteins. Recognizing multiple causation is productive, because it can suggest exciting new experiments and analyses. For example, if food-chain length does have multiple causes, then habitats that are particularly productive, stable, and highly complex in physical structure should have the longest food chains. Research continues on this fundamental question in ecosystem ecology.

Analyzing Energy Flow: A Case History

Research on energy flow in ecosystems has uncovered a series of important general principles. In both terrestrial and marine ecosystems, NPP varies with region and biome. On land, the most important constraints on productivity are warmth and moisture; in aquatic habitats, nutrient availability is key. The chemical energy in biomass flows into consumer or decomposer food webs, where it is passed up a series of trophic levels. In terrestrial ecosystems, the total biomass declines with each trophic level.

To see these general principles in action, let's analyze energy flow in a specific ecosystem. For almost five decades, a team of researchers has been studying how energy and nutrients flow through a temperate forest ecosystem in the northeastern United States: the Hubbard Brook Experimental Forest in New Hampshire. Hubbard Brook may qualify as the most intensively studied ecosystem in the world.

As **Figure 54.8** shows, energy flow in this ecosystem begins when plants capture the energy in solar radiation via photosynthesis. At Hubbard Brook, the amount of energy entering the ecosystem from sunlight varies throughout the year and, to a lesser extent, from year to year. From June 1, 1969, to May 31, 1970, which was a typical year, 1,254,000 kilocalories (kcal) of solar radiation per square meter (m^2) reached the forest. If this amount of energy were available in the form of electricity, it would easily power two 75-watt lightbulbs that burned continuously for one year.

By documenting rates of photosynthesis in a large sample of forest plants, the biologists calculated that the plants used 10,400 kcal/m^2 of energy in photosynthesis. This value represents **gross primary productivity**, which is the total amount of photosynthesis in a given area and time period. The team also calculated **gross photosynthetic efficiency**, or the efficiency with which plants use the total amount of energy available to them, as the ratio of gross photosynthesis to solar radiation in kcal/m^2. At Hubbard Brook, efficiency was 10,400 ÷ 1,254,000 = 0.8 percent. This value is typical of other ecosystems as well.

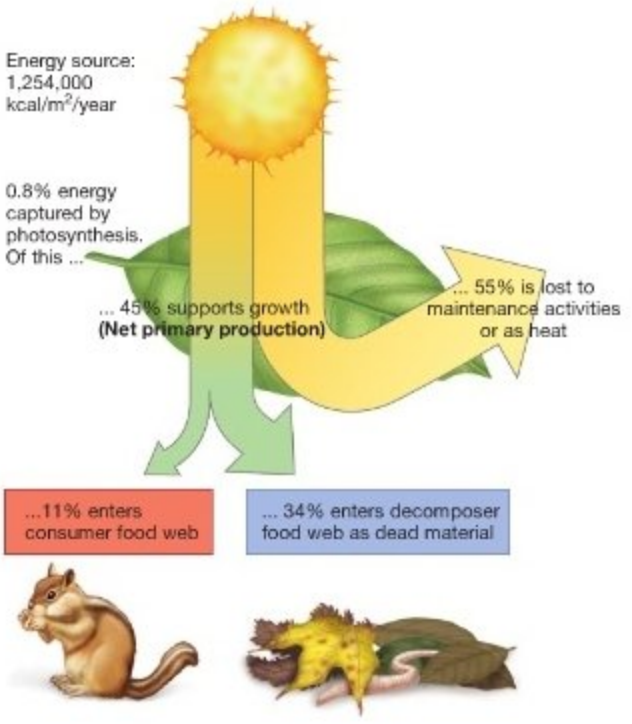

FIGURE 54.8 Energy Flow through the Hubbard Brook Forest Ecosystem. Energy from sunlight is transformed to chemical energy by photosynthesis. Photosynthetic products fuel new plant growth, which eventually enters either the consumer or decomposer food web.

EXERCISE Calculate the amount of energy transferred to primary consumers and decomposers each year, in kcal/m^2.

QUESTION If NPP in this ecosystem increases due to global warming, predict the impact on primary consumers and decomposers.

Why is efficiency so low? The answer has several components. Plants in temperate biomes cannot photosynthesize at all in winter, although sunlight is available. If conditions get dry during the summer, stomata close to conserve water and photosynthesis stops due to a lack of CO_2. Even when conditions are ideal, the pigments that drive photosynthesis can respond to only a fraction of the wavelengths available and thus a fraction of the total energy received.

Given that only a tiny fraction of incoming sunlight is converted to chemical energy and that only a fraction of this gross primary productivity is used to build biomass, let's consider the next question: What happens to the NPP at Hubbard Brook?

How Does Energy Flow through the Hubbard Brook Ecosystem? Between 1969 and 1971 the amount of energy that entered the consumer food web at Hubbard Brook varied from about 1 percent of net primary productivity per year to more than 40 percent. Leaves, seeds, and fruits were the most commonly consumed plant parts; wood was rarely eaten.

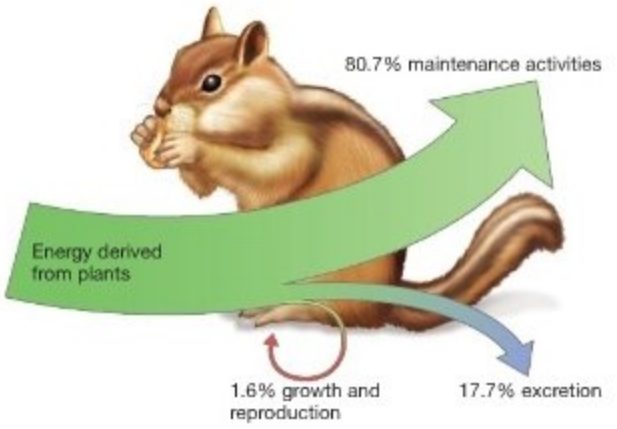

FIGURE 54.9 How Do Consumers Use Primary Production? A small fraction of the energy consumed by chipmunks, which are primary consumers (herbivores), is used for secondary production. Most of the energy is used for cellular respiration.

QUESTION Aphids are ectothermic, largely sedentary, and feed on high-quality foods containing almost no indigestible molecules. Describe how the percentages given here would compare in aphids.

Figure 54.9 illustrates what happened to the energy obtained by consumers, using chipmunks as an example consumer. Chipmunks are small rodents that are seed predators. On average, these primary consumers harvest 31 kcal/m^2 of energy each year. Of that total, 17.7 percent is unused and excreted and 80.7 percent is lost to respiration and other maintenance processes. Just 1.6 percent of the yearly 31 kcal/m^2 goes into the production of new chipmunk tissue by growth and reproduction. The production of new tissue by primary consumers is called **secondary production.**

Compared to endotherms such as chipmunks, secondary production is much higher in ectothermic consumers. Caterpillars, for example, transform about 5.4 percent of the energy they ingest into new tissue. Because ectotherms rely principally on heat gained from the environment and do not oxidize sugars to keep warm, they devote much less energy to cellular respiration than endotherms do. Even in the case of the ectotherms, though, it is clear that only a tiny fraction of the available solar radiation is involved in secondary production.

What about biomass that enters the decomposer food web? At Hubbard Brook, about 75 percent of total net primary productivity is not eaten while alive. This energy enters the decomposer food web and is passed up subsequent trophic levels, just as it is in the consumer food web. But in addition, the researchers at Hubbard Brook found that large amounts of energy leave the decomposer food web in the form of detritus that washes into streams. This transfer of energy from the forest ecosystem to the aquatic ecosystem is important, because it is a major source of energy for aquatic organisms. At Hubbard Brook, photosynthesis by aquatic algae and plants introduced only about 10 kcal/m^2/yr of energy. In contrast, each year 6039 kilocalories washed into each square meter of streambed from the surrounding forest.

Long-term studies have documented the flow of energy into, through, and out of Hubbard Brook and other types of ecosystems. Although the specific numbers found at Hubbard Brook are unique to that site and the time interval of that study, the general patterns have turned out to be typical of ecosystems around the globe.

Check Your Understanding

If you understand that...

- In an ecosystem, energy flows from sunlight or inorganic compounds with high potential energy to producers, and from there to consumers and decomposers.
- In most ecosystems, NPP is limited by conditions that limit the rate of photosynthesis: temperature and/or the availability of sunlight, water, and nutrients.
- Productivity diminishes at each subsequent trophic level in the ecosystem.

You should be able to...

1) Summarize variation in annual NPP among ecosystems and briefly explain why some ecosystems are particularly high or low.
2) Give two reasons that the amount of biomass present in terrestrial ecosystems diminishes with increasing trophic levels.
3) Evaluate at least one hypothesis to explain why most food chains have only two or three links.
4) Predict what will happen to consumer and decomposer food chains in ecosystems where global warming leads to increases or decreases in NPP.

54.2 Biogeochemical Cycles

Energy is not the only quantity that is transferred when one organism eats another. The organisms that are eaten also contain carbon (C), nitrogen (N), phosphorus (P), calcium (Ca), and other elements that act as nutrients. Atoms are constantly reused as they cycle through trophic levels and air, water, and soil. The path that an element takes as it moves from abiotic systems through organisms and back again is referred to as its **biogeochemical** ("life-Earth-chemical") **cycle.**

Because humans are now disturbing biogeochemical cycles on a massive scale, research on this aspect of ecosystem ecology is exploding. To get a basic understanding of how a particular biogeochemical cycle works, researchers focus on three fundamental questions:

1. What are the nature and size of the **reservoirs**, or areas where elements are stored for a period of time? In the case of carbon, the biomass of living organisms is an important reservoir, as are sediments and soils. Another significant carbon reservoir is buried in the form of coal and oil.
2. How fast does the element move between reservoirs, and what factors influence these rates? The global photosynthetic rate, for example, measures the rate of carbon flow from CO_2 in the atmosphere to living biomass. When fossil fuels burn, carbon that was buried in coal or petroleum moves into the atmosphere as carbon dioxide (CO_2).
3. How does a biogeochemical cycle interact with other cycles? For example, researchers are trying to understand how changes in the nitrogen cycle affect carbon.

Before taking up these issues, though, let's begin with a general overview of what nutrient cycling is.

Biogeochemical Cycles in Ecosystems

Figure 54.10 shows a simplified version of a generalized terrestrial nutrient cycle. In this case, the cycle starts when nutrients are taken up from the soil by plants and assimilated into plant tissue. If the plant is eaten, the nutrients pass to the animal members of the ecosystem's consumer food web; if the plant dies, the nutrients enter the decomposer food web. Once consumed by an animal, nutrients are excreted in fecal matter or urine, taken up by a parasite or predator, or added to the dead biomass reservoir when the animal dies.

The nutrients in plant litter, animal excretions, and dead animal bodies are used by bacteria, archaea, roundworms, fungi, and other primary decomposers. The combination of microscopic decomposers and the ions and molecules they release combine to form the soil organic matter. Soil organic matter is a complex mixture of partially and completely decomposed detritus. Completely decayed organic material is called **humus**, because it is rich in a family of carbon-containing molecules called humic acids. (Chapter 38 described other components of the soil.) Eventually, the nutrients in soil organic matter are converted to an inorganic form. For example, cellular respiration by soil-dwelling bacteria and archaea converts the nitrogen present in amino acids that are found in detritus to ammonium (NH_4^+) or nitrate (NO_3^-) ions. Once this step is accomplished, the nutrients are available for uptake by plants.

A key feature of this process is that nutrients are reused. Reuse is not complete, however. Nutrients leave the ecosystem whenever plant or animal biomass leaves. For example, plant biomass is removed if an herbivore enters the ecosystem, eats a plant, and migrates out of the ecosystem before excreting nutrients or dying. Nutrients also leave ecosystems when flowing water or wind removes particles or inorganic ions and deposits them somewhere else. Soil erosion has a huge impact on nutrient cycles: It removes nutrients rapidly and in potentially large quantities.

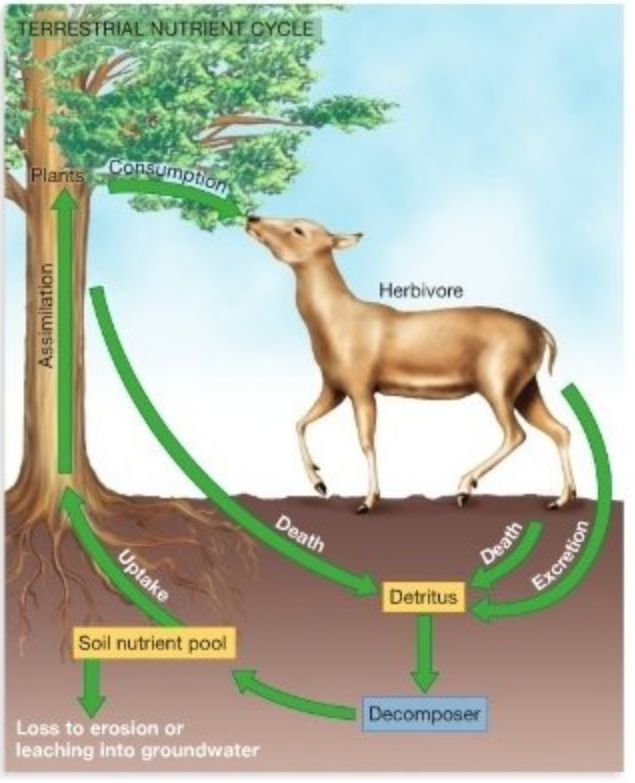

FIGURE 54.10 Generalized Terrestrial Nutrient Cycle. Nutrients cycle from organism to organism in an ecosystem via assimilation, consumption, and decomposition. Nutrients are exported from ecosystems when water or organisms leave the area.

What Factors Control the Rate of Nutrient Cycling? Of the many links in a nutrient cycle, the decomposition of detritus most often limits the overall rate at which nutrients move through an ecosystem. Until decomposition occurs, nutrients stay tied up in intact tissues. The decomposition rate, in turn, is influenced by two types of factors: abiotic conditions such as temperature and precipitation, and the quality of the detritus as a nutrient source for the fungi, bacteria, and archaea that accomplish decomposition.

To appreciate the importance of abiotic conditions on the decomposition rate, consider the difference in detritus accumulation between boreal forests and tropical wet forests. Chapter 50 indicated that boreal forests are found in areas where temperature is low. As a result, soils in these ecosystems are cold and wet. Tropical wet forests, in contrast, occur in areas where temperatures and rainfall are high. Soils tend to remain moist and warm all year long.

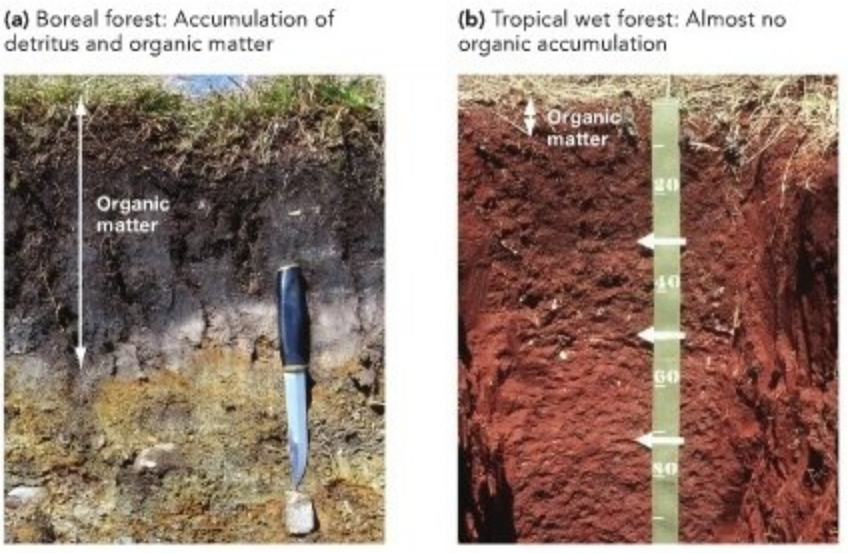

FIGURE 54.11 Temperature and Moisture Affect Decomposition Rates. (a) In boreal forests, decomposition rates are limited by cold soil temperatures. Organic matter builds up, because the input of detritus into the soil exceeds the decomposition rate. **(b)** In tropical wet forests, warm temperatures allow decomposition to proceed rapidly, so organic matter does not build up.

Figure 54.11 illustrates typical soils from boreal forests and tropical wet forests. Notice that the uppermost part of the soil in a boreal forest consists of partially decomposed detritus and organic matter. There is no such layer at the top of the soil in a tropical forest. The contrast occurs because the cold and wet conditions in boreal forests limit the metabolic rates of decomposers. As a result, decomposition fails to keep up with the input of detritus, and organic matter accumulates there. In the tropics, conditions are so favorable for fungi, bacteria, and archaea that decomposition keeps pace with detrital inputs. Nutrients cycle slowly through boreal forests but rapidly through wet tropical forests.

The quality of detritus also exerts a powerful influence on the decomposition rate and thus on nutrient availability. For example, decomposers can be hampered by the presence of large compounds in detritus that are difficult to digest, such as lignin. The presence of lignin, which is a primary constituent of wood, is one reason that wood takes much longer to decompose than leaves do. As Chapter 31 pointed out, only basidiomycete fungi, ascomycete fungi, and a few bacteria have the enzymes required to completely degrade lignin. The growth of decomposers is also inhibited if detritus is low in nitrogen.

What Factors Influence the Rate of Nutrient Loss?

Nutrient availability has a profound effect on productivity, so the rate of nutrient loss is an important characteristic of an ecosystem. Several of the major impacts that humans have on ecosystems—such as farming, logging, burning, and soil erosion—accelerate nutrient loss.

To test the effect of vegetation removal on nutrient export, researchers initiated a large-scale experiment at the Hubbard Brook Experimental Forest. They chose two similar **watersheds**—areas drained by a single stream—for study (**Figure 54.12**). They then cut all vegetation, including the trees, from the forests in one of the two watersheds. In the following three years, this clear-cut area was treated with an herbicide to prevent vegetation from regrowing. As a result, the experimental watershed was devegetated. An untreated watershed served as a control.

Before removing the vegetation, the researchers had documented that 90 percent of the nutrients in the ecosystems was in soil organic matter, and an additional 9.5 percent was in plant biomass. After the vegetation was removed, the team monitored the concentrations of nutrients in the streams exiting the two watersheds. The graph in Figure 54.12 documents the amount of dissolved substances that subsequently washed out of the stream in each watershed over the course of four years. Losses from the deforested site were typically 10 times as high as they were from the control site.

Based on these data, the researchers concluded that devegetation has a huge impact on nutrient export. Instead of being held in the ecosystem and recycled, nutrients wash out in the absence of vegetation. The loss occurs because nutrients in the soil are either dissolved in water or attached to small particles of sand or clay (see Chapter 38). If plant roots no longer hold the soil particles in place and if they no longer take up and recycle aqueous nutrients, then the molecules and ions wash out of the soil and are lost to the ecosystem. Consequently, productivity may decline over time if the area is kept

(a) Hubbard Brook Experimental Forest

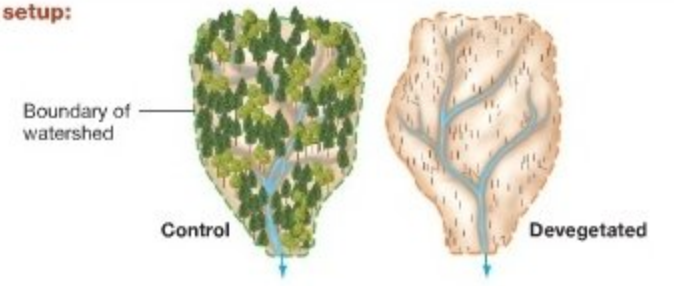
Experiment

(b) Question: How does the presence of vegetation affect the rate of nutrient export in a temperate-forest ecosystem?

Hypothesis: Presence of vegetation lowers the rate of nutrient export because it increases soil stability and recycling of nutrients.

Null hypothesis: Presence of vegetation has no effect on the rate of nutrient export.

Experimental setup:

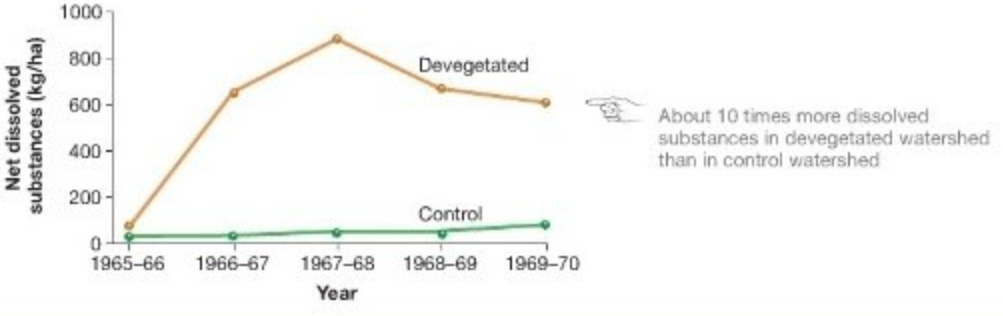


1. Choose two similar watersheds. Document nutrient levels in soil organic matter, plants, and streams.
2. Devegetate one watershed, and leave the other intact.
3. Monitor the amount of dissolved substances in streams.

Prediction: Amount of dissolved substances in stream in devegetated watershed will be much higher than amount of dissolved substances in stream in control watershed.

Prediction of null hypothesis: No difference will be observed in amount of dissolved substances in the two streams.

Results:



Conclusion: Presence of vegetation limits nutrient loss. Removing vegetation leads to large increases in nutrient export.

FIGURE 54.12 Experimental Evidence that Deforestation Increases the Rate of Nutrient Loss from Ecosystems.

QUESTION In effect, this experiment removed one of the arrows in Figure 54.10. Which one?

in a devegetated state. Long-term devegetation of this type has occurred in formerly forested areas of the Middle East, North Africa, and elsewhere due to intensive farming and grazing. As a result, the productivity of these regions is a tiny fraction of what it once was.

Global Biogeochemical Cycles

When nutrients leave one ecosystem, they enter another. In this way, the movement of ions and molecules among ecosystems links local biogeochemical cycles into one massive global system. Local and global cycles interact when water, organisms, or wind move nutrients. As an introduction to how these global biogeochemical cycles work, let's consider the global water, carbon, and nitrogen cycles. These cycles have recently been heavily modified by human activities—with serious ecological consequences.

The Global Water Cycle A simplified version of the **global water cycle** appears in **Figure 54.13**. The diagram shows the estimated amount of water that moves between major components of the cycle over the course of a year.

To analyze this cycle, begin with evaporation of water out of the ocean and the subsequent precipitation of water back into the water. For the marine component of the cycle, evaporation exceeds precipitation—meaning that, over the oceans, there is a net gain of water to the atmosphere. When this water vapor moves over the continents, it is joined by a small amount of water that evaporates from lakes and streams and a large volume of water that is transpired by plants. The total volume of water in the atmosphere over land is balanced by the amount of rain and other forms of precipitation that occurs on the continents. The cycle is completed by the water that moves from the land to the oceans via streams and **groundwater**—water that is found in soil.

Humans are affecting the water cycle in complex ways. Perhaps the simplest and most direct impacts concern rates of groundwater replenishment. Asphalt and concrete surfaces added through suburbanization reduce the amount of precipitation that percolates from the surface to enter deep soil layers. The conversion of grasslands and forests into agricultural fields also increases the amount of water that runs off Earth's surface into streams instead of penetrating to groundwater layers. Intact fields and forests lose less water than croplands do because extensive root systems that hold water are in place year-round. Most importantly, the dramatic increases in irrigated agriculture over the past three decades have resulted in massive quantities of water being removed from groundwater storage and brought to the surface.

In combination, these impacts have resulted in alarming drops in groundwater storage. The **water table** is the upper limit below the surface that the ground is saturated with stored water, and it is dropping on every continent. Between 1986 and 2006, the water table north of Beijing, China, experienced drops averaging almost 61 m (200 ft). Throughout India, water tables are falling at a rate of between 1 m and 3 m per year. Similar rates are being documented in Yemen, parts of Mexico, and states in the southern Great Plains region of the United States. Lack of water is exacerbating political tensions in several areas of the world, including the Middle East. Humans are mining water in many parts of the world—meaning that populations have already grown beyond carrying capacity for water.

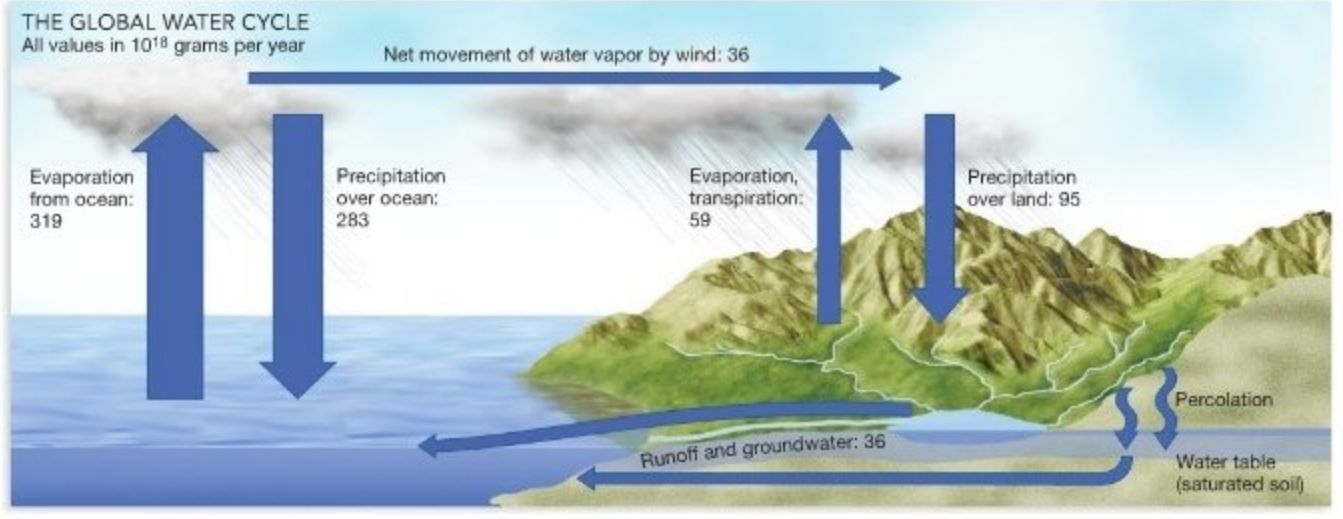


FIGURE 54.13 The Global Water Cycle.

QUESTION Predict how the amount of water evaporated from the ocean is changing in response to global warming. Discuss one possible consequence of this change.

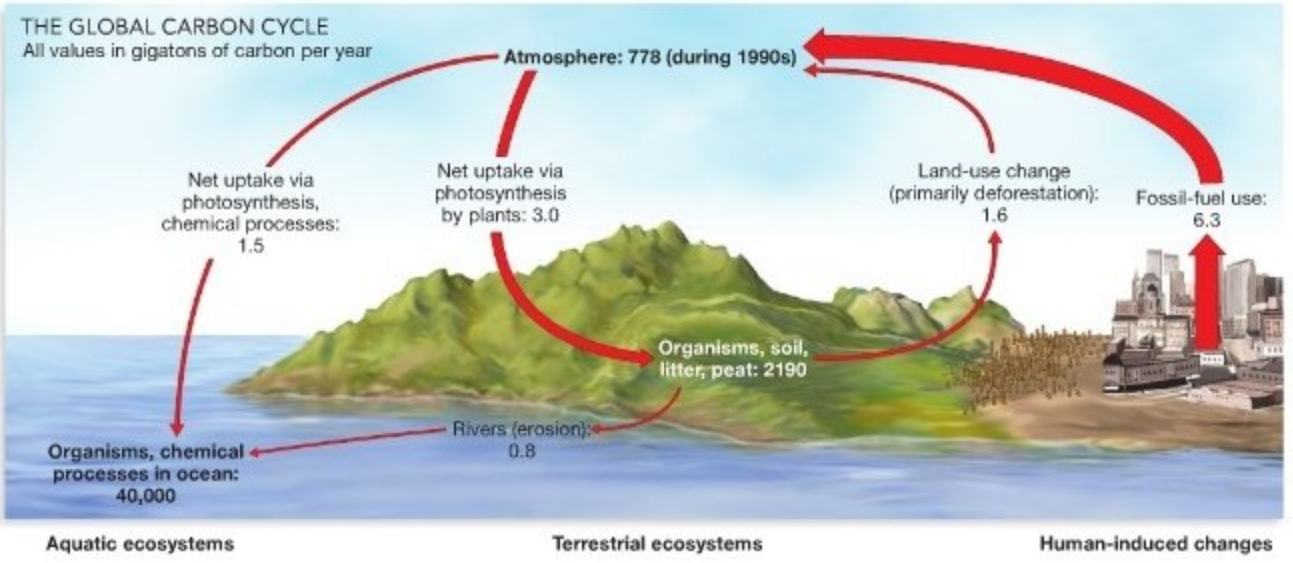

FIGURE 54.14 The Global Carbon Cycle. The arrows indicate how carbon moves into and out of ecosystems. Deforestation and the use of fossil fuels are adding 7.9 gigatons of carbon to the atmosphere each year. Of that 7.9 gigatons of carbon produced by human activities, 2 gigatons are fixed by photosynthesis in terrestrial ecosystems and 2 gigatons are fixed by physical and chemical processes in the oceans. The remainder—3.9 gigatons—is added to the atmosphere.

The Global Carbon Cycle As **Figure 54.14** shows, the **global carbon cycle** documents the movement of carbon among terrestrial ecosystems, the oceans, and the atmosphere. Of these three reservoirs, the ocean is by far the largest. The atmospheric reservoir is also important despite its relatively small size, because carbon moves into and out of it rapidly.

The arrows in Figure 54.14 emphasize that carbon frequently moves into and out of the atmospheric pool through organisms. In both terrestrial and aquatic ecosystems, for example, photosynthesis is responsible for taking carbon out of the atmosphere and incorporating it into tissue. Cellular respiration, in contrast, releases carbon that has been incorporated into living organisms to the atmosphere, in the form of carbon dioxide.

How have humans changed the carbon cycle? The fossil fuels found on Earth, which are derived from carbon-rich sediments, are estimated to contain a total of 5000–10,000 gigatons of carbon. (A gigaton, symbolized Gt, is a billion tons). This is one-eighth to one-fourth the size of the oceanic reservoir and 2.5 to 5 times the size of the terrestrial reservoir. In effect, burning fossil fuels moves carbon from an inactive geological reservoir to an active reservoir—the atmosphere. When you burn gasoline, you are releasing carbon atoms that have been locked up in coal or petroleum reservoirs for hundreds of millions of years.

Land-use changes have also altered the global carbon cycle. Deforestation, for example, reduces an area's net primary productivity. It also releases CO_2 when fire is used for clear-cutting or when dead limbs, twigs, and stumps are left to decompose. Researchers who used data on the amount of land cleared for agriculture and forestry to estimate the amount of carbon released found that, at a global scale, a net movement of carbon to the atmosphere has been occurring from terrestrial ecosystems for at least the past 100 years. The change from net carbon storage to net carbon release is the result of expanding human populations (see Chapter 52).

Figure 54.15a shows the amount of carbon released from fossil-fuel burning over the past century; **Figure 54.15b** shows the consequences of this accelerated carbon release. In just 45 years, CO_2 in the atmosphere at Mauna Loa Observatory on the island of Hawaii has increased from about 315 to over 375 parts per million (ppm)—meaning milligrams of CO_2 per kilogram of air. The same trend has been observed at sites around the globe. As the data in **Figure 54.15c** show, CO_2 concentrations in the atmosphere have now risen to levels far above the 280 ppm that was typical prior to 1860.

These changes in the global carbon cycle are important because carbon dioxide functions as a **greenhouse gas**: It traps heat that has been radiated from Earth and keeps it from being lost to space, similar to the way the glass of a greenhouse traps heat. More specifically, carbon dioxide is one of several gases in the atmosphere that absorb and reflect the infrared wavelengths radiating from Earth's surface. Increases in amounts of greenhouse gases are warming Earth's climate by increasing the atmosphere's heat-trapping potential.

The Global Carbon Cycle

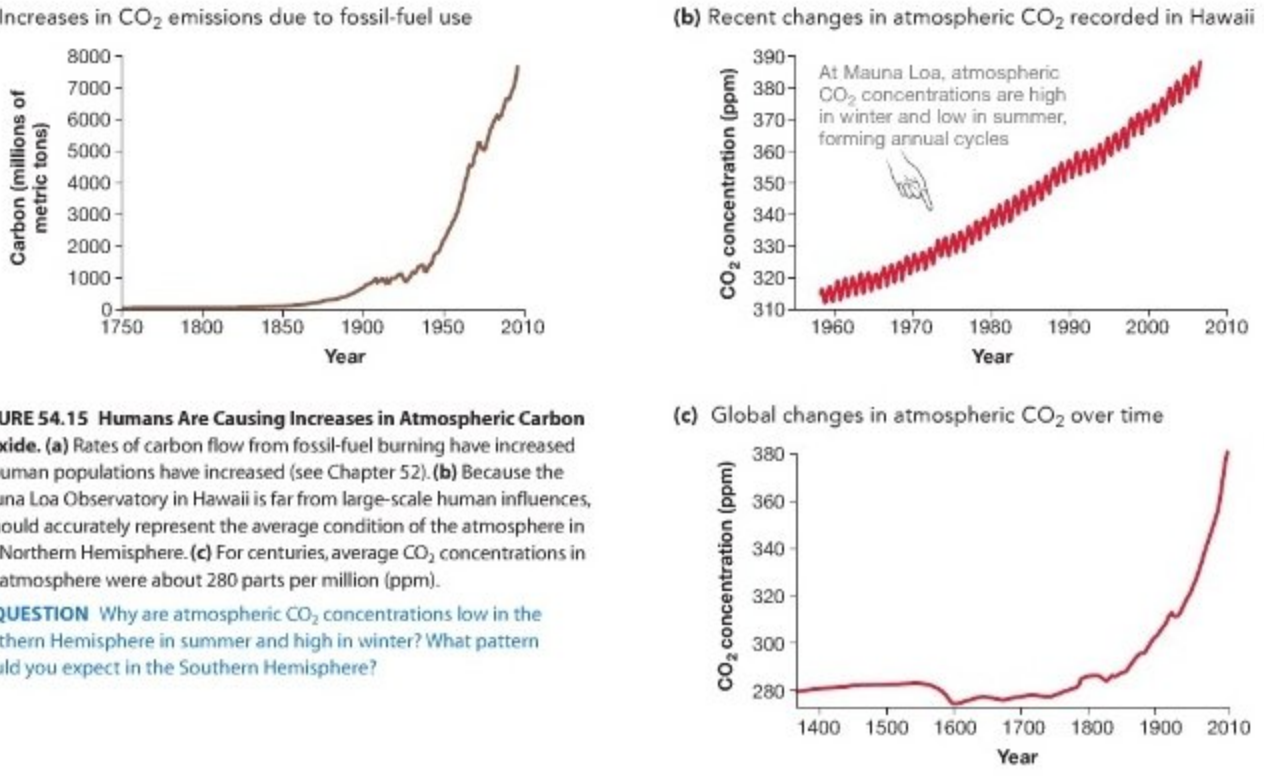

FIGURE 54.15 Humans Are Causing Increases in Atmospheric Carbon Dioxide. (a) Rates of carbon flow from fossil-fuel burning have increased as human populations have increased (see Chapter 52). **(b)** Because the Mauna Loa Observatory in Hawaii is far from large-scale human influences, it should accurately represent the average condition of the atmosphere in the Northern Hemisphere. **(c)** For centuries, average CO_2 concentrations in the atmosphere were about 280 parts per million (ppm).

QUESTION Why are atmospheric CO_2 concentrations low in the Northern Hemisphere in summer and high in winter? What pattern would you expect in the Southern Hemisphere?

The Global Nitrogen Cycle **Figure 54.16** illustrates the **global nitrogen cycle**. A key aspect of this biogeochemical cycle is that plants are able to use nitrogen only in the form of ammonium or nitrate ions (NH_4^+ or NO_3^-). As a result, the vast pool of molecular nitrogen (N_2) that is in the air blanketing Earth—N_2 makes up 78 percent of the atmosphere—is unavailable to plants. Nitrogen is added to ecosystems in a usable form only when it is reduced, or "fixed," meaning when it is converted from N_2 to NH_3. Nitrogen fixation results from lightning-driven reactions in the atmosphere and from enzyme-catalyzed reactions in bacteria that live in the soil and oceans. (Chapter 38 explained how bacteria fix nitrogen.)

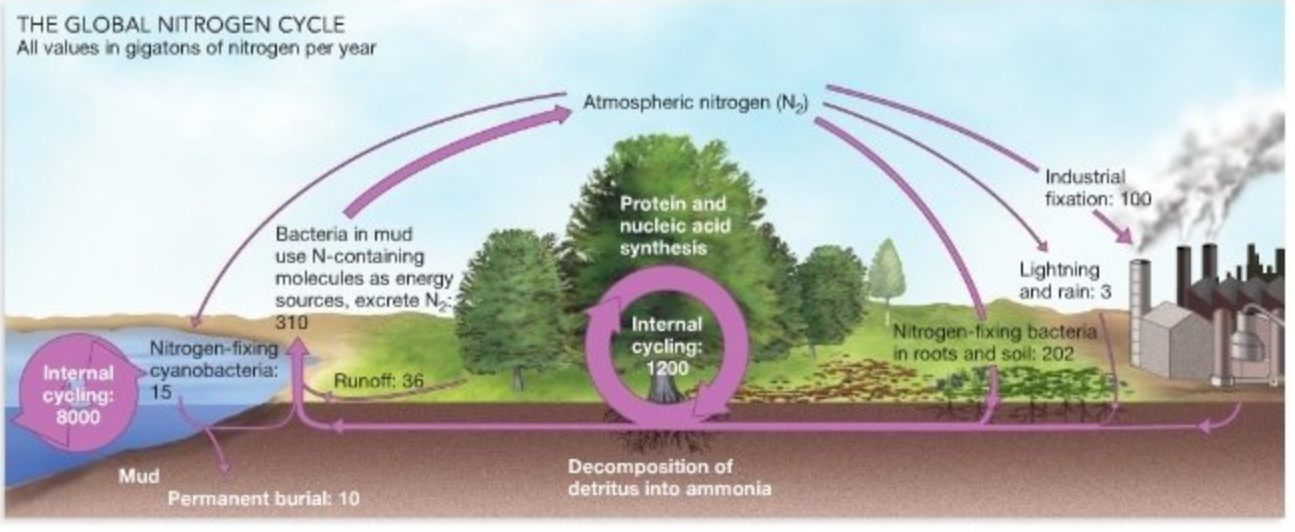

FIGURE 54.16 The Global Nitrogen Cycle. Nitrogen enters ecosystems as ammonia or nitrate via fixation from atmospheric nitrogen. It is exported in runoff and as nitrogen gas given off by bacteria that use nitrogen-containing compounds as an electron acceptor.

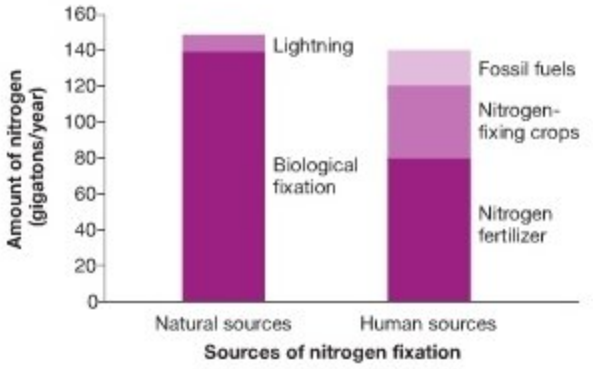

FIGURE 54.17 Humans Are Adding Large Amounts of Nitrogen to Ecosystems. Human activities now fix almost as much nitrogen each year as natural sources do. Thus, human activities have almost doubled the total amount of nitrogen available to organisms.

The nitrogen cycle has been profoundly altered by human activities. The amount of nitrogen fixation from human sources is now approximately equal to the amount of nitrogen fixation from natural sources (**Figure 54.17**). There are three major sources of this human-fixed nitrogen: (1) industrially produced fertilizers, (2) the cultivation of crops, such as soybeans and peas that harbor nitrogen-fixing bacteria, and (3) the release of nitric oxide during the combustion of fossil fuels.

Adding nitrogen to terrestrial ecosystems usually increases productivity. In some cases, then, a massive increase in nitrogen availability is beneficial. But in other situations, it is not. Chapter 28, for example, detailed how excessive applications of nitrogen-containing fertilizers on farmlands have produced nitrogen-laced runoff, which has had disastrous impacts—the formation of oxygen-free "dead zones"—in numerous aquatic ecosystems. Researchers have also documented that nitrogen inputs can lead to a significant loss of biodiversity in terrestrial ecosystems. For example, when biologists added nitrogen to plots of native grasslands in midwestern North America, a few competitively dominant species tended to take over. As those species grew rapidly, they displaced other species that did not respond to nitrogen inputs as strongly. In the grassland ecosystem, increased nitrogen boosted productivity but decreased species diversity, by altering the balance of competitive interactions. The same result has occurred in study plots within the Park Grass experiment, introduced in Chapter 52. The plots that have been fertilized with nitrogen since 1856 contain many fewer species than unfertilized plots do.

As the data in this section make clear, several of the most pressing environmental problems facing our species result from recent and massive alterations in biogeochemical cycles. Even local changes in biogeochemical cycles tend to have large-scale consequences, because nutrients are transported among ecosystems. If you are in your late teens or early twenties as you read this text, you are part of a generation that is expected to experience the most traumatic episode of environmental change in human history. The trauma has two sources: the massive loss of species documented in Chapter 55 and the profound changes in global biogeochemistry recorded here. Let's take a closer look at the consequences of altering biogeochemical cycles.

BOX 54.1 What Is Your "Ecological Footprint"?

The Ecological Footprint is an online tool that helps individuals evaluate their resource consumption. Once you've completed a questionnaire, the program calculates your resource-use "footprint"—meaning, the amount of productive land and water area required to support your lifestyle. The calculation is based on information about four aspects of resource use:

- *Food consumption* Because so much energy is lost between trophic levels, people who eat only primary producers have much smaller footprints than do individuals who eat a great deal of meat and dairy products. Eating foods that are transported long distances also inflates a footprint.
- *Consumer goods* Purchasing manufactured goods and generating large amounts of solid waste increases a footprint; recycling reduces it.
- *Shelter* Footprints are maximized by people who live alone in large homes and do not limit their use of electricity and running water.
- *Transportation* As you might predict, footprints increase when individuals drive gas-guzzling cars long distances by themselves, and when people fly a great deal. Footprints are reduced by fuel-efficient vehicles, car-pooling, bicycling, walking, and public transportation.

Many students (and professors!) who live in industrialized nations are shocked to find that their lifestyle demands over 20 acres of productive land—even though the world average is 2.2 acres/person.

In addition to raising personal awareness, the footprint makes another important point: It is not possible for Earth's resources to support a "westernized" lifestyle for more than a tiny fraction of the total human population. Most researchers agree that the human population has already overshot carrying capacity for high-resource-use lifestyles.

Check Your Understanding

If you understand that...

- Biogeochemical cycles trace the movement of water or elements among components of an ecosystem.
- Biologists analyze three aspects of these cycles: (1) the nature and size of reservoirs where elements are stored or captured, (2) the rate of movement between reservoirs, and (3) interactions among cycles.

You should be able to...

Describe how human activities are affecting these three aspects of the water, carbon, and nitrogen cycles.

54.3 Human Impacts on Ecosystems

Two factors are responsible for the human impacts on ecosystems being documented by biologists. The first is the increase in human population size, analyzed in Chapter 52. The second is an increase in resources used by people. Figure 54.15a documented increases in fossil-fuel use over about the past 150 years; **Figure 54.18** provides data from 2006 on the average annual oil consumption per person around the world. The key point is that residents of industrialized countries, though relatively few in number, have a disproportionately large impact on biogeochemical cycles because they use so much energy, water, food, and other resources (**Box 54.1** on page 1237).

Chapter 55 will assess how changes in human population size and resource use are affecting species extinctions. Here let's focus on the consequences for biogeochemical cycles. Explosive human population growth and intensive resource consumption are causing the average global temperature to rise and, in many biomes, NPP to increase. How are ecosystems responding?

Global Warming

Recall that carbon dioxide concentration in the atmosphere has been increasing throughout the twentieth century and that most analyses indicate that the increase is due to the burning of fossil fuels and clear-cutting of land, particularly forests, for homes and agriculture. Whether the increase in CO_2 is producing global warming—an increase in Earth's surface temperature, averaged over the globe, has been controversial until recently, however.

In 1988 an international group of scientists, called the Intergovernmental Panel on Climate Change (IPCC), was formed to evaluate the consequences of rising CO_2. The group has since produced a series of reports summarizing the state of scientific knowledge on the issue. The 1998 IPCC report concluded that current evidence suggests a "discernible human influence on climate." This was the IPCC's first statement supporting the hypothesis that rising CO_2 concentrations due to human activities are having a measurable impact on climate. The IPCC's next major report, released in 2001, stated that "There is new

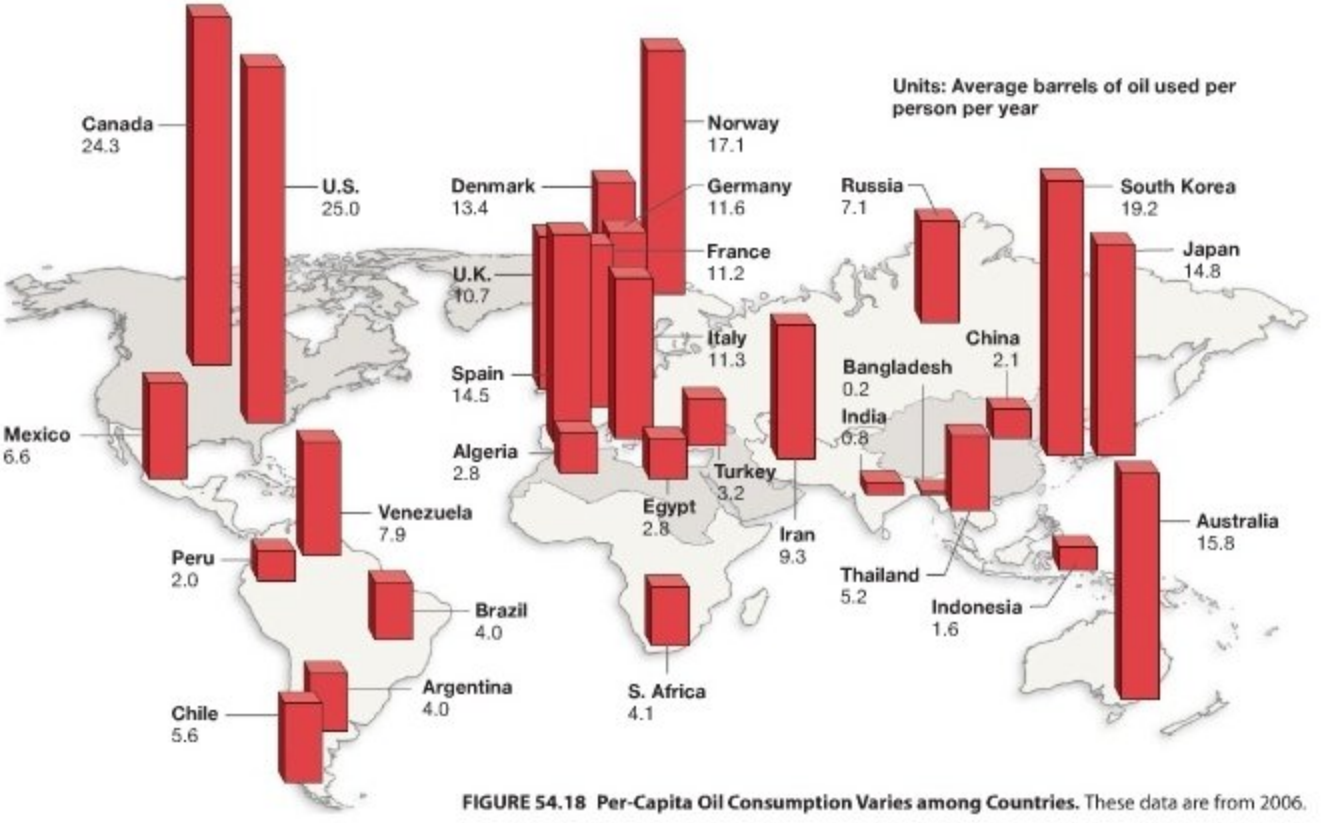

FIGURE 54.18 Per-Capita Oil Consumption Varies among Countries. These data are from 2006.

and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities." In their most recent report, issued in 2007, the IPCC declared that evidence for global warming is unequivocal and that it is "very likely" due to human-induced changes in greenhouse gases.

How much will average temperatures rise in our lifetimes? Predicting the future state of a system as complex and variable as Earth's climate is extremely difficult. Global climate models are the primary tools that scientists use to make these projections. A global climate model is based on a large series of equations that describe how the concentrations of various gases in the atmosphere, solar radiation, transpiration rates, and other parameters interact to affect climate. The models currently being used suggest that average global temperature will undergo additional increases of 1.1–6.4°C (2.0–11.5°F) by the year 2100. The low number is based on models that assume no further increase in greenhouses gases over present levels; the high number is based on models that assume continued intensive use of fossil fuels and increases in greenhouse gases.

How will ecosystems respond to this increase? Answering this question is equally difficult, because ecosystems respond to warming in ways that increase or decrease CO_2 concentrations and thus exacerbate or mitigate warming. Positive feedbacks, for example, occur when warmer and drier climate conditions lead to more fires, which in turn release more CO_2, which leads to even more warming. Researchers recently documented that a form of positive feedback is already occurring in arctic tundras. Traditionally, tundras sequester carbon in the form of soil organic matter, because decomposition rates are extremely low there. During a series of warm summers in the 1980s, however, researchers found that decomposition rates increased sufficiently to release carbon from stored soil organic matter and to produce a net flow of carbon to the atmosphere.

Negative feedbacks, in contrast, arise when warmer conditions lead to increased rates of photosynthesis and hence to an increase in the uptake of CO_2. For example, experiments have shown that the growth rates of several tree species and some agricultural crops increase in direct response to increasing atmospheric CO_2. Because CO_2 is required for photosynthesis, it can act as a fertilizer.

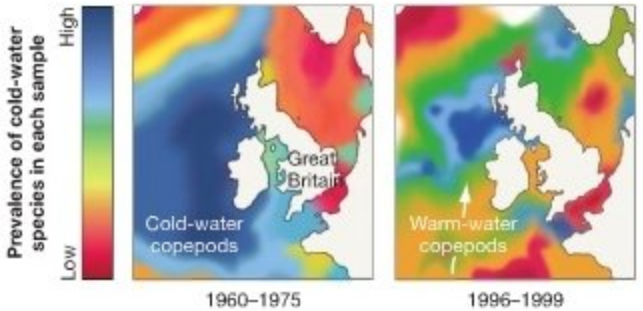
Will ecosystem responses increase or decrease global warming? Currently, it is not clear whether positive or negative feedbacks will predominate. Researchers are working to answer this question by using computer models, experiments like the two highlighted in Chapter 50, and analyses of how ecosystems responded to past climate changes.

Even though global temperatures have risen only slightly in comparison with projections for the next 50–100 years, biologists have already documented dramatic impacts on organisms.

- The geographic ranges of many organisms—including the malaria parasite—are changing. Figure 54.19a shows recent data on the ranges of small crustaceans, called copepods, in the North Atlantic. Copepods are important predators in marine plankton and are eaten by many fish. The maps show changes that occurred in a 40-year period, beginning in 1960, in the number of copepod species typical of marine waters off southern Europe versus the number of copepod species typical of northern European waters. The key observation is that southern species have moved north, while the range of cold-water species has declined.

- The timing of events is changing in many seasonal environments. The graph in **Figure 54.19b** shows changes in the date of first flowering for a plant native to the Midwestern United States. Over the past 60 years, the first day of the year when flowers are produced by *Baptisia leucantha* plants has moved up by about 10 days. To interpret this observation, biologists hypothesize that the climate has warmed enough to promote growth and flowering earlier in the year. Similarly, recent studies have confirmed that migratory

(a) Cold-water copepods are declining in the North Atlantic.



(b) Flowering times for some species in midwestern North America are earlier in the year.

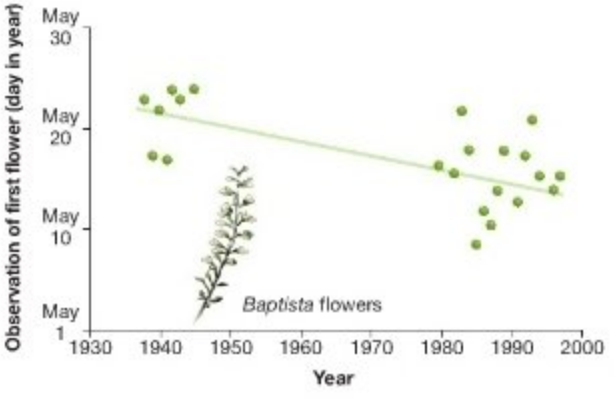


FIGURE 54.19 Global Warming Is Causing Changes in Geographic Ranges and Behavior. (a) Most species of copepod are restricted to waters of a certain temperature. **(b)** In a data set from Wisconsin, 19 of the 55 events tracked over a 61-year period occurred significantly earlier. Only one event occurred later; the remaining 35 showed no change.

bird species are arriving on their breeding grounds in Europe earlier and that fungi are fruiting earlier in some seasonal environments.

- There is strong evidence that most of the 122 frog species that have gone extinct recently succumbed to a parasitic fungus. Data published in 2006 suggest that global warming has increased the frequency and severity of these fungal infections.
- Coral reefs are among the most productive and species-rich ecosystems in the world. Their integrity is threatened, however, by increases in water temperature that cause reef-building corals to expel their photosynthetic algae. When this "coral bleaching" continues due to sustained exposure to warm water, corals begin to die of starvation.
- In some populations, changing temperatures are already causing allele frequencies to change—meaning that some species are evolving in response to global warming. In the fruit fly *Drosophila subobscura*, for example, alleles that increase fitness in hot habitats have increased in frequency in Europe, South America, and North America independently.

Global warming has already caused significant changes in geographic ranges, behavior, and allele frequencies. If the climate models published to date are correct, it will cause many more changes over the course of your lifetime.

Productivity Changes

Several of the changes that humans are inducing in biogeochemical cycles have the same effect: They alter NPP. For example, experiments have documented that warming temperatures, the addition of nitrogen and other nutrients, and rising CO_2 levels increase NPP in some terrestrial ecosystems.

Figure 54.20 shows how average annual NPP has changed globally, in (1) terrestrial environments between 1982 and 1999 (Figure 54.20a) and (2) marine environments from 1999 to 2004 (Figure 54.20b). These are the most recent intervals for which data are available. On land, global NPP increased by over 6 percent during the 17-year study interval. In the oceans, though, the 1999–2004 data show a convincing correlation between increased surface water temperatures and *decreased* productivity.

The overall increase in terrestrial productivity is thought to be due to rising temperatures, increased rainfall in the tropics, and CO_2 fertilization—all factors that increase the rate of photosynthesis in plants. The leading explanation for the drop in marine productivity is more involved. You might recall from Chapter 50 that lakes can become stratified because water is most dense at 4°C and much less dense at higher temperatures. Seawater also becomes stratified. For example, water in the benthic zone is at 4°C year-round in large regions of the ocean (**Figure 54.21a**). When the temperature of surface water rises due to global warming, the water at the surface becomes even less dense than benthic water. This is important because water in the benthic zone is nutrient rich, due to the rain of decomposing organic material from the surface. When surface water becomes lighter, water currents are much less likely to be strong enough to overcome the density difference and bring nutrient-rich, 4°C water all the way up to the surface, where nutrients can spur the growth of photosynthetic bacteria and algae (**Figure 54.21b**). If currents don't become stronger, then global warming causes surface waters to become more nutrient poor.

It's important to note, though, that these global changes are underlain by considerable local variation. On land, productivity during the 1982–1999 interval tended to increase near the equator and at 60°N latitude but to decrease in the arctic and an array of more localized areas. In the ocean, productivity during the 1999–2004 interval dropped dramatically in large areas of the pelagic zone but increased in a number of other regions.

What are the consequences of these local and global changes in NPP? The short answer is, "It depends."

In local areas of the ocean, the consequences of dramatically increased productivity have usually been negative. For example, Chapter 28 detailed how nitrate ions—derived from fertilizers applied to cornfields in midwestern North America—are washing into the Gulf of Mexico. Increased nitrate concentrations have stimulated the growth of planktonic organisms, whose subsequent decomposition has used up available oxygen and triggered the formation of an anoxic "dead zone." Biologists also hypothesize that increases in nitrate and other fertilizers of human origin have contributed to the frequency or intensity of harmful algal blooms in the ocean—large populations of dinoflagellates that release toxins into the surrounding water (see Chapter 29).

Biologists are concerned that if overall NPP in the ocean continues to decline in response to global warming, positive feedback will occur: Atmospheric CO_2 will rise due to less atmospheric CO_2 being fixed by photosynthesis. In contrast, increased NPP on land provides a negative feedback on CO_2 concentrations and global warming. In addition, lower NPP in the ocean means that the productivity of the world's fisheries may decline, but biomass increases in terrestrial environments should boost the numbers of primary and higher-level consumers.

Overall, it is not clear whether changes in productivity will be beneficial or detrimental to ecosystems. The answer should be forthcoming, however. Because global temperatures continue to rise and large-scale additions of nitrogen, phosphorus, and carbon dioxide are ongoing, humans are implementing a global-scale experiment on the effects of altering NPP. Some of the most urgent problems facing your generation are rooted in ecosystem ecology.

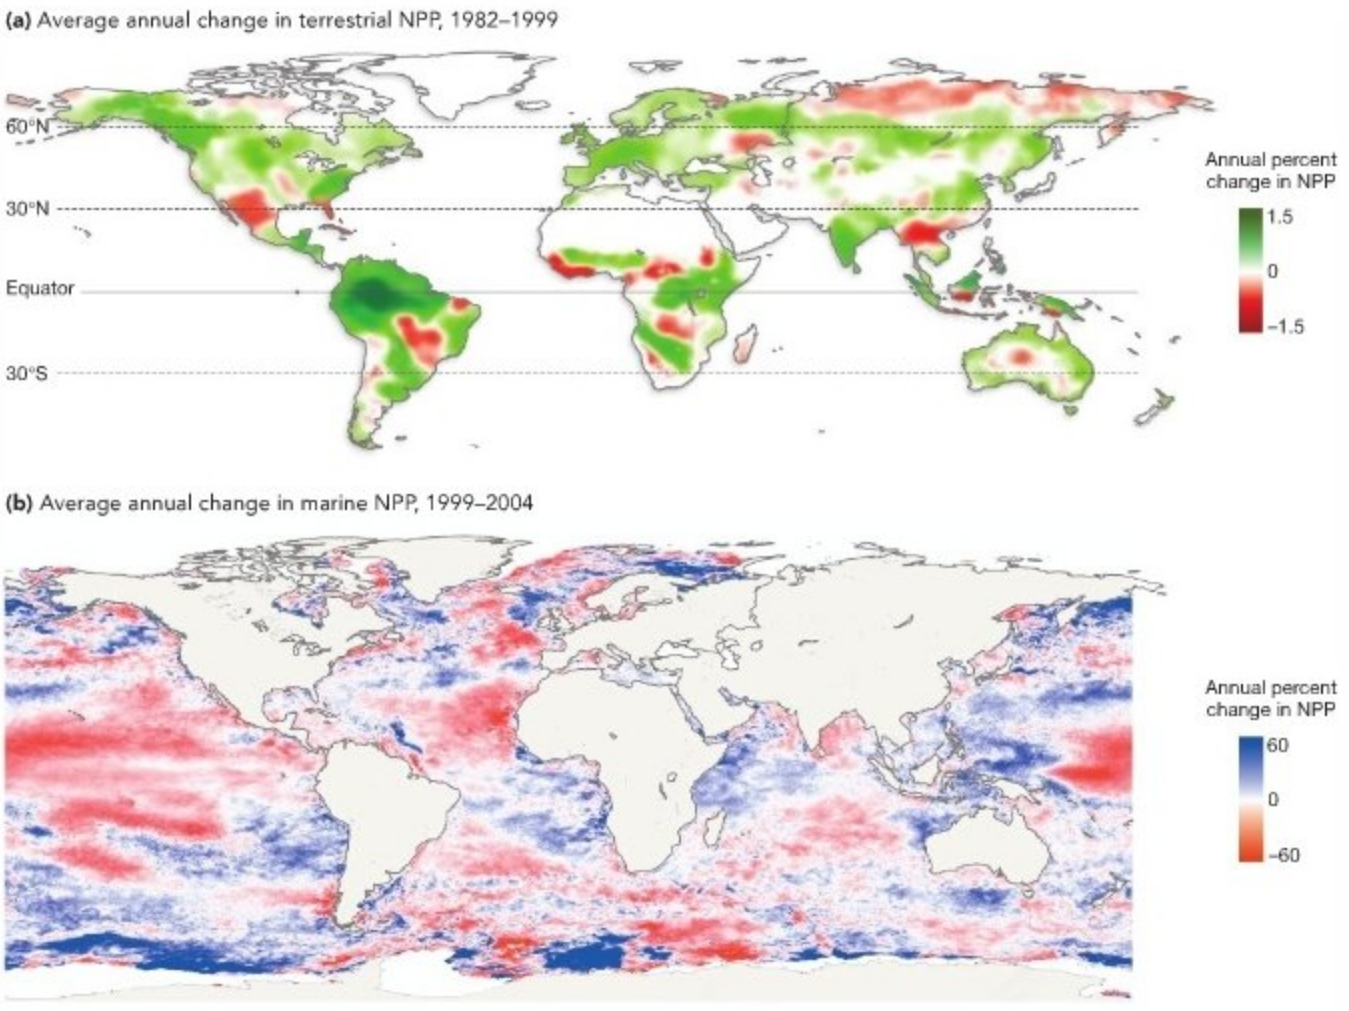

FIGURE 54.20 Consequences of Global Warming: Recent Changes in Terrestrial and Marine NPP.

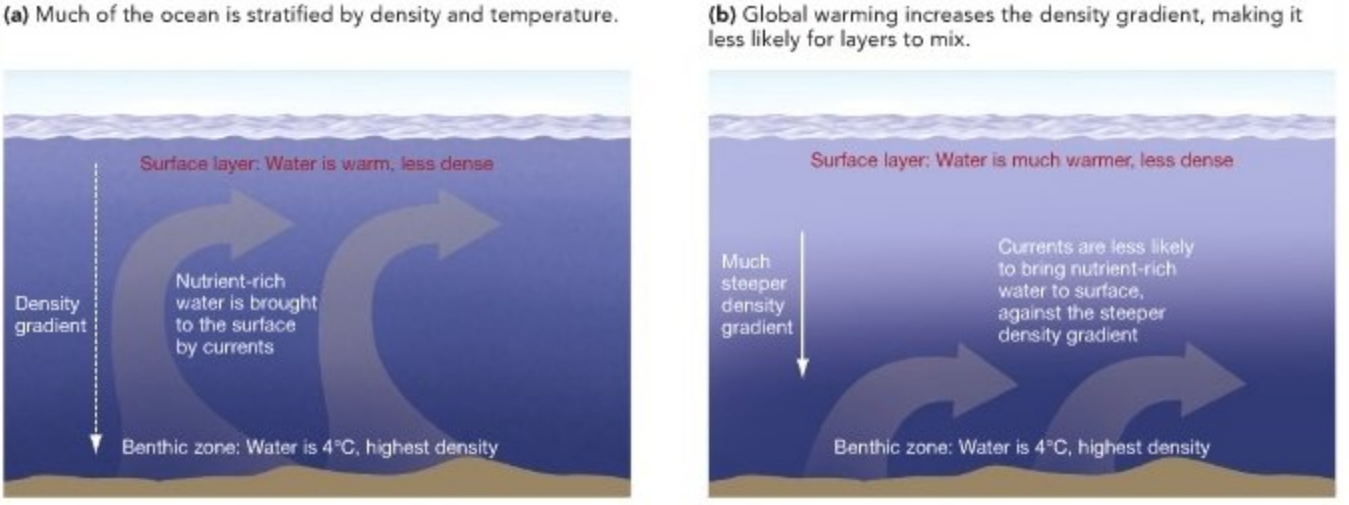

FIGURE 54.21 Temperature Stratification in the Ocean May Affect Productivity.

Chapter Review

SUMMARY OF KEY CONCEPTS

An ecosystem has four components: (1) the abiotic environment, (2) primary producers, (3) consumers, and (4) decomposers. These components are linked by the movement of energy and nutrients.

An ecosystem consists of one or more communities of interacting species and their abiotic environment. As energy flows through ecosystems and as nutrients cycle through them, energy and nutrients are exchanged between biotic and abiotic components of the ecosystem. Energy flows into ecosystems as a result of photosynthesis or the respiration of inorganic molecules with high potential energy. Chemical energy from producers enters food webs via primary consumers or decomposers.

You should be able to draw the relationships among the four components of an ecosystem where no photosynthesis occurs—the outside source of energy is iron- and sulfur-containing compounds released from magma (liquid rock).

The productivity of terrestrial ecosystems is limited by warmth and moisture, while nutrient availability is the key constraint in aquatic ecosystems. As energy flows from producers to consumers and decomposers, much of it is lost.

Among terrestrial ecosystems, net primary productivity (NPP) is highest in tropical wet forests and tropical dry forests. Among aquatic ecosystems, productivity is highest in coral reefs, wetlands, and estuaries. Although productivity is extremely low in the oceanic zone, the area covered by this ecosystem is so extensive that the open ocean accounts for the highest percentage of Earth's overall productivity.

Organisms that acquire energy from the same type of source are said to occupy the same trophic level. Most ecosystems have at least three trophic levels: primary producers, herbivores or primary decomposers, and carnivores. Because energy transfer from one trophic level to the next is inefficient, ecosystems have a pyramid of productivity: Biomass production is highest at the lowest trophic level and lower at each higher trophic level.

The feeding relationships among species in a particular ecosystem are described by a food chain or food web. Food chains rarely exceed five or six trophic levels. The energy-flow, dynamic-stability, and environmental-complexity hypotheses have been proposed to explain why food webs and food chains are not longer.

You should be able to describe the nature of a food chain where a minimum of energy would be lost.

To analyze nutrient cycles, biologists focus on the nature of the reservoirs where elements reside and on how quickly elements move between reservoirs.

Nutrients move through ecosystems in biogeochemical cycles. The rate of nutrient cycling is strongly affected by the rate of decomposition of detritus. The decomposition rate, in turn, is affected by abiotic environmental conditions such as temperature and by the quality of the detritus. Nutrients are also lost from ecosystems. Experiments have shown that the loss of vegetation greatly increases the rate of nutrient loss.

You should be able to describe conditions under which decomposition rates in terrestrial and marine environments are extremely low—creating a carbon sink due to a buildup of organic matter.

Humans are causing large, global changes in the abiotic environment. The burning of fossil fuels has led to rapid global warming. Extensive fertilization is increasing productivity and causing pollution.

Average global temperatures are increasing rapidly because land-use changes and burning of fossil fuels have increased the flow of carbon in the form of CO_2 into the atmosphere, and because carbon dioxide acts as a greenhouse gas. Nitrogen fixation from fertilizer production and from the planting of nitrogen-fixing crop species is now approximately equal to the amount of nitrogen fixation from natural sources. These increases have led to increased productivity, but also to pollution and to loss of biodiversity.

You should be able to propose three steps to reduce global warming and explain the logic behind each.

The Global Carbon Cycle

QUESTIONS

Test Your Knowledge

1. What is the difference between a community or group of communities and an ecosystem?
   a. An ecosystem comprises a community and the abiotic environment.
   b. An ecosystem is a type of community.
   c. A biome includes only the plant community or communities present in an environment.
   d. An ecosystem includes only the abiotic aspects of a particular environment.

2. Which of the following ecosystems would you expect to have the highest primary production?
   a. subtropical desert
   b. temperate grassland
   c. boreal forest
   d. tropical dry forest

3. Most of the net primary productivity that is consumed is used for what purpose?
   a. respiration by primary consumers
   b. respiration by secondary consumers
   c. growth by primary consumers
   d. growth by secondary consumers
4. According to the dynamic-stability hypothesis for food-chain length, food chains will be shorter in which type of environment?
   a. cold
   b. constant
   c. variable
   d. low in nutrient availability
5. Which of the following is normally the longest-lived reservoir for carbon?
   a. atmosphere (CO_2)
   b. marine plankton (primary producers *and* consumers)
   c. petroleum
   d. wood
6. Devegetation has what effect on ecosystem dynamics?
   a. It increases belowground biomass.
   b. It increases nutrient export.
   c. It increases rates of groundwater recharge (penetration of precipitation to the water table).
   d. It increases the pool of soil organic matter.

Test Your Knowledge answers: 1. a; 2. d; 3. a; 4. c; 5. c; 6. b

Test Your Understanding

Answers are available at www.masteringbio.com

1. Draw a pyramid of productivity for a temperate-forest ecosystem, and explain its shape.
2. Explain the difference between gross primary productivity and net primary productivity. Which is larger, and why?
3. Explain why decomposition rates are higher in some ecosystems than in others, and give examples. How does the decomposer food web regulate nutrient availability in an ecosystem?
4. Compare and contrast the energy-flow, dynamic-stability, and environmental-complexity hypotheses for food-chain length.
5. Draw a diagram of the global water, carbon, or nitrogen cycle. Label major reservoirs and flows. Compare and contrast the life span of water or an element in each reservoir, and evaluate factors that affect the rate of movement between reservoirs.
6. Why are the open oceans nutrient poor? Why are neritic zones and intertidal habitats relatively nutrient rich?

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Suppose you had a small set of experimental ponds at your disposal and an array of pond-dwelling algae, plants, and animals. How could you use radioactive isotopes of carbon or phosphorus to study energy flows or nutrient cycling in these experimental ecosystems?
2. Some researchers are concerned that fertilizing the open oceans with iron would lead to overfertilization of neritic zones, because larger amounts of nutrients would be carried into coastal regions by ocean currents. Outline an experiment and a computer simulation study to test this hypothesis. Evaluate which approach—the experiment or the computer simulation—would likely be more effective in addressing the hypothesis.
3. Suppose that herbivores were removed from a temperate deciduous forest ecosystem. Predict what would happen to the rate of nitrogen cycling. Explain the logic behind your prediction.
4. Explain why human-caused changes to the global carbon cycle are affecting Earth's climate. State why you think that these changes are beneficial or detrimental.

55 Biodiversity and Conservation Biology

KEY CONCEPTS

- Biodiversity can be analyzed at the genetic, species, and ecosystem levels.
- If recent rates of extinction due to human population growth and habitat destruction continue, a mass extinction will occur.
- Humans depend on biodiversity for the products that wild species provide and for ecosystem services that protect the quality of the abiotic environment.

Wangari Maathai, 2004 Nobel Peace Prize Winner, founded the Green Belt Movement that has sponsored the planting of over 1 billion trees, beginning in Kenya and expanding internationally. She is shown here planting a tree.

Most biologists choose their profession for two reasons: They love organisms, and they love answering questions about organisms. But even as the extent of our knowledge about life explodes and the science of biology expands, the number of species decreases. For people who have devoted their lives to the study of life, the irony is cruel. In response, many students cite a third reason for becoming a biologist: Learning how to preserve biodiversity. That is the focus of this chapter.

Let's start by getting a better understanding of what biodiversity is, and how biologists quantify and analyze the diversity of life. Section 55.2 follows up by exploring data on where biodiversity is highest.

The second half of the chapter focuses on efforts to preserve biodiversity. Section 55.3 delves into data on the extent and causes of extinction, and Section 52.4 focuses on efforts to prevent extinction—beginning with the question of why we should bother. As biologists, what reasons can we provide for preserving species? Are these reasons compelling enough to influence real estate developers, farmers, fishermen, loggers, miners, and others whose lives are directly affected by conservation efforts?

Biologists who are concerned about conservation realize that to be effective, they have to do more than collect and analyze data on threatened species and communities. They must also be comfortable in the economic and public policy arenas. A conservation biologist is similar to a physician managing the recovery of an acutely ill patient. Success demands more than the clinical skills of making a correct diagnosis and prescribing medication; it requires an empathy with the person affected, the ability to manage the cost and implementation of care, and a

devotion to collaborating with other professionals to achieve a cure. Conservation biology is a demanding and synthetic field.

55.1 What Is Biodiversity?

Perhaps the simplest way to think about biodiversity is in terms of the tree of life—the phylogenetic tree of all organisms, introduced in Chapter 1 and explored in detail in Chapters 28 through 35. If biologists are eventually able to estimate the complete tree of life, using the techniques reviewed in Chapter 27, the branches would represent all of the lineages of organisms living today and the tips would represent all of the species.

When biodiversity increases, branches and tips are added and the tree of life gets fuller and bushier. When extinctions occur, tips and perhaps branches are removed; the tree of life becomes thinner and sparser.

Coordinated, multinational efforts are under way to estimate the phylogenetic tree of major branches on the tree of life, including the fungi, brown algae, and land plants. These and other efforts to estimate phylogenies are producing a better and better picture of the relationships among lineages and species, and a clearer understanding of how extinction is affecting biodiversity. But even though the tree of life is a compelling way to document biodiversity, it does not tell the entire story.

Biodiversity Can Be Measured and Analyzed at Several Levels

To get a complete understanding of the diversity of life, biologists recognize and analyze biodiversity on three levels:

1. **Genetic diversity** is the total genetic information contained within all individuals of a species and is measured as the number and relative frequency of all alleles present in a species. Because no two members of the same species are genetically identical, each species is the repository of an immense array of alleles. At this level, biodiversity is everywhere around you, from the variety of apples at the grocery store to the variation in coloration and singing ability of sparrows in your backyard. **Box 55.1** details recent technical innovations that are allowing biologists to document genetic diversity at a large scale.
2. **Species diversity** is based on the variety of species on Earth. Recall from Chapter 53 that, in practice, species diversity is measured by quantifying the number and relative frequency of species in a particular region. There is an additional aspect of species diversity, however, that biologists call taxonomic diversity and document by estimating phylogenies. Besides understanding the number and relative frequency of species present, researchers also want to know their

BOX 55.1 Environmental Sequencing: A New Approach to Quantifying Genetic Diversity

When the first techniques for analyzing genes and proteins became available in the 1960s, biologists immediately began quantifying the level of genetic diversity within species. The basic approach was to collect tissue samples from many individuals within a population or species, isolate proteins or DNA from the samples, and document how many different alleles existed at a particular gene or suite of genes. With some notable exceptions, the overall message of this work is that most species contain a remarkably high level of allelic diversity. This was an important result, because it indicated that changes in natural selection or other evolutionary processes could cause rapid changes in the frequencies of existing alleles and thus a rapid evolutionary response to environmental change. It also demonstrated that losing a species to extinction means that a large number of unique alleles are lost.

Recent work on genetic diversity has focused on studying entire communities or ecosystems rather than individual populations or species. Research on bacteria from the Sargasso Sea furnishes a good example of this approach. The Sargasso Sea is located in the Caribbean region, near the islands of the Bahamas. Because it is exceptionally nutrient poor and species poor, it is considered one of the ocean's great deserts in terms of biodiversity. The Sargasso Sea was an attractive ecosystem to study for just this reason: Biologists routinely start by studying simple systems before progressing to more complex situations.

To inventory the complete array of bacterial genes present, a research team collected cells from different water depths and locations. The team isolated DNA from the samples and sequenced it using techniques introduced in Chapter 20. They called the work **environmental sequencing**, because their goal was to analyze all of the genes present in an ecosystem. After analyzing over 1 billion base pairs, the team concluded that at least 1800 bacterial species were present, of which 148 were previously undiscovered. They also identified more than 1.2 million alleles that had never before been characterized.

The results suggest that an enormous amount of genetic diversity exists even in Earth's simplest ecosystems. To grasp why this is important, consider that the researchers discovered more than 780 new bacterial alleles that code for proteins similar to the rhodopsin molecules found in your eyes. Do these proteins function as light receptors, like rhodopsin does? Or are these molecules absorbing light energy and using it to pump protons out of the cells, establishing a proton gradient that can drive synthesis of ATP and keep the organisms alive? No one knows—yet. New knowledge inspires new questions.

evolutionary relationships. For example, some lineages on the tree of life are extremely species rich. Prominent examples include the African cichlid fish, introduced in Chapter 27, and the 35,000 species of orchids. Other lineages, in contrast, are represented by a single species (**Figure 55.1**). Some biologists argue that it is particularly important to preserve populations from species-poor lineages, because they are the last living representatives of their lineages. If those populations go extinct, an entire lineage is lost forever.

3. **Ecosystem diversity** is the variety of biotic communities in a region along with abiotic components, such as soil, water, and nutrients. Ecosystem diversity is more difficult to define and measure than genetic diversity or species diversity, because ecosystems do not have sharp boundaries. Recall from Chapter 54 that ecosystems are complex and dynamic assemblages of organisms that interact with each other and their nonliving environment. Attempts to measure ecosystem diversity focus on capturing the array of biotic communities in a region, along with variation in the physical conditions present. Areas around estuaries, for example, tend to have high ecosystem diversity due to the combination of stream, wetland, intertidal, neritic, and upland habitats (see Chapter 50). When an estuary is dredged or filled, biodiversity is affected at all three levels: genetic and species diversity change due to the different numbers and types of individuals present, and ecosystem diversity is altered due to the change in abiotic conditions.

Biodiversity can be recognized and quantified on several distinct levels, but it is also dynamic. Mutations that create new alleles increase genetic diversity; natural selection, genetic drift, and gene flow may eliminate certain alleles or change their frequency, leading to an increase or decrease in overall genetic diversity. Speciation increases species diversity; extinction decreases it. Changes in climate or other physical conditions can result in the formation of new ecosystems, as can the evolution of new species that interact in novel ways. Disturbances such as volcanic eruptions, human activities, and glaciation can destroy ecosystems.

Biodiversity is not static. It has been changing since life on Earth began.

How Many Species Are Living Today?

One of the simplest questions about biodiversity is also one of the most difficult to answer. How many species are there on Earth? The answer is not known. Given the massive effort that it would take to document every form of life on Earth, the answer will probably never be known.

Biologists are well aware, though, that the approximately 1.5 million species cataloged to date represent a tiny fraction of the number actually present. Chapter 31, for example, noted that an average of 6 fungal species live on each well-studied

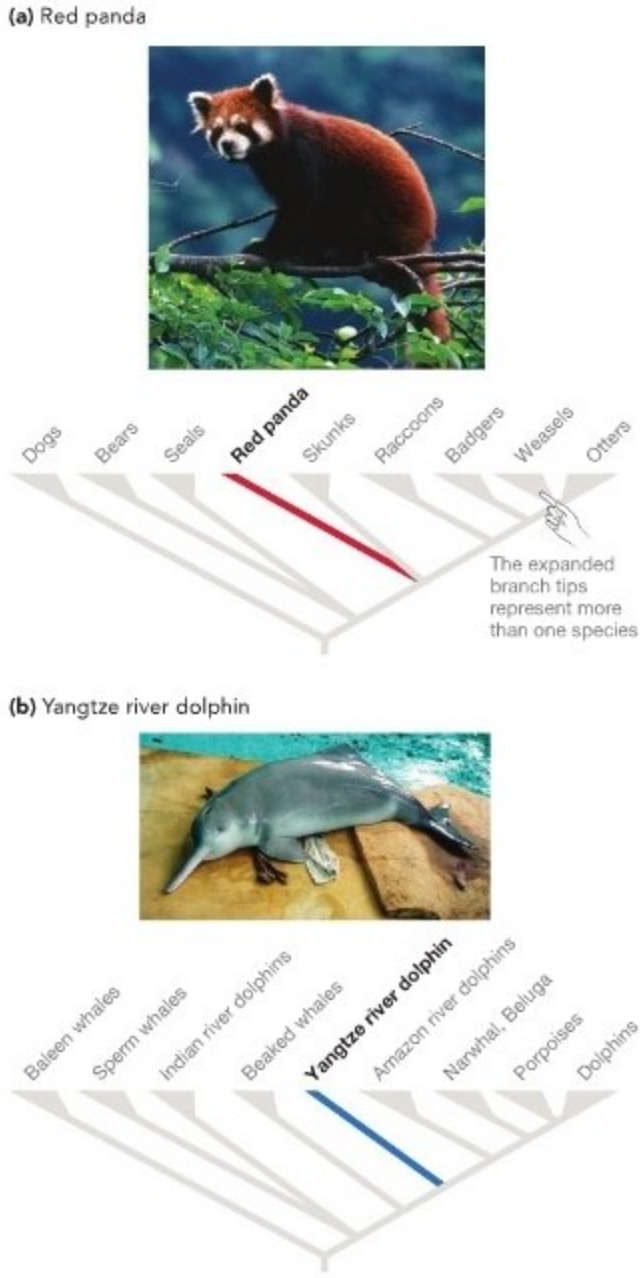

FIGURE 55.1 Phylogenetically Distinct Species May Be High-Priority Targets for Conservation. The red panda and the Yangtze river dolphin have few close relatives and represent distinct branches on the tree of life. If conservation measures attempt to preserve taxonomic diversity, these species would be a high priority for preservation. Unfortunately, preservation efforts for the Yangtze river dolphin are too little too late—this species is now functionally extinct (too few individuals remain to breed and sustain the population).

plant species. Because over 300,000 plant species have been described, a conservative estimate based on the 6:1 fungi:plant ratio suggests that 1.65 million species of fungi exist, even though only 80,000 have been described thus far. The issue is

even more acute in poorly studied lineages like bacteria and archaea, where researchers routinely discover dozens or hundreds of previously unknown species with each new direct sequencing or environmental sequencing study (see Chapter 28 and Box 55.1). For example, a recent direct sequencing study estimated that over 500 species of bacteria live in the human mouth, although only about half have been described and named. Even among well-studied groups like birds and mammals, new species are discovered almost every year.

Given that only a fraction of the organisms alive have been discovered to date, how can biologists go about estimating the total number of species on Earth? Two general approaches have been used. One is based on intensive surveys of species-rich groups at small sites. A second is based on attempts to identify all of the species present in a particular region.

Taxon-Specific Surveys Terry Erwin and J. C. Scott published a classic study of species diversity in a single taxon. They began by estimating the number of insect species that live in the canopy of a single tropical tree (**Figure 55.2**). After using an insecticidal fog to knock down insects from the top of a *Luehea seemannii* tree, they identified over 900 species of beetles among the individuals that fell. Most of these species were new to science.

FIGURE 55.2 Estimating Species Richness via Intensive Local Sampling. A small sample of the insects collected from a single tree in the Amazonian rain forest.

To use these data as an indicator of global arthropod species diversity, Erwin and Scott used the following train of logic: Based on earlier work with insects on this tree species, they estimated that 160 of the 900 beetle species live only on *L. seemannii*. Worldwide, beetles represent about 40 percent of all known arthropods. Thus, it was reasonable to suggest that 400 species of arthropods live only in the canopy of *L. seemannii*. By adding an estimate of arthropods specializing on the trunk and roots of this tree, Erwin projected that it is host to 600 specialist arthropods. If each of the 50,000 species of tropical tree harbors the same number of arthropod specialists, then the world total of arthropod species exceeds 30 million species. Based on such studies, biologists estimate that at least 10 million, and possibly as many as 100 million, species of all types exist today.

More recent single-taxon surveys have sampled larger geographic areas. For example, Philippe Bouchet and colleagues conducted a massive survey of marine molluscs in coral-reef habitats along the west coast of New Caledonia, a tropical island in the southwest Pacific Ocean. The team spent more than a year collecting molluscs at 42 sites over a total area of almost 300 square kilometers. The survey represented the most thorough sampling effort ever made to determine the species diversity of molluscs, and produced more than 127,000 individuals representing 2738 species. These numbers far exceed the mollusc diversity recorded for any comparable-sized area. The species total was 2 to 3 times the total number of mollusc species that had been reported for similar habitats in the region.

In reporting their findings, the biologists emphasized that 20 percent of the species found were represented by a single specimen. This observation suggests that many species are exceedingly rare and thus likely to be missed by less-intensive sampling efforts. And when the investigators compared their data with a survey in progress at a second site, different in reef structure but only 200 kilometers away from the original site, they found that only 36 percent of species were shared between the two sites. These results support the hypothesis that the global biodiversity of molluscs—currently thought to be about 93,000 species—is an underestimate.

All-Taxa Surveys The first effort to find and catalog all of the species present in a large area is now under way. The location is the Great Smoky Mountains National Park in the southeastern United States (**Figure 55.3**). A consortium of biologists, volunteers, and research organizations initiated this all-taxa survey in 1999. To date, the survey has discovered over 650 species that are new to science and over 4650 species that had never before been found in the park. When the inventory is complete, in 2015, biologists will have a much better database to use in estimating the extent of global biodiversity.

- Biologists document biodiversity at the genetic, species, and ecosystem levels.

You should be able to...

Outline a study that would quantify levels of genetic, species, and ecosystem diversity on your campus.

55.2 Where Is Biodiversity Highest?

If documenting the extent of genetic, species, and ecosystem diversity is the most fundamental goal of research on biodiversity, then the second-most important aim is to understand its geographic distribution. Chapter 53 introduced the most prominent geographic pattern in the distribution of biodiversity: In most taxonomic groups, species richness is highest in the tropics and declines toward the poles. Tropical rain forests are particularly species rich. Even though they represent just 7 percent of Earth's land area, they are thought to contain at least 50 percent of all species present. As Chapter 53 noted, understanding why tropical forests are so species rich and why a latitudinal gradient occurs is one of the most active areas of research in community ecology and biodiversity.

Biologists have also been working to understand the distribution of species richness at finer spatial scales, however. For example, the map in **Figure 55.4a** was constructed by dividing the world's landmasses into a grid of cells 1° latitude by 1° longitude. In the tropics, this translates to rectangles approximately 111 km by 111 km (69 mi by 69 mi); because lines of longitude converge at the poles, the rectangles are about 111 km by 55 km at 60° latitude. Using published data, researchers then plotted how many species of birds breed in each cell in the grid. These data are consistent with the latitudinal gradient in species richness, but indicate that some areas of the tropics are much more species rich than others. Biologists use the term **hotspot** to capture this point. In terms of bird species richness, the Andes mountains, the Amazon River basin, portions of East Africa, and southwest China are important hotspots.

Researchers have also been keenly interested in understanding which regions of the world have a high proportion of **endemic species**—meaning, species that are found in an area and nowhere else. **Figure 55.4b** maps the location of endemic species of breeding birds, based on the same cells and data as the species richness map in Figure 55.4a.

Mapping species richness hotspots and centers of endemism can inspire interesting questions—principally, efforts to understand *why* certain regions contain many species or a high proportion of endemic taxa. But in addition, biologists are studying the geographic distribution of biodiversity as a way of focusing conservation efforts. In the year 2000, for example, a team set out to identify regions of the world that meet two criteria: (1) They contain at least 1500 endemic plant species, and (2) at least 70 percent of their traditional or primary vegetation has been lost. The goal of the study was to identify regions of the world that are in most urgent need of conservation action—areas where efforts to preserve habitat would have the highest return on investment. The idea was that efforts to protect a diversity of primary producers would guarantee the protection of a wide array of primary, secondary, tertiary, and quaternary consumers.

The 25 regions that met the two "conservation hotspot" criteria are shown in **Figure 55.4c**. Although these areas represent just 1.4 percent of the Earth's land area, they contain 44 percent of all known plant species and 35 percent of all known vertebrate species. It's also important to note that key regions with high plant species diversity—specifically the rain forests found in the Amazon, the Congo River basin, and New Guinea—are not included as conservation hotspots, because they have not yet lost 70 percent of their primary vegetation. Effectively protecting these areas along with the hotspots defined on the map would provide protection for 60 percent of all land plants in just 5 percent of the Earth's land surface.

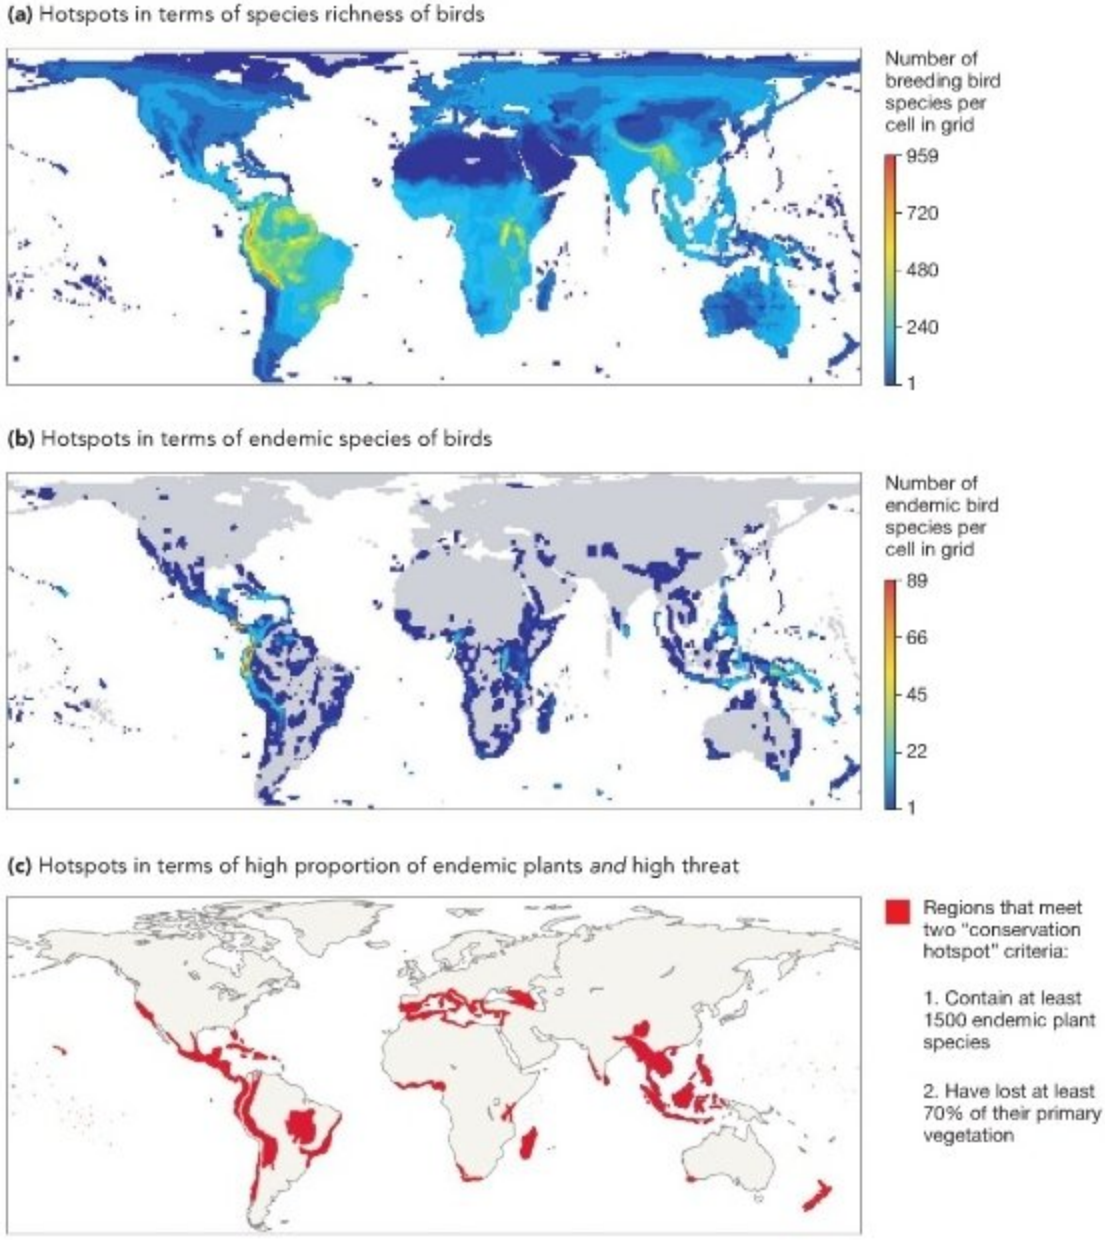

FIGURE 55.4 Conservation "Hotspots" Can Be Defined in Different Ways. The maps in **(a)** and **(b)** are based on a grid that is 1° longitude by 1° latitude. The areas shown in red in **(c)** have lost 70 percent of their original vegetation and contain a high diversity of vascular plant species.

QUESTION Suppose you were going to set up natural areas focused on preserving bird species. Which areas on the three maps are in agreement in terms of conservation priorities? Which are in conflict?

This analysis serves as your introduction to the applied aspects of biodiversity studies—the field known as conservation biology. To understand the importance of the data in Figure 55.4 thoroughly, we need to explore two things in depth: why so many species are threatened with annihilation, and why we should do something about it. Let's consider each issue in turn.

55.3 Threats to Biodiversity

No species lasts forever. Climate change, disease, competition from newly arrived species, and habitat alteration are all natural processes. They have been happening since life began. Extinction, like death, is a fact of life.

If extinction is natural, why are biologists so concerned about habitat and species conservation? The answer is rate. Today species are vanishing faster than at virtually any other time in Earth's history. Modern rates of extinction are 100 to 1000 times greater than the average, or "background," rate recorded in the fossil record over the past 550 million years.

Either directly or indirectly, current extinctions are being caused by the demands of a rapidly growing human population, which is currently increasing by about 77 million people per year. If present trends in human population growth and species extinctions continue, a mass extinction on the scale of events described in Chapter 27 will occur. Based on the data in hand, the vast majority of biologists agree with the claim that the sixth mass extinction in the history of multicellular life is now under way. Between the time you are reading this and the time your great-grandchildren are grown, human impacts on the planet promise to equal or exceed those of the gigantic asteroid that smashed into Earth 65 million years ago. It's important to note, however, that human impacts on biodiversity are not a new phenomenon.

Humans Have Affected Biodiversity throughout History

Historically, humans have a poor record of conserving resources and protecting species. For example, recent research on fossil birds found on islands in the South Pacific suggests that about 2000 bird species were wiped out as people colonized this area about A.D. 1200. Many of these extinctions occurred due to predation by humans or rats, pigs, and other animals introduced by humans.

Humans even have a poor record of preserving species they depend on for survival. To drive this point home, consider data on the easternmost island in the South Pacific—Easter Island (**Figure 55.5**). When European explorers arrived on Easter Island in 1722, about 1000 people lived there. The island was treeless and dotted with gigantic stone statues. Researchers who analyzed buried pollen samples taken from swamps on the island discovered that it had once been covered with lush forest dominated by palm trees. A rapid decline in tree pollen coincided with the arrival of the first human settlers.

Fossil digs confirmed that the fauna of the island underwent drastic changes at the same time. In the oldest human garbage piles excavated by biologists, bones from dolphins, seabirds, and land birds are abundant. But these species dropped out of the fossil record by around A.D. 1300—about the time that loss of forests, or deforestation, was complete.

Jared Diamond interpreted these data as evidence of an ecological disaster. In his view, people arrived to find a lush tropical island brimming with natural resources. The human population flourished and people had the leisure time and resources to carve the gigantic statues and roll them into place on beds of palm logs. But after deforestation was complete and local extinctions had begun, the system collapsed. Without palm trunks to make canoes, Easter Island natives did less dolphin hunting and less fishing. Soil erosion may have cut into the productivity of banana and sweet potato plantations. The population crashed, and the great statues fell.

FIGURE 55.5 On Easter Island, Social Decline Coincided with the Exhaustion of Natural Resources. Easter Island was one of the last Pacific Islands to be colonized by humans. The prosperity that supported the artwork shown in the inset was based on resources that were overexploited.

Current Threats to Biodiversity

Most extinctions that have occurred over the past 1000 years took place on islands and were caused by overhunting or the introduction of **exotic species**—nonnative competitors, diseases, or predators. Starting in the twentieth century, though, the situation began to change. **Endangered species**, which are almost certain to go extinct unless effective conservation programs are put in place, are now more likely to live on continents than islands. In addition, habitat destruction has replaced overhunting and species introductions as the primary threat to such species.

Figure 55.6 shows the results of a recent analysis on causes of endangerment for 488 endangered species native to Canada. Several patterns jump out of the data:

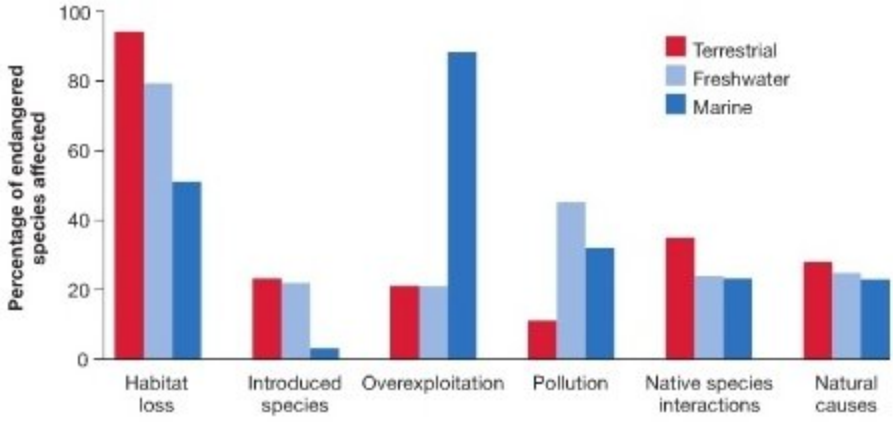

FIGURE 55.6 Endangerment Is Caused by Multiple Factors. These data are from Canada.

QUESTION Why do the data for terrestrial, freshwater, and marine species each add up to more than 100 percent?

- Virtually all of the endangered species are affected by more than one factor. This is important, because it means that conservation biologists may have to solve more than one problem for any given species to recover.
- Habitat loss is the single most important factor in the decline of these species. It is a significant issue for over 90 percent of endangered species in terrestrial environments.
- Overharvesting is the dominant problem for marine species, while pollution plays a large role for freshwater species.
- Factors beyond human control can be important. These include predation or competition with native species, natural disturbances such as fires or droughts, or the fact that some species have narrow niches and have historically been rare.

Stated another way, background extinctions will continue to occur.

Do these conclusions hold up for other parts of the world? Although invasive species are a more significant problem in some regions (**Figure 55.7**; also see Chapter 50), most analyses completed to date are broadly consistent with the Canadian data. For example, overexploitation is a grave concern for marine fisheries worldwide. Two-thirds of harvestable species are now considered fully exploited or depleted, and a recent study of the global fishing industry concluded that 90 percent of large bottom-dwelling and open-water fish have been removed from the world's oceans. The species affected include tuna, swordfish, marlin, cod, halibut, and flounder. Overhunting has also emerged recently as a dire threat to

(a) Invasive species increase **competition**.

Purple loosestrife is crowding out native organisms in North American marshes.

(b) Invasive species introduce **disease**.

An introduced fungus has virtually wiped out the American chestnut.

(c) Invasive species increase **predation**.

The brown tree snake has extinguished dozens of bird species on Guam.

FIGURE 55.7 Invasive Species Are Destructive. In many parts of the world, invasive species are a leading cause of endangerment. [Photo (b) © Gary Braasch.]

FIGURE 55.8 Overhunting Continues to Be a Problem in Some Regions. The recent growth of the "bushmeat" trade has devastated many populations of primates and other mammals in Africa. Overharvesting is also a major cause of endangerment in marine species worldwide (see Figure 55.6).

FIGURE 55.9 Suburbanization Is a Major Cause of Habitat Loss in North America.

many African mammal populations (**Figure 55.8**). Biologists view habitat changes driven by global warming—already implicated in the extinction of dozens or hundreds of amphibians—a serious enough threat to deserve close monitoring. Due to the numbers of species and ecosystems affected, human alteration of natural habitat is now the dominant cause of biodiversity decline worldwide, as it is in Canada.

Habitat Destruction Humans cause **habitat destruction** by logging and burning forests, damming rivers, dredging or filling estuaries and wetlands, plowing prairies, grazing livestock, excavating minerals, and building housing developments, golf courses, shopping centers, office complexes, airports, and roads (**Figure 55.9**).

On a global scale, one of the most important types of habitat destruction is deforestation—especially the conversion of primary forests to agricultural fields and human settlements. To appreciate the extent of deforestation in some areas, consider satellite images of wet tropical rain forest in Rondônia, Brazil, that were made in 1975 and in 2001 (**Figure 55.10**). Analyses of satellite photos such as these have shown that as many as 3 million hectares, an area about 10 percent larger than the state of Maryland, was deforested in the Amazon each year during the 1990s. (A hectare, abbreviated ha, is 100 meters by 100 meters, approximately the size of two football fields.)

More recent analyses suggest that the global rate of deforestation has now slowed compared to peak rates in the 1990s. The latest report from the United Nations Food and Agriculture Organization, released in 2005, states that the world's

(a) The devastation of deforestation

(b) Satellite view of deforestation in Rondônia, Brazil

FIGURE 55.10 Rates of Deforestation in Tropical Wet Forests Are Approaching 1 Percent per Year. These satellite photos show the extent of deforestation in Rondônia, Brazil, in less than 30 years. The dark green areas are intact forest; the lighter areas have been burned or logged and converted to agricultural fields and pastures.

forests experienced a net loss of about 7.3 million ha/year between 2000 and 2005. This is down from the average net loss of 8.9 million ha/year during the previous decade. Although most conservationists greeted this report as good news, they also urged caution. Net losses dropped because of extensive forest planting and regrowth in China, North America, and Europe, even though over 8 million ha/year of primary forest were lost in South America and Africa each year from 2000 to 2005. Forest loss in South America and Africa is particularly important because it affects biodiversity hotspots.

Habitat Fragmentation In addition to destroying natural areas outright, human activities fragment large, contiguous areas of natural habitats into small, isolated fragments. **Habitat fragmentation** concerns biologists for several reasons.

1. It can reduce habitats to a size that is too small to support some species. This is especially true for keystone predators such as mountain lions, grizzly bears, and bluefin tuna, which need vast natural spaces in which to feed, find mates, and reproduce successfully.
2. By creating islands of habitat in a sea of human-dominated landscapes, fragmentation reduces the ability of individuals to disperse from one habitat to another. In effect, habitat fragmentation is forcing many species into the metapopulation structure introduced in Chapter 52. The small, isolated populations that make up a metapopulation are much more likely than large populations to be wiped out by catastrophic events such as storms, disease outbreaks, or fires. They can also suffer from inbreeding depression and random loss of alleles due to genetic drift (see **Box 55.2**).
3. Fragmentation creates large amounts of "edge" habitat. The edges of intact habitat are subject to invasion by weedy species and are exposed to more intense sunlight and wind, creating difficult conditions for plants.

The decline in habitat quality caused by fragmentation is being documented in a long-term experiment in a tropical wet forest. In an area near Manaus, Brazil, that was slated for clear-cutting, a research group set up 66 square, 1-hectare experimental plots that remained uncut. Thirty-nine of these study plots were located in fragments designed to contain 1, 10, or 100 hectares of intact forest. Twenty-seven of the plots were set up nearby, in continuous wet forest. As the "Experimental setup" section of **Figure 55.11** shows, the distribution of the study plots allowed the research team to monitor changes inside forest fragments of different sizes and to compare these changes with conditions in unfragmented forest.

When the research group surveyed the plots at least 10 years after the initial cut, they recorded two predominant effects: a rapid loss of species diversity, especially from the smaller fragments, and a startling drop in **biomass**, or

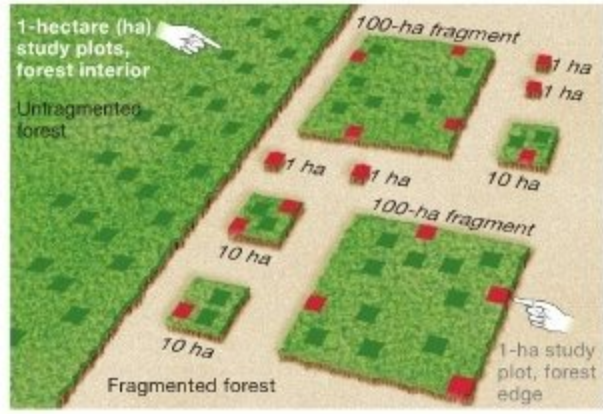
Experiment

Question: How does fragmentation affect the quality of tropical wet forest habitats?

Hypothesis: Fragmentation reduces the quality of wet forest habitats.

Null hypothesis: Fragmentation has no effect on the quality of wet forest habitats.

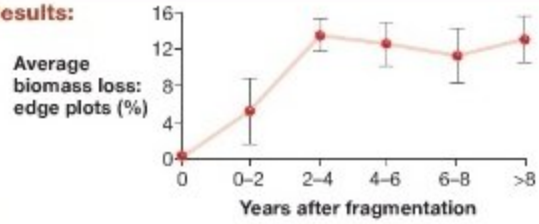
Experimental setup:



Prediction: Species diversity and biomass will decline in forest fragments compared with those of the forest interior, particularly along edges of fragments.

Prediction of null hypothesis: Species diversity and biomass will be the same inside forest fragments and along edges as in the forest interior.

Results:



Conclusion: Biomass declines sharply along edges of forest fragments. To interpret this result, hypothesize that large trees near forest edges tend to die.

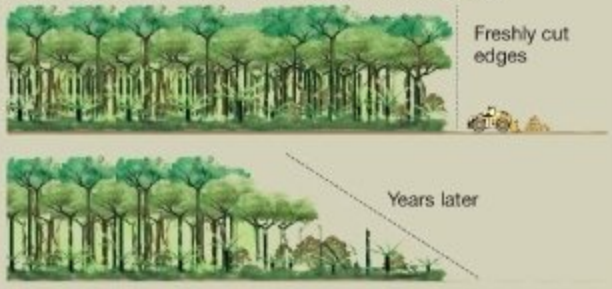


FIGURE 55.11 Experimental Evidence for Edge Effects in Fragmented Forests. Researchers tracked 66 study plots among four 1-hectare fragments, three 10-hectare fragments, and two 100-hectare fragments.

BOX 55.2 An Introduction to Conservation Genetics

Analyses presented in Chapters 24 and 25 highlighted the four evolutionary forces—natural selection, genetic drift, gene flow, and mutation—that affect allele frequencies and cause evolution. In addition, inbreeding and other forms of nonrandom mating change genotype frequencies. Conservation biologists have been keenly interested in how these processes are affecting small, endangered populations.

Several decades of observational and experimental work on conservation genetics supports the following conclusions:

- When populations are fragmented into a metapopulation structure, gene flow between isolated groups is reduced or eliminated. You might recall from Chapter 25 that the major impact of gene flow between populations is to homogenize them genetically. When gene flow is reduced, then, isolated populations begin to differentiate.
- Genetic drift is much more pronounced in small populations than large populations. Chapter 25 presented theory and experiments on the major impact of drift: Because it leads to the random loss or fixation of alleles, drift reduces genetic variation in populations. Loss of genetic variation has now been documented in a wide array of endangered species and other small populations. This is a concern because if the environment is changed by the evolution of a new disease or through global warming, the population may lack alleles that confer high fitness in the new environment.
- Small populations become inbred, and inbreeding often leads to lowered fitness—the phenomenon known as inbreeding depression.

In general, then, small populations that are isolated from each other are expected to be much less healthy, genetically, than robust populations that occupy large, contiguous areas.

When biologists document fitness declines in small, isolated populations, one option is to increase gene flow experimentally by importing individuals of the same species from a different population. For example, **Figure 55.12** shows data on annual population growth rate (λ; see Chapter 52) in a small population of bighorn sheep isolated on a refuge in northwest Montana. From the time the population was founded in 1922 until gene flow was experimentally increased, the average population size was about 42 individuals and average growth rate declined. After introducing 5 new individuals in 1985 and 10 additional sheep in 1990–1994, though, λ has stabilized and population size has increased. Introducing new alleles in this way can counteract the effects of genetic drift and inbreeding.

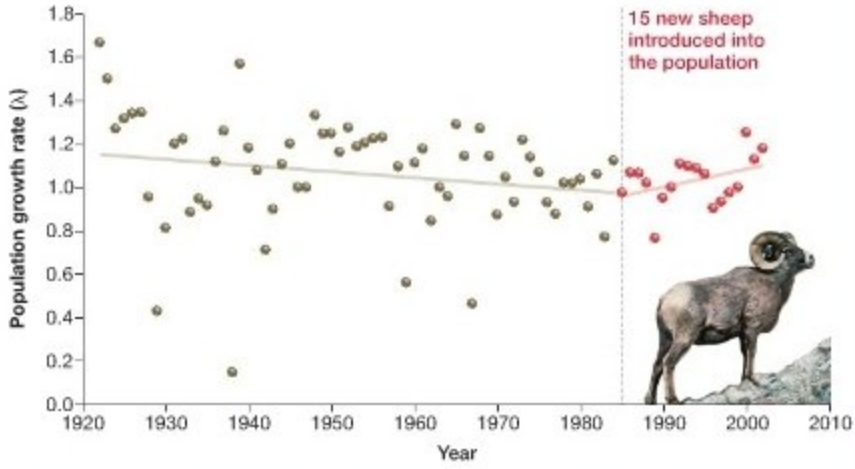

FIGURE 55.12 Experimental Evidence that Gene Flow Can Alleviate Genetic Problems in Small Populations. The y-axis plots the finite rate of increase (λ) in an isolated population of bighorn sheep, before and after unrelated individuals were introduced.

EXERCISE Draw a horizontal line indicating the value of λ where population size is constant (no growth).

the total amount of fixed carbon, in the study plots located near the edges of logged fragments. In tropical wet forests, most of the biomass is concentrated in large trees. The edges of the experimental plots contained many downed and dying trees. Based on this observation, the researchers inferred that the decrease in biomass occurred because large trees near the edges of fragments died from exposure to high winds and dry conditions. Follow-up work showed that in edge habitats and in the fragmented patches, large-seeded, slow-growing trees typical of undisturbed forests are being replaced by early successional, "weedy" species (see Chapter 53). A large number of bird and understory plant species have disappeared as well.

The take-home message of this experiment and other research is clear: When habitats are fragmented, the quality *and* quantity of habitat decline drastically. In addition to losing over 8 million hectares of primary forest in South America and Africa each year, we are losing large amounts of high-quality habitat to fragmentation. Just how many extinctions are all of these problems projected to cause?

Habitat Fragmentation

How Can Biologists Predict Future Extinction Rates?

If the most fundamental question about biodiversity is how many species are alive, then the most basic question in conservation biology is how rapidly species are going extinct. Both questions have been difficult to answer.

Biologists use two approaches to estimate current extinction rates and predict how they might change in the near future. The first is based on direct counts of species that are known to have gone extinct recently or are in imminent danger of going extinct. The second is based on predicting the consequences of habitat loss, using existing data on the relationship between the size of habitats and the number of species present.

Estimates Based on Direct Counts The best information on current extinction rates comes from studies on the best-studied of all major lineages on the tree of life: birds. Based on data in the fossil record, background extinctions in lineages like birds are estimated to occur at the rate of 1 extinction per million species alive per year. Of the approximately 10,000 bird species known, then, one species should go extinct every 100 years due to normal or background events.

Recent analyses have focused on species that were wiped out over the past 1000 years, coincident with the expansion of Polynesian people throughout the Pacific and Europeans throughout the world. These data suggest that birds have been going extinct at a rate 100 times background levels—meaning that a bird species has gone extinct every year, on average. Although the success of conservation programs targeted at birds has lowered this rate in the last few decades, estimates based on the numbers of species that are currently endangered suggest that the rate could reach 1000–1500 extinctions per million species alive per year by the end of this century. If this prediction holds, you may live long enough to see 10 or more species of bird go extinct each year.

Similar trends are occurring in listings of other well-studied groups. For example, a research group looked at endemic species of birds, mammals, reptiles, amphibians, and conifers, and determined that 794 of the species are in imminent danger of extinction. This is three times the number of all species from these groups known to have gone extinct since the year 1500. Instead of a handful of species going extinct each year, we may be losing dozens or hundreds. The message from these analyses is that the current rate of extinction is already many times higher than background or normal levels, and it is poised to increase dramatically in the near future.

Species–Area Relationships A second strategy for predicting the future of Earth's biodiversity focuses on the consequences of the most urgent problem: habitat destruction. Given reasonable projections of habitat loss, biologists can estimate rates of extinction based on well-documented **species–area relationships**.

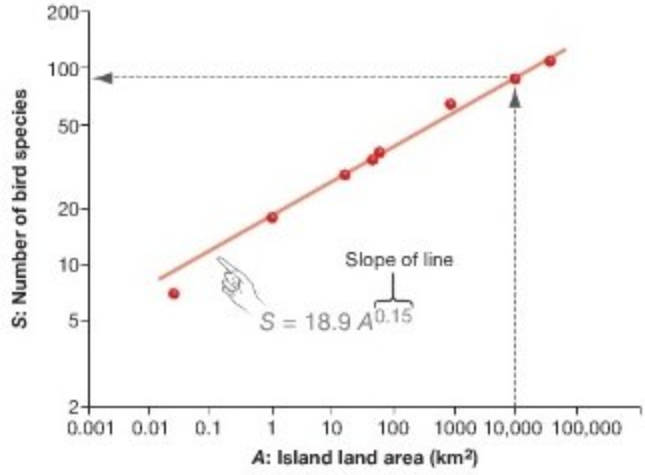

FIGURE 55.13 Species–Area Plots Quantify the Relationship between Species Richness and Habitat Area. Graph plotting the sizes of islands in the South Pacific (horizontal axis) versus the number of bird species present on each island (vertical axis). Notice the log-log scale. The dashed arrows show the number of bird species that are expected to live on an island with an area of 10,000 km².

To understand how this work is done, consider that recent estimates of habitat destruction in the world's tropical wet forests suggest that about 10 percent of the original area covered by these biomes is being lost each decade. It is not unreasonable, then, to project that 90 percent of the world's tropical forest habitat will be lost over the next century.

To predict how many species will be driven to extinction as a result, biologists use species–area curves like the one shown in **Figure 55.13**. This graph was generated by a biologist who analyzed the number of bird species found on islands in the Bismarck Archipelago near New Guinea, in the South Pacific. The graph shows the number of species on islands of various sizes. Notice that both axes on the graph are logarithmic. The solid line drawn through the points is described by the function $S = (18.9)A^{0.15}$, where S is the number of species and A is the area. In this island group, the function indicates that each tenfold increase in island area increases the number of bird species present by about 40 percent; a tenfold decline in area reduces bird species by about 30 percent.

These data turn out to be typical for other habitats and taxonomic groups as well. When biologists have plotted species–area relationships for plants, butterflies, mammals, or birds from islands or continental habitats around the globe, the relationship is consistently described by a function of the form $S = cA^z$. The c term is a constant that scales the data. Its value is high in species-rich areas, such as coral reefs or tropical wet forests, and low in species-poor areas, such as arctic tundras. The exponent z represents the slope of the line on a log-log plot. Thus, z describes how rapidly species numbers change with area. Typically, z is about 0.25.

To understand how biologists use these analyses to project extinction rates, study Figure 55.13 again. Ask yourself: If 90 percent of the habitats were destroyed—for example, if A were reduced from 10,000 km^2 to 1000 km^2—what percentage of species would disappear? According to the graph, the number of bird species in the Bismarck Archipelago would drop from about 75 to about 53. Thus, the answer is roughly 30 percent. This is an important conclusion. If z is higher than 0.25 for taxa that inhabit tropical wet forests and other threatened habitats, the prediction is that more than 30 percent of all species will be wiped out in the next 100 years.

Check Your Understanding

If you understand that...

- Until recently, most human-induced extinctions have occurred on islands and were due to overhunting or the impact of introduced species.
- Although invasive species remain a major threat to biodiversity, the majority of current problems are on continents and are due to habitat destruction and fragmentation.
- Current and projected extinction rates can be estimated from direct counts and from an analysis of species–area relationships.

You should be able to...

1) Explain why fragmentation reduces habitat quality and leads to genetic problems.
2) Use the species–area relationship to compare the proportion of species lost when 90 percent of a 100,000 km^2 habitat is destroyed in a region where $c = 0.19$ and $z = 0.20$ versus the same-sized region where $c = 0.19$ and $z = 0.25$.

55.4 Preserving Biodiversity

The conservation of biodiversity is among the most urgent but least-recognized issues facing us today. Unlike ozone holes, acid rain, phosphorus pollution, global warming, and other environmental problems that humans have recently begun to address, extinction is irreversible. The only solution to the biodiversity crisis is to prevent the loss of alleles, species, and ecosystems.

Solving any global problem requires a common goal to be defined. In the case of preserving biodiversity, the objective is to sustain diverse communities in natural landscapes while supporting the extraction of resources required to maintain the health and well-being of the human population.

In almost every case, the underlying causes of the biodiversity crisis are political and economic pressures that encourage short-term overexploitation of land and other resources and discourage **sustainability**—the managed use of resources at a rate only as fast as the rate at which they are replaced. What reasons can biologists give for preserving biodiversity, in addition to the direct economic benefits listed in **Box 55.3**? From a biological point of view, why does biodiversity matter?

Why Is Biodiversity Important?

The benefits of biodiversity extend beyond the direct use of diverse genes and species by humans to include **ecosystem services**—processes that increase the quality of the abiotic environment. Recall from Chapter 10 that green plants and other photosynthetic organisms produce the oxygen we breathe, and from Chapter 30 that the presence of land plants builds soil, reduces soil erosion, moderates local temperature and wind conditions, and increases the volume of water retained in lakes, streams, and soils. Species from throughout the tree of life are involved in cycling nitrogen, carbon, and other nutrients through ecosystems (see Chapters 28–31 and 54). But do ecosystems improve the abiotic environment more when biodiversity is high?

The effort to answer this question began in the mid-1980s and has blossomed into one of the most active research frontiers in community ecology and conservation biology.

Biodiversity Increases Productivity **Figure 55.14** summarizes a classic experiment on how species richness affects one of the most basic aspects of an ecosystem function: the production of biomass. As the "Experimental Setup" portion of the figure shows, David Tilman and colleagues classified 32 grassland plant species into five functional categories. The functional groups differ by the timing of their growing season and by whether they allocate most of their resources to manufacturing woody stems or seeds. The researchers planted plots measuring 13 m × 13 m with a mixture of between 0 and 32 randomly chosen species, representing from 0 to 5 functional categories. After 2 years of plant growth, the researchers harvested and weighed the aboveground tissues from the plots. The data provided an index of **net primary productivity** (**NPP**)—the total amount of photosynthesis per unit area per year that ends up in biomass.

Tilman's group compared the productivity of plots with different numbers of species and functional groups, and found that both the number and type of species present had important effects. Plots with more species and with a wider diversity of functional groups were more productive. Total biomass leveled off as species richness and functional diversity increased, however. This observation suggests that increasing species diversity improves ecosystem function only up to a point. The data support the hypothesis that at least some species in ecosystems are redundant.

Follow-up experiments in an array of ecosystems not only supported the conclusion that species richness has a positive impact on NPP, but showed that several causal mechanisms may be at work.

Experiment

Question: Do high species richness and high functional diversity of species increase aspects of ecosystem function such as net primary productivity (NPP)?

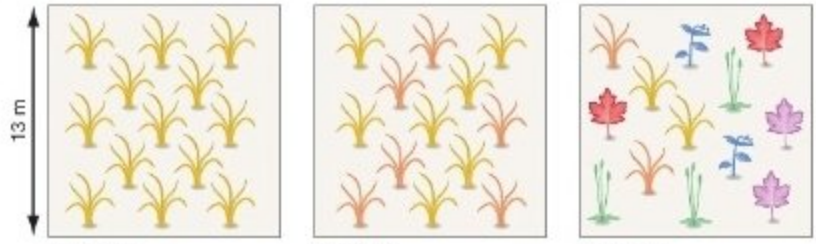
Hypothesis: NPP increases with increasing species richness and with increasing functional diversity of species.

Null hypothesis:

Experimental setup:

Plant a total of 289 experimental plots, each with up to 32 species and up to 5 functional groups:

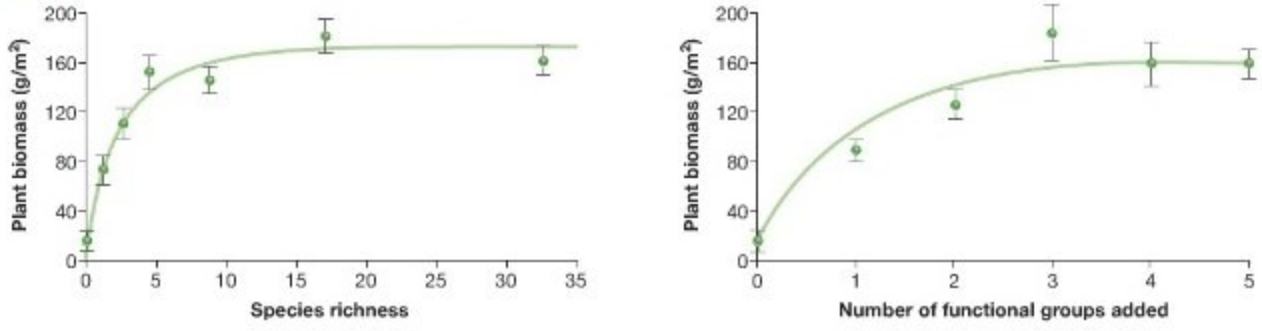
Examples of experimental plots:



Prediction:

Prediction of null hypothesis:

Results:



Conclusion: In this plant community, NPP increases with increasing species richness and increasing functional diversity of plants, at least up to a point.

FIGURE 55.14 Evidence that the Productivity of Ecosystems Depends on the Number and Types of Species Present.

EXERCISE Write in the null hypothesis and both sets of predictions.

- *Resource use efficiency* Diverse assemblages of plant species make more efficient use of the sunlight, water, and other resources available and thus lead to greater overall productivity. For example, some prairie plants extract water near the soil surface, while others use water available a meter or more below the surface. When species diversity is high, more overall water is used and more photosynthesis can occur.
- *Facilitation* Certain species or functional groups facilitate the growth of other species by providing them with nutrients, partial shade, or other benefits. In prairies, the presence of onion-family plants may discourage herbivores, or decaying roots from nitrogen-fixing species may fertilize other species.
- *Sampling effects* In many habitats it is common to observe that one or two species are extremely productive. If the number of species in a study plot is low, it is likely that the "big producer" will be missing and NPP will be low. But if the number of species in a study plot is high, then it is likely

BOX 55.3 Economic Benefits of Biodiversity

The first large-scale, highly organized human societies began to form about 10,000 years ago, when people at several locations around the world began to domesticate wild plants and farm their food. Since that time, wild species have provided the raw material to fuel the continued development of human societies. Vast tracts of forest have been felled for building materials and fuel; wild plants have been selectively bred to yield food and fibers; animals have been domesticated to provide food, labor, and material goods; the oceans have been harvested for protein; and plants, animals, and fungi have been processed as sources of medicines. For thousands of years, humans have relied on a diversity of wild species to survive.

The direct use of biodiversity continues today:

- Research programs collectively known as bioprospecting focus on assessing bacteria, archaea, plants, fungi, and frogs as novel sources of drugs or ingredients in consumer products. Bioprospecting has benefited from the recent explosion of genetic and phylogenetic information, because biologists can now search genomes from a wide array of species to find alleles with desired functions. Recent advances in biotechnology facilitated the development of a new painkiller from the paralyzing sting of tropical cone snails, and a blood anticoagulant from the saliva of vampire bats.
- Agricultural scientists are preserving diverse strains of crop plants in seed banks and continue to use wild relatives of domesticated species in breeding programs aimed at improving crop traits. In addition, genetic engineering techniques are being used to transfer alleles from a diverse array of species into crop plants. In some cases these efforts have reduced dependence on pesticides, increased resistance to diseases and drought, and improved nutritional value and overall crop yields (see Chapter 19).
- The production of almonds, apples, cherries, chocolate, alfalfa, and an array of other crops depends on the presence of wild pollinators. In the United States alone, insect-pollinated crops produce $40 billion worth of products annually.
- Strategies for cleaning up oil spills, abandoned mines, and contaminated industrial sites are incorporating bioremediation—the use of bacteria, archaea, and plants to metabolize pollutants and render them harmless (see Chapters 28 and 30).
- Recreation based on visiting wild places, or ecotourism, is a major industry internationally and is growing rapidly. In South Africa, for example, the number of tourists visiting wildlife preserves increased from 454,428 in 1986 to over 6 million in 1999. In 2004, ecotourism grew three times faster than the tourism industry as a whole.
- High ecosystem diversity—particularly the presence of forests or grasslands on steep slopes and the presence of wetlands in low-lying areas—dramatically reduces flood damage and the danger posed by mudslides.

An array of biologists, philosophers, and religious leaders argue that, in addition to making money from biodiversity, humans have an ethical obligation to preserve species and ecosystems. Their position is that organisms have intrinsic worth, and that humans diminish the world by extinguishing species and destroying ecosystems. If this is so, then extinction is a moral issue as well as a biological and economic problem. One of the most important reasons to preserve biodiversity may simply be that it is the right thing to do.

the big producer is present and NPP will be high. Simply due to sampling, then, high-species plots will tend to outproduce low-species plots.

The three mechanisms listed are not mutually exclusive—several can operate at the same time. Further, long-term experiments like the one diagrammed in Figure 55.14 have shown that the reason for the pattern can change over time. As plants mature, resource use efficiency and facilitation may become more important than sampling effects.

Does Biodiversity Lead to Stability? When biologists refer to the stability of a community, they mean its ability to (1) withstand a disturbance without changing, (2) recover to former levels of productivity or species richness after a disturbance, and (3) maintain productivity and other aspects of ecosystem function as conditions change over time. **Resistance** is a measure of how much a community is affected by a disturbance. **Resilience** is a measure of how quickly a community recovers following a disturbance.

To test the hypothesis that diversity increases resistance and resilience, the team that did the work highlighted in Figure 55.14 followed up on a natural experiment. In 1987–1988 a severe drought hit their study site. When the drought ended, the team asked whether species richness affected the response to the disturbance. The results are shown in **Figure 55.15**. The graph documents the change in total biomass that occurred from the year prior to the drought until the height of the drought. This quantity reflects how resistant the community is to disturbance. A completely resistant community would show no change. As predicted, drought resistance appeared to be higher in more diverse communities than in less diverse ones.

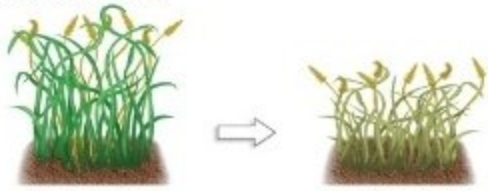
Experiment

Question: Are more species-rich communities more stable than less-diverse communities?

Hypothesis: Resistance to disturbance should increase with increasing species richness.

Null hypothesis: There is no relationship between species richness and resistance.

Experimental setup:

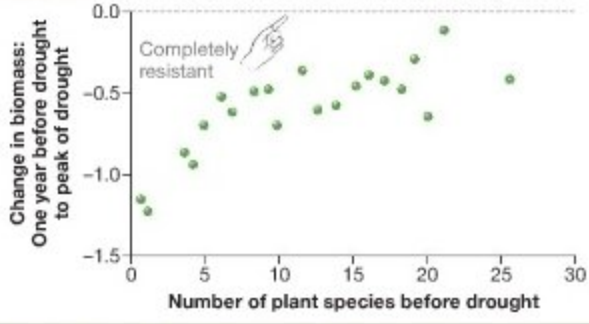


Compare biomass of experimental plots before drought and at peak of drought. (This was a natural experiment—severe drought just happened to occur during study.)

Prediction: Plots that were more species rich before the drought will be more resistant to change.

Prediction of null hypothesis: All the plots will have similar resistance regardless of species richness before the drought.

Results:



Conclusion: Resistance to disturbance increases with increasing species richness.

FIGURE 55.15 Evidence that Species-Rich Communities Resist Disturbance. Data support the hypothesis that diverse communities are more stable, meaning they change less during a disturbance, than less-diverse communities are.

QUESTION The 0.0 values on the vertical graph axes are labeled "Completely resistant." Why?

In addition, the group analyzed the change in biomass in each plot four years after the drought versus biomass prior to the drought. This analysis focused on how resilient the community is. A completely resilient community would recover quickly from the disturbance and have the same biomass at both times. The data indicated that most plots containing five or fewer species showed a significant lowering of biomass after the disturbance, indicating that they had not recovered. But in all of the plots that contained more than five species, biomass after the drought was the same as biomass prior to the disturbance.

More recent experiments on California grasslands suggests that species-rich ecosystems may also be less prone to invasion by exotic species. Taken together, these results lead biologists to be increasingly confident that species richness has a strongly positive effect on how ecosystems function. In North American grasslands, at least, communities that are more diverse appear to be more productive, more resistant to disturbance and invasion, and more resilient than communities that are less diverse. Increased richness increases the services provided by ecosystems. By implication, biologists can infer that if ecosystems are simplified by extinctions, then productivity and other attributes might decrease.

Designing Effective Protected Areas

When biologists first recognized the growing threats to biodiversity worldwide, they joined with government agencies, economists, community leaders, private landowners, and others to set aside protected areas. To assess the progress of this effort, the International Union for the Conservation of Nature (IUCN) sponsors the World Parks Congress every decade. In 1992 the Congress met in Caracas, Venezuela, and established a goal of setting aside 10 percent of Earth's land surface in protected areas. In 2003 the Congress met in Durban, South Africa, and announced that this goal had been surpassed: Protected areas covered 11.5 percent of Earth's terrestrial surface.

How efficiently is the existing network of protected areas protecting biodiversity? Researchers are attempting to answer this question via a geographic approach called the **Gap Analysis Program** (**GAP**). A GAP analysis tries to identify gaps between geographic areas that are particularly rich in biodiversity and areas that are actually managed for the preservation of biodiversity. One GAP analysis combined data sets on the distribution of mammals, birds, amphibians, and freshwater turtles with a map of world protected areas. The analysis revealed that many species' ranges occur completely outside any protected areas. It also pinpointed regions in Mexico, Madagascar, and elsewhere where the gap between species' ranges and protected areas is particularly high.

To date, most GAP analyses suggest that, because relatively few species richness hotspots are included in existing protected areas, the 11.5 percent of Earth's surface area that is now being managed for biodiversity will not be enough to conserve many species. Efforts to fill these gaps are now focused on preserving species richness hotspots and centers of endemism like those illustrated in Figure 55.4.

In addition to working on where reserves are set up, biologists are focusing more attention on how reserves are designed. For example, it is often impossible to preserve large areas of high-quality habitat. In most cases, biologists have to accept the fact that habitats are fragmented and species exist as

metapopulations. Given this reality, what is the best way to prevent small, isolated populations from going extinct?

The leading hypothesis in reserve design was to make sure that strips of undeveloped habitat, called **wildlife corridors**, connected populations that would otherwise be isolated. In some cases wildlife corridors were as simple as a walkway under a major highway, so that animals could move from one side to the other without being killed. By facilitating the movement of individuals, the goals of corridors were to (1) allow areas to be recolonized if a species was lost, and (2) introduce new alleles that would counteract the deleterious effects of genetic drift and inbreeding, detailed in Box 55.2.

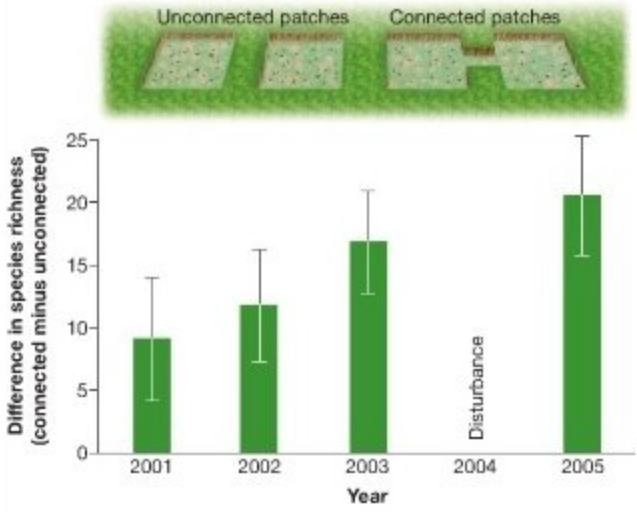


FIGURE 55.16 Experimental Evidence that Wildlife Corridors Work. Species richness could not be assessed in 2004 because the study plots were burned as part of a program to restore natural habitats.

EXERCISE Draw and label bars showing what this graph would look like if corridors had no effect on species richness.

Do corridors work? A recent experiment suggests that the answer is yes. A research team established a series of restored natural areas in the middle of a large, species-poor pine plantation. This was the equivalent of restoring patches of grassland habitat in the middle of an enormous cornfield. Some of the restoration sites were connected by corridors, while others were isolated. By monitoring the composition of species inside each habitat patch over time, the group was able to show that connected patches are steadily gaining more species over time compared to unconnected patches (**Figure 55.16**). This is strong evidence that wildlife corridors can increase overall species richness in a metapopulation.

Experiments like these bring us to the forefront of work on biodiversity and conservation biology. Your generation is facing the most serious global environmental crisis in the history of our species. As someone with a background in biology, you have the intellectual tools to help solve it. In addition to studying life, biologists have to save it.

Check Your Understanding

If you understand that...

- Experimental plots with higher species richness tend to have higher productivity and show increased stability in response to disturbance or changed abiotic conditions.
- Wildlife corridors are an effective way to minimize the loss of subpopulations from a metapopulation due to (1) genetic problems, and (2) catastrophic events.

You should be able to...

Design an experiment to test the hypothesis that species-rich areas are more effective at building soil, retaining soil nutrients, and minimizing soil erosion than are species-poor areas.

Chapter Review

SUMMARY OF KEY CONCEPTS

Biodiversity can be analyzed at the genetic, species, and ecosystem levels.

Genetic diversity is well characterized within some species, but biologists are only beginning to use genome sequencing techniques to explore the extent of genetic diversity in ecosystems. Research on the total number of species alive today is also at a preliminary stage, with estimates ranging from 10 to 100 million. To date, the message from efforts to characterize biodiversity is that it is much more extensive than expected and that a great deal remains to be learned.

You should be able to describe conditions that maximize genetic, species, and ecosystem diversity.

If recent rates of extinction due to human population growth and habitat destruction continue, a mass extinction will occur.

Historically, most human-caused extinctions have occurred on islands because of direct exploitation or the introduction of exotic herbivores and predators. Habitat destruction is currently the leading cause of extinctions, however. Experiments in the Brazilian Amazon have shown that habitat loss leads not only to a rapid decline in biodiversity but also to a decline in the quality of the remaining habitats due to fragmentation.

To estimate how many species will go extinct in the near future, biologists combine data on current rates of habitat loss—usually estimated from satellite images taken over time—with

data on the average number of species found in habitats of a given size. These species–area analyses suggest that if 90 percent of habitats are destroyed as expected during the next century, then over 30 percent of all species will become extinct. According to data on the rates of extinction in birds and other well-studied groups, it is likely that 60 percent of all species will be wiped out within 500 years.

You should be able to explain why species that have a metapopulation structure, due to habitat fragmentation, may be at higher risk of extinction than a species of similar abundance that exists in a large, contiguous habitat.

Web Animation at www.masteringbio.com
Habitat Fragmentation

Humans depend on biodiversity for the products that wild species provide and for ecosystem services that protect the quality of the abiotic environment.

Species diversity is important for maintaining the productivity of natural ecosystems and their ability to build and hold soil, moderate local climates, retain and cycle nutrients, retain surface water and recharge groundwater, prevent flooding, and produce oxygen. At the ecosystem level, experiments have shown that high species richness increases aspects of ecosystem function such as productivity, resistance to disturbance, and ability to recover from disturbance. Humans also gain direct economic benefits from fishing, forestry, agriculture, tourism, and other activities that depend on biodiversity.

You should be able to outline a plan for restoring an abandoned airstrip that would maximize its ability to deliver ecosystem services.

QUESTIONS

Test Your Knowledge

1. What does a species–area plot show?
   a. The overall distribution, or area, occupied by a species.
   b. The relationship between the body size of a species and the amount of territory or home range it requires.
   c. The number of species found, on average, in tropical versus northern areas.
   d. The number of species found, on average, in a habitat of a given size.
2. What does a GAP analysis do?
   a. It compares the current distributions of species with the locations of preserved habitats.
   b. It quantifies *g*ross *a*boveground *p*roductivity.
   c. It uses data on the rates at which lists of threatened species are growing to project the rate of future extinctions.
   d. It uses genome sequencing techniques to quantify genetic (allelic) diversity in an ecosystem.
3. What is the difference between species richness and species diversity?
   a. Species diversity incorporates data on species interactions.
   b. Species diversity takes relative abundance into account.
   c. Species diversity is weighted by taxonomic (phylogenetic) diversity.
   d. Species diversity is adjusted for conservation priority (endangered status of species present).
4. What is a biodiversity "hotspot?"
   a. an area where an all-taxon survey is underway
   b. an area where an environmental sequencing study has been completed
   c. a habitat with high NPP
   d. an area with high species richness
5. Why do small populations become inbred?
   a. They are often part of a metapopulation structure.
   b. Genetic drift becomes a prominent evolutionary force.
   c. Over time, all individuals become related.
   d. Natural selection does not operate efficiently in small populations.
6. What is the primary cause of endangerment in marine environments?
   a. overexploitation
   b. pollution
   c. global warming
   d. invasive species

Test Your Knowledge answers: 1. d; 2. a; 3. b; 4. d; 5. c; 6. a

Test Your Understanding

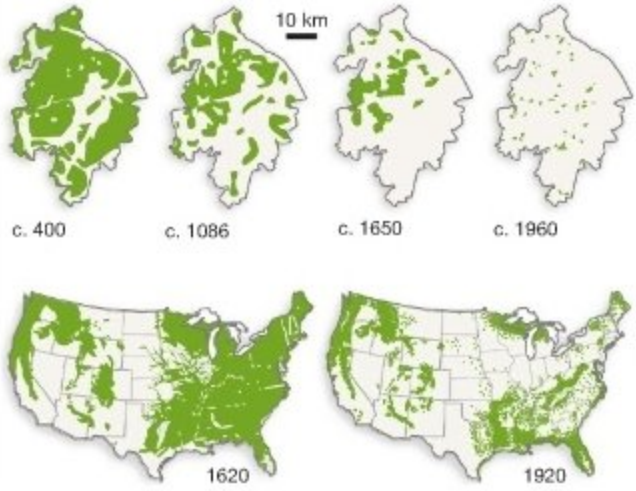
Answers are available at www.masteringbio.com

1. The primary cause of endangerment on continents has changed from direct exploitation to habitat loss. Explain why this change occurred.
2. Compare and contrast biodiversity at the genetic, species, and ecosystem levels. How do biologists analyze the extent of biodiversity at each of these levels?
3. Biologists claim that the all-taxa survey now under way at the Great Smoky Mountains National Park in the United States will improve their ability to estimate the total number of species living today. Discuss the benefits and limitations that this data set will provide in understanding the extent of global biodiversity.
4. How are species–area curves used to relate rates of habitat destruction to projected extinction rates?
5. Discuss evidence to support the hypotheses that species richness increases ecosystem functions such as productivity, resistance to disturbance, and resilience. Describe the logic behind the resource use efficiency, facilitation, and sampling effect hypotheses to explain why species richness increases productivity, and thus the ecosystem services that benefit humans.
6. Explain why the fragmentation of habitats reduces their ability to support biodiversity. Explain why the construction of wildlife corridors can help maintain biodiversity in a fragmented landscape.

Applying Concepts to New Situations

Answers are available at www.masteringbio.com

1. Projections for an impending mass extinction are contingent on the continuation of present trends in human population growth and in habitat destruction. Do you believe that these trends will continue? In general, are you optimistic or pessimistic about the future of biodiversity? Explain your logic.
2. You are helping design a series of reserves in a tropical country. List the steps you would recommend for gathering data and creating a plan that would protect a large number of species in a small amount of land.
3. The maps that follow chronicle the loss of old-growth forest (>200 years old) that occurred in Warwickshire, England, and in the United States. In your opinion, under what conditions is it ethical for conservationists who live in these countries to lobby government officials in Brazil, Indonesia, and other tropical countries to slow the rate of loss of old-growth forest?



4. Make a list of characteristics that would render a species particularly vulnerable to extinction by humans. Make a list of characteristics that would render a species particularly resistant to pressure from humans. Try to think of an example of each type of species.

Glossary

A-PDF Image To PDF Demo. Purchase from www.A-PDF.com to remove the watermark

abiotic Not alive (e.g., air, water, and soil). Compare with **biotic.**

ABO blood types Genetically determined classes of human blood that are distinguished by the presence or absence of specific glycolipids on the surface of red blood cells. Also called *ABO blood groups.*

aboveground biomass The total mass of living plants in an area, excluding roots.

abscisic acid (ABA) A plant hormone that inhibits cell elongation and stimulates leaf shedding and dormancy.

abscission In plants, the normal (often seasonal) shedding of leaves, fruits, or flowers.

abscission zone The region at the base of a petiole that thins and breaks during dropping of leaves.

absorption In animals, the uptake of ions and small molecules derived from food across the lining of the intestine and into the bloodstream.

absorption spectrum The amount of light of different wavelengths absorbed by a pigment. Usually depicted as a graph of light absorbed versus wavelength. Compare with **action spectrum.**

acclimation, acclimatization Gradual physiological adjustment of an organism to new environmental conditions that occur naturally or as part of a laboratory experiment.

acetylation Addition of an acetyl group (CH_3COO^-) to a molecule.

acetylcholine (ACh) A neurotransmitter, released by nerve cells at neuromuscular junctions, that triggers contraction of muscle cells. Also used as a neurotransmitter between neurons.

acetyl CoA A molecule produced by oxidation of pyruvate (the final product of glycolysis) in a reaction catalyzed by pyruvate dehydrogenase. Can enter the Krebs cycle and also is used as a carbon source in the synthesis of fatty acids, steroids, and other compounds.

acid Any compound that gives up protons or accepts electrons during a chemical reaction or that releases hydrogen ions when dissolved in water.

acid-growth hypothesis The hypothesis that auxin triggers elongation of plant cells by inducing the synthesis of proton pumps whose activity makes the cell wall more acidic, leading to expansion of the cell wall and an influx of water.

acoelomate An animal that lacks an internal body cavity (coelom). Compare with **coelomate** and **pseudocoelomate.**

acquired immune deficiency syndrome (AIDS) A human disease characterized by death of immune system cells (in particular helper T cells and macrophages) and subsequent vulnerability to other infections. Caused by the human immunodeficiency virus (HIV).

acquired immune response See **acquired immunity.**

acquired immunity Immunity to a particular pathogen or other antigen conferred by antibodies and activated B and T cells following exposure to the antigen. Is characterized by specificity, diversity, memory, and self-nonself recognition. Compare with **innate immunity.**

acrosomal reaction A set of events occurring in a sperm cell upon encountering an egg cell, including release of acrosomal enzymes and formation of the acrosomal process, which helps the sperm cell reach the egg.

acrosome A caplike structure, located on the head of a sperm cell, that contains enzymes capable of dissolving the outer coverings of an egg.

ACTH See **adrenocorticotropic hormone.**

actin A globular protein that can be polymerized to form filaments. Actin filaments are part of the cytoskeleton and constitute the thin filaments in skeletal muscle cells.

actin filament A long fiber, about 7 nm in diameter, composed of two intertwined strands of polymerized actin protein; one of the three types of cytoskeletal fibers. Involved in cell movement. Also called a *microfilament*. Compare with **intermediate filament** and **microtubule.**

action potential A rapid, temporary change in electrical potential across a membrane, from negative to positive and back to negative. Occurs in cells, such as neurons and muscle cells, that have an excitable membrane.

action spectrum The relative effectiveness of different wavelengths of light in driving a light-dependent process such as photosynthesis. Usually depicted as a graph of some measure of the process versus wavelength. Compare with **absorption spectrum.**

activation energy The amount of energy required to initiate a chemical reaction; specifically, the energy required to reach the transition state.

active site The portion of an enzyme molecule where substrates (reactant molecules) bind and react.

active transport The movement of ions or molecules across a plasma membrane or organelle membrane against an electrochemical gradient. Requires energy (e.g., from hydrolysis of ATP) and assistance of a transport protein (e.g., pump).

adaptation Any heritable trait that increases the fitness of an individual with that trait, compared with individuals without that trait, in a particular environment.

adaptive radiation Rapid evolutionary diversification within one lineage, producing numerous descendant species with a wide range of adaptive forms.

adenosine diphosphate (ADP) A molecule consisting of adenine, a sugar, and two phosphate groups. Addition of a third phosphate group produces adenosine triphosphate (ATP).

adenosine triphosphate (ATP) A molecule consisting of adenine, a sugar, and three phosphate groups that can be hydrolyzed to release energy. Universally used by cells to store and transfer energy.

adenylyl cyclase An enzyme that can catalyze the formation of cyclic AMP (cAMP) from ATP. Involved in controlling transcription of various operons in prokaryotes and in some eukaryotic signal-transduction pathways.

adhesion The tendency of certain dissimilar molecules to cling together due to attractive forces. Compare with **cohesion.**

adipocyte A fat cell.

adipose tissue A type of connective tissue whose cells store fats.

ADP See **adenosine diphosphate.**

adrenal glands Two small endocrine glands that sit above each kidney. The outer portion (cortex) secretes several steroid hormones; the inner portion (medulla) secretes epinephrine and norepinephrine.

adrenaline See **epinephrine.**

adrenocorticotropic hormone (ACTH) A peptide hormone, produced and secreted by the anterior pituitary, that stimulates release of steroid hormones (e.g., cortisol, aldosterone) from the adrenal cortex.

adventitious root A root that develops from a plant's shoot system instead of from the plant's root system.

aerobic Referring to any metabolic process, cell, or organism that uses oxygen as an electron acceptor. Compare with **anaerobic.**

afferent division The part of the nervous system, consisting mainly of sensory neurons, that transmits information about the internal and external environment to the central nervous system. Compare with **efferent division.**

agar A gelatinous mix of polysaccharides that is commonly used to grow cells on solid media.

age class All the individuals of a specific age in a population.

age structure The proportion of individuals in a population that are of each possible age.

age-specific fecundity The average number of female offspring produced by a female in a certain age class.

agglutination Clumping together of cells, typically caused by antibodies.

aggregate fruit A fruit (e.g., raspberry) that develops from a single flower that has many separate carpels. Compare with **multiple** and **simple fruit.**

AIDS See **acquired immune deficiency syndrome.**

albumen A solution of water and protein (particularly albumins), found in amniotic eggs, that nourishes the growing embryo. Also called *egg white.*

albumin A class of large proteins found in plants and animals, particularly in the albumen of eggs and in blood plasma.

alcohol fermentation Catabolic pathway in which pyruvate produced by glycolysis is converted to ethanol in the absence of oxygen.

aldosterone A hormone produced in the adrenal cortex that stimulates the kidney to conserve salt and water and promotes retention of sodium.

alimentary canal See **digestive tract.**

allele A particular version of a gene.

allopatric speciation The divergence of populations into different species by physical isolation of populations in different geographic areas. Compare with **sympatric speciation.**

allopatry Condition in which two or more populations live in different geographic areas. Compare with **sympatry.**

allopolyploidy (adjective: allopolyploid) The state of having more than two full sets of chromosomes (polyploidy) due to hybridization between different species. Compare with **autopolyploidy.**

allosteric regulation Regulation of a protein's function by binding of a regulatory molecule, usually to a specific site distinct from the active site, causing a change in the protein's shape.

alpha(α)-helix A protein secondary structure in which the polypeptide backbone coils into a spiral shape stabilized by hydrogen bonds between atoms.

alternation of generations A life cycle involving alternation of a multicellular haploid stage (gametophyte) with a multicellular diploid stage (sporophyte). Occurs in most plants and some protists.

alternative splicing In eukaryotes, the splicing of primary RNA transcripts from a single gene in different ways to produce different mature mRNAs and thus different polypeptides.

altruism Any behavior that has a cost to the individual (such as lowered survival or reproduction) and a benefit to the recipient. See **reciprocal altruism.**

alveolus (plural: alveoli) One of the tiny air-filled sacs of a mammalian lung.

ambisense virus A virus whose genome contains both positive-sense and negative-sense sequences.

amino acid A small organic molecule with a central carbon atom bonded to an amino group ($-NH_3$), a carboxyl group ($-COOH$), a hydrogen atom, and a side group. Proteins are polymers of 20 common amino acids.

aminoacyl tRNA A transfer RNA molecule that is covalently bound to an amino acid.

aminoacyl tRNA synthetase An enzyme that catalyzes the addition of a particular amino acid to its corresponding tRNA molecule.

ammonia (NH_3) A small molecule, produced by the breakdown of proteins and nucleic acids, that is very toxic to cells. Is a strong base that gains a proton to form the ammonium ion (NH_4^+).

amnion The membrane within an amniotic egg that surrounds the embryo and encloses it in a protective pool of fluid (amniotic fluid).

amniotes A major lineage of vertebrates (Amniota) that reproduce with amniotic eggs. Includes all reptiles (including birds) and mammals.

amniotic egg An egg that has a watertight shell or case enclosing a membrane-bound water supply (the amnion), food supply (yolk sac), and waste sac (allantois).

amoeba Any unicellular protist that lacks a cell wall, is extremely flexible in shape, and moves by means of pseudopodia.

amoeboid motion See **cell crawling.**

amphibians A lineage of vertebrates many of whom breathe through their skin and feed on land but lay their eggs in water; represent the earliest tetrapods. Include frogs, salamanders, and caecilians.

amphipathic Containing hydrophilic and hydrophobic elements.

amylase Any enzyme that can break down starch by catalyzing hydrolysis of the glycosidic linkages between the glucose residues.

amyloplasts Dense, starch-storing organelles that settle to the bottom of plant cells and that may be used as gravity detectors.

anabolic pathway Any set of chemical reactions that synthesizes larger molecules from smaller ones. Generally requires an input of energy. Compare with **catabolic pathway.**

anadromous Having a life cycle in which adults live in the ocean (or large lakes) but migrate up freshwater streams to breed and lay eggs.

anaerobic Referring to any metabolic process, cell, or organism that uses an electron acceptor other than oxygen, such as nitrate or sulfate. Compare with **aerobic.**

anaphase A stage in mitosis or meiosis during which chromosomes are moved to opposite ends of the cell.

anatomy The study of the physical structure of organisms.

androgens A class of steroid hormones that generally promote male-like traits (although females have some androgens, too). Secreted primarily by the gonads and adrenal glands.

aneuploidy (adjective: aneuploid) The state of having an abnormal number of copies of a certain chromosome.

angiosperm A flowering vascular plant that produces seeds within mature ovaries (fruits). The angiosperms form a single lineage. Compare with **gymnosperm.**

animal A member of a major lineage of eukaryotes (Animalia) whose members typically have a complex, large, multicellular body, eat other organisms, and are mobile.

animal model Any disease that occurs in a nonhuman animal and has many parallels to a similar disease of humans. Studied by medical researchers in hope that findings may apply to human disease.

anion A negatively charged ion.

annelids Members of the phylum Annelida (segmented worms). Distinguished by a segmented body and a coelom that functions as a hydrostatic skeleton. Annelids belong to the lophotrochozoan branch of the protostomes.

annual Referring to a plant whose life cycle normally lasts only one growing season—less than one year. Compare with **perennial.**

anoxygenic Referring to any process or reaction that does not produce oxygen. Photosynthesis in purple sulfur and purple nonsulfur bacteria, which does not involve photosystem II, is anoxygenic. Compare with **oxygenic.**

antenna (plural: antennae) A long appendage that is used to touch or smell.

antenna complex Part of a photosystem, containing an array of chlorophyll molecules and accessory pigments, that receives energy from light and directs the energy to a central reaction center during photosynthesis.

anterior Toward an animal's head and away from its tail. The opposite of posterior.

anterior pituitary The part of the pituitary gland containing endocrine cells that produce and release a variety of peptide hormones in response to other hormones from the hypothalamus. Compare with **posterior pituitary.**

anther The pollen-producing structure at the end of a stamen in flowering plants (angiosperms).

antheridium (plural: antheridia) The sperm-producing structure in most land plants except angiosperms.

anthropoids One of the two major lineages of primates, including apes, humans, and all monkeys. Compare with **prosimians.**

antibiotic Any substance, such as penicillin, that can kill or inhibit the growth of bacteria.

antibody An immunoglobulin protein, produced by B cells, that can bind to a specific part of an antigen, tagging it for attack by the immune system. All antibody molecules have a similar Y-shaped structure and, in their monomer form, consist of two identical light chains and two identical heavy chains.

anticodon The sequence of three bases (triplet) in a transfer RNA molecule that can bind to a mRNA codon with a complementary sequence.

antidiuretic hormone (ADH) A peptide hormone, secreted from the posterior pituitary gland, that stimulates water retention by the kidney. Also called *vasopressin.*

antigen Any foreign molecule, often a protein, that can stimulate a specific response by the immune system.

antigen presentation Process by which small peptides, derived from ingested particulate antigens (e.g., bacteria) or intracellular antigens (e.g., viruses in infected cell) are complexed with MHC proteins and transported to the cell surface where they are displayed and can be recognized by T cells.

antiparallel Describing the opposite orientation of the strands in a DNA double helix with one strand running in the $5' \rightarrow 3'$ direction and the other in the $3' \rightarrow 5'$ direction.

antiporter A carrier protein that allows an ion to diffuse down an electrochemical gradient, using the energy of that process to transport a different substance in the opposite direction *against* its concentration gradient. Compare with **symporter.**

antiviral Any drug or other agent that can kill or inhibit the transmission or replication of viruses.

anus In a multicellular animal, the end of the digestive tract where wastes are expelled.

aorta In terrestrial vertebrates, the major artery carrying oxygenated blood away from the heart.

aphotic zone Deep water receiving no sunlight. Compare with **photic zone.**

apical Toward the top. In plants, at the tip of a branch. In animals, on the side of an epithelial layer that faces the environment and not other body tissues. Compare with **basal.**

apical bud A bud at the tip of a stem, where growth occurs to lengthen the stem.

apical dominance Inhibition of lateral bud growth by the apical meristem at the tip of a plant branch.

apical meristem A group of undifferentiated plant cells, at the tip of a stem or root, that is responsible for primary growth. Compare with **lateral meristem.**

apomixis The formation of mature seeds without fertilization occurring; a type of asexual reproduction.

apoplast In plant roots, a continuous pathway through which water can flow, consisting of the porous cell walls of adjacent cells and the intervening extracellular space. Compare with **symplast.**

apoptosis Series of genetically controlled changes that lead to death of a cell. Occurs frequently during embryological development and later may occur in response to infections or cell damage. Also called *programmed cell death.*

aquaporin A type of channel protein through which water can move by osmosis across a plasma membrane.

arbuscular mycorrhizal fungi (AMF) Fungi whose hyphae enter the root cells of their host plants.

Archaea One of the three taxonomic domains of life consisting of unicellular prokaryotes distinguished by cell walls made of certain polysaccharides not found in bacterial or eukaryotic cell walls, plasma membranes composed of unique isoprene-containing phospholipids, and ribosomes and RNA polymerase similar to those of eukaryotes. Compare with **Bacteria** and **Eukarya.**

archegonium (plural: archegonia) The egg-producing structure in most land plants except angiosperms.

arteriole One of the many tiny vessels that carry blood from arteries to capillaries.

artery Any thick-walled blood vessel that carries blood (oxygenated or not) under relatively high pressure away from the heart to organs throughout the body. Compare with **vein.**

arthropods Members of the phylum Arthropoda. Distinguished by a segmented body; a hard, jointed exoskeleton; paired appendages; and an extensive body cavity called a hemocoel. Arthropods belong to the ecdysozoan branch of the protostomes.

articulation A movable point of contact between two bones of a skeleton. See **joint.**

artificial selection Deliberate manipulation by humans, as in animal and plant breeding, of the genetic composition of a population by allowing only individuals with desirable traits to reproduce.

ascocarp A large, cup-shaped reproductive structure produced by some ascomycete fungi. Contains many microscopic asci, which produce spores.

ascomycete See **sac fungus.**

ascus (plural: asci) Specialized spore-producing cell found at the ends of hyphae in sac fungi (ascomycetes).

asexual reproduction Any form of reproduction resulting in offspring that are genetically identical to the parent. Includes binary fission, budding, and parthenogenesis. Compare with **sexual reproduction.**

asymmetric competition Ecological competition between two species in which one species suffers a much greater fitness decline than the other. Compare with **symmetric competition.**

atomic mass unit (amu) A unit of mass equal to 1/12 the mass of one carbon-12 atom; about the mass of 1 proton or 1 neutron. Also called *dalton.*

atomic number The number of protons in the nucleus of an atom, giving the atom its identity as a particular chemical element.

ATP See **adenosine triphosphate.**

ATP synthase A large membrane-bound protein complex in chloroplasts, mitochondria, and some bacteria that uses the energy of protons flowing through it to synthesize ATP. Also called F_oF_1 *complex.*

atrioventricular (AV) node A region of the heart between the right atrium and right ventricle where electrical signals from the atrium are slowed briefly before spreading to the ventricle. This delay allows the ventricle to fill with blood before contracting. Compare with **sinoatrial (SA) node.**

atrium (plural: atria) A thin-walled chamber of the heart that receives blood from veins and pumps it to a neighboring chamber (the ventricle).

autocrine Relating to a chemical signal that affects the same cell that produced and released it.

autoimmunity A pathological condition in which the immune system attacks self cells or tissues of an individual's own body.

autonomic nervous system The part of the peripheral nervous system that controls internal organs and involuntary processes, such as stomach contraction, hormone release, and heart rate. Includes parasympathetic and sympathetic nerves. Compare with **somatic nervous system.**

autophagy The process by which damaged organelles are surrounded by a membrane and delivered to a lysosome to be destroyed.

autopolyploidy (adjective: autopolyploid) The state of having more than two full sets of chromosomes (polyploidy) due to a mutation that doubled the chromosome number.

autoradiography A technique for detecting radioactively labeled molecules separated by gel electrophoresis by placing an unexposed film over the gel. A black dot appears on the film wherever a radioactive atom is present in the gel. Also can be used to locate labeled molecules in fixed tissue samples.

autosomal inheritance The inheritance patterns that occur when genes are located on autosomes rather than on sex chromosomes.

autosome Any chromosome that does not carry genes involved in determining the sex of an individual.

autotroph Any organism that can synthesize reduced organic compounds from simple inorganic sources such as CO_2 or CH_4. Most plants and some bacteria and archaea are autotrophs. Also called *primary producer.* Compare with **heterotroph.**

auxin Indoleacetic acid, a plant hormone that stimulates phototropism and some other responses.

avirulence (*avr*) loci Genes in pathogens encoding proteins that trigger a defense response in plants. Compare with **resistance (R) loci.**

axillary bud A bud that forms in the angle between a leaf and a stem and may develop into a lateral (side) branch. Also called *lateral bud.*

axon A long projection of a neuron that can propagate an action potential and transmit it to another neuron.

axon hillock The site in a neuron where an axon joins the cell body and where action potentials are first triggered.

axoneme A structure found in eukaryotic cilia and flagella and responsible for their motion; composed of two central microtubules surrounded by nine doublet microtubules (9 + 2 arrangement).

background extinction The average rate of low-level extinction that has occurred continuously throughout much of evolutionary history. Compare with **mass extinction.**

Bacteria One of the three taxonomic domains of life consisting of unicellular prokaryotes distinguished by cell walls composed largely of peptidoglycan, plasma membranes similar to those of eukaryotic cells, and ribosomes and RNA polymerase that differ from those in archaeans or eukaryotes. Compare with **Archaea** and **Eukarya.**

bacterial artificial chromosome (BAC) An artificial version of a bacterial chromosome that can be used as a cloning vector to produce many copies of large DNA fragments.

bacteriophage Any virus that infects bacteria.

baculum A bone inside the penis usually present in mammals with a penis that lacks erectile tissue.

bark The protective outer layer of woody plants, composed of cork cells, cork cambium, and secondary phloem.

baroreceptors Specialized nerve cells in the walls of the heart and certain major arteries that detect changes in blood pressure and trigger appropriate responses by the brain.

basal Toward the base. In plants, at the base of a branch where it joins the stem. In animals, on the side of an epithelial layer that abuts underlying body tissues. Compare with **apical.**

basal body A structure of nine pairs of microtubules arranged in a circle at the base of eukaryotic cilia and flagella where they attach to the cell. Structurally similar to a centriole.

basal lamina A thick, collagen-rich extracellular matrix that underlies most epithelial tissues (e.g., skin) in animals.

basal metabolic rate (BMR) The total energy consumption by an organism at rest in a comfortable environment. For aerobes, often measured as the amount of oxygen consumed per hour.

basal transcription complex A large multiprotein structure that assembles near the promoter of eukaryotic genes and initiates transcription. Composed of basal transcription factors, TATA-binding protein, coactivators, and RNA polymerase.

basal transcription factor General term for proteins, present in all cell types, that bind to eukaryotic promoters and help initiate transcription. Compare with **regulatory transcription factor.**

base Any compound that acquires protons or gives up electrons during a chemical reaction or accepts hydrogen ions when dissolved in water.

basidiomycete See **club fungus.**

basidium (plural: basidia) Specialized spore-producing cell at the ends of hyphae in club fungi.

basilar membrane The membrane in the vertebrate cochlea on which the bottom portion of hair cells sit.

basolateral Toward the bottom and sides. In animals, the side of an epithelial layer that faces other body tissues and not the environment.

Batesian mimicry A type of mimicry in which a harmless or palatable species resembles a dangerous or poisonous species. Compare with **Müllerian mimicry.**

B cell A type of leukocyte that matures in the bone marrow and, with T cells, is responsible for acquired immunity. Produces antibodies and also functions in antigen presentation. Also called *B lymphocyte.*

B-cell receptor (BCR) An immunoglobulin protein (antibody) embedded in the plasma membrane of mature B cells and to which antigens bind.

behavior Any action by an organism.

benign tumor A mass of abnormal tissue that grows slowly or not at all, does not disrupt surrounding tissues, and does not spread to other organs. Benign tumors are not cancers. Compare with **malignant tumor.**

benthic Living at the bottom of an aquatic environment.

benthic zone The area along the bottom of an aquatic environment.

beta(β)-pleated sheet A protein secondary structure in which the polypeptide backbone folds into a sheetlike shape stabilized by hydrogen bonding.

bilateral symmetry An animal body pattern in which there is one plane of symmetry dividing the body into a left side and a right side. Typically, the body is long and narrow, with a distinct head end and tail end. Compare with **radial symmetry.**

bilaterian A member of a major lineage of animals (Bilateria) that are bilaterally symmetrical at some point in their life cycle, have three embryonic germ layers, and have a coelom. All protostomes and deuterostomes are bilaterians.

bile A complex solution produced by the liver, stored in the gall bladder, and secreted into the intestine. Contains steroid derivatives called bile salts that are responsible for emulsification of fats during digestion.

binary fission See **fission** (1).

binomial nomenclature A system of naming species by using two-part Latinized names composed of a genus name and a species name (e.g., *Homo sapiens*, humans; *Canis familiaris*, dogs). Always italicized, with genus name capitalized.

biodiversity The diversity of life considered at three levels: genetic diversity (variety of alleles in a population, species, or group of species); species diversity (variety and relative abundance of species present in a certain area); and ecosystem diversity (variety of communities and abiotic components in a region).

biogeochemical cycle The pattern of circulation of an element or molecule among living organisms and the environment.

biogeography The study of how species and populations are distributed geographically.

bioinformatics The field of study concerned with managing, analyzing, and interpreting biological information, particularly DNA sequences.

biological species concept The definition of a species as a population or group of populations that are reproductively isolated from other groups. Members of a species have the potential to interbreed in nature to produce viable, fertile offspring but cannot produce viable, fertile hybrid offspring with members of other species. Compare with **morphological** and **phylogenetic species concept.**

bioluminescence The emission of light by a living organism.

biomass The total mass of all organisms in a given population or geographical area; usually expressed as total dry weight.

biome A large terrestrial ecosystem characterized by a distinct type of vegetation and climate.

bioremediation The use of living organisms, usually bacteria or archaea, to degrade environmental pollutants.

biotechnology The application of biological techniques and discoveries to medicine, industry, and agriculture.

biotic Living, or produced by a living organism. Compare with **abiotic.**

bipedal Walking primarily on two legs.

bipolar cell A cell in the vertebrate retina that receives information from one or more photoreceptors and passes it to other bipolar cells or ganglion cells.

bivalves A lineage of molluscs that have two shells, such as clams and mussels.

bladder A mammalian organ that holds urine until it can be excreted.

blade The wide, flat part of a plant leaf.

blastocoel Fluid-filled cavity in the blastula of many animal species.

blastocyst Specialized type of blastula in mammals. A spherical structure composed of trophoblast cells on the exterior and a cluster of cells (the inner cell mass), which fills part of the interior space.

blastomere A small cell created by cleavage divisions in early animal embryos.

blastopore A small opening (pore) in the surface of an early vertebrate embryo, through which cells move during gastrulation.

blastula In vertebrate development, a hollow ball of cells (blastomere cells) that is formed by cleavage of a zygote and immediately undergoes gastrulation. See **blastocyst.**

blood A type of connective tissue consisting of red blood cells and leukocytes suspended in a fluid portion called plasma.

blood pressure See **diastolic blood pressure** and **systolic blood pressure.**

body mass index (BMI) A mathematical relationship of weight and height used to assess obesity in humans. Calculated as weight (kg) divided by the square of height (m^2).

body plan The basic architecture of an animal's body, including the number and arrangement of limbs, body segments, and major tissue layers.

bog A wetland that has no or almost no water flow, resulting in very low oxygen levels and acidic conditions.

Bohr shift The rightward shift of the oxygen-hemoglobin dissociation curve that occurs with decreasing pH. Results in hemoglobin being more likely to release oxygen in the acidic environment of exercising muscle.

bone A type of vertebrate connective tissue consisting of living cells and blood vessels within a hard extracellular matrix composed of calcium phosphate ($CaPO_4$) and small amounts of calcium carbonate ($CaCO_3$) and protein fibers.

bone marrow The soft tissue filling the inside of long bones containing stem cells that develop into red blood cells and leukocytes throughout life.

Bowman's capsule The hollow, double-walled cup-shaped portion of a nephron that surrounds a glomerulus in the vertebrate kidney.

braincase See **cranium.**

brain stem The most posterior portion of the vertebrate brain, connecting to the spinal cord and responsible for autonomic body functions such as heart rate, respiration, and digestion.

branch (1) A part of a phylogenetic tree that represents populations through time. (2) Any extension of a plant's shoot system.

bronchiole One of the small tubes in mammalian lungs that carry air from the bronchi to the alveoli.

bronchus (plural: bronchi) In mammals, one of a pair of large tubes that lead from the trachea to each lung.

brown adipose tissue A specialized form of adipose tissue whose cells contain a high density of mitochondria as well as stored fats and that can produce extra body heat. Found in some mammals.

bryophytes Members of several phyla of green plants that lack vascular tissue including liverworts, hornworts, and mosses. Also called *nonvascular plants.*

budding Asexual reproduction via outgrowth from the parent that eventually break free as an independent individual; occurs in yeasts and some invertebrates.

buffer A substance that, in solution, acts to minimize changes in the pH of that solution when acid or base is added.

bulbourethral glands In male mammals, small paired glands at the base of the urethra that secrete an alkaline mucus (part of semen), which lubricates the tip of the penis and neutralizes acids in the urethra during copulation. In humans, also called *Cowper's glands.*

bulk flow The directional movement of a substantial volume of fluid due to pressure differences, such as movement of water through plant phloem and movement of blood in animals.

bundle-sheath cell A type of cell found around the vascular tissue (veins) of plant leaves.

C_3 photosynthesis The most common form of photosynthesis in which atmospheric CO_2 is used to form 3-phosphoglycerate, a three-carbon sugar.

C_4 photosynthesis A variant type of photosynthesis in which atmospheric CO_2 is first fixed into four-carbon sugars, rather than the three-carbon sugars of classic C_3 photosynthesis. Enhances photosynthetic efficiency in hot, dry environments, by reducing loss of oxygen due to photorespiration.

cadherin Any of a class of cell-surface proteins involved in cell adhesion and important for coordinating movements of cells during embryological development.

callus In plants, a mass of undifferentiated cells that can generate roots and other tissues necessary to create a mature plant.

Calorie A unit of energy often used to measure the energy content of food. Also called *kilocalorie.*

Calvin cycle In photosynthesis, the set of light-independent reactions that use NADPH and ATP formed in the light-dependent reactions to drive the fixation of atmospheric CO_2 and reduction of the fixed carbon, ultimately producing sugars. Also called *carbon fixation* and *light-independent reactions.*

calyx All of the sepals of a flower.

CAM See **crassulacean acid metabolism.**

cambium (plural: cambia) See **lateral meristem.**

Cambrian explosion The rapid diversification of animal body types that began about 543 million years ago and continued for approximately 40 million years.

camera eye The type of eye in vertebrates and cephalopods, consisting of a hollow chamber with a hole at one end (through which light enters) and a sheet of light-sensitive cells against the opposite wall.

cAMP See **cyclic AMP.**

cancer General term for any tumor whose cells grow in an uncontrolled fashion, invade nearby tissues, and spread to other sites in the body.

canopy The uppermost layers of branches in a forest (i.e., those fully exposed to the Sun).

5′ cap A chemical grouping, consisting of 7-methylguanylate and three phosphate groups, that is added to the 5′ end of newly transcribed messenger RNA molecules.

CAP binding site A DNA sequence upstream of certain prokaryotic operons to which catabolite activator protein can bind, increasing gene transcription.

capillarity The tendency of water to move up a narrow tube due to surface tension, adhesion, and cohesion.

capillary One of the numerous small, thin-walled blood vessels that permeate all tissues and organs, and allow exchange of gases and other molecules between blood and body cells.

capillary bed A thick network of capillaries.

capsid A shell of protein enclosing the genome of a virus particle.

carapace In crustaceans, a large platelike section of the exoskeleton that covers and protects the cephalothorax (e.g., a crab's "shell").

carbohydrate Any of a class of molecules that contain a carbonyl group, several hydroxyl groups, and several to many carbon-hydrogen bonds. See **monosaccharide** and **polysaccharide.**

carbon cycle, global The worldwide movement of carbon among terrestrial ecosystems, the oceans, and the atmosphere.

carbon fixation See **Calvin cycle.**

carbonic anhydrase An enzyme that catalyzes the formation of carbonic acid (H_2CO_3) from carbon dioxide and water.

cardiac cycle One complete heartbeat cycle, including systole and diastole.

cardiac muscle The muscle tissue of the vertebrate heart. Consists of long branched fibers that are electrically connected and that initiate their own contractions; not under voluntary control. Compare with **skeletal** and **smooth muscle.**

carnivore (adjective: carnivorous) An animal whose diet consists predominantly of meat. Most members of the mammalian taxon Carnivora are carnivores. Some plants are carnivorous, trapping and killing small animals, then absorbing nutrients from the prey's body. Compare with **herbivore** and **omnivore.**

carotenoid Any of a class of accessory pigments, found in chloroplasts, that absorb wavelengths of light not absorbed by chlorophyll; typically appear yellow, orange, or red. Includes carotenes and xanthophylls.

carpel The female reproductive organ in a flower. Consists of the stigma, to which pollen grains adhere; the style, through which pollen grains move; and the ovary, which houses the ovule. Compare with **stamen.**

carrier A heterozygous individual carrying a normal allele and a recessive allele for an inherited trait; does not display the phenotype of the trait but can pass the recessive gene to offspring.

carrier protein A membrane protein that facilitates diffusion of a small molecule (e.g., glucose) across the plasma membrane by a process involving a reversible change in the shape of the protein. Also called *carrier* or *transporter.*

carrying capacity (*K*) The maximum population size of a certain species that a given habitat can support.

cartilage A type of vertebrate connective tissue that consists of relatively few cells scattered in a stiff matrix of polysaccharides and protein fibers.

Casparian strip In plant roots, a waxy layer containing suberin, a water-repellent substance, that prevents movement of water through the walls of endodermal cells, thus blocking the apoplastic pathway.

catabolic pathway Any set of chemical reactions that breaks down larger, complex molecules into smaller ones, releasing energy in the process. Compare with **anabolic pathway.**

catabolite activator protein (CAP) A protein that can bind to the CAP binding site upstream of certain prokaryotic operons, facilitating binding of RNA polymerase and stimulating gene expression.

catabolite repression A type of positive transcriptional control in which the end product of a catabolic pathway inhibits further transcription of the gene encoding an enzyme early in the pathway.

catalysis (verb: catalyze) Acceleration of the rate of a chemical reaction due to a decrease in the free energy of the transition state, called the activation energy.

catalyst Any substance that increases the rate of a chemical reaction without itself undergoing any permanent chemical change.

catecholamines A class of small compounds, derived from the amino acid tyrosine, that are used as hormones or neurotransmitters. Include epinephrine, norepinephrine, and dopamine.

cation A positively charged ion.

cation exchange In botany, the release (displacement) of cations, such as magnesium and calcium from soil particles, by protons in acidic soil water. The released cations are available for uptake by plants.

CD4 A membrane protein on the surface of some T cells in humans. $CD4^+$ T cells can give rise to helper T cells.

CD8 A membrane protein on the surface of some T cells in humans. $CD8^+$ T cells can give rise to cytotoxic T cells.

Cdk See **cyclin-dependent kinase.**

cDNA See **complementary DNA.**

cDNA library A set of cDNAs from a particular cell type or stage of development. Each cDNA is carried by a plasmid or other cloning vector and can be separated from other cDNAs. Compare with **genomic library.**

cecum A blind sac between the small intestine and the colon. Is enlarged in some species (e.g., rabbits) that use it as a fermentation vat for digestion of cellulose.

cell A highly organized compartment bounded by a thin, flexible structure (plasma membrane) and containing concentrated chemicals in an aqueous (watery) solution. The basic structural and functional unit of all organisms.

cell body The part of a neuron that contains the nucleus and where incoming signals are integrated. Also called the *soma.*

cell crawling A form of cellular movement involving actin filaments in which the cell produces bulges (pseudopodia) that stick to the substrate and pull the cell forward. Also called *amoeboid motion.*

cell cycle Ordered sequence of events in which a eukaryotic cell replicates its chromosomes, evenly partitions the chromosomes to two daughter cells, and then undergoes division of the cytoplasm.

cell-cycle checkpoint Any of several points in the cell cycle at which progression of a cell through the cycle can be regulated.

cell division Creation of new cells by division of pre-existing cells.

cell-mediated (immune) response The type of immune response that involves generation of cytotoxic T cells from $CD8^+$ T cells. Defends against pathogen-infected cells, cancer cells, and transplanted cells. Compare with **humoral (immune) response.**

cell membrane See **plasma membrane.**

cell plate A double layer of new plasma membrane that appears in the middle of a dividing plant cell; ultimately divides the cytoplasm into two separate cells.

cell sap An aqueous solution found in the vacuoles of plant cells.

cell theory The theory that all organisms are made of cells and that all cells come from preexisting cells.

cellular respiration A common pathway for production of ATP, involving transfer of electrons from compounds with high potential energy (often NADH and $FADH_2$) to an electron transport chain and ultimately to an electron acceptor (often oxygen).

cellulose A structural polysaccharide composed of β-glucose monomers joined by β-1,4-glycosidic linkages. Found in the cell wall of algae, plants, bacteria, fungi, and some other groups.

cell wall A protective layer located outside the plasma membrane and usually composed of polysaccharides. Found in algae, plants, bacteria, fungi, and some other groups.

Cenozoic era The most recent period of geologic time, beginning 65 million years ago, during which mammals became the dominant vertebrates and angiosperms became the dominant plants. Also called *Age of Mammals.*

central dogma The long-accepted hypothesis that information in cells flows in one direction: DNA codes for RNA, which codes for proteins. Exceptions are now known (e.g., retroviruses).

central nervous system (CNS) The brain and spinal cord of vertebrate animals. Compare with **peripheral nervous system (PNS).**

centriole One of two small cylindrical structures, structurally similar to a basal body, found together within the centrosome near the nucleus of a eukaryotic cell.

centromere Constricted region of a replicated chromosome where the two sister chromatids are joined and the kinetochore is located.

centrosome Structure in animal and fungal cells, containing two centrioles, that serves as a microtubule-organizing center for the cell's cytoskeleton and for the mitotic spindle during cell division.

cephalization The formation of a distinct anterior region (the head) where sense organs and a mouth are clustered.

cephalochordates One of the three major chordate lineages (Cephalochordata), comprising small, mobile organisms that live in marine sands; also called *lancelets* or *amphioxi.* Compare with **urochordates** and **vertebrates.**

cephalopods A lineage of molluscs including the squid, octopuses, and nautiluses. Distinguished by large brains, excellent vision, tentacles, and a reduced or absent shell.

cerebellum Posterior section of the vertebrate brain that is involved in coordination of complex muscle movements, such as those required for locomotion and maintaining balance.

cerebrum The most anterior section of the vertebrate brain. Divided into left and right hemispheres and four lobes: parietal lobe, involved in complex decision making (in humans); occipital lobe, receives and interprets visual information; parietal lobe, involved in integrating sensory and motor functions; and temporal lobe, functions in memory, speech (in humans), and interpreting auditory information.

cervix The narrow passageway between the vagina and the uterus of female mammals.

chaetae (singular: chaeta) Bristle-like extensions found in some annelids.

channel protein A membrane protein that facilitates diffusion of a specific ion or small molecule across a plasma membrane through a central pore in the protein. Includes water channels (aquaporins) and ion channels. Also called simply *channel*.

character displacement The tendency for the traits of similar species that occupy overlapping ranges to change in a way that reduces interspecific competition.

chelicerae A pair of clawlike appendages found around the mouth of certain arthropods called chelicerates (spiders, mites, and allies).

chemical bond An attractive force binding two atoms together. Covalent bonds, ionic bonds, and hydrogen bonds are types of chemical bonds.

chemical carcinogen Any chemical that can cause cancer.

chemical energy The potential energy stored in covalent bonds between atoms.

chemical equilibrium A dynamic but stable state of a reversible chemical reaction in which the forward reaction and reverse reactions proceed at the same rate, so that the concentrations of reactants and products remain constant.

chemical evolution The theory that simple chemical compounds in the ancient atmosphere and ocean combined by spontaneous chemical reactions to form larger, more complex substances, eventually leading to the origin of life and the start of biological evolution.

chemical reaction Any process in which one compound or element is combined with others or is broken down; involves the making and/or breaking of chemical bonds.

chemiosmosis An energetic coupling mechanism whereby energy stored in an electrochemical proton gradient (proton-motive force) is used to drive an energy-requiring process such as production of ATP.

chemokine Any of several chemical signals that attract leukocytes to a site of tissue injury or infection.

chemolithotroph An organism that produces ATP by oxidizing inorganic molecules with high potential energy such as ammonia (NH_3) or methane (CH_4). Also called *lithotroph*. Compare with **chemoorganotroph.**

chemoorganotroph An organism that produces ATP by oxidizing organic molecules with high potential energy such as sugars. Also called *organotroph*. Compare with **chemolithotroph.**

chemoreceptor A sensory cell or organ specialized for detection of specific molecules or classes of molecules.

chemotaxis Movement toward or away from a certain chemical.

chiasma (plural: chiasmata) The X-shaped structure formed during meiosis by crossing over between non-sister chromatids in a pair of homologous chromosomes.

chitin A structural polysaccharide composed of *N*-acetylglucosamine monomers joined end to end by β-1,4-glycosidic linkages. Found in cell walls of fungi and many algae, and in external skeletons of insects and crustaceans.

chitons A lineage of marine mollusc that have a protective shell formed of eight calcium carbonate plates.

chlorophyll Any of several closely related green pigments, found in chloroplasts and photosynthetic protists, that absorb light during photosynthesis.

chloroplast A chlorophyll-containing organelle, bounded by a double membrane, in which photosynthesis occurs; found in plants and photosynthetic protists. Also the location of amino acid, fatty acid, purine, and pyrimidine synthesis.

choanocyte A specialized flagellated feeding cell found in choanoflagellates (protists that are the closest living relatives of animals) and sponges (the oldest animal phylum).

cholecystokinin A peptide hormone secreted by cells in the lining of the small intestine. Stimulates the secretion of digestive enzymes from the pancreas and of bile from the liver and gallbladder.

chordates Members of the phylum Chordata, deuterostomes distinguished by a dorsal hollow nerve cord, pharyngeal gill slits, a notochord, a dorsal hollow nerve cord, and a post-anal tail. Include vertebrates, cephalochordata, and urochordata.

chromatid One of the two identical strands composing a replicated chromosome that is connected at the centromere to the other strand.

chromatin The complex of DNA and proteins, mainly histones, that compose eukaryotic chromosomes. Can be highly compact (heterochromatin) or loosely coiled (euchromatin).

chromatin remodeling The process by which the DNA in chromatin is unwound from its associated proteins to allow transcription or replication. May involve chemical modification of histone proteins or reshaping of the chromatin by large multi-protein complexes in an ATP-requiring process.

chromosome Gene-carrying structure consisting of a single long molecule of DNA and associated proteins (e.g., histones). Most prokaryotic cells contain a single, circular chromosome; eukaryotic cells contain multiple noncircular (linear) chromosomes located in the nucleus.

chromosome inversion See **inversion.**

chromosome painting A technique for producing high-resolution karyotypes by "painting" chromosomes with fluorescent tags that bind to particular regions of certain chromosomes. Also called *spectral karyotyping*.

chromosome theory of inheritance The principle that genes are located on chromosomes and that patterns of inheritance are determined by the behavior of chromosomes during meiosis.

chromosome translocation See **translocation** (2).

chylomicron A ball of protein-coated lipids used to transport the lipids through the bloodstream.

chytrid A member of a paraphyletic group of fungi (Chytridiomycota) that produce motile spores and gametes (both have flagella similar to those in sperm cells). Also called *chytridiomycete*.

cilium (plural: cilia) One of many short, filamentous projections of some eukaryotic cells containing a core of microtubules. Used to move the cell and/or to move fluid or particles along a stationary cell. See **axoneme.**

circadian clock An internal mechanism found in most organisms that regulates many body processes (sleep-wake cycles, hormonal patterns, etc.) in a roughly 24-hour cycle.

circulatory system The system in animals responsible for moving oxygen, carbon dioxide, and other materials (hormones, nutrients, wastes) around the body.

cisternae (singular: cisterna) Flattened, membrane-bound compartments that make up the Golgi apparatus.

clade See **monophyletic group.**

cladistic approach A method for constructing a phylogenetic tree that is based on identifying the unique traits of each monophyletic group. Compare with **phenetic approach.**

class In Linnaeus' system, a taxonomic category above the order level and below the phylum level.

Class I MHC protein An MHC protein that is present on the plasma membrane of virtually all nucleated cells and functions in presenting antigen to $CD8^+$ T cells.

Class II MHC protein An MHC protein that is present only on the plasma membrane of dendritic cells, macrophages, and B cells and functions in presenting antigen to $CD4^+$ T cells.

classical conditioning A type of learning in which an animal learns to associate two stimuli, so that a response originally given to just one stimulus can be evoked by the second stimulus as well.

cleavage In animal development, the series of rapid mitotic cell divisions, with little cell growth, that produces successively smaller cells and transforms a zygote into a multicellular blastula, or blastocyst in mammals.

cleavage furrow A pinching-in of the plasma membrane that occurs as cytokinesis begins in animal cells and deepens until the cytoplasm is divided.

climate The prevailing long-term weather conditions in a particular region.

climax community The stable, final community that develops from ecological succession.

clitoris A small rod of erectile tissue in the external genitalia of female mammals. Is formed from the same embryonic tissue as the male penis and has a similar function in sexual arousal.

cloaca An opening to the outside used by the excretory and reproductive systems in many nonmammalian vertebrate but few vertebrates.

clonal expansion Rapid cell division by a T cell or B cell in response to its binding the specific antigen recognized by receptors on the cell surface. Produces a large population of descendant cells all specific for that particular antigen.

clonal-selection theory The dominant explanation of the development of acquired immunity in vertebrates. According to the theory, the immune

system retains a vast pool of inactive lymphocytes, each with a unique receptor for a unique antigen. Lymphocytes that encounter their antigens are stimulated to divide (selected and cloned), producing daughter cells that combat infection and confer immunity.

clone (1) An individual that is genetically identical to another individual. (2) A lineage of genetically identical individuals or cells. (3) As a verb, to make one or more genetic replicas of a cell or individual.

cloning vector A plasmid or other agent used to transfer recombinant genes into cultured host cells. Also called simply *vector*.

closed circulatory system A circulatory system in which the circulating fluid (blood) is confined to blood vessels and flows in a continuous circuit. Compare with **open circulatory system.**

club fungus A member of a lineage of fungi (Basidiomycota) that produce complex reproductive structures (e.g., mushrooms, puffballs) containing specialized spore-forming cells (basidia). Also called *basidiomycete*.

cnidocyte A specialized stinging cell found in cnidarians (e.g., jellyfish, corals, and anemones) that is used in capturing prey.

coactivator Any regulatory protein that help initiate transcription by bringing together the necessary transcription factors but does not itself bind to DNA.

cochlea The organ of hearing in the inner ear of mammals, birds, and crocodilians. A coiled, fluid-filled tube containing specialized pressure-sensing neurons (hair cells) that detect sounds of different pitches.

coding strand See **non-template strand.**

codominance An inheritance pattern in which heterozygotes exhibit both of the traits seen in either kind of homozygous individual.

codon A sequence of three nucleotides in DNA or RNA that codes for a certain amino acid or that initiates or terminates protein synthesis.

coefficient of relatedness (*r*) A measure of how closely two individuals are related. Calculated as the probability that an allele in two individuals is inherited from the same ancestor.

coelom An internal, usually fluid-filled, body cavity that is lined with mesoderm.

coelomate An animal that has a true coelom. Compare with **acoelomate** and **pseudocoelomate.**

coenocytic Containing many nuclei and a continuous cytoplasm through a filamentous body, without the body being divided into distinct cells. Some fungi are coenocytic.

coenzyme A small organic molecule that is a required cofactor for an enzyme-catalyzed reaction. Often donates or receives electrons or functional groups during the reaction.

coenzyme A (CoA) A nonprotein molecule that is required for many cellular reactions involving transfer of acetyl groups ($-COCH_3$).

coenzyme Q A nonprotein molecule that shuttles electrons between membrane-bound complexes in the mitochondrial electron transport chain. Also called *ubiquinone* or *Q*.

coevolution A pattern of evolution in which two interacting species reciprocally influence each other's adaptations over time.

cofactor A metal ion or small organic compound that is required for an enzyme to function normally. May be bound tightly to an enzyme or associate with it transiently during catalysis.

cognition The mental processes involved in recognition and manipulation of facts about the world, particularly to form novel associations or insights.

cohesion The tendency of certain like molecules (e.g., water molecules) to cling together due to attractive forces. Compare with **adhesion.**

cohesion-tension theory The theory that water movement upward through plant vascular tissues is due to loss of water from leaves (transpiration), which pulls a cohesive column of water upward.

cohort A group of individuals that are the same age and can be followed through time.

coleoptile A modified leaf that covers and protects the stems and leaves of young grasses.

collagen A fibrous, pliable, cable-like glycoprotein that is a major component of the extracellular matrix of animal cells. Various subtypes differ in their tissue distribution.

collecting duct In the vertebrate kidney, a large straight tube that receives filtrate from the distal tubules of several nephrons. Involved in the regulated reabsorption of water.

collenchyma cell In plants, an elongated cell with cell walls thickened at the corners that provides support to growing plant parts; usually found in strands along leaf veins and stalks. Compare with **parenchyma cell** and **sclerenchyma cell.**

colon The portion of the large intestine where feces are formed by compaction of wastes and reabsorption of water.

colony An assemblage of individuals. May refer to an assemblage of semi-independent cells or to a breeding population of multicellular organisms.

commensalism (adjective: commensal) A symbiotic relationship in which one organism (the commensal) benefits and the other (the host) is not harmed. Compare with **mutualism** and **parasitism.**

communication In ecology, any process in which a signal from one individual modifies the behavior of another individual.

community All of the species that interact with each other in a certain area.

companion cell In plants, a cell in the phloem that is connected via numerous plasmodesmata to adjacent sieve-tube members. Companion cells provide materials to maintain sieve-tube members and function in the loading and unloading of sugars into sieve-tube members.

compass orientation A type of navigation in which movement occurs in a specific direction.

competition In ecology, the interaction of two species or two individuals trying to use the same limited resource (e.g., water, food, living space). May occur between individuals of the same species (intraspecific competition) or different species (interspecific competition).

competitive exclusion principle The principle that two species cannot coexist in the same ecological niche in the same area because one species will out-compete the other.

competitive inhibition Inhibition of an enzyme's ability to catalyze a chemical reaction via a nonreactant molecule that competes with the substrate(s) for access to the active site.

complementary base pairing The association between specific nitrogenous bases of nucleic acids stabilized by hydrogen bonding. Adenine pairs only with thymine (in DNA) or uracil (in RNA), and guanine pairs only with cytosine.

complementary DNA (cDNA) DNA produced in the laboratory using an RNA transcript as a template and reverse transcriptase; corresponds to a gene but lacks introns. Also produced naturally by retroviruses.

complementary strand A newly synthesized strand of RNA or DNA that has a base sequence complementary to that of the template strand.

complement system A set of proteins that circulate in the bloodstream and can form holes in the plasma membrane of bacteria, leading to their destruction.

complete metamorphosis See **holometabolous metamorphosis.**

compound eye An eye formed of many independent light-sensing columns (ommatidia); occurs in arthropods. Compare with **simple eye.**

concentration gradient Difference across space (e.g., across a membrane) in the concentration of a dissolved substance.

condensation reaction A chemical reaction in which two molecules are joined covalently with the removal of an $-OH$ from one and an $-H$ from another to form water. Also called a *dehydration reaction*. Compare with **hydrolysis.**

conduction (1) Direct transfer of heat between two objects that are in physical contact. Compare with **convection.** (2) Transmission of an electrical impulse along the axon of a nerve cell.

cone In conifers (e.g., pines, cedars, and spruces), the reproductive structure in which microspores and macrospores are formed.

cone cell A photoreceptor cell with a cone-shaped outer portion that is particularly sensitive to bright light of a certain color. Also called simply *cone*. Compare with **rod cell.**

conjugation The process by which DNA is exchanged between unicellular individuals. Occurs in bacteria, archaea, and some protists.

connective tissue An animal tissue consisting of scattered cells in a liquid, jellylike, or solid extracellular matrix. Includes bone, cartilage, tendons, ligaments, and blood.

conservation biology The effort to study, preserve, and restore threatened populations, communities, and ecosystems.

constant (C) region The portion of an antibody's light chains or heavy chains that has the same amino acid sequence in the antibodies produced by every B cell of an individual. Compare with **variable (V) region.**

constitutive Always occurring; always present. Commonly used to describe enzymes and other proteins that are synthesized continuously or mutants in which one or more genetic loci are constantly expressed due to defects in gene control.

constitutive defense A defensive trait that is always manifested even in the absence of a predator or pathogen. Also called *standing defense*. Compare with **inducible defense.**

consumer See **heterotroph.**

continuous strand See **leading strand.**

control In a scientific experiment, a group of organisms or samples that do not receive the experimental treatment but are otherwise identical to the group that does.

convection Transfer of heat by movement of large volumes of a gas or liquid. Compare with **conduction.**

convergent evolution The independent evolution of analogous traits in distantly related organisms due to adaptation to similar environments and a similar way of life.

cooperative binding The tendency of the protein subunits of hemoglobin to affect each other's oxygen binding such that each bound oxygen molecule increases the likelihood of further oxygen binding.

copulation The act of transferring sperm from a male directly into a female's reproductive tract.

coral reef A large assemblage of colonial marine corals that usually serves as shallow-water, sunlit habitat for many other species as well.

co-receptor Any membrane protein that acts with some other membrane protein in a cell interaction or cell response.

cork cambium One of two types of lateral meristem, consisting of a ring of undifferentiated plant cells found just under the cork layer of woody plants; produces new cork cells on its outer side. Compare with **vascular cambium.**

cork cell A waxy cell in the protective outermost layer of a woody plant.

corm A rounded, thick underground stem that can produce new plants via asexual reproduction.

cornea The transparent sheet of connective tissue at the very front of the eye in vertebrates and some other animals. Protects the eye and helps focus light.

corolla All of the petals of a flower.

corona The cluster of cilia at the anterior end of a rotifer.

corpus callosum A thick band of neurons that connects the two hemispheres of the cerebrum in the mammalian brain.

corpus luteum A yellowish structure in an ovary that secretes progesterone. Is formed from a follicle that has recently ovulated.

cortex (1) The outermost region of an organ, such as the kidney or adrenal gland. (2) In plants, a layer of ground tissue found outside the vascular bundles and pith of a plant stem.

cortical granules Small enzyme-filled vesicles in the cortex of an egg cell. Involved in formation of the fertilization envelope after fertilization.

corticosterone A steroid hormone, produced and secreted by the adrenal cortex, that increases blood glucose and prepares the body for stress. The major glucocorticoid hormone in most reptiles, birds, and many mammals.

corticotropin-releasing hormone (CRH) A peptide hormone, produced and secreted by the hypothalamus, that stimulates the anterior pituitary to release ACTH.

cortisol A steroid hormone, produced and secreted by the adrenal cortex, that increases blood glucose and prepares the body for stress. The major glucocorticoid hormone in some mammals. Also called *hydrocortisone.*

cotransporter A transmembrane protein that facilitates diffusion of an ion down its previously established electrochemical gradient and uses the energy of that process to transport some other substance, in the same or opposite direction, *against* its concentration gradient. See **antiporter** and **symporter.**

cotyledon The first leaf, or seed leaf, of a plant embryo. Used for storing and digesting nutrients and/or for early photosynthesis.

countercurrent exchanger In animals, any anatomical arrangement that allows the maximum transfer of heat or a soluble substance from one fluid to another. The two fluids must be flowing in opposite directions and have a heat or concentration gradient between them.

covalent bond A type of chemical bond in which two atoms share one or more pairs of electrons. Compare with **hydrogen bond** and **ionic bond.**

cranium A bony, cartilaginous, or fibrous case that encloses and protects the brain of vertebrates. Forms part of the skull. Also called *braincase.*

crassulacean acid metabolism (CAM) A variant type of photosynthesis in which CO_2 is stored in organic acids at night when stomata are open and then released to feed the Calvin cycle during the day when stomata are closed. Helps reduce water loss and oxygen loss by photorespiration in hot, dry environments.

cristae (singular: crista) Sac-like invaginations of the inner membrane of a mitochondrion. Location of the electron transport chain and ATP synthase.

critical period See **sensitive period.**

Cro-Magnon A prehistoric European population of modern humans (*Homo sapiens*) known from fossils, paintings, sculptures, and other artifacts.

crossing over The exchange of segments of nonsister chromatids between a pair of homologous chromosomes that occurs during meiosis I.

cross-pollination Pollination of a flower by pollen from another individual, rather than by self-fertilization. Also called *crossing.*

crustaceans A lineage of arthropods that includes shrimp, lobster, and crabs. Many have a carapace (a platelike portion of the exoskeleton) and mandibles for biting or chewing.

culture In cell biology, a collection of cells or a tissue growing under controlled conditions, usually in suspension or on the surface of a dish on solid growth medium.

cup fungus See **sac fungus.**

Cushing's disease A human endocrine disorder caused by loss of feedback inhibition of cortisol on ACTH secretion. Characterized by high ACTH and cortisol levels and wasting of body protein reserves.

cuticle A protective coating secreted by the outermost layer of cells of an animal or a plant.

cyanobacteria A lineage of photosynthetic bacteria formerly known as blue-green algae. Likely the first life-forms to carry out oxygenic photosynthesis.

cyclic AMP (cAMP) Cyclic adenosine monophosphate; a small molecule, derived from ATP, that is widely used by cells in signal transduction and transcriptional control.

cyclic photophosphorylation Path of electron flow during the light-dependent reactions of photosynthesis in which photosystem I transfers excited electrons back to the electron transport chain of photosystem II, rather than to $NADP^+$. Also called *cyclic electron flow.* Compare with **Z scheme.**

cyclin One of several regulatory proteins whose concentrations fluctuate cyclically throughout the cell cycle.

cyclin-dependent kinase (Cdk) Any of several related protein kinases that are active only when bound to a cyclin. Involved in control of the cell cycle.

cytochrome *c* (cyt *c*) A soluble iron-containing protein that shuttles electrons between membrane-bound complexes in the mitochondrial electron transport chain.

cytokines A diverse group of autocrine signaling proteins, secreted largely by cells of the immune system, whose effects include stimulating leukocyte production, tissue repair, and fever. Generally function to regulate the intensity and duration of an immune response.

cytokinesis Division of the cytoplasm to form two daughter cells. Typically occurs immediately after division of the nucleus by mitosis or meiosis.

cytokinins A class of plant hormones that stimulate cell division and retard aging.

cytoplasm All of the contents of a cell, excluding the nucleus, and bounded by the plasma membrane.

cytoplasmic determinant A regulatory transcription factor or signaling molecule that is distributed unevenly in the cytoplasm of the egg cells of many animals and that directs early pattern formation in an embryo.

cytoplasmic streaming The directed flow of cytosol and organelles that facilitates distribution of materials within some large plant and fungal cells. Occurs along actin filaments and is powered by myosin.

cytoskeleton In eukaryotic cells, a network of protein fibers in the cytoplasm that are involved in cell shape, support, locomotion, and transport of materials within the cell. Prokaryotic cells have a similar but much less extensive network of fibers.

cytosol The fluid portion of the cytoplasm.

cytotoxic T cell An effector T cell that destroys infected cells and cancer cells. Is descended from an activated $CD8^+$ T cell that has interacted with antigen on an infected cell or cancer cell. Also called *cytotoxic T lymphocyte (CTL)* and *killer T cell.* Compare with **helper T cell.**

dalton (Da) See **atomic mass unit.**

Darwinian fitness See **fitness.**

day-neutral plant A plant whose flowering time is not affected by the relative length of day and night (the photoperiod). Compare with **long-day** and **short-day plant.**

dead space Portions of the air passages that are not involved in gas exchange with the blood, such as the trachea and bronchi.

deciduous Describing a plant that sheds leaves or other structures at regular intervals (e.g., each fall)

decomposer See **detritivore.**

decomposer food chain An ecological network of detritus, decomposers that eat detritus, and predators and parasites of the decomposers.

definitive host The host species in which a parasite reproduces sexually. Compare with **intermediate host.**

dehydration reaction See **condensation reaction.**

deleterious In genetics, referring to any mutation, allele, or trait that reduces an individual's fitness.

demography The study of factors that determine the size and structure of populations through time.

denaturation (verb: denature) For a macromolecule, loss of its three-dimensional structure and

biological activity due to breakage of hydrogen bonds and disulfide bonds, usually caused by treatment with excess heat or extreme pH conditions.

dendrite A short extension from a neuron's cell body that receives signals from other neurons.

dendritic cell A type of leukocyte that ingests and digests foreign antigens, moves to a lymph node, and presents the antigens displayed on its membrane to $CD4^+$ T cells.

density dependent In population ecology, referring to any characteristic that varies depending on population density.

density independent In population ecology, referring to any characteristic that does not vary with population density.

deoxyribonucleic acid (DNA) A nucleic acid composed of deoxyribonucleotides that carries the genetic information of a cell. Generally occurs as two intertwined strands, but these can be separated. See **double helix.**

deoxyribonucleoside triphosphate (dNTP) A monomer that can be polymerized to form DNA. Consists of deoxyribose, a base (A, T, G, or C), and three phosphate groups; similar to a nucleotide, but with two more phosphate groups.

deoxyribonucleotide See **nucleotide.**

depolarization Change in membrane potential from its resting negative state to a less negative or a positive state; a normal phase in an action potential. Compare with **hyperpolarization.**

deposit feeder An animal that eats its way through a food-containing substrate.

dermal tissue system The tissue forming the outer layer of an organism. In plants, also called *epidermis;* in animals, forms two distinct layers: *dermis* and *epidermis.*

descent with modification The phrase used by Darwin to describe his hypothesis of evolution by natural selection.

desmosome A type of cell-cell attachment structure, consisting of cadherin proteins, that bind the cytoskeletons of adjacent animal cells together. Found where cells are strongly attached to each other. Compare with **gap junction** and **tight junction.**

determination In embryogenesis, progressive changes in a cell that commit it to a particular cell fate. Once a cell is fully determined, it can differentiate only into a particular cell type (e.g., liver cell, brain cell).

detritivore An organism whose diet consists mainly of dead organic matter (detritus). Various bacteria, fungi, and protists are detritivores. Also called *decomposer.*

detritus A layer of dead organic matter that accumulates at ground level or on seafloors and lake bottoms.

deuterostomes A major lineage of animals that share a pattern of embryological development, including radial cleavage, formation of the anus earlier than the mouth, and formation of the coelom by pinching off of layers of mesoderm from the gut. Includes echinoderms and chordates. Compare with **protostomes.**

developmental homology A similarity in embryonic form, or in the fate of embryonic tissues, that is due to inheritance from a common ancestor.

diabetes insipidus A human disease caused by defects in the kidney's system for conserving water. Characterized by production of large amounts of dilute urine.

diabetes mellitus A human disease caused by defects in insulin production (type I) or the response of cells to insulin (type II). Characterized by abnormally high blood glucose levels and large amounts of glucose-containing urine.

diaphragm An elastic, sheetlike structure. In mammals, the muscular sheet of tissue that separates the chest and abdominal cavities. Contracts and moves downward during inhalation, expanding the chest cavity.

diastole The portion of the heartbeat cycle during which the atria or ventricles of the heart are relaxed. Compare with **systole.**

diastolic blood pressure The force exerted by blood against artery walls during relaxation of the heart's left ventricle. Compare with **systolic blood pressure.**

dicot Any plant that has two cotyledons (embryonic leaves) upon germination. The dicots do not form a monophyletic group. Also called *dicotyledonous plant.* Compare with **eudicot** and **monocot.**

dideoxy sequencing A laboratory technique for determining the exact nucleotide sequence of DNA. Relies on the use of dideoxynucleotide triphosphates (ddNTPs), which terminate DNA replication.

diencephalon The part of the mammalian brain that relays sensory information to the cerebellum and functions in maintaining homeostasis.

differential centrifugation Procedure for separating cellular components according to their size and density by spinning a cell homogenate in a series of centrifuge runs. After each run, the supernatant is removed from the deposited material (pellet) and spun again at progressively higher speeds.

differential gene expression Expression of different sets of genes in cells with the same genome. Responsible for creating different cell types.

differentiation The process by which a relatively unspecialized cell becomes a distinct specialized cell type (e.g., liver cell, brain cell) usually by changes in gene expression. Also call *cell differentiation.*

diffusion Spontaneous movement of a substance from a region of high concentration to one of low concentration (i.e., down a concentration gradient).

digestion The physical and chemical breakdown of food into molecules that can be absorbed into the body of an animal.

digestive tract The long tube that begins at the mouth and ends at the anus. Also called *alimentary canal, gastrointestinal(GI) tract,* or the *gut.*

dihybrid cross A mating between two parents that are heterozygous for both of the two genes being studied.

dimer An association of two molecules, which may be identical (homodimer) or different (heterodimer).

dioecious Describing an angiosperm species that has male and female reproductive structures on separate plants. Compare with **monoecious.**

diploblast (adjective: diploblastic) An animal whose body develops from two basic embryonic cell layers—ectoderm and endoderm. Compare with **triploblast.**

diploid (1) Having two sets of chromosome s ($2n$). (2) A cell or an individual organism with two sets of chromosomes, one set inherited from the maternal parent and one set from the paternal parent. Compare with **haploid.**

directional selection A pattern of natural selection that favors one extreme phenotype with the result that the average phenotype of a population changes in one direction. Generally reduces overall genetic variation in a population.

direct sequencing A technique for identifying and studying microorganisms that cannot be grown in culture. Involves detecting and amplifying copies of certain specific genes in their DNA, sequencing these genes, and then comparing the sequences with the known sequences from other organisms.

disaccharide A carbohydrate consisting of two monosaccharides (sugar residues) linked together.

discontinuous strand See **lagging strand.**

discrete trait An inherited trait that exhibits distinct phenotypic forms rather than the continuous variation characteristic of a quantitative traits such as body height.

dispersal The movement of individuals from their place of origin (birth, hatching) to a new location.

disruptive selection A pattern of natural selection that favors extreme phenotypes at both ends of the range of phenotypic variation. Maintains overall genetic variation in a population. Compare with **stabilizing selection.**

distal tubule In the vertebrate kidney, the convoluted portion of a nephron into which filtrate moves from the loop of Henle. Involved in the regulated reabsorption of sodium and water. Compare with **proximal tubule.**

disturbance In ecology, any event that disrupts a community, usually causing loss of some individuals or biomass from it.

disturbance regime The characteristic disturbances that affect a given ecological community.

disulfide bond A covalent bond between two sulfur atoms, typically in the side groups of some amino acids (e.g., cysteine). Often contributes to tertiary structure of proteins.

DNA See **deoxyribonucleic acid.**

DNA cloning Any of several techniques for producing many identical copies of a particular gene or other DNA sequence.

DNA fingerprinting Any of several methods for identifying individuals by unique features of their genomes. Commonly involves using PCR to produce many copies of certain simple sequence repeats (microsatellites) and then analyzing their lengths.

DNA footprinting A technique used to identify stretches of DNA that are bound by particular regulatory proteins.

DNA library See **cDNA library** and **genomic library.**

DNA ligase An enzyme that joins pieces of DNA by catalyzing formation of a phosphodiester bond between the pieces.

DNA microarray A set of single-stranded DNA fragments, representing thousands of different genes, that are permanently fixed to a small glass slide. Can be used to determine which genes are expressed in different cell types, under different conditions, or at different developmental stages.

DNA polymerase Any enzyme that catalyzes synthesis of DNA from deoxyribonucleotides.

domain (1) A section of a protein that has a distinctive tertiary structure and function. (2) A taxonomic category, based on similarities in basic cellular biochemistry, above the kingdom level. The three recognized domains are Bacteria, Archaea, and Eukarya.

dominant Referring to an allele that determines the phenotype of a heterozygous individual. Compare with **recessive.**

dopamine A catecholamine neurotransmitter that functions mainly in a part of the mammalian brain involved with muscle control. Also functions as a hypothalamic inhibitory hormone that inhibits release of prolactin from the interior pituitary; also called *prolactin-inhibiting hormone (PIH).*

dormancy A temporary state of greatly reduced, or no, metabolic activity and growth in plants or plant parts (e.g., seeds, spores, bulbs, and buds).

dorsal Toward an animal's back and away from its belly. The opposite of ventral.

double fertilization An unusual form of reproduction seen in flowering plants, in which one sperm nucleus fuses with an egg to form a zygote and the other sperm nucleus fuses with two polar nuclei to form the triploid endosperm.

double helix The secondary structure of DNA, consisting of two antiparallel DNA strands wound around each other.

downstream In genetics, the direction in which RNA polymerase moves along a DNA strand. Compare with **upstream.**

Down syndrome A human developmental disorder caused by trisomy of chromosome 21.

dyad symmetry A type of symmetry in which an object can be superimposed on itself if rotated 180°. Occurs in some regulatory sequences of DNA. Also called *two-fold rotational symmetry.*

dynein Any one of a class of motor proteins that use the chemical energy of ATP to "walk" along an adjacent microtubule. Dyneins are responsible for bending of cilia and flagella, play a role in chromosome movement during mitosis, and can transport certain organelles.

early endosome A small membrane-bound vesicle, formed by endocytosis, that is an early stage in the formation of a lysosome.

ecdysone An insect hormone that triggers either molting (to a larger larval form) or metamorphosis (to the adult form), depending on the level of juvenile hormone.

ecdysozoans A major lineage of protostomes (Ecdysozoa) that grow by shedding their external skeletons (molting) and expanding their bodies. Includes arthropods, insects, crustaceans, nematodes, and centipedes. Compare with **lophotrochozoans.**

echinoderms A major lineage of deuterostomes (Echinodermata) distinguished by adult bodies with five-sided radial symmetry, a water vascular system, and tube feet. Includes sea urchins, sand dollars, and sea stars.

echolocation The use of echoes from vocalizations to obtain information about locations of objects in the environment.

ecology The study of how organisms interact with each other and with their surrounding environment.

ecosystem All the organisms that live in a geographic area, together with the nonliving (abiotic) components that affect or exchange materials with the organisms; a community and its physical environment.

ecosystem diversity The variety of biotic components in a region along with abiotic components, such as soil, water, and nutrients.

ecosystem services Alterations of the physical components of an ecosystem by living organisms, especially beneficial changes in the quality of the atmosphere, soil, water, etc.

ectoderm The outermost of the three basic cell layers in most animal embryos; gives rise to the outer covering and nervous system. Compare with **endoderm** and **mesoderm.**

ectomycorrhizal fungi (EMF) Fungi whose hyphae form a dense network that covers their host plant's roots but do not enter the root cells.

ectoparasite A parasite that lives on the outer surface of the host's body.

ectotherm An animal that does not use internally generated heat to regulate its body temperature. Compare with **endotherm.**

effector Any cell, organ, or structure with which an animal can respond to external or internal stimuli. Usually functions, along with a sensor and integrator, as part of a homeostatic system.

efferent division The part of the nervous system, consisting primarily of motor neurons, that carries commands from the central nervous system to the body.

egg A mature female gamete and any associated external layers (such as a shell). Larger and less mobile than the male gamete. In animals, also called *ovum.*

ejaculation The release of semen from the copulatory organ of a male animal.

ejaculatory duct A short duct connecting the vas deferens to the urethra, through which sperm move during ejaculation.

elastic Referring to a structure (e.g., lungs) with the ability to stretch and then spring back to its original shape.

electrical potential Potential energy created by a separation of electric charges between two points. Also called *voltage.*

electric current A flow of electrical charge past a point. Also called *current.*

electrocardiogram (EKG) A recording of the electrical activity of the heart, as measured through electrodes on the skin.

electrochemical gradient The combined effect of an ion's concentration gradient and electrical (charge) gradient across a membrane that affects the diffusion of ions across the membrane.

electrolyte Any compound that dissociates into ions when dissolved in water. In nutrition, refers to the major ions necessary for normal cell function.

electromagnetic spectrum The entire range of wavelengths of radiation extending from short wavelengths (high energy) to long wavelengths (low energy). Includes gamma rays, x-rays, ultraviolet, visible light, infrared, microwaves, and radio waves (from short to long wavelengths).

electron acceptor A reactant that gains an electron and is reduced in a reduction-oxidation reaction.

electron carrier Any molecule that readily accepts electrons from and donates electrons to other molecules.

electron donor A reactant that loses an electron and is oxidized in a reduction-oxidation reaction.

electronegativity A measure of the ability of an atom to attract electrons toward itself from an atom to which it is bonded.

electron microscope See **scanning electron microscope** and **transmission electron microscope.**

electron shell A group of orbitals of electrons with similar energies. Electron shells are arranged in roughly concentric layers around the nucleus of an atom, with electrons in outer shells having more energy than those in inner shells. Electrons in the outermost shell, the valence shell, often are involved in chemical bonding.

electron transport chain (ETC) Any set of membrane-bound protein complexes and smaller soluble electron carriers involved in a coordinated series of redox reactions in which the potential energy of electrons transferred from reduced donors is successively decreased and used to pump protons from one side of a membrane to the other.

electroreceptor A sensory cell or organ specialized to detect electric fields.

element A substance, consisting of atoms with a specific number of protons, that cannot be separated into or broken down to any other substance. Elements preserve their identity in chemical reactions.

elongation (1) The process by which messenger RNA lengthens during transcription. (2) The process by which a polypeptide chain lengthens during translation.

elongation factors Proteins involved in the elongation phase of translation, assisting ribosomes in the synthesis of the growing peptide chain.

embryo A young developing organism; the stage after fertilization and zygote formation.

embryo sac The female gametophyte in flowering plants that exhibit alternation of generations.

embryogenesis The process by which a single-celled zygote becomes a multicellular embryo.

embryophyte A plant that nourishes its embryos inside its own body. All land plants are embryophytes.

emergent vegetation Any plants in an aquatic habitat that extend above the surface of the water.

emerging disease Any infectious disease, often a viral disease, that suddenly afflicts significant numbers of humans for the first time; often due to changes in the host species for a pathogen or host population movements.

emigration The migration of individuals away from one population to other populations. Compare with **immigration.**

emulsification (verb: emulsify) The dispersion of fat into an aqueous solution. Usually requires the aid of an amphipathic substance such as a detergent or bile salts, which can break large fat globules into microscopic fat droplets.

endangered species A species whose numbers have decreased so much that it is in danger of extinction throughout all or part of its range.

endemic species A species that lives in one geographic area and nowhere else.

endergonic Referring to a chemical reaction that requires an input of energy to occur and for which the Gibbs free-energy change (ΔG) > 0. Compare with **exergonic.**

endocrine Relating to a chemical signal (hormone) that is released into the bloodstream by a producing cell and acts on a distant target cell.

endocrine gland A gland that secretes hormones directly into the bloodstream or interstitial fluid instead of into ducts. Compare with **exocrine gland.**

endocrine system All of the glands and tissues that produce and secrete hormones into the bloodstream.

endocytosis General term for any pinching off of the plasma membrane that results in the uptake of material from outside the cell. Includes phagocytosis, pinocytosis, and receptor-mediated endocytosis. Compare with **exocytosis.**

endoderm The innermost of the three basic cell layers in most animal embryos; gives rise to the digestive tract and organs that connect to it (liver, lungs, etc.). Compare with **ectoderm** and **mesoderm.**

endodermis In plant roots, a cylindrical layer of cells that separates the cortex from the vascular tissue.

endomembrane system A system of organelles in eukaryotic cells that performs most protein and lipid synthesis. Includes the endoplasmic reticulum (ER), Golgi apparatus, and lysosomes.

endoparasite A parasite that lives inside the host's body.

endophyte (adjective: endophytic) A fungus that lives inside the aboveground parts of a plant in a symbiotic relationship. Compare with **epiphyte.**

endoplasmic reticulum (ER) A network of interconnected membranous sacs and tubules found inside eukaryotic cells. See **rough** and **smooth endoplasmic reticulum.**

endoskeleton Bony and/or cartilaginous structures within the body that provide support. Examples are the spicules of sponges, the plates in echinoderms, and the bony skeleton of vertebrates. Compare with **exoskeleton.**

endosome See **early** and **late endosome.**

endosperm A triploid ($3n$) tissue in the seed of a flowering plant (angiosperm) that serves as food for the plant embryo. Functionally analogous to the yolk in some animal eggs.

endosymbiont An organism that lives in a symbiotic relationship inside the body of its host.

endosymbiosis theory The theory that mitochondria and chloroplasts evolved from prokaryotes that were engulfed by host cells and took up a symbiotic existence within those cells, a process termed primary endosymbiosis. In some eukaryotes, chloroplasts originated by secondary endosymbiosis, that is, by engulfing a chloroplast-containing protist and retaining its chloroplasts.

endotherm An animal whose primary source of body heat is internally generated heat. Compare with **ectotherm.**

endothermic Referring to a chemical reaction that absorbs heat. Compare with **exothermic.**

energetic coupling In cellular metabolism, the mechanism by which energy released from an exergonic reaction (commonly, hydrolysis of ATP) is used to drive an endergonic reaction.

energy The capacity to do work or to supply heat. May be stored (potential energy) or available in the form of motion (kinetic energy).

enhancer A regulatory sequence in eukaryotic DNA that may be located far from the gene it controls or within introns of the gene. Binding of specific proteins to an enhancer enhances the transcription of certain genes.

enrichment culture A method of detecting and obtaining cells with specific characteristics by placing a sample, containing many types of cells, under a specific set of conditions (e.g., temperature, salt concentration, available nutrients) and isolating those cells that grow rapidly in response.

entropy (S) A quantitative measure of the amount of disorder of any system, such as a group of molecules.

envelope, viral A membrane-like covering that encloses some viruses and their capsid coats, shielding them from attack by the host's immune system.

environmental sequencing The inventory of all the genes in a community or ecosystem by sequencing, analyzing, and comparing the genomes of the component organisms.

enzyme A protein catalyst used by living organisms to speed up and control biological reactions.

epicotyl In some embryonic plants, a portion of the embryonic stem that extends above the cotyledons.

epidemic The spread of an infectious disease throughout a population in a short time period. Compare with **pandemic.**

epidermis The outermost layer of cells of any multicellular organism.

epididymis A coiled tube wrapped around the testis in reptiles, birds, and mammals. The site of the final stages of sperm maturation and storage.

epigenetic inheritance Pattern of inheritance involving differences in phenotype that are not due to changes in the nucleotide sequence of genes.

epinephrine A catecholamine hormone, produced and secreted by the adrenal medulla, that triggers rapid responses relating to the fight-or-flight response. Also called *adrenaline.*

epiphyte (adjective: epiphytic) A nonparasitic plant that grows on trees or other solid objects and is not rooted in soil.

epithelium (plural: epithelia) An animal tissue consisting of sheet-like layers of tightly packed cells that lines an organ, a duct, or a body surface. Also called *epithelial tissue.*

epitope A small region of a particular antigen to which an antibody, B-cell receptor, or T-cell receptor binds.

equilibrium curve See **oxygen-hemoglobin equilibrium curve.**

equilibrium potential The membrane potential at which there is no net movement of a particular ion into or out of a cell.

ER signal sequence A short amino acid sequence that marks a polypeptide for transport to the endoplasmic reticulum where synthesis of the polypeptide chain is completed and the signal sequence removed. See **signal recognition particle.**

erythrocyte See **red blood cell.**

erythropoietin (EPO) A peptide hormone, released by the kidney in response to low blood oxygen levels, that stimulates the bone marrow to produce more red blood cells.

esophagus The muscular tube that connects the mouth to the stomach.

essential amino acid An amino acid that an animal cannot synthesize and must obtain from the diet. May refer specifically to one of the eight essential amino acids of adult humans: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine.

essential nutrient Any chemical element, ion, or compound that is required for normal growth, reproduction, and maintenance of a living organism and that cannot be synthesized by the organism.

ester linkage The covalent bond formed by a condensation reaction between a carboxyl group (−COOH) and a hydroxyl group (−OH). Ester linkages join fatty acids to glycerol to form a fat or phospholipid.

estradiol The major estrogen produced by the ovaries of female mammals. Stimulates development of the female reproductive tract, growth of ovarian follicles, and growth of breast tissue.

estrogens A class of steroid hormones, including estradiol, estrone, and estriol, that generally promote female-like traits. Secreted by the gonads, fat tissue, and some other organs.

estrous cycle A female reproductive cycle, seen in all mammals except Old World monkeys and apes (including humans), in which the uterine lining is reabsorbed rather than shed in the absence of pregnancy, and the female is sexually receptive only briefly during mid-cycle (estrus). Compare with **menstrual cycle.**

estuary An environment of brackish (partly salty) water where a river meets the ocean.

ethylene A gaseous plant hormone that induces fruits to ripen, flowers to fade, and leaves to drop.

eudicot A member of a monophyletic group (lineage) of angiosperms that includes complex flowering plants and trees (e.g., roses, daisies, maples). All eudicots have two cotyledons, but not all dicots are members of this lineage. Compare with **dicot** and **monocot.**

Eukarya One of the three taxonomic domains of life consisting of unicellular organisms (most protists, yeast) and multicellular organisms (fungi, plants, animals) distinguished by a membrane-bound cell nucleus, numerous organelles, and an extensive cytoskeleton. Compare with **Archaea** and **Bacteria.**

eukaryote A member of the domain Eukarya; an organism whose cells contain a nucleus, numerous membrane-bound organelles, and an extensive cytoskeleton. May be unicellular or multicellular. Compare with **prokaryote.**

eutherians A lineage of mammals (Eutheria) whose young develop in the uterus and are not housed in an abdominal pouch. Also called *placental mammals.*

evaporation The energy-absorbing phase change from a liquid state to a gaseous state. Many organisms evaporate water as a means of heat loss.

evo-devo Research field focused on how changes in developmentally important genes have led to the evolution of new phenotypes.

evolution (1) The theory that all organisms on Earth are related by common ancestry and that they have changed over time, predominantly via natural selection. (2) Any change in the genetic characteristics of a population over time, especially, a change in allele frequencies.

excitable membrane A plasma membrane that is capable of generating an action potential. Neurons, muscle cells, and some other cells have excitable membranes.

excitatory postsynaptic potential (EPSP) A change in membrane potential, usually depolarization, at a neuron dendrite that makes an action potential more likely.

exergonic Referring to a chemical reaction that can occur spontaneously, releasing heat and/or increasing entropy, and for which the Gibbs free-energy change (ΔG) < 0. Compare with **endergonic.**

exocrine gland A gland that secretes some substance through a duct into a space other than the circulatory system, such as the digestive tract or the skin surface. Compare with **endocrine gland.**

exocytosis Secretion of intracellular molecules (e.g., hormones, collagen), contained within membrane-bounded vesicles, to the outside of the cell by fusion of vesicles to the plasma membrane. Compare with **endocytosis.**

exon A region of a eukaryotic gene that is translated into a peptide or protein. Compare with **intron.**

exoskeleton A hard covering secreted on the outside of the body, used for body support, protection, and muscle attachment. Examples are the shell of molluscs and the outer covering (cuticle) of arthropods. Compare with **endoskeleton.**

exothermic Referring to a chemical reaction that releases heat. Compare with **endothermic.**

exotic species A nonnative species that is introduced into a new area. Exotic species often are competitors, pathogens, or predators of native species.

expansins A class of plant proteins that actively increase the length of the cell wall when the pH of the wall falls below 4.5.

exponential population growth The accelerating increase in the size of a population that occurs when the growth rate is constant and density independent. Compare with **logistic population growth.**

extensor A muscle that pulls two bones farther apart from each other, as in the extension of a limb or the spine. Compare with **flexor.**

extinct Said of a species that has died out.

extracellular digestion Digestion that takes place outside of an organism, as occurs in many fungi that make and secrete digestive enzymes.

extracellular matrix (ECM) A complex meshwork of proteins (e.g., collagen, fibronectin) and polysaccharides secreted by animal cells and in which they are embedded.

extremophile A bacterium or archaean that thrives in an "extreme" environment (e.g., high-salt, high-temperature, low-temperature, or low-pressure).

F_1 generation First filial generation. The first generation of offspring produced from a mating (i.e., the offspring of the parental generation).

facilitated diffusion Movement of a substance across a plasma membrane down its concentration gradient with the assistance of transmembrane carrier proteins or channel proteins.

facilitation In ecological succession, the phenomenon in which early-arriving species make conditions more favorable for later-arriving species. Compare with **inhibition** and **tolerance.**

facultative aerobe Any organism that can perform aerobic respiration when oxygen is available to serve as an electron acceptor but can switch to fermentation when it is not.

FAD/$FADH_2$ Oxidized and reduced forms, respectively, of flavin adenine dinucleotide. A nonprotein electron carrier that functions in the Krebs cycle and oxidative phosphorylation.

fallopian tube A narrow tube connecting the uterus to the ovary in humans, through which the egg travels after ovulation. Site of fertilization and cleavage. In nonhuman animals, called *oviduct.*

family In Linnaeus' system, a taxonomic category above genus and below order. In animals, family names usually end in the suffix *-idae*; Canidae (dogs, wolves and foxes) and Felidae (cats) are both in the order Carnivora.

fat A lipid consisting of three fatty acid molecules joined by ester linkages to a glycerol molecule. Also called *triacylglycerol* or *triglyceride.*

fatty acid A lipid consisting of a hydrocarbon chain bonded to a carboxyl group ($-COOH$) at one end. Used by many organisms to store chemical energy; a major component of animal and plant fats.

fauna All the animals characteristic of a particular region, period, or environment.

feather A specialized skin outgrowth, composed of β-keratin, present in all birds and only in birds. Used for flight, insulation, display, and other purposes.

feces The waste products of digestion.

fecundity The average number of female offspring produced by a single female in the course of her lifetime.

feedback inhibition A type of metabolic control in which high concentrations of the product of a metabolic pathway inhibit one of the enzymes early in the pathway. A form of negative feedback.

fermentation Any of several metabolic pathways that make ATP by transferring electrons from a reduced compound such as glucose to a final electron acceptor other than oxygen. Allows glycolysis to proceed in the absence of oxygen.

ferredoxin In photosynthetic organisms, an iron- and sulfur-containing protein in the electron transport chain of photosystem I. Can transfer electrons to the enzyme $NADP^+$ reductase, which catalyzes formation of NADPH.

fertilization Fusion of the nuclei of two haploid gametes to form a zygote with a diploid nucleus.

fertilization envelope A physical barrier that forms around a fertilized egg in amphibians and some other animals. Formed by an influx of water under the vitelline membrane.

fetal alcohol syndrome A condition, marked by hyperactivity, severe learning disabilities, and depression, thought to be caused by exposure of an individual to high blood alcohol concentrations during embryonic development.

fetus In live-bearing animals, the unborn offspring after the embryonic stage, which usually are developed sufficiently to be recognizable as belonging to a certain species. In humans, from 9 weeks after fertilization until birth.

fiber In plants, a type of elongated sclerenchyma cell that provides support to vascular tissue. Compare with **sclereid.**

fibronectin An abundant protein in the extracellular matrix that binds to other ECM components and to integrins in plasma membranes; helps anchor cells in place. Numerous subtypes are found in different tissues.

Fick's law of diffusion A mathematical relationship that describes the rates of gas exchange in animal respiratory systems.

fight-or-flight response Rapid physiological changes that prepare the body for emergencies. Includes increased heart rate, increased blood pressure, and decreased digestion.

filament Any thin, threadlike structure, particularly (1) the threadlike extensions of a fish's gills or (2) the slender stalk that bears the anthers in a flower.

filter feeder See **suspension feeder.**

filtrate Any fluid produced by filtration, in particular the fluid (pre-urine) in the nephrons of vertebrate kidneys.

filtration A process of removing large components from a fluid by forcing it through a filter. Occurs in a renal corpuscle of the vertebrate kidney, allowing water and small solutes to pass from the blood into the nephron.

finite rate of increase (λ) The rate of increase of a population over a given period of time. Calculated as the ending population size divided by the starting population size. Compare with **intrinsic rate of increase.**

first law of thermodynamics The principle of physics that energy is conserved in any process. Energy can be transferred and converted into different forms, but it cannot be created or destroyed.

fission (1) A form of asexual reproduction in which a prokaryotic cell divides to produce two genetically similar daughter cells by a process similar to mitosis of eukaryotic cells. Also called *binary fission.* (2) A form of asexual reproduction in which an animal splits into two or more individuals of approximately equal size; common among invertebrates.

fitness The relative ability of an individual to produce viable offspring compared with other individuals in the same population. Also called *Darwinian fitness.*

fitness trade-off See **trade-off.**

fixed action pattern (FAP) Highly stereotyped behavior pattern that occurs in a certain invariant way in a certain species. A form of innate behavior.

flaccid Limp as a result of low internal pressure (e.g., a wilted plant leaf). Compare with **turgid.**

flagellum (plural: flagella) A long, cellular projection that undulates (in eukaryotes) or rotates (in prokaryotes) to move the cell through an aqueous environment. See **axoneme.**

flatworms Members of the phylum Platyhelminthes. Distinguished by a broad, flat, unsegmented body that lacks a coelom. Flatworms belong to the lophotrochozoan branch of the protostomes.

flavin adenine dinucleotide See **FAD/$FADH_2$.**

flexor A muscle that pulls two bones closer together, as in the flexing of a limb or the spine. Compare with **extensor.**

floral meristem A group of undifferentiated plant cells that can give rise to the four organs making up a flower.

florigen In plants, a protein hormone that is synthesized in leaves and transported to the shoot apical meristem where it stimulates flowering.

flower In angiosperms, the part of a plant that contains reproductive structures. Typically includes a calyx, a corolla, and one or more stamens and/or carpels. See **perfect** and **imperfect flower.**

fluid feeder An animal that feeds by sucking or mopping up liquids such as nectar, plant sap, or blood.

fluid-mosaic model The widely accepted hypothesis that the plasma membrane and organelle membranes consist of proteins embedded in a fluid phospholipid bilayer.

fluorescence The spontaneous emission of light from an excited electron falling back to its normal (ground) state.

follicle An egg cell and its surrounding ring of supportive cells in a mammalian ovary.

follicle-stimulating hormone (FSH) A peptide hormone, produced and secreted by the anterior pituitary, that stimulates (in females) growth of eggs and follicles in the ovaries or (in males) sperm production in the testes.

follicular phase The first major phase of a menstrual cycle during which follicles grow and estrogen levels increase; ends with ovulation.

food Any nutrient-containing material that can be consumed and digested by animals.

food chain A relatively simple pathway of energy flow through a few species, each at a different trophic level, in an ecosystem. Might include, for example, a primary producer, a primary consumer, a secondary consumer, and a decomposer. Compare with **food web.**

food vacuole A membrane-bound organelle containing food ingested by a cell via phagocytosis.

food web Any complex pathway along which energy moves among many species at different trophic levels of an ecosystem.

foot One of the three main parts of the mollusc body; a muscular appendage, used for movement and/or burrowing into sediment.

forebrain One of the three main regions of the vertebrate brain; includes the cerebrum, thalamus, and hypothalamus. Compare with **hindbrain** and **midbrain.**

fossil Any trace of an organism that existed in the past. Includes tracks, burrows, fossilized bones, casts, etc.

fossil record All of the fossils that have been found anywhere on Earth and that have been formally described in the scientific literature.

founder effect A change in allele frequencies that often occurs when a new population is established from a small group of individuals (founder event) due to sampling error (i.e., the small group is not a representative sample of the source population).

free energy See **Gibbs free-energy change.**

free radical Any substance containing one or more atoms with an unpaired electron. Unstable and highly reactive.

frequency The number of wave crests per second traveling past a stationary point. Determines the pitch of sound and the color of light.

fronds The large leaves of ferns.

fruit In flowering plants (angiosperms), a mature, ripened plant ovary (or group of ovaries), along with the seeds it contains and any adjacent fused parts. See **aggregate, multiple,** and **simple fruit.**

fruiting body A structure formed in some prokaryotes, fungi, and protists for spore dispersal; usually consists of a base, a stalk, and a mass of spores at the top.

functional genomics The study of how a genome works, that is, when and where specific genes are expressed and how their products interact to produce a functional organism.

functional group A small group of atoms bonded together in a precise configuration and exhibiting particular chemical properties that it imparts to any organic molecule in which it occurs.

fundamental niche The ecological space that a species occupies in its habitat in the absence of competitors. Compare with **realized niche.**

fungi A lineage of eukaryotes that typically have a filamentous body (mycelium) and obtain nutrients by absorption.

fungicide Any substance that can kill fungi or slow their growth.

G_1 phase The phase of the cell cycle that constitutes the first part of interphase before DNA synthesis (S phase).

G_2 phase The phase of the cell cycle between synthesis of DNA (S phase) and mitosis (M phase); the last part of interphase.

gall A tumorlike growth that forms on plants infected with certain bacteria or parasites.

gallbladder A small pouch that stores bile from the liver and releases it as needed into the small intestine during digestion of fats.

gametangium (plural: gametangia) (1) The gamete-forming structure found in all land plants except angiosperms. Contains a sperm-producing antheridium and an egg-producing archegonium. (2) The gamete-forming structure of some chytrid fungi.

gamete A haploid reproductive cell that can fuse with another haploid cell to form a zygote. Most multicellular eukaryotes have two distinct forms of gametes: egg cells (ova) and sperm cells.

gametogenesis The production of gametes (eggs or sperm).

gametophyte In organisms undergoing alternation of generations, the multicellular haploid form that arises from a single haploid spore and produces gametes. A female gametophyte is commonly called an *embryo sac*; a male gametophyte, a *pollen grain*. Compare with **sporophyte.**

ganglion cell A neuron in the vertebrate retina that collects visual information from one or several bipolar cells and sends it to the brain via the optic nerve.

gap junction A type of cell-cell attachment structure that directly connects the cytoplasms of adjacent animal cells, allowing passage of water, ions, and small molecules between the cells. Compare with **desmosome** and **tight junction.**

gastrin A hormone produced by cells in the stomach lining in response to the arrival of food or to a neural signal from the brain. Stimulates other stomach cells to release hydrochloric acid.

gastrointestinal (GI) tract See **digestive tract.**

gastropods A lineage of mollusc distinguished by a large muscular foot and a unique feeding structure, the radula. Include slugs and snails.

gastrulation The process by which some cells on the outside of a young embryo move to the interior of the embryo, resulting in the three distinct germ layers (endoderm, mesoderm, and ectoderm).

gated channel A channel protein that opens and closes in response to a specific stimulus, such as the binding of a particular molecule or a change in the electrical charge on the outside of the membrane.

gel electrophoresis A technique for separating molecules on the basis of size and electric charge, which affect their differing rates of movement through a gelatinous substance in an electric field.

gemma (plural: gemmae) A small reproductive structure that is produced in some liverworts during the gametophyte phase and can grow into mature gametophyte.

gene A section of DNA (or RNA, for some viruses) that encodes information for building one or more related polypeptides or functional RNA molecules along with the regulatory sequences required for its transcription.

gene duplication The formation of an additional copy of a gene, typically by misalignment of chromosomes during crossing over. Thought to be an important evolutionary process in creating new genes.

gene expression Overall process by which the information encoded in genes is converted into an active product, most commonly a protein. Includes transcription and translation of a gene and in some cases protein activation.

gene family A set of genetic loci whose DNA sequences are extremely similar. Thought to have arisen by duplication of a single ancestral gene and subsequent mutations in the duplicated sequences.

gene flow The movement of alleles between populations; occurs when individuals leave one population, join another, and breed.

gene-for-gene hypothesis The hypothesis that there is a one-to-one correspondence between the resistance (*R*) loci of plants and the avirulence (*avr*) loci of pathogenic fungi; particularly, that *R* genes produce receptors and *avr* genes produce molecules that bind to those receptors.

gene pool All of the alleles of all of the genes in a certain population.

generation The average time between a mother's first offspring and her daughter's first offspring.

gene therapy The treatment of an inherited disease by introducing normal alleles.

genetic bottleneck A reduction in allelic diversity resulting from a sudden reduction in the size of a large population (population bottleneck) due to a random event.

genetic code The set of all 64 codons and the particular amino acids that each specifies.

genetic correlation A type of evolutionary constraint in which selection on one trait causes a change in another trait as well; may occur when the same gene(s) affect both traits.

genetic diversity The diversity of alleles in a population, species, or group of species.

genetic drift Any change in allele frequencies due to random events. Causes allele frequencies to drift up and down randomly over time, and eventually can lead to the fixation or loss of alleles.

genetic homology Similarities in DNA sequences or amino acid sequences that are due to inheritance from a common ancestor.

genetic map An ordered list of genes on a chromosome that indicates their relative distances from each other. Also called a *linkage map* or *meiotic map*. Compare with **physical map.**

genetic marker A genetic locus that can be identified and traced in populations by laboratory techniques or by a distinctive visible phenotype.

genetic model A set of hypotheses that explain how a certain trait is inherited.

genetic recombination A change in the combination of genes or alleles on a given chromosome or in a given individual. Also called *recombination*.

genetics The field of study concerned with the inheritance of traits.

genetic screen Any of several techniques for identifying individuals with a particular type of mutation. Also called a *screen*.

genetic variation (1) The number and relative frequency of alleles present in a particular population. (2) The proportion of phenotypic variation in a trait that is due to genetic rather than environmental influences in a certain population in a certain environment.

genitalia External copulatory organs.

genome All of the hereditary information in an organism, including not only genes but also other non-gene stretches of DNA.

genomic library A set of DNA segments representing the entire genome of a particular organism. Each segment is carried by a plasmid or other cloning vector and can be separated from other segments. Compare with **cDNA library.**

genomics The field of study concerned with sequencing, interpreting, and comparing whole genomes from different organisms.

genotype All of the alleles of every gene present in a given individual. May refer specifically to the alleles of a particular set of genes under study. Compare with **phenotype.**

genus (plural: genera) In Linnaeus' system, a taxonomic category of closely related species. Always italicized and capitalized to indicate that it is a recognized scientific genus.

geologic time scale The sequence of eons, epochs, and periods used to describe the geologic history of Earth.

geometric isomer A molecule that shares the same molecular formula as another molecule but differs in the arrangement of atoms or groups on either side of a double bond or ring structure. Compare with **optical isomer** and **structural isomer.**

germ cell In animals, any cell that can potentially give rise to gametes. Also called *germ-line cells*.

germination The process by which a seed becomes a young plant.

germ layer In animals, one of the three basic types of tissue formed during gastrulation; gives rise to all other tissues. See **endoderm, mesoderm,** and **ectoderm.**

germ theory of disease The theory that infectious diseases are caused by bacteria, viruses, and other microorganisms.

gestation The duration of embryonic development from fertilization to birth in those species that have live birth.

gibberellins A class of hormones found in plants and fungi that stimulate growth. Gibberellic acid is one of the major gibberellins.

Gibbs free-energy change (ΔG) A measure of the change in potential energy and entropy that occurs in a given chemical reaction. $\Delta G < 0$ for spontaneous reactions and >0 for nonspontaneous reactions.

gill Any organ in aquatic animals that exchanges gases and other dissolved substances between the blood and the surrounding water. Typically, a filamentous outgrowth of a body surface.

gill arch In aquatic vertebrates, curved region of tissue between the gills. Gills are suspended from the gill arches.

gill filament In fish, one of the many long, thin structures that extend from gill arches into the water and across which gas exchange occurs.

gill lamella (plural: gill lamellae) One of hundreds to thousands of sheetlike structures, each containing a capillary bed, that makes up a gill filament.

gland An organ whose primary function is to secrete some substance, either into the blood (endocrine gland) or into some other space such as the gut or skin (exocrine gland).

glia Collective term for several types of cells in nervous tissue that are not neurons and do not conduct electrical signals but provide support, nourishment, and electrical insulation and perform other functions. Also called *glial cells*.

global warming A sustained increase in Earth's average surface temperature.

glomerulus (plural: glomeruli) (1) In the vertebrate kidney, a ball-like cluster of capillaries, surrounded by Bowman's capsule, at the beginning of a nephron. (2) In the brain, a ball-shaped cluster of neurons in the olfactory bulb.

glucagon A peptide hormone produced by the pancreas in response to low blood glucose. Raises blood glucose by triggering breakdown of glycogen and stimulating gluconeogenesis. Compare with **insulin.**

glucocorticoids A class of steroid hormones, produced and secreted by the adrenal cortex, that increase blood glucose and prepare the body for stress. Include cortisol and corticosterone. Compare with **mineralocorticoids.**

gluconeogenesis Synthesis of glucose from non-carbohydrate sources (e.g., proteins and fatty acids). Occurs in the liver in response to low insulin levels and high glucagon levels.

glucose Six-carbon monosaccharide whose oxidation in cellular respiration is the major source of ATP in animal cells.

glyceraldehyde-3-phosphate (G3P) The phosphorylated three-carbon compound formed as the result of carbon fixation in the first step of the Calvin cycle.

glycerol A three-carbon molecule that forms the "backbone" of phospholipids and most fats.

glycogen A highly branched storage polysaccharide composed of α-glucose monomers joined by 1,4- and 1,6-glycosidic linkages. The major form of stored carbohydrate in animals.

glycolipid Any lipid molecule that is covalently bonded to a carbohydrate group.

glycolysis A series of 10 chemical reactions that oxidize glucose to produce pyruvate and ATP. Used by all organisms as part of fermentation or cellular respiration.

glycoprotein Any protein with one or more covalently bonded carbohydrate groups.

glycosidic linkage The covalent bond formed by a condensation reaction between two sugar monomers; joins the residues of a polysaccharide.

glycosylation Addition of a carbohydrate group to a molecule.

glyoxisome Specialized type of peroxisome found in plant cells and packed with enzymes for processing the products of photosynthesis.

goblet cell A cell in the stomach lining that secretes mucus.

goiter A pronounced swelling of the thyroid gland; usually caused by a deficiency of iodine in the diet.

Golgi apparatus A eukaryotic organelle, consisting of stacks of flattened membranous sacs (cisternae), that functions in processing and sorting proteins and lipids destined to be secreted or directed to other organelles. Also called *Golgi complex*.

gonad An organ that produces reproductive cells, such as a testis or an ovary.

gonadotropin-releasing hormone (GnRH) A peptide hormone, produced and secreted by the hypothalamus, that stimulates release of FSH and LH from the anterior pituitary.

G protein Any of various peripheral membrane proteins that bind GTP and function in signal transduction. Binding of a signal to its receptor triggers activation of the G protein, leading to production of a second messenger or initiation of a phosphorylation cascade.

grade In taxonomy, a group of species that share a position in an inferred evolutionary sequence of lineages but that are not a monophyletic group. Also called a *paraphyletic group*.

Gram-negative Describing bacteria that look pink when treated with a Gram stain. These bacteria have a cell wall composed of a thin layer of peptidoglycan and an outer phospholipid layer.

Gram-positive Describing bacteria that look purple when treated with a Gram stain. These bacteria have cell walls composed of a thick layer of peptidoglycan.

Gram stain A dye that distinguishes the two general types of cell walls found in bacteria. Used to routinely classify bacteria as Gram-negative or Gram-positive.

granum (plural: grana) In chloroplasts, a stack of flattened, membrane-bound vesicles (thylakoids) where the light reactions of photosynthesis occur.

gravitropism The growth or movement of a plant in a particular direction in response to gravity.

grazing food chain The ecological network of herbivores and the predators and parasites that consume them.

great apes See **hominids.**

green algae A paraphyletic group of photosynthetic organisms that contain chloroplasts similar to those in green plants. Often classified as protists, green algae are the closest living relatives of land plants and form a monophyletic group with them.

greenhouse gas An atmospheric gas that absorbs and reflects infrared radiation, so that heat radiated from Earth is retained in the atmosphere instead of being lost to space.

green plant A member of a lineage of eukaryotes that includes green algae and land plants.

gross photosynthetic productivity The efficiency with which all the plants in a given area use the light energy available to them to produce sugars.

gross primary productivity In an ecosystem, the total amount of carbon fixed by photosynthesis, including that used for cellular respiration, over a given time period. Compare with **net primary productivity.**

ground meristem The middle layer of a young plant embryo. Gives rise to the ground tissue system.

ground tissue system In plants, all the tissues beneath the outer protective layers of epidermis and cork except for vascular tissue. Also called simply *ground tissue.*

groundwater Any water below the land surface.

growth factor Any of a large number of signaling molecules that are secreted by certain cells and that stimulate other cells to divide or to differentiate.

growth hormone (GH) A peptide hormone, produced and secreted by the mammalian anterior pituitary, that promotes lengthening of the long bones in children and muscle growth, tissue repair, and lactation in adults. Also called *somatotropin.*

GTP See **guanosine triphosphate.**

guanosine triphosphate (GTP) A molecule consisting of guanine, a sugar, and three phosphate groups. Can be hydrolyzed to release free energy. Commonly used in many cellular reactions; also functions in signal transduction in association with G proteins.

guard cell One of two specialized, crescent-shaped cells forming the border of a plant stoma. Guard cells can change shape to open or close the stoma. See also **stoma.**

gustation The perception of taste.

guttation Excretion of water droplets from plant leaves in the early morning, caused by root pressure.

gymnosperm A vascular plant that makes seeds but does not produce flowers. The gymnosperms include four lineages of green plants (cycads, ginkgoes, conifers, and gnetophytes). Compare with **angiosperm.**

habitat destruction Human-caused destruction of a natural habitat with replacement by an urban, suburban, or agricultural landscape.

habitat fragmentation The breakup of a large region of a habitat into many smaller regions, separated from others by a different type of habitat.

Hadley cell An atmospheric cycle of large-scale air movement in which warm equatorial air rises, moves north or south, and then descends at approximately 30°N or 30°S latitude.

hair cell A pressure-detecting sensory cell, found in the cochlea, that has tiny "hairs" (stereocilia) jutting from its surface.

hairpin A secondary structure in RNA consisting of a stable loop formed by hydrogen bonding between purine and pyrimidine bases on the same strand.

halophile A bacterium or archaean that thrives in high-salt environments.

halophyte A plant that thrives in salty habitats.

Hamilton's rule The proposition that an allele for altruistic behavior will be favored by natural selection only if $Br > C$, where B = the fitness benefit to the recipient, C = the fitness cost to the actor, and r = the coefficient of relatedness between recipient and actor.

haploid (1) Having one set of chromosomes ($1n$). (2) A cell or an individual organism with one set of chromosomes. Compare with **diploid.**

haploid number The number of distinct chromosome sets in a cell. Symbolized as n.

haplotype The set of alleles found on a single chromosome.

Hardy-Weinberg principle A principle of population genetics stating that genotype frequencies in a large population do not change from generation to generation in the absence of evolutionary processes (e.g., mutation, migration, genetic drift, random mating, and selection).

heart A muscular pump that circulates blood throughout the body.

heart murmur A distinctive sound caused by backflow of blood through a defective heart valve.

heartwood The older xylem in the center of an older stem or root, containing protective compounds and no longer functioning in water transport.

heat Thermal energy that is transferred from an object at higher temperature to one at lower temperature.

heat of vaporization The energy required to vaporize 1 gram of a liquid into a gas.

heavy chain The larger of the two types of polypeptide chains in an antibody molecule; composed of a variable (V) region, which contributes to the antigen-binding site, and a constant (C) region. Differences in heavy-chain constant regions determine the different classes of immunoglobulins (IgA, IgE, etc.). Compare with **light chain.**

helicase An enzyme that catalyzes the breaking of hydrogen bonds between nucleotides of DNA, "unzipping" a double-stranded DNA molecule.

helix-turn-helix motif A motif seen in many repressor proteins in prokaryotes, consisting of two α-helices connected by a short stretch of amino acids that form a turn.

helper T cell An effector T cell that secretes cytokines and in other ways promotes the activation of other lymphocytes. Is descended from an activated $CD4^+$ T cell that has interacted with antigen presented by dendritic cells, macrophages, or B cells.

hemimetabolous metamorphosis A type of metamorphosis in which the animal increases in size from one stage to the next, but does not dramatically change its body form. Also called *incomplete metamorphosis.*

hemocoel A body cavity, present in arthropods and some molluscs, containing a pool of circulatory fluid (hemolymph) bathing the internal organs.

hemoglobin An oxygen-binding protein consisting of four polypeptide subunits, each containing an oxygen-binding heme group. The major oxygen carrier in mammalian blood.

hemolymph The circulatory fluid of animals with open circulatory systems (e.g., insects) in which the fluid is not confined to blood vessels.

hemophilia A human disease, caused by an X-linked recessive allele, that is characterized by defects in the blood-clotting system.

herbaceous Referring to a plant that is not woody.

herbivore (adjective: herbivorous) An animal that eats primarily plants and rarely or never eats meat. Compare with **carnivore** and **omnivore.**

herbivory The practice of eating plant tissues.

heredity The transmission of traits from parents to offspring via genetic information.

heritable Referring to traits that can be transmitted from one generation to the next.

hermaphrodite An organism that produces both male and female gametes.

heterokaryotic Describing a cell or fungal mycelium containing two or more nuclei that are genetically distinct.

heterospory (adjective: heterosporous) In seed plants, the production of two distinct types of spore-producing structures and thus two distinct types of spores: microspores, which become the male gametophyte, and megaspores, which become the female gametophyte. Compare with **homospory.**

heterotherm An animal whose body temperature varies markedly with environmental conditions. Compare with **homeotherm.**

heterotroph Any organism that cannot synthesize reduced organic compounds from inorganic sources and that must obtain them by eating other organisms. Some bacteria, some archaea, and virtually all fungi and animals are heterotrophs. Also called *consumer.* Compare with **autotroph.**

heterozygote advantage A pattern of natural selection that favors heterozygous individuals compared with homozygotes. Tends to maintain genetic variation in a population. Also called *heterozygote superiority.*

heterozygous Having two different alleles of a certain gene.

hexose A monosaccharide (simple sugar) containing six carbon atoms.

hibernation An energy-conserving physiological state, marked by a decrease in metabolic rate, body temperature, and activity, that lasts for a prolonged period (weeks to months). Occurs in some animals in response to winter cold and scarcity of food. Compare with **torpor.**

hindbrain One of the three main regions of the vertebrate brain; includes the cerebellum and medulla oblongata. Compare with **forebrain** and **midbrain.**

histamine A molecule released from mast cells during an inflammatory response that causes blood vessels to dilate and become more permeable.

histone One of several positively charged (basic) proteins associated with DNA in the chromatin of eukaryotic cells.

histone acetyl transferase (HAT) In eukaryotes, one of a class of enzymes that loosen chromatin structure by adding acetyl groups to histone proteins.

histone deacetylase (HDAC) In eukaryotes, one of a class of enzymes that recondense chromatin by removing acetyl groups from histone proteins.

HIV See human immunodeficiency virus (HIV).

holoenzyme A multipart enzyme consisting of a core enzyme (containing the active site for catalysis) along with other required proteins.

holometabolous metamorphosis A type of metamorphosis in which the animal completely changes its form. Also called *complete metamorphosis*.

homeosis Replacement of one body part by another normally found elsewhere in the body as the result of mutation in certain developmentally important genes (homeotic genes).

homeostasis (adjective: homeostatic) The array of relatively stable chemical and physical conditions in an animal's cells, tissues, and organs. May be achieved by the body's passively matching the conditions of a stable external environment (conformational homeostasis) or by active physiological processes (regulatory homeostasis) triggered by variations in the external or internal environment.

homeotherm An animal that has a constant or relatively constant body temperature. Compare with **heterotherm.**

homeotic gene Any gene that specifies a particular location within an embryo, leading to the development of structures appropriate for that location. Mutations in homeotic genes cause the development of extra body parts or body parts in the wrong places.

hominids Members of the family Hominidae, which includes humans and extinct related forms; chimpanzees, gorillas, and orangutans. Distinguished by large body size, no tail, and an exceptionally large brain. Also called *great apes*.

hominins Humans and extinct related forms; species in the lineage that branched off from chimpanzees and eventually led to humans.

homologous chromosomes In a diploid organism, chromosomes that are similar in size, shape, and gene content. Also called *homologs*.

homology (adjective: homologous) Similarity among organisms of different species due to their inheritance from a common ancestor. Features that exhibit such similarity (e.g., DNA sequences, proteins, body parts) are said to be homologous. Compare with **homoplasy.**

homoplasy Similarity among organisms of different species due to convergent evolution. Compare with **homology.**

homospory (adjective: homosporous) In seedless vascular plants, the production of just one type of spore. Compare with **heterospory.**

homozygous Having two identical alleles of a certain gene.

hormone Any of numerous different signaling molecules that circulate throughout the body in blood or other body fluids and can trigger characteristic responses in distant target cells at very low concentrations.

hormone-response element A specific sequence in DNA to which a steroid hormone-receptor complex can bind and affect gene transcription.

host An individual or a species in or on which a parasite lives.

host cell A cell that has been invaded by an organism such as a parasite or a virus.

***Hox* genes** A class of homeotic genes found in several animal phyla, including vertebrates, that are expressed in a distinctive pattern along the anterior-posterior axis in early embryos and control formation of segment-specific structures.

human Any member of the genus *Homo*, which includes modern humans (*Homo sapiens*) and several extinct species.

human chorionic gonadotropin (hCG) A glycoprotein hormone produced by the human placenta from about week 3 to week 14 of pregnancy. Maintains the corpus luteum, which produces hormones that preserve the uterine lining.

Human Genome Project The multinational research project that sequenced the human genome.

human immunodeficiency virus (HIV) A retrovirus that causes AIDS (acquired immune deficiency syndrome) in humans.

humoral (immune) response The type of immune response that involves generation of antibody-secreting plasma cells from activated B cells. Defends against extracellular pathogens. Compare with **cell-mediated (immune) response.**

humus The completely decayed organic matter in soils.

Huntington's disease A degenerative brain disease of humans caused by an autosomal dominant allele.

hybrid The offspring of parents from two different strains, populations, or species.

hybrid zone A geographic area where interbreeding occurs between two species, sometimes producing fertile hybrid offspring.

hydrocarbon An organic molecule that contains only hydrogen and carbon atoms.

hydrogen bond A weak interaction between two molecules or different parts of the same molecule resulting from the attraction between a hydrogen atom with a partial positive charge and another atom (usually O or N) with a partial negative charge. Compare with **covalent bond** and **ionic bond.**

hydrogen ion (H^+) A single proton with a charge of 1+; typically, one that is dissolved in solution or that is being transferred from one atom to another in a chemical reaction.

hydrolysis A chemical reaction in which a molecule is split into smaller molecules by reacting with water. In biology, most hydrolysis reactions involve the splitting of polymers into monomers. Compare with **condensation reaction.**

hydrophilic Interacting readily with water. Hydrophilic compounds are typically polar compounds containing charged or electronegative atoms. Compare with **hydrophobic.**

hydrophobic Not interacting readily with water. Hydrophobic compounds are typically nonpolar compounds that lack charged or electronegative atoms and often contain many C−C and C−H bonds. Compare with **hydrophilic.**

hydroponic growth Growth of plants in liquid cultures instead of soil.

hydrostatic skeleton A system of body support involving fluid-filled compartments that can change in shape but cannot easily be compressed.

hydroxide ion (OH^-) An oxygen atom and a hydrogen atom joined by a single covalent bond and carrying a negative charge; formed by dissociation of water.

hyperpolarization Change in membrane potential from its resting negative state to an even more negative state; a normal phase in an action potential. Compare with **depolarization.**

hypersensitive response In plants, the rapid death of a cell that has been infected by a pathogen, thereby reducing the potential for infection to spread throughout a plant. Compare with **systemic acquired resistance.**

hypertension Abnormally high blood pressure.

hypertonic Comparative term designating a solution that has a greater solute concentration, and therefore a lower water concentration, than another solution. Compare with **hypotonic** and **isotonic.**

hypha (plural: hyphae) One of the strands of a fungal mycelium (the meshlike body of a fungus). Also found in some protists.

hypocotyl The stem of a very young plant; the region between the cotyledon (embryonic leaf) and the radicle (embryonic root).

hypothalamic-pituitary axis The functional interaction of the hypothalamus and the pituitary gland, which are anatomically distinct but work together to regulate most of the other endocrine glands in the body.

hypothalamus A part of the brain that functions in maintaining the body's internal physiological state by regulating the autonomic nervous system, endocrine system, body temperature, water balance, and appetite.

hypothesis A proposed explanation for a phenomenon or for a set of observations.

hypotonic Comparative term designating a solution that has a lower solute concentration, and therefore a higher water concentration, than another solution. Compare with **hypertonic** and **isotonic.**

immigration The migration of individuals into a particular population from other populations. Compare with **emigration.**

immune system In vertebrates, the system whose primary function is to defend the body against pathogens. Includes several types of cells (e.g., lymphocytes and macrophages) and several organs where they develop or reside (e.g., lymph nodes and thymus).

immunity (adjective: immune) State of being protected against infection by disease-causing pathogens either by relatively nonspecific mechanisms (innate immunity) or by specific mechanisms triggered by exposure to a particular antigen (acquired immunity).

immunization The conferring of immunity to a particular disease by artificial means.

immunoglobulin (Ig) Any of the class of proteins that function as antibodies.

immunological memory The ability of the immune system to "remember" an antigen and mount a rapid, effective response to a pathogen encountered years or decades earlier.

imperfect flower A flower that contains male parts (stamens) *or* female parts (carpels) but not both. Compare with **perfect flower.**

implantation The process by which an embryo buries itself in the uterine wall and forms a placenta. Occurs in mammals and a few other vertebrates.

imprinting A type of rapid, irreversible learning in which a young animal learns to recognize the individual caring for it. Occurs in birds and mammals.

inbreeding Mating between closely related individuals. Increases homozygosity of a population and often leads to a decline in the average fitness (inbreeding depression).

incomplete dominance An inheritance pattern in which the heterozygote phenotype is a blend or combination of both homozygote phenotypes.

incomplete metamorphosis See **hemimetabolous metamorphosis.**

independent assortment, principle of The concept that each pair of hereditary elements (alleles of the same gene) behaves independently of other genes during meiosis. One of Mendel's two principles of genetics.

indeterminate growth A pattern of growth in which an individual continues to increase its overall body size throughout its life.

indicator plate A laboratory technique for detecting mutant cells by growing them on agar plates containing a compound that when metabolized by wild-type cells yields a colored product.

induced fit Change in the shape of the active site of an enzyme, as the result of the initial weak binding of a substrate, so that it binds substrate more tightly.

inducer A small molecule that triggers transcription of a specific gene, often by binding to and inactivating a repressor protein.

inducible defense A defensive trait that is manifested only in response to the presence of a predator or pathogen. Compare with **constitutive defense.**

induction (1) The process by which one embryonic cell, or group of cells, alters the differentiation of neighboring cells. (2) Positive control of gene expression by a regulatory protein that binds to DNA and triggers transcription of a specific gene(s).

infection thread An invagination of the membrane of a root hair through which beneficial nitrogen-fixing bacteria enter the roots of their host plants (legumes).

inflammatory response An aspect of the innate immune response, seen in most cases of infection or tissue injury, in which the affected tissue becomes swollen, red, warm, and painful.

inhibition In ecological succession, the phenomenon in which early-arriving species make conditions less favorable for the establishment of certain later-arriving species. Compare with **facilitation** and **tolerance.**

inhibitory postsynaptic potential (IPSP) A change in membrane potential, usually hyperpolarization, at a neuron dendrite that makes an action potential less likely.

initiation (1) In an enzyme-catalyzed reaction, the stage during which enzymes orient reactants precisely as they bind at specific locations within the enzyme's active site. (2) In DNA transcription, the stage during which RNA polymerase and other proteins assemble at the promoter sequence. (3) In RNA translation, the stage during which a complex consisting of a ribosome, a mRNA molecule, and an aminoacyl tRNA corresponding to the start codon is formed.

initiation factors A class of proteins that assist ribosomes in binding to a messenger RNA molecule to begin translation.

innate behavior Behavior that is inherited genetically, does not have to be learned, and is typical of a species.

innate immune response See **innate immunity.**

innate immunity A set of nonspecific defenses against pathogens that exist before exposure to an antigen and involves mast cells, neutrophils, and macrophages; typically results in an inflammatory response. Compare with **acquired immunity.**

inner cell mass (ICM) A cluster of cells in the interior of a mammalian blastocyst that undergo gastrulation and eventually develop into the embryo.

inner ear The innermost portion of the mammalian ear, consisting of a fluid-filled system of tubes that includes the cochlea (which receives sound vibrations from the middle ear) and the semicircular canals (which function in balance).

insects The largest lineage of arthropods distinguished by having three body regions (a head, thorax, and abdomen), walking legs, and in most species one or two pairs of wings.

in situ hybridization A technique for detecting specific DNAs and mRNAs in cells and tissues by use of labeled probes. Can be used to determine where and when particular genes are expressed in embryos.

insulin A peptide hormone produced by the pancreas in response to high levels of glucose (or amino acids) in blood. Enables cells to absorb glucose and coordinates synthesis of fats, proteins, and glycogen. Compare with **glucagon.**

integral membrane protein Any membrane protein that spans the entire lipid bilayer. Also called *transmembrane protein.* Compare with **peripheral membrane protein.**

integration In the nervous system, processing of information from many sources.

integrator A component of an animal's nervous system that functions as part of a homeostatic system by evaluating sensory information and triggering appropriate responses. See **effector** and **sensor.**

integrin Any of a class of cell-surface proteins that bind to fibronectins and other proteins in the extracellular matrix, thus holding cells in place.

intercalated disc A specialized junction between adjacent heart muscle cells that contains gap junctions, allowing electrical signals to pass between the cells.

intermediate disturbance hypothesis The hypothesis that moderate ecological disturbance is associated with higher species diversity than either low or high disturbance.

intermediate filament A long fiber, about 10 nm in diameter, composed of one of various proteins (e.g., keratins, lamins); one of the three types of cytoskeletal fibers. Form networks that help maintain cell shape and hold the nucleus in place. Compare with **actin filament** and **microtubule.**

intermediate host The host species in which a parasite reproduces asexually. Compare with **definitive host.**

interneuron A neuron that passes signals from one neuron to another. Compare with **motor neuron** and **sensory neuron.**

internode The section of a plant stem between two nodes (sites where leaves attach).

interphase The portion of the cell cycle between one mitotic (M) phase and the next. Includes the G_1 phase, S phase, and G_2 phase.

interspecific competition Competition between members of different species for the same limited resource. Compare with **intraspecific competition.**

interstitial fluid The plasma-like fluid found in the region (interstitial space) between cells.

intertidal zone The region between the low-tide and high-tide marks on a seashore.

intraspecific competition Competition between members of the same species for the same limited resource. Compare with **interspecific competition.**

intrinsic rate of increase (r_{max}) The rate at which a population will grow under optimal conditions (i.e., when birthrates are as high as possible and death rates are as low as possible). Compare with **finite rate of increase.**

intron A region of a eukaryotic gene that is transcribed into RNA but is later removed, so it is not translated into a peptide or protein. Compare with **exon.**

invasive species An exotic (nonnative) species that, upon introduction to a new area, spreads rapidly and competes successfully with native species.

inversion A mutation in which a segment of a chromosome breaks from the rest of the chromosome, flips, and rejoins with the opposite orientation as before.

invertebrates A paraphyletic group composed of animals without a backbone; includes about 95 percent of all animal species. Compare with **vertebrates.**

ion An atom or a molecule that has lost or gained electrons and thus carries an electric charge, either positive (cation) or negative (anion), respectively.

ion channel A type of channel protein that allows certain ions to diffuse across a plasma membrane down an electochemical gradient.

ionic bond A chemical bond that is formed when an electron is completely transferred from one atom to another so that the atoms remain associated due to their opposite electric charges. Compare with **covalent bond** and **hydrogen bond.**

iris A ring of pigmented muscle just below the cornea in the vertebrate eye that contracts or expands to control the amount of light entering the eye through the pupil.

islets of Langerhans Clusters of cells in the pancreas that secrete insulin and glucagon directly into the blood.

isomer A molecule that has the same molecular formula as another molecule but differs from it in three-dimensional structure.

isotonic Comparative term designating a solution that has the same solute concentration and water concentration than another solution. Compare with **hypertonic** and **hypotonic.**

isotope Any of several forms of an element that have the same number of protons but differ in the number of neutrons.

joint A place where two components (bones, cartilages, etc.) of a skeleton meet. May be movable (an articulated joint) or immovable (e.g., skull sutures).

juvenile hormone An insect hormone that prevents larvae from metamorphosing into adults.

karyogamy Fusion of two haploid nuclei to form a diploid nucleus. Occurs in many fungi, and in animals and plants during fertilization of gametes.

karyotype The distinctive appearance of all of the chromosomes in an individual, including the number of chromosomes and their length and banding patterns (after staining with dyes).

keystone species A species that has an exceptionally great impact on the other species in its ecosystem relative to its abundance.

kidney In terrestrial vertebrates, one of a paired organ situated at the back of the abdominal cavity that filters the blood, produces urine, and secretes several hormones.

kilocalorie (kcal) A unit of energy often used to measure the energy content of food. Also called *Calorie*.

kinesin Any one of a class of motor proteins that use the chemical energy of ATP to transport vesicles, particles, or chromosomes along microtubules.

kinetic energy The energy of motion. Compare with **potential energy.**

kinetochore A protein structure at the centromere where spindle fibers attach to the sister chromatids of a replicated chromosome. Contains motor proteins that move a chromosome along a microtubule.

kingdom In Linnaeus' system, a taxonomic category above the phylum level and below the domain level.

kinocilium (plural: kinocilia) A single cilium that juts from the surface of many hair cells and functions in detection of sound or pressure.

kin selection A form of natural selection that favors traits that increase survival or reproduction of an individual's kin at the expense of the individual.

Klinefelter syndrome A syndrome seen in humans who have an XXY karyotype. People with this syndrome have male sex organs, may have some female traits, and are sterile.

knock-out mutant A mutant allele that does not function at all, or an organism homozygous for such a mutation. Also called *null mutant* or *loss-of-function mutant*.

Koch's postulates Four criteria used to determine whether a suspected infectious agent causes a particular disease.

Krebs cycle A series of chemical reactions, occurring in mitochondria, in which acetyl CoA is oxidized to CO_2, producing ATP and reduced compounds for the electron transport chain. Also called *citric acid cycle*.

labia major (plural: labium majus) One of two outer folds of skin that protect the labia minora, clitoris, and vaginal opening of female mammals.

labia minora (plural: labium minus) One of two inner folds of skin that protect the opening of the urethra and vagina.

labor The strong muscular contractions of the uterus that expel the fetus during birth.

lactation (verb: lactate) Production of milk from mammary glands of mammals.

lacteal A small lymphatic vessel extending into the center of a villus in the small intestine. Receives chylomicrons containing fat absorbed from food.

lactic acid fermentation Catabolic pathway in which pyruvate produced by glycolysis is converted to lactic acid in the absence of oxygen.

lagging strand In DNA replication, the strand of new DNA that is synthesized discontinuously in a series of short pieces that are later joined together. Also called *discontinuous strand*. Compare with **leading strand.**

lamellae (singular: lamella) Any set of parallel platelike structures (e.g., the crescent-shaped flaps on the gill filaments of fish gills that serve to increase surface area for gas exchange).

large intestine The distal portion of the digestive tract consisting of the cecum, colon, and rectum. Its primary function is to compact the wastes delivered from the small intestine and absorb enough water to form feces.

larva (plural: larvae) An immature stage of a species in which the immature and adult stages have different body forms.

late endosome A membrane-bound vesicle that arises from an early endosome and develops into a lysosome.

lateral bud A bud that forms in the angle between a leaf and a stem and may develop into a lateral (side) branch. Also called *axillary bud*.

lateral gene transfer Transfer of DNA between two different species, especially distantly related species. Commonly occurs among bacteria and archaea via plasmid exchange; also can occur in eukaryotes via viruses and some other mechanisms.

lateral meristem A layer of undifferentiated plant cells found in older stems and roots that is responsible for secondary growth. Also called *cambium* or *secondary meristem*. Compare with **apical meristem.**

lateral root A plant root extending from another, older root.

leaching Loss of nutrients from soil via percolating water.

leading strand In DNA replication, the strand of new DNA that is synthesized in one continuous piece, with nucleotides added to the 3′ end of the growing molecule. Also called *continuous strand*. Compare with **lagging strand.**

leaf The main photosynthetic organ of vascular plants.

leak channel Potassium channel that allows potassium ions to leak out of a neuron in its resting state.

learning An enduring change in an individual's behavior that results from specific experience(s).

leghemoglobin An iron-containing protein similar to hemoglobin. Found in root nodules of legume plants where it binds oxygen, preventing it from poisoning a bacterial enzyme needed for nitrogen fixation.

legumes Members of the pea plant family that form symbiotic associations with nitrogen-fixing bacteria in their roots.

lens A transparent, crystalline structure that focuses incoming light onto a retina or other light-sensing apparatus of an eye.

leptin A hormone produced and secreted by fat cells (adipocytes) that acts to stabilize fat tissue mass in part by inhibiting appetite and increasing energy expenditure.

leukocytes Several types of blood cells, including neutrophils, macrophages, and lymphocytes, that circulate in blood and lymph and function in defense against pathogens. Also called *white blood cells*.

lichen A symbiotic association of a fungus and a photosynthetic alga.

life cycle The sequence of developmental events and phases that occurs during the life span of an organism, from fertilization to offspring production.

life history The sequence of events in an individual's life from birth to reproduction to death, including how an individual allocates resources to growth, reproduction, and activities or structures that are related to survival.

life table A data set that summarizes the probability that an individual in a certain population will survive and reproduce in any given year over the course of its lifetime.

ligand Any molecule that binds to a specific site on a receptor molecule.

ligand-gated channel An ion channel that opens or closes in response to binding by a certain molecule. Compare with **voltage-gated channel.**

light chain The smaller of the two types of polypeptide chains in an antibody molecule; composed of a variable (V) region, which contributes to the antigen-binding site, and a constant (C) region. Compare with **heavy chain.**

light-dependent reactions In photosynthesis, the set of reactions, occurring in photosystem I and II, that use the energy of sunlight to split water, producing ATP, NADPH, and oxygen.

light-independent reactions See **Calvin cycle.**

lignin A substance found in the secondary cell walls of some plants that is exceptionally stiff and strong. Most abundant in woody plant parts.

limiting nutrient Any essential nutrient whose scarcity in the environment significantly reduces growth and reproduction of organisms.

limnetic zone Open water (not near shore) that receives enough light to support photosynthesis.

lineage See **monophyletic group.**

LINEs (long interspersed nuclear elements) The most abundant class of transposable elements in human genomes; can create copies of itself and insert them elsewhere in the genome. Compare with **SINEs.**

linkage In genetics, a physical association between two genes because they are on the same chromosome; the inheritance patterns resulting from this association.

linkage map See **genetic map.**

lipase Any enzyme that can break down fat molecules into fatty acids and monoglycerides.

lipid Any organic substance that does not dissolve in water, but dissolves well in nonpolar organic solvents. Lipids include fats, oils, phospholipids, and waxes.

lipid bilayer The basic structural element of all cellular membranes consisting of a two-layer sheet of phospholipid molecules whose hydrophobic tails are oriented toward the inside and hydrophilic heads, toward the outside. Also called *phospholipid bilayer*.

littoral zone Shallow water near shore that receives enough sunlight to support photosynthesis. May be marine or freshwater; often flowering plants are present.

liver A large, complex organ of vertebrates that performs many functions including storage of glycogen, processing and conversion of food and wastes, and production of bile.

locomotion Movement of an organism under its own power.

locus (plural: loci) A gene's physical location on a chromosome.

logistic population growth The density-dependent decrease in growth rate as population size approaches the carrying capacity. Compare with **exponential population growth.**

long-day plant A plant that blooms in response to short nights (usually in late spring or early summer in the northern hemisphere). Compare with **day-neutral** and **short-day plant.**

long interspersed nuclear elements See **LINEs.**

loop of Henle In the vertebrate kidney, a long U-shaped loop in a nephron that extends into the medulla. Functions as a countercurrent exchanger to set up an osmotic gradient that allows reabsorption of water from a subsequent portion of the nephron.

loose connective tissue A type of connective tissue consisting of fibrous proteins in a soft matrix. Often functions as padding for organs.

lophophore A specialized feeding structure found in some lophotrochozoans and used in filter feeding.

lophotrochozoans A major lineage of protostomes (Lophotrochozoa) that grow by extending the size of their skeletons rather than by molting. Many phyla have a specialized feeding structure (lophophore) and/or ciliated larvae (trochophore). Includes rotifers, flatworms, segmented worms, and molluscs. Compare with **ecdysozoans.**

loss-of-function mutant See **knock-out mutant.**

lumen The interior space of any hollow structure (e.g., the rough ER) or organ (e.g., the stomach).

lung Any respiratory organ used for gas exchange between blood and air.

luteal phase The second major phase of a menstrual cycle, after ovulation, when the progesterone levels are high and the body is preparing for a possible pregnancy.

luteinizing hormone (LH) A peptide hormone, produced and secreted by the anterior pituitary, that stimulates estrogen production, ovulation, and formation of the corpus luteum in females and testosterone production in males.

lymph The mixture of fluid and white blood cells that circulates through the ducts and lymph nodes of the lymphatic system in vertebrates.

lymphatic system In vertebrates, a body-wide network of thin-walled ducts (or vessels) and lymph nodes, separate from the circulatory system. Collects excess fluid from body tissues and returns it to the blood; also functions as part of the immune system.

lymph node One of numerous small oval structures through which lymph moves in the lymphatic system. Filter the lymph and screen it for pathogens and other antigens. Major sites of lymphocyte activation.

lymphocytes Two types of leukocyte—B cells and T cells—that circulate through the bloodstream and lymphatic system and that are responsible for the development of acquired immunity.

lysogenic cycle A type of viral replication in which a viral genome enters a host cell, is inserted into the host's chromosome, and is replicated whenever the host cell divides. When activated, the viral DNA enters the lytic cycle, leading to production of new virus particles. Also called *lysogeny* or *latent growth*. Compare with **lytic cycle.**

lysosome A small organelle in an animal cell containing acids and enzymes that catalyze hydrolysis reactions and can digest large molecules. Compare with **vacuole.**

lysozyme An enzyme that functions in innate immunity by digesting bacterial cell walls. Occurs in saliva, tears, mucus, and egg white.

lytic cycle A type of viral replication in which a viral genome enters a host cell, new virus particles (virions) are made using host enzymes and eventually burst out of the cell, killing it. Also called *replicative growth*. Compare with **lysogenic cycle.**

macromolecule Any very large organic molecule, usually made up of smaller molecules (monomers) joined together into a polymer. The main biological macromolecules are proteins, nucleic acids, and polysaccharides.

macronutrient Any element (e.g., carbon, oxygen, nitrogen) that is required in large quantities for normal growth, reproduction, and maintenance of a living organism. Compare with **micronutrient.**

macrophage A type of leukocyte, capable of moving through body tissues, that engulfs and digests pathogens and other foreign particles; also secretes cytokines and presents foreign antigens to $CD4^+$ T cells.

MADS box A DNA sequence that codes for a DNA-binding motif in proteins; present in floral organ identity genes in plants. Functionally similar sequences are found in some fungal and animal genes.

major histocompatibility protein See **MHC protein.**

malaria A human disease caused by four species of the protist *Plasmodium* and passed to humans by mosquitoes.

malignant tumor A tumor that is actively growing and disrupting local tissues and/or is spreading to other organs. Cancer consists of one or more malignant tumors. Compare with **benign tumor.**

Malpighian tubules A major excretory organ of insects, consisting of blind-ended tubes that extend from the gut into the hemocoel. Filter hemolymph to form pre-urine and then send it to the hindgut for further processing.

mammals One of the two lineages of amniotes (vertebrates that produce amniotic eggs) distinguished by hair (or fur) and mammary glands. Includes the monotremes (platypuses), marsupials, and eutherians (placental mammals).

mammary glands Specialized exocrine glands that produce and secrete milk for nursing offspring. A diagnostic feature of mammals.

mandibles Any mouthpart used in chewing. In vertebrates, the lower jaw. In insects, crustaceans, and myriapods, the first pair of mouthparts.

mantle One of the three main parts of the mollusc body; the thick outer tissue that protects the visceral mass and may secrete a calcium carbonate shell.

Marfan syndrome A human syndrome involving increased height, long limbs and fingers, an abnormally shaped chest, and heart disorders. Probably caused by mutation in one pleiotropic gene.

marsh A wetland that lacks trees and usually has a slow but steady rate of water flow.

marsupials A lineage of mammals (Marsupiala) that nourish their young in an abdominal pouch after a very short period of development in the uterus.

mass extinction The extinction of a large number of diverse evolutionary groups during a relatively short period of geologic time (about 1 million years). May occur due to sudden and extraordinary environmental changes. Compare with **background extinction.**

mass feeder An animal that takes chunks of food into its mouth.

mass number The total number of protons and neutrons in an atom.

mast cell A type of leukocyte that is stationary (embedded in tissue) and helps trigger the inflammatory response to infection or injury, including secretion of histamine. Particularly important in allergic responses and defense against parasites.

maternal chromosome A chromosome inherited from the mother.

mechanoreceptor A sensory cell or organ specialized for detecting distortions caused by touch or pressure. One example is hair cells in the cochlea.

medium A liquid or solid in which cells can grow in vitro.

medulla The innermost part of an organ (e.g., kidney or adrenal gland).

medulla oblongata In vertebrates, a region of the brain stem that along with the cerebellum forms the hindbrain.

medusa (plural: medusae) The free-floating stage in the life cycle of some cnidarians (e.g., jellyfish). Compare with **polyp.**

megapascal (MPa) A unit of pressure (force per unit area), equivalent to 1 million pascals (Pa).

megaspore In seed plants, a haploid (n) spore that is produced in a megasporangium by meiosis of a diploid ($2n$) megasporocyte; develops into a female gametophyte. Compare with **microspore.**

meiosis In sexually reproducing organisms, a special two-stage type of cell division in which one diploid ($2n$) parent cell produces four haploid (n) reproductive cells (gametes); results in halving of the chromosome number. Also called *reduction division.*

meiosis I The first cell division of meiosis, in which synapsis and crossing over occur, and homologous chromosomes are separated from each other, producing daughter cells with half as many chromosomes (each composed of two sister chromatids) as the parent cell.

meiosis II The second cell division of meiosis, in which sister chromatids are separated from each other. Similar to mitosis.

meiotic map See **genetic map.**

membrane potential A difference in electric charge across a cell membrane; a form of potential energy. Also called *membrane voltage.*

memory Retention of learned information.

memory cells A type of lymphocyte responsible for maintenance of immunity for years or decades after an infection. Descended from a B cell or T cell activated during a previous infection.

meniscus (plural: menisci) The concave boundary layer formed at most air-water interfaces due to surface tension.

menstrual cycle A female reproductive cycle seen in Old World monkeys and apes (including humans) in which the uterine lining is shed (menstruation) if no pregnancy occurs. Compare with **estrous cycle.**

menstruation The periodic shedding of the uterine lining through the vagina that occurs in females of Old World monkeys and apes, including humans.

meristem (adjective: meristematic) In plants, a group of undifferentiated cells that can develop into various adult tissues throughout the life of a plant.

mesoderm The middle of the three basic cell layers in most animal embryos; gives rise to muscles, bones, blood, and some internal organs (kidney, spleen, etc.). Compare with **ectoderm** and **endoderm.**

mesoglea A gelatinous material, containing scattered ectodermal cells, that is located between the ectoderm and endoderm of cnidarians (e.g., jellyfish, corals, and anemones).

mesophyll cell A type of cell, found near the surfaces of plant leaves, that is specialized for the light-dependent reactions of photosynthesis.

Mesozoic era The period of geologic time, from 250 million to 65 million years ago, during which gymnosperms were the dominant plants and dinosaurs the dominant vertebrates. Ended with extinction of the dinosaurs. Also called *Age of Reptiles.*

messenger RNA (mRNA) An RNA molecule that carries encoded information, transcribed from DNA, that specifies the amino acid sequence of a polypeptide.

meta-analysis A comparative analysis of the results of many smaller, previously published studies.

metabolic pathway An ordered series of chemical reactions that build up or break down a particular molecule. Often, each reaction is catalyzed by a different enzyme.

metabolic rate The total energy use by all the cells of an individual. For aerobic organisms, often measured as the amount of oxygen consumed per hour.

metabolic water The water that is produced as a by-product of cellular respiration.

metabolism All the chemical reactions occurring in a living cell or organism.

metallothioneins Small plant proteins that bind to and prevent excess metal ions from acting as toxins.

metamorphosis Transition from one developmental stage to another, such as from the larval to the adult form of an animal.

metaphase A stage in mitosis or meiosis during which chromosomes line up in the middle of the cell.

metaphase plate The plane along which chromosomes line up during metaphase of mitosis or meiosis; not an actual structure.

metastasis The spread of cancerous cells from their site of origin to distant sites in the body where they may establish additional tumors.

methanogen A prokaryote that produces methane (CH_4) as a by-product of cellular respiration.

methanotroph An organism that uses methane (CH_4) as its primary electron donor and source of carbon.

methylation The addition of a methyl ($-CH_3$) group to a molecule.

MHC protein One of a large set of mammalian cell-surface glycoproteins involved in marking cells as self and in antigen presentation to T cells. Also called *MHC molecule.* See **Class I** and **Class II MHC protein.**

microbe Any microscopic organism, including bacteria, archaea, and various tiny eukaryotes.

microbiology The field of study concerned with microscopic organisms.

microfilament See **actin filament.**

micrograph A photograph of an image produced by a microscope.

micronutrient Any element (e.g., iron, molybdenum, magnesium) that is required in very small quantities for normal growth, reproduction, and maintenance of a living organism. Compare with **macronutrient.**

micropyle The tiny pore in a plant ovule through which the pollen tube reaches the embryo sac.

microRNA (miRNA) A small, single-stranded RNA associated with proteins in an RNA-induced silencing complex. Can bind to complementary sequences in mRNA molecules, allowing the associated proteins to degrade the bound mRNA or inhibit its translation. See **RNA interference.**

microsatellite A noncoding stretch of eukaryotic DNA consisting of a repeating sequence 1- to 5-base pair long. Also called *simple sequence repeat.*

microspore In seed plants, a haploid (n) spore that is produced in a microsporangium by meiosis of a diploid ($2n$) microsporocyte; develops into a male gametophyte. Compare with **megaspore.**

microtubule A long, tubular fiber, about 25 nm in diameter, formed by polymerization of tubulin protein dimers; one of the three types of cytoskeletal fibers. Involved in cell movement and transport of materials within the cell. Compare with **actin filament** and **intermediate filament.**

microtubule-organizing center (MTOC) General term for any structure (e.g., centrosome and basal body) that organizes microtubules in cells.

microvilli (singular:microvillus) Tiny protrusions from the surface of an epithelial cell that increase the surface area for absorption of substances.

midbrain One of the three main regions of the vertebrate brain; includes sensory integrating and relay centers. Compare with **forebrain** and **hindbrain.**

middle ear The air-filled middle portion of the mammalian ear, which contains three small bones (ossicles) that transmit and amplify sound from the tympanic membrane to the inner ear. Is connected to the throat via the eustachian tube.

middle lamella The layer of gelatinous pectins between the primary cell walls of adjacent plant cells. Helps hold the cells together.

migration (1) In ecology, a cyclical movement of large numbers of organisms from one geographic location or habitat to another. (2) In population genetics, movement of individuals from one population to another.

millivolt (mV) A unit of voltage equal to 1/1000 of a volt.

mimicry A phenomenon in which one species has evolved (or learns) to look or sound like another species. See **Batesian mimicry** and **Müllerian mimicry.**

mineralocorticoids A class of steroid hormones, produced and secreted by the adrenal cortex, that regulate electrolyte levels and the overall volume of body fluids. Aldosterone is the principal one in humans. Compare with **glucocorticoids.**

minisatellite A noncoding stretch of eukaryotic DNA consisting of a repeating sequence that is 6 to 500 base pairs long. Also called *variable number tandem repeat (VNTR).*

mismatch repair The process by which mismatched base pairs in DNA are fixed.

missense mutation A point mutation (change in a single base pair) that causes a change in the amino acid sequence of a protein. Also called *replacement mutation.*

mitochondrial matrix Central compartment of a mitochondrion, which is lined by the inner membrane; contains the enzymes and substrates of the Krebs cycle and mitochondrial DNA.

mitochondrion (plural: mitochondria) A eukaryotic organelle that is bounded by a double membrane and is the site of aerobic respiration.

mitosis In eukaryotic cells, the process of nuclear division that results in two daughter nuclei genetically identical to the parent nucleus. Subsequent cytokinesis (division of the cytoplasm) yields two daughter cells.

mitosis-promoting factor (MPF) A complex of a cyclin and cyclin-dependent kinase that phosphorylates a number of specific proteins needed to initiate mitosis in eukaryotic cells.

mitotic (M) phase The phase of the cell cycle during which cell division occurs. Includes mitosis and cytokinesis.

mitotic spindle Temporary structure, composed largely of microtubules, that is involved in the movement of chromosomes to the equatorial plate and then to opposite sides of the cell during mitosis and meiosis.

model organism An organism selected for intensive scientific study based on features that make it easy to work with (e.g., body size, life span), in the hope that findings will apply to other species.

molarity A common unit of solute concentration equal to the number of moles of a dissolved solute in 1 liter of solution.

mole The amount of a substance that contains 6.022×10^{23} of its elemental entities (e.g., atoms, ions, or molecules). This number of molecules of a compound will have a mass equal to the molecular weight of that compound expressed in grams.

molecular chaperone A protein that facilitates the three-dimensional folding of newly synthesized proteins, usually by an ATP-dependent mechanism.

molecular clock The hypothesis that certain types of mutations tend to reach fixation in populations at a steady rate over large spans of time. As a result, comparisons of DNA sequences can be used to infer the timing of evolutionary divergences.

molecular formula A notation that indicates only the numbers and types of atoms in a molecule, such as H_2O for the water molecule. Compare with **structural formula.**

molecular weight The sum of the mass numbers of all of the atoms in a molecule; roughly, the total number of protons and neutrons in the molecule.

molecule A combination of two or more atoms held together by covalent bonds.

molluscs Members of the phylum Mollusca. Distinguished by a body plan with three main parts: a muscular foot, a visceral mass, and a

mantle. Include bivalves (clams, oysters), gastropods (snails, slugs), chitons, and cephalopods (squid, octopuses). Molluscs belong to the lophotrochozoan branch of the protostomes.

molting A method of body growth, used by ecdysozoans, that involves the shedding of an external protective cuticle or skeleton, expansion of the soft body, and growth of a new external layer.

monocot Any plant that has a single cotyledon (embryonic leaf) upon germination. Monocots form a monophyletic group. Also called a monocotyledonous plant. Compare with **dicot.**

monoecious Describing an angiosperm species that has both male and female reproductive structures on each plant. Compare with **dioecious.**

monohybrid cross A mating between two parents that are both heterozygous for a given gene.

monomer A small molecule that can covalently bind to other similar molecules to form a larger macromolecule. Compare with **polymer.**

monophyletic group An evolutionary unit that includes an ancestral population and all of its descendants but no others. Also called a *clade* or *lineage*. Compare with **paraphyletic group.**

monosaccharide A small carbohydrate, such as glucose, that has the molecular formula $(CH_2O)_n$ and cannot be hydrolyzed to form any smaller carbohydrates. Also called *simple sugar*. Compare with **disaccharide** and **polysaccharide.**

monosomy Having only one copy of a particular type of chromosome.

monotremes A lineage of mammals (Monotremata) that lay eggs and then nourish the young with milk. Includes just three living species: the platypus and two species of echidna.

morphological species concept The definition of a species as a population or group of populations that have measurably different anatomical features from other groups. Also called *morphospecies concept*. Compare with **biological** and **phylogenetic species concept.**

morphology The shape and appearance of an organism's body and its component parts.

motif In molecular biology, a domain (a section of a protein with a distinctive tertiary structure) found in many different proteins and often having specific functional properties.

motor neuron A nerve cell that carries signals from the central nervous system (brain and spinal cord) to an effector, such as a muscle or gland. Compare with **interneuron** and **sensory neuron.**

motor protein A class of proteins whose major function is to convert the chemical energy of ATP into motion. Includes dynein, kinesin, and myosin.

MPF See **mitosis-promoting factor.**

mRNA. See **messenger RNA.**

mucigel A slimy substance secreted by plant root caps that eases passage of the growing root through the soil.

mucosal-associated lymphoid tissue (MALT) Collective term for lymphocytes and other leukocytes associated with skin cells and with mucus-secreting epithelial tissues in the gut and respiratory tract. Plays important role in preventing entry of pathogens into the body.

mucus (adjective: mucous) A slimy mixture of glycoproteins (called mucins) and water that is secreted in many animal organs for lubrication.

Müllerian inhibitory substance A peptide hormone secreted by the embryonic testis that causes regression (withering away) of the female reproductive ducts.

Müllerian mimicry A type of mimicry in which two (or more) harmful species resemble each other. Compare with **Batesian mimicry.**

multicellularity The state of being composed of many cells that adhere to each other and do not all express the same genes with the result that some cells have specialized functions.

multiple fruit A fruit (e.g., pineapple) that develops from many separate flowers and thus many carpels. Compare with **aggregate** and **simple fruit.**

multiple sclerosis (MS) A human autoimmune disease caused by the immune system attacking the myelin sheaths that insulate nerve axons.

muscle fiber A single muscle cell.

muscle tissue An animal tissue consisting of bundles of long, thin contractile cells (muscle fibers).

mutagen Any physical or chemical agent that increases the rate of mutation.

mutant An individual that carries a mutation, particularly a new or rare mutation.

mutation Any change in the hereditary material of an organism (DNA in most organisms, RNA in some viruses).

mutualism (adjective: mutualistic) A symbiotic relationship between two organisms (mutualists) that benefits both. Compare with **commensalism** and **parasitism.**

mycelium (plural: mycelia) A mass of underground filaments (hyphae) that form the body of a fungus. Also found in some protists and bacteria.

mycorrhiza (plural: mycorrhizae) A mutualistic association between certain fungi and most vascular plants, sometimes visible as nodules or nets in or around plant roots.

myelin sheath Multiple layers of myelin, derived from the cell membranes of certain glial cells, that is wrapped around the axon of a neuron, providing electrical insulation.

myofibril Long, slender structure composed of contractile proteins organized into repeating units (sarcomeres) in vertebrate heart muscle and striated muscle.

myosin Any one of a class of motor proteins that use the chemical energy of ATP to move along actin filaments in muscle contraction, cytokinesis, and vesicle transport.

myriapods A lineage of arthropods with long segmented trunks, each segment bearing one or two pairs of legs. Includes millipedes and centipedes.

NAD^+/NADH Oxidized and reduced forms, respectively, of nicotinamide adenine dinucleotide. A nonprotein electron carrier that functions in many of the redox reactions of metabolism.

$NADP^+$/NADPH Oxidized and reduced forms, respectively, of nicotinamide adenine dinucleotide phosphate. A nonprotein electron carrier that is reduced during the light-dependent reactions in photosynthesis and extensively used in biosynthetic reactions.

natural experiment A situation in which groups to be compared are created by an unplanned, natural change in conditions rather than by manipulation of conditions by researchers.

natural selection The process by which individuals with certain heritable traits tend to produce more surviving offspring than do individuals without those traits, often leading to a change in the genetic makeup of the population. A major mechanism of evolution.

nauplius A distinct planktonic larval stage seen in many crustaceans.

Neanderthal A recently extinct European species of hominid, *Homo neanderthalensis*, closely related to but distinct from modern humans.

nectar The sugary fluid produced by flowers to attract and reward pollinating animals.

negative feedback A self-limiting, corrective response in which a deviation in some variable (e.g., body temperature, blood pH, concentration of some compound) triggers responses aimed at returning the variable to normal. Compare with **positive feedback.**

negative pressure ventilation Ventilation of the lungs that is accomplished by "pulling" air into the lungs by expansion of the rib cage. Compare with **positive pressure ventilation.**

negative-sense virus A virus whose genome contains sequences complementary to those in the mRNA required to produce viral proteins. Compare with **ambisense virus** and **positive-sense virus.**

nematodes. See **roundworms.**

nephron One of the tiny tubes within the vertebrate kidney that filter blood and concentrate salts to produce urine. Also called *renal tubule*.

neritic zone Shallow marine waters beyond the intertidal zone, extending down to about 200 meters, where the continental shelf ends.

nerve A long, tough strand of nervous tissue typically containing thousands of axons wrapped in connective tissue; carries impulses between the central nervous system and some other part of the body.

nerve cord A bundle of nerves extending from the brain along the dorsal (back) side of a chordate animal, with cerebrospinal fluid inside a hollow central channel. One of the defining features of chordates.

nervous tissue An animal tissue consisting of nerve cells (neurons) and various supporting cells.

net primary productivity (NPP) In an ecosystem, the total amount of carbon fixed by photosynthesis over a given time period minus the amount oxidized during cellular respiration. Compare with **gross primary productivity.**

net reproductive rate (R_0) The growth rate of a population per generation; equivalent to the average number of female offspring that each female produces over her lifetime.

neural Relating to nerve cells (neurons) and the nervous system.

neural tube A folded tube of ectoderm that forms along the dorsal side of a young vertebrate embryo and that will give rise to the brain and spinal cord.

neuroendocrine Referring to nerve cells (neurons) that release hormones into the blood or to such hormones themselves.

neuron A cell that is specialized for the transmission of nerve impulses. Typically has dendrites, a cell body, and a long axon that forms synapses with other neurons. Also called *nerve cell*.

neurosecretory cell A nerve cell (neuron) that produces and secretes hormones into the bloodstream. Principally found in the hypothalamus. Also called *neuroendocrine cell*.

neurotoxin Any substance that specifically destroys or blocks the normal functioning of neurons.

neurotransmitter A molecule that transmits electrical signals from one neuron to another or from a neuron to a muscle or gland. Examples are acetylcholine, dopamine, serotonin, and norepinephrine.

neutral In genetics, referring to any mutation or mutant allele that has no effect on an individual's fitness.

neutrophil A type of leukocyte, capable of moving through body tissues, that engulfs and digests pathogens and other foreign particles; also secretes various compounds that attack bacteria and fungi.

niche The particular set of habitat requirements of a certain species and the role that species plays in its ecosystem.

niche differentiation The change in resource use by competing species that occurs as the result of character displacement.

nicotinamide adenine dinucleotide See **NAD^+/NADH.**

nicotinamide adenine dinucleotide phosphate See **$NADP^+$/NADPH.**

nitrogen cycle, global The movement of nitrogen among terrestrial ecosystems, the oceans, and the atmosphere.

nitrogen fixation The incorporation of atmospheric nitrogen (N_2) into forms such as ammonia (NH_3) or nitrate (NO_3^-), which can be used to make many organic compounds. Occurs in only a few lineages of bacteria and archaea.

nociceptor A sensory cell or organ specialized to detect tissue damage, usually producing the sensation of pain.

node (1) In animals, any small thickening (e.g., a lymph node). (2) In plants, the part of a stem where leaves or leaf buds are attached. (3) In a phylogenetic tree, the point where two branches diverge, representing the point in time when an ancestral group split into two or more descendant groups. Also called *fork*.

node of Ranvier One of the periodic unmyelinated sections of a neuron's axon at which an action potential can be regenerated.

Nod factors Molecules produced by nitrogen-fixing bacteria that help them recognize and bind to roots of legumes.

nodule Lumplike structure on roots of legume plants that contain symbiotic nitrogen-fixing bacteria.

noncyclic electron flow See **Z scheme.**

nondisjunction An error that can occur during meiosis or mitosis in which one daughter cell receives two copies of a particular chromosome, and the other daughter cell receives none.

nonpolar covalent bond A covalent bond in which electrons are equally shared between two atoms of the same or similar electronegativity. Compare with **polar covalent bond.**

non-sister chromatids The chromatids of a particular type of chromosome (after replication) with respect to the chromatids of its homologous chromosome. Crossing over occurs between non-sister chromatids. Compare with **sister chromatids.**

non-template strand The strand of DNA that is not transcribed during synthesis of RNA. Its sequence corresponds to that of the mRNA produced from the other strand. Also called *coding strand*.

nonvascular plants See **bryophytes.**

norepinephrine A catecholamine used as a neurotransmitter in the sympathetic nervous system. Also is produced by the adrenal medulla and functions as a hormone that triggers rapid responses relating to the fight-or-flight response.

Northern blotting A technique for identifying specific RNAs separated by gel electrophoresis by transferring them to filter paper and hybridizing with a labeled DNA probe complementary to the RNA of interest. Compare with **Southern blotting** and **Western blotting.**

notochord A long, gelatinous, supportive rod down the back of a chordate embryo, below the developing spinal cord. Replaced by vertebrae in most adult vertebrates. A defining feature of chordates.

nuclear envelope The double-layered membrane enclosing the nucleus of a eukaryotic cell.

nuclear lamina A lattice-like sheet of fibrous nuclear lamins, which are one type of intermediate filaments. Lines the inner membrane of the nuclear envelope, stiffening the envelope and helping organize the chromosomes.

nuclear localization signal (NLS) A short amino acid sequence that marks a protein for delivery to the nucleus.

nuclear pore An opening in the nuclear envelope that connects the inside of the nucleus with the cytoplasm and through which molecules such as mRNA and some proteins can pass.

nuclear pore complex A large complex of dozens of proteins lining a nuclear pore, defining its shape and transporting substances through the pore.

nuclease Any enzyme that can break down RNA or DNA molecules.

nucleic acid A macromolecule composed of nucleotide monomers. Generally used by cells to store or transmit hereditary information. Includes ribonucleic acid and deoxyribonucleic acid.

nucleic acid hybridization Base pairing between a single-stranded nucleic acid and a complementary sequence in a different nucleic acid (e.g., a labeled probe). Is used experimentally in Southern blotting and Northern blotting.

nucleoid In prokaryotic cells, a dense, centrally located region that contains DNA but is not surrounded by a membrane.

nucleolus In eukaryotic cells, specialized structure in the nucleus where ribosomal RNA processing occurs and ribosomal subunits are assembled.

nucleosome A repeating, bead-like unit of eukaryotic chromatin, consisting of about 200 nucleotides of DNA wrapped twice around eight histone proteins.

nucleotide A molecule consisting of a five-carbon sugar (ribose or deoxyribose), a phosphate group, and one of several nitrogen-containing bases. DNA and RNA are polymers of nucleotides containing deoxyribose (deoxyribonucleotides) and ribose (ribonucleotides), respectively. Equivalent to a nucleoside plus one phosphate group.

nucleotide excision repair The process of removing a damaged region in one strand of DNA and correctly replacing it using the undamaged strand as a template.

nucleus (1) The center of an atom, containing protons and neutrons. (2) In eukaryotic cells, the large organelle containing the chromosomes and surrounded by a double membrane. (3) A discrete clump of neuron cell bodies in the brain, usually sharing a distinct function.

null hypothesis A hypothesis that specifies what the results of an experiment will be if the main hypothesis being tested is wrong. Often states that there will be no difference between experimental groups.

null mutant See **knock-out mutant.**

nutrient A substance that an organism requires for normal growth, maintenance, or reproduction.

nutritional balance A state in which an organism is taking in enough nutrients to maintain normal health and activity.

nymph The juvenile form of an animal that undergoes hemimetabolous (incomplete) metamorphosis; resembles a miniature version of the adult form.

oceanic zone The waters of the open ocean beyond the continental shelf.

oil A fat that is liquid at room temperature.

Okazaki fragment Short segment of DNA produced during replication of the 5′ to 3′ template strand. Many Okazaki fragments make up the lagging strand in newly synthesized DNA.

olfaction The perception of odors.

olfactory bulb A bulb-shaped projection of the brain just above the nose. Receives and interprets odor information from the nose.

oligodendrocyte A type of glial cell that wraps around axons of some neurons in the central nervous system, forming a myelin sheath that provides electrical insulation. Compare with **Schwann cell.**

oligopeptide A chain composed of fewer than 50 amino acids linked together by peptide bonds. Often referred to simply as *peptide*.

ommatidium (plural: ommatidia) A light-sensing column in an arthropod's compound eye.

omnivore (adjective: omnivorous) An animal whose diet regularly includes both meat and plants. Compare with **carnivore** and **herbivore.**

oncogene Any gene whose protein product stimulates cell division at all times and thus promotes cancer development. Often is a mutated form of a gene involved in regulating the cell cycle. See **proto-oncogene.**

one-gene, one-enzyme hypothesis The hypothesis that each gene is responsible for making one (and only one) protein, in most cases an enzyme that catalyzes a specific reaction. Many exceptions to this hypothesis are now known.

oocyte A cell in the ovary that can undergoes meiosis to produce an ovum.

oogenesis The production of egg cells (ova).

oogonia (singular: oogonia) The diploid cells in an ovary that can divide by mitosis to create more oogonia and primary oocytes, which can undergo meiosis.

open circulatory system A circulatory system in which the circulating fluid (hemolymph) is not confined to blood vessels. Compare with **closed circulatory system.**

open reading frame (ORF) Any DNA sequence, ranging in length from several hundred to thousands of base pairs long, that is flanked by a start codon and a stop codon. ORFs identified by computer analysis of DNA may be functional genes, especially if they have other features characteristic of genes (e.g., promoter sequence).

operator In prokaryotic DNA, a binding site for a repressor protein; located near the start of an operon.

operculum The stiff flap of tissue that covers the gills of teleost fishes.

operon A region of prokaryotic DNA that codes for a series of functionally related genes and is transcribed from a single promoter into a polycistronic mRNA.

opsin A transmembrane protein that is covalently linked to retinal, the light-detecting pigment in rod and cone cells.

optical isomer A molecule that shares the same molecular formula as another molecule but differs in the arrangement of atoms or groups around a carbon atom; left-handed or right-handed form of a molecule. Compare with **geometric** and **structural isomer.**

optimal foraging The concept that animals forage in a way that maximizes the amount of usable energy they take in, given the costs of finding and ingesting their food and the risk of being eaten while they're at it.

orbital The spherical region around an atomic nucleus in which an electron is present most of the time.

order In Linnaeus' system, a taxonomic category above the family level and below the class level.

ORF See **open reading frame.**

organ A group of tissues organized into a functional and structural unit.

organelle Any discrete, membrane-bound structure within a cell (e.g., mitochondrion) that has a characteristic structure and functions.

organic For a compound, containing carbon and hydrogen and usually containing carbon-carbon bonds. Organic compounds are widely used by living organisms.

organism Any living entity that contains one or more cells.

organogenesis A stage of embryonic development, just after gastrulation in vertebrate embryos, during which major organs develop from the three embryonic germ layers.

orientation A deliberate movement that results in a change in position relative to some external cue, such as toward the Sun or away from a sound.

origin of replication The site on a chromosome at which DNA replication begins.

osmoconformer An animal that does not actively regulate the osmolarity of its tissues but conforms to the osmolarity of the surrounding environment.

osmolarity The concentration of dissolved substances in a solution, measured in moles per liter.

osmoregulation The process by which a living organism controls the concentration of water and salts in its body.

osmoregulator An animal that actively regulates the osmolarity of its tissues.

osmosis Diffusion of water across a selectively permeable membrane from a region of high water concentration (low solute concentration) to a region of low water concentration (high solute concentration).

osmotic potential See **solute potential.**

ossicle One of three small bones, in the middle ear of mammals, that transmit and amplify sound from the tympanic membrane to the inner ear.

ouabain A plant toxin that poisons the sodium-potassium pumps of animals.

outcrossing Reproduction by fusion of the gametes of different individuals, rather than self-fertilization. Typically refers to plants.

outer ear The outermost portion of the mammalian ear, consisting of the pinna (ear flap) and the ear canal. Funnels sound to the tympanic membrane.

outgroup A taxon that is closely related to a particular monophyletic group but is not part of it.

out-of-Africa hypothesis The hypothesis that modern humans (*Homo sapiens*) evolved in Africa and spread to other continents, replacing other *Homo* species without interbreeding with them.

oval window A membrane separating the fluid-filled cochlea from the air-filled middle ear through which sound vibrations pass from the middle ear to the inner ear in mammals.

ovary The egg-producing organ of a female animal, or the seed-producing structure in the female part of a flower.

oviduct See **fallopian tube.**

oviparous Producing eggs that are laid outside the body where they develop and hatch. Compare with **ovoviviparous** and **viviparous.**

ovoviviparous Producing eggs that are retained inside the body until they are ready to hatch. Compare with **oviparous** and **viviparous.**

ovulation The release of an ovum from an ovary of a female vertebrate. In humans, an ovarian follicle releases an egg at the end of the follicular phase of the menstrual cycle.

ovule In flowering plants, the structure inside an ovary that contains the female gametophyte and eventually (if fertilized) becomes a seed.

ovum (plural: ova) See **egg.**

oxidation The loss of electrons from an atom during a redox reaction, either by donation of an electron to another atom or by the shared electrons in covalent bonds moving farther from the atomic nucleus.

oxidative phosphorylation Production of ATP molecules from the redox reactions of an electron transport chain.

oxygen-hemoglobin equilibrium curve The graphical depiction of the percentage of hemoglobin in the blood that will bind to oxygen at various partial pressures of oxygen.

oxygenic Referring to any process or reaction that produces oxygen. Photosynthesis in plants, algae, and cyanobacteria, which involves photosystem II, is oxygenic. Compare with **anoxygenic.**

oxytocin A peptide hormone, secreted by the posterior pituitary, that triggers labor and milk production in females and that stimulates pair bonding, parental care, and affiliative behavior in both sexes.

p53 A tumor-suppressor protein (molecular weight of 53 kilodaltons) that responds to DNA damage by stopping the cell cycle and/or triggering apoptosis. Encoded by the *p53* gene.

pacemaker cell A specialized cardiac muscle cell in the sinoatrial (SA) node of the vertebrate heart that has an inherent rhythm and can generate an electrical impulse that spreads to other heart cells.

paleontology The study of organisms that lived in the distant past.

Paleozoic era The period of geologic time, from 543 million to 250 million years ago, during which fungi, land plants, and animals first appeared and diversified. Began with the Cambrian explosion and ended with the extinction of many invertebrates and vertebrates.

pancreas A large gland in vertebrates that has both exocrine and endocrine functions. Secretes digestive enzymes into a duct connected to the intestine and several hormones (notably, insulin and glucagon) into the bloodstream.

pandemic The spread of an infectious disease in a short time period over a wide geographic area and affecting a very high proportion of the population. Compare with **epidemic.**

parabiosis An experimental technique for determining whether a certain physiological phenomenon is regulated by a hormone, by surgically uniting two individuals so that hormones can pass between them.

parabronchus (plural: parabronchi) One of the many tiny parallel air tubes that run through a bird's lung where gas exchange occurs.

paracrine Relating to a chemical signal that is released by one cell and affects neighboring cells.

paraphyletic group An evolutionary unit that includes an ancestral population and *some* but not all of its descendants. Paraphyletic groups are not meaningful units in evolution. Compare with **monophyletic group.**

parapodia (singular: parapodium) Appendages found in some annelids from which bristle-like structures (chaetae) extend.

parasite An organism that lives on or in a host species and that damages its host.

parasitism (adjective: parasitic) A symbiotic term relationship between two organisms that is beneficial to one organism (the parasite) but detrimental to the other (the host). Compare with **commensalism** and **mutualism.**

parasitoid An organism that has a parasitic larval stage and a free-living adult stage. Most parasitoids are insects that lay eggs in the bodies of other insects.

parasympathetic nervous system The part of the autonomic nervous system that stimulates functions for conserving or restoring energy, such as reduced heart rate and increased digestion. Compare with **sympathetic nervous system.**

parathyroid glands Four small glands, located near or embedded in the thyroid gland of vertebrates, that secrete parathyroid hormone.

parathyroid hormone (PTH) A peptide hormone, secreted from the parathyroid glands, that increases blood calcium by promoting Ca^{2+} release from bones, Ca^{2+} uptake in the intestines, and Ca^{2+} reabsorption in the kidneys.

parenchyma cell In plants, a general type of cell with a relatively thin primary cell wall. These cells, found in leaves, the centers of stems and roots, and fruits, are involved in photosynthesis, starch storage, and new growth. Compare with **collenchyma cell** and **sclerenchyma cell.**

parental care Any action by which an animal expends energy or assumes risks to benefit its

offspring (e.g., nest-building, feeding of young, defense).

parental generation The adult organisms used in the first experimental cross in a formal breeding experiment.

parietal cell A cell in the stomach lining that secretes hydrochloric acid.

parsimony The logical principle that the most likely explanation of a phenomenon is the most economical or simplest. When applied to comparison of alternative phylogenetic trees, it suggests that the one requiring the fewest evolutionary changes is most likely to be correct.

parthenogenesis Development of offspring from unfertilized eggs; a type of asexual reproduction.

partial pressure The pressure of one particular gas in a mixture; the contribution of that gas to the overall pressure.

pascal (Pa) A unit of pressure (force per unit area).

passive transport Diffusion of a substance across a plasma membrane or organelle membrane. When this occurs with the assistance of membrane proteins, it is called facilitated diffusion.

patch clamping A technique for studying the electrical currents that flow through individual ion channels by sucking a tiny patch of membrane to the hollow tip of a microelectrode.

paternal chromosome A chromosome inherited from the father.

pathogen (adjective: pathogenic) Any entity capable of causing disease, such as a microbe, virus, or prion.

pattern formation The series of events that determines the spatial organization of an embryo, including alignment of the major body axes and orientation of the limbs.

pattern-recognition receptor One of a class of membrane proteins on leukocytes that bind to molecules on the surface of many bacteria. Part of the innate immune response.

PCR See **polymerase chain reaction.**

peat Semidecayed organic matter that accumulates in moist, low-oxygen environments such as bogs.

pectin A gelatinous polysaccharide found in the primary cell wall and middle lamella of plant cells. Attracts and holds water, forming a gel that helps keep the cell wall moist.

pedigree A family tree of parents and offspring, showing inheritance of particular traits of interest.

pellet Any solid material that collects at the bottom of a test tube below a layer of liquid (the supernatant) during centrifugation.

penis The copulatory organ of male mammals, used to insert sperm into a female.

pentose A monosaccharide (simple sugar) containing five carbon atoms.

PEP carboxylase An enzyme that catalyzes addition of CO_2 to phosphoenol pyruvate, a three-carbon compound, forming a four-carbon organic acid. Found in mesophyll cells of plants that perform C_4 photosynthesis.

pepsin A protein-digesting enzyme present in the stomach.

pepsinogen The precursor of the digestive enzyme pepsin. Is secreted from cells in the stomach lining and converted to pepsin by the acidic environment of the stomach lumen.

peptide See **oligopeptide.**

peptide bond The covalent bond (C–N) formed by a condensation reaction between two amino acids; links the residues in peptides and proteins.

peptidoglycan A complex structural polysaccharide found in bacterial cell walls.

per capita rate of increase (*r*) The growth rate of a population, expressed per individual. Calculated as the per capita birthrate minus the per capita death rate. Also called *per capita growth rate.*

perennial Describing a plant whose life cycle normally lasts for **more than one year.** Compare with **annual.**

perfect flower A flower that contains both male parts (stamens) and female parts (carpels). Compare with **imperfect flower.**

perforation In plants, a small hole in the primary and secondary cell walls of vessel elements that allow passage of water.

pericarp The part of a fruit, formed from the ovary wall, that surrounds the seeds and protects them. Corresponds to the flesh of most edible fruits and the hard shells of most nuts.

pericycle In plant roots, a layer of cells that give rise to lateral roots.

periderm The outermost portion of bark consisting of cork cambium, cork cells, and a third small layer of cells (phelloderm).

peripheral membrane protein Any membrane protein that does not span the entire lipid bilayer and associates with only one side of the bilayer. Compare with **integral membrane protein.**

peripheral nervous system (PNS) All the components of the nervous system that are outside the central nervous system (the brain and spinal cord). Includes the somatic nervous system and the autonomic nervous system.

peristalsis Rhythmic waves of muscular contraction that push food along the digestive tract.

permafrost A permanently frozen layer of icy soil found in most tundra and some taiga.

permeability The tendency of a structure, such as a membrane, to allow a given substance to diffuse across it.

peroxisome An organelle found in most eukaryotic cells that contains enzymes for oxidizing fatty acids and other compounds including many toxins, rendering them harmless. See **glyoxisome.**

petal One of the leaflike organs arranged around the reproductive organs of a flower. Often colored and scented to attract pollinators.

petiole The stalk of a leaf.

pH A measure of the concentration of protons in a solution and thus of acidity or alkalinity. Defined as the negative of the base-10 logarithm of the proton concentration: $pH = -\log[H^+]$.

phagocytosis Uptake by a cell of small particles or cells by pinching off the plasma membrane to form small membrane-bound vesicles; one type of endocytosis.

pharyngeal gill slits A set of parallel openings from the throat through the neck to the outside. A diagnostic trait of chordates.

phelloderm In the stems of woody plants, a thin layer of cells located between the outer cork cells and inner cork cambium.

pharyngeal jaw A secondary jaw in the back of the mouth, found in some fishes. Derived from modified gill arches.

phenetic approach A method for constructing a phylogenetic tree by computing a statistic that summarizes the overall similarity among populations, based on the available data. Compare with **cladistic approach.**

phenotype The detectable physical and physiological traits of an individual, which are determined its genetic makeup. Also the specific trait associated with a particular allele. Compare with **genotype.**

phenotypic plasticity Within-species variation in phenotype that is due to differences in environmental conditions. Occurs more commonly in plants than animals.

pheophytin In photosystem II, a molecule that accepts excited electrons from a reaction center chlorophyll and passes them to an electron transport chain.

pheromone A chemical signal, released by one individual into the external environment, that can trigger responses in a different individual.

phloem A plant vascular tissue that conducts sugars; contains sieve-tube members and companion cells. Primary phloem develops from the procambium of apical meristems; secondary phloem, from the vascular cambium of lateral meristems. Compare with **xylem.**

phonotaxis Orientation toward or away from sound.

phosphodiester linkage Chemical linkage between adjacent **nucleotide residues** in DNA and RNA. Forms when the phosphate group of one nucleotide condenses with the hydroxyl group on the sugar of another nucleotide. Also known as *phosphodiester bond.*

phosphofructokinase The enzyme that catalyzes synthesis of fructose-1,6-bisphosphate from fructose-6-phosphate, a key reaction (step 3) in glycolysis.

phospholipid A class of lipid having a hydrophilic head (a phosphate group) and a hydrophobic tail (one or more fatty acids). Major components of the plasma membrane and organelle membranes.

phosphorylase An enzyme that breaks down glycogen by catalyzing hydrolysis of the α-glycosidic linkages between the glucose residues.

phosphorylation (verb: phosphorylate) The addition of a phosphate group to a molecule.

phosphorylation cascade A series of enzyme-catalyzed phosphorylation reactions commonly used in signal transduction pathways to amplify and convey a signal inward from the plasma membrane.

photic zone In an aquatic habitat, water that is shallow enough to receive some sunlight (whether or not it is enough to support photosynthesis). Compare with **aphotic zone.**

photon A discrete packet of light energy; a particle of light.

photoperiodism Any response by an organism to the relative lengths of day and night (i.e., photoperiod).

photophosporylation Production of ATP molecules using the energy released as light-excited electrons flow through an electron transport chain during photosynthesis. Involves generation

of a proton-motive force during electron transport and its use to drive ATP synthesis.

photoreceptor A molecule, a cell, or an organ that is specialized to detect light.

photorespiration A series of light-driven chemical reactions that consumes oxygen and releases carbon dioxide, basically reversing photosynthesis. Usually occurs when there are high O_2 and low CO_2 concentrations inside plant cells, often in bright, hot, dry environments when stomata must be kept closed.

photoreversibility A change in conformation that occurs in certain plant pigments when they are exposed to their preferred wavelengths of light and that triggers responses by the plant.

photosynthesis The complex biological process that converts the energy of light into chemical energy stored in glucose and other organic molecules. Occurs in plants, algae, and some bacteria.

photosystem One of two types of units, consisting of a central reaction center surrounded by antenna complexes, that is responsible for the light-dependent reactions of photosynthesis.

photosystem I A photosystem that contains a pair of P700 chlorophyll molecules and uses absorbed light energy to produce NADPH.

photosystem II A photosystem that contains a pair of P680 chlorophyll molecules and uses absorbed light energy to split water into protons and oxygen and to produce ATP.

phototaxis Orientation toward or away from light.

phototroph An organism that produces ATP through photosynthesis.

phototropins A class of plant photoreceptors that detect blue light and initiate phototropic responses.

phototropism Growth or movement of an organism in a particular direction in response to light.

phylogenetic species concept The definition of a species as the smallest monophyletic group in a phylogenetic tree. Compare with **biological** and **morphological species concept.**

phylogenetic tree A diagram that depicts the evolutionary history of a group of species and the relationships among them.

phylogeny The evolutionary history of a group of organisms.

phylum (plural: phyla) In Linnaeus' system, a taxonomic category above the class level and below the kingdom level. In plants, sometimes called a *division*.

physical map A map of a chromosome that shows the number of base pairs between various genetic markers. Compare with **genetic map.**

physiology The study of how an organism's body functions.

phytoalexin Any small compound produced by a plant to combat an infection (usually a fungal infection).

phytochrome A specialized plant photoreceptor that exists in two shapes depending on the ratio of red to far-red light and is involved in the timing certain physiological processes, such as flowering, stem elongation, and germination.

phytoplankton Small drifting aquatic organisms (plankton) that are photosynthetic.

phytoremediation The use of plants to clean contaminated soils.

pigment Any molecule that absorbs certain wavelengths of visible light and reflects or transmits other wavelengths.

piloting A type of navigation in which animals use familiar landmarks to find their way.

pinocytosis Uptake by a cell of extracellular fluid by pinching off the plasma membrane to form small membrane-bound vesicles; one type of endocytosis.

pioneering species Those species that appear first in recently disturbed areas.

pit In plants, a small hole in the secondary cell walls of tracheids that allow passage of water.

pitch The sensation produced by a particular frequency of sound. Low frequencies are perceived as low pitches; high frequencies, as high pitches.

pituitary gland A small gland directly under the brain that is physically and functionally connected to the hypothalamus. Produces and secretes an array of hormones that affect many other glands and organs.

placenta A structure that forms in the pregnant uterus from maternal and fetal tissues. Exchanges nutrients and wastes between mother and fetus, anchors the fetus to the uterine wall, and produces some hormones. Occurs in most mammals and in a few other vertebrates.

placental mammals See **eutherians.**

plankton Any small organism that drifts near the surface of oceans or lakes and swims little if at all.

Plantae The monophyletic group that includes red, green, and glaucophyte algae and land plants.

plant-defense hypothesis The hypothesis that rates of herbivory are limited by plant defenses such as toxins and spines.

plantlet A small plant, particularly one that forms on a parent plant via asexual reproduction and drops, becoming an independent individual.

plasma cell An effector B cell, which produces large quantities of antibodies. Is descended from an activated B cell that has interacted with antigen.

plasma membrane A membrane that surrounds a cell, separating it from the external environment and selectively regulating passage of molecules and ions into and out of the cell. Also called *cell membrane*.

plasmid A small, usually circular, supercoiled DNA molecule independent of the cell's main chromosome(s) in prokaryotes and some eukaryotes.

plasmodesmata (singular: plasmodesma) Physical connection between two plant cells, consisting of gaps in the cell walls through which the two cells' plasma membranes, cytoplasm, and smooth ER can connect directly. Functionally similar to gap junctions in animal cells.

plasmogamy Fusion of the cytoplasm of two individuals. Occurs in many fungi.

plastid One of a family of plant organelles, bounded by a double membrane, that includes chloroplasts; chromoplasts, which house pigment-containing vacuoles; and leucoplasts, which store oils, starch, or proteins.

plastocyanin A small protein that shuttles electrons from photosystem II to photosystem I during photosynthesis.

plastoquinone (PQ) A nonprotein electron carrier in the chloroplast electron transport chain. Receives excited electrons from pheophytin and passes them to more electronegative molecules in the chain. Also carries protons to the lumen side of the thylakoid membrane, generating a proton-motive force.

platelet A small membrane-bound cell fragment in vertebrate blood that functions in blood clotting. Derived from large cells in the bone marrow.

pleiotropy (adjective: pleiotropic) The ability of a single gene to affect more than one phenotypic trait.

ploidy The number of complete chromosome sets present. *Haploid* refers to a ploidy of 1; *diploid*, a ploidy of 2; *triploid*, a ploidy of 3; and *tetraploid*, a ploidy of 4.

podium (plural: podia) See **tube foot.**

point mutation A mutation that results in a change in a single nucleotide pair in a DNA molecule.

polar (1) Asymmetrical or unidirectional. (2) Carrying a partial positive charge on one side of a molecule and a partial negative charge on the other. Polar molecules are generally hydrophilic.

polar bodies The tiny, nonfunctional cells produced during meiosis of a primary oocyte, due to most of the cytoplasm going to the ovum.

polar covalent bond A covalent bond in which electrons are shared unequally between atoms differing in electronegativity, resulting in the more electronegative atom having a partial negative charge and the other atom, a partial positive charge. Compare with **nonpolar covalent bond.**

polar nuclei In flowering plants, the nuclei in the female gametophyte that fuse with one sperm nucleus to produce the endosperm. Most species have two.

pollen grain In seed plants, a male gametophyte enclosed within a protective coat.

pollen tube In flowering plants, a structure that grows out of a pollen grain after it reaches the stigma, extends down the style, and through which two sperm cells are delivered to the ovule.

pollination The process by which pollen reaches the carpel of a flower (in flowering plants) or reaches the ovule directly (in conifers and their relatives).

poly(A) tail In eukaryotes, a sequence of 100–250 adenine nucleotides added to the 3′ end of newly transcribed messenger RNA molecules.

polycistronic mRNA An mRNA molecule that contains more than one protein-coding segment, each with its own start and stop codons and each coding for a different protein. Common in prokaryotes.

polygenic inheritance The inheritance patterns that result when many genes influence one trait.

polymer Any long molecule composed of small repeating units (monomers) bonded together. The main biological polymers are proteins, nucleic acids, and polysaccharides.

polymerase chain reaction (PCR) A laboratory technique for rapidly generating millions of identical copies of a specific stretch of DNA by incubating the original DNA sequence of

interest with primers, nucleotides, and DNA polymerase.

polymerization (verb: polymerize) The process by which many identical or similar small molecules (monomers) are covalently bonded to form a large molecule (polymer).

polymorphism (adjective: polymorphic) (1) The occurrence of more than one allele at a certain genetic locus in a population. (2) The occurrence of more than two distinct phenotypes of a trait in a population.

polyp The immotile (sessile) stage in the life cycle of some cnidarians (e.g., jellyfish). Compare with **medusa.**

polypeptide A chain of 50 or more amino acids linked together by peptide bonds. Compare with **oligopeptide** and **protein.**

polyploidy (adjective: polyploid) The state of having more than two full sets of chromosomes.

polyribosome A structure consisting of one messenger RNA molecule along with many attached ribosomes and their growing peptide strands.

polysaccharide A linear or branched polymer consisting of many monosaccharides joined by glycosidic linkages. Carbohydrate polymers with relatively few residues often are called *oligosaccharides.*

polyspermy Fertilization of an egg by multiple sperm.

poor-nutrition hypothesis The hypothesis that herbivore populations are limited by the poor nutritional content of plants, especially low nitrogen.

population A group of individuals of the same species living in the same geographic area at the same time.

population cycle A regular fluctuation in size exhibited by certain populations.

population density The number of individuals of a population per unit area.

population dynamics Changes in the size and other characteristics of populations through time.

population ecology The study of how and why the number of individuals in a population changes over time.

population viability analysis (PVA) A method of estimating the likelihood that a population will avoid extinction for a given time period.

positive feedback A physiological mechanism in which a change in some variable stimulates a response that increases the change. Relatively rare in organisms but is important in generation of the action potential. Compare with **negative feedback.**

positive pressure ventilation Ventilation of the lungs that is accomplished by "pushing" air into the lungs by positive pressure in the mouth. Compare with **negative pressure ventilation.**

positive-sense virus A virus whose genome contains the same sequences as the mRNA required to produce viral proteins. Compare with **ambisense virus** and **negative-sense virus.**

posterior Toward an animal's tail and away from its head. The opposite of anterior.

posterior pituitary The part of the pituitary gland that contains the ends of hypothalamic neurosecretory cells and from which oxytocin and antidiuretic hormone are secreted. Compare with **anterior pituitary.**

postsynaptic neuron A neuron that receives signals, usually via neurotransmitters, from another neuron at a synapse. Muscle and gland cells also may receive signals from presynaptic neurons.

post-translational control Regulation of gene expression by modification of proteins (e.g., addition of a phosphate group or sugar residues) after translation.

postzygotic isolation Reproductive isolation resulting from mechanisms that operate after mating of individuals of two different species occurs. The most common mechanisms are the death of hybrid embryos or reduced fitness of hybrids.

potential energy Energy stored in matter as a result of its position or molecular arrangement. Compare with **kinetic energy.**

prebiotic soup A hypothetical solution of sugars, amino acids, nitrogenous bases, and other building blocks of larger molecules that may have formed in shallow waters or deep-ocean vents of ancient Earth and given rise to larger biological molecules.

Precambrian era The interval between the formation of the Earth, about 4.6 billion years ago, and the appearance of most animal groups about 543 million years ago. Unicellular organisms were dominant for most of this era, and oxygen was virtually absent for the first 2 billion years.

predation The killing and eating of one organism (the prey) by another (the predator).

predator Any organism that kills other organisms for food.

prediction A measurable or observable result of an experiment based on a particular hypothesis. A correct prediction provides support for the hypothesis being tested.

pressure-flow hypothesis The hypothesis that sugar movement through phloem tissue is due to differences in the turgor pressure of phloem sap.

pressure potential (ψ_P) A component of the potential energy of water caused by physical pressures on a solution. In plant cells, it equals the wall pressure plus turgor pressure. Compare with **solute potential (ψ_S).**

presynaptic neuron A neuron that transmits signals, usually by releasing neurotransmitters, to another neuron or to an effector cell at a synapse.

pre-urine See **filtrate.**

prezygotic isolation Reproductive isolation resulting from any one of several mechanisms that prevent individuals of two different species from mating.

primary cell wall The outermost layer of a plant cell wall, made of cellulose fibers and gelatinous polysaccharides, that defines the shape of the cell and withstands the turgor pressure of the plasma membrane.

primary consumer An herbivore; an organism that eats plants, algae, or other primary producers. Compare with **secondary consumer.**

primary decomposer A decomposer (detritivore) that consumes detritus from plants.

primary growth In plants, an increase in the length of stems and roots due to the activity of apical meristems. Compare with **secondary growth.**

primary immune response An acquired immune response to a pathogen that the immune system has not encountered before. Compare with **secondary immune response.**

primary oocyte The large diploid cell in an ovarian follicle that can initiate meiosis to produce a haploid ovum.

primary producer Any organism that creates its own food by photosynthesis or from reduced inorganic compounds and that is a food source for other species in its ecosystem. Also called *autotroph.*

primary RNA transcript In eukaryotes, a newly transcribed messenger RNA molecule that has not yet been processed (i.e., it has not received a 5′ cap or poly(A) tail, and still contains introns).

primary spermatocyte A diploid cell in the testis that can initiate meiosis I to produce two secondary spermatocytes.

primary structure The sequence of amino acids in a peptide or protein; also the sequence of nucleotides in a nucleic acid. Compare with **secondary, tertiary,** and **quaternary structure.**

primary succession The gradual colonization of a habitat of bare rock or gravel, usually after an environmental disturbance that removes all soil and previous organisms. Compare with **secondary succession.**

primase An enzyme that synthesizes a short stretch of RNA to use as a primer during DNA replication.

primates The lineage of mammals that includes prosimians (lemurs, lorises, etc.), monkeys, and great apes (including humans).

primer A short, single-stranded RNA molecule that base pairs with the 5′ end of a DNA template strand and is elongated by DNA polymerase during DNA replication.

prion An infectious form of a protein that is thought to cause disease by inducing the normal form to assume an abnormal three-dimensional structure. Cause of spongiform encephalopathies, such as mad cow disease.

probe A radioactively or chemically labeled single-stranded fragment of a known DNA or RNA sequence that can bind to and thus detect its complementary sequence in a sample containing many different sequences.

proboscis A long, narrow feeding appendage through which food can be obtained.

procambium A group of cells in the center of a young plant embryo that gives rise to the vascular tissue.

product Any of the final materials formed in a chemical reaction.

productivity The total amount of carbon fixed by photosynthesis per unit area per year.

progesterone A steroid hormone produced in the ovaries and secreted by the corpus luteum after ovulation; causes the uterine lining to thicken.

programmed cell death See **apoptosis.**

prokaryote A member of the domain Bacteria or Archaea; a unicellular organism lacking a nucleus and containing relatively few organelles or cytoskeletal components. Compare with **eukaryote.**

prolactin A peptide hormone, produced and secreted by the anterior pituitary, that promotes milk production in female mammals and has a variety of effects on parental behavior and seasonal reproduction in other vertebrates.

prometaphase A stage in mitosis or meiosis during which the nuclear envelope breaks down and spindle fibers attach to chromatids.

promoter A short nucleotide sequence in DNA that binds RNA polymerase, enabling transcription to begin. In prokaryotic DNA, a single promoter often is associated with several contiguous genes. In eukaryotic DNA, each gene generally has its own promoter.

promoter-proximal elements In eukaryotes, regulatory sequences in DNA that are close to a promoter and that can bind regulatory transcription factors.

proofreading The process by which a DNA polymerase recognizes and removes a wrong base added during DNA replication and then continues synthesis.

prophase The first stage in mitosis or meiosis during which chromosomes become visible and the mitotic spindle forms. Synapsis and crossing over occur during prophase of meiosis I.

prosimians One of the two major lineages of primates, including lemurs, tarsiers, pottos, and lorises. Compare with **anthropoids.**

prostate gland A gland in male mammals that surrounds the base of the urethra and secretes a fluid that is a component of semen.

protease An enzyme that can degrade proteins by cleaving the peptide bonds between amino acid residues.

protein A macromolecule consisting of one or more polypeptide chains composed of 50 or more amino acids linked together. Each protein has a unique sequence of amino acids and, in its native state, a characteristic three-dimensional shape.

protein kinase An enzyme that catalyzes the addition of a phosphate group to another protein, typically activating or inactivating the substrate protein.

proteome The complete set of proteins produced by a particular cell type.

proteomics The systematic study of the interactions, localization, functions, regulation, and other features of the full protein set (proteome) in a particular cell type.

protist Any eukaryote that is not a green plant, animal, or fungus. Protists are a diverse paraphyletic group. Most are unicellular, but some are multicellular or form aggregations called colonies.

protoderm The exterior layer of a young plant embryo that gives rise to the epidermis.

proton-motive force The combined effect of a proton gradient and an electric potential gradient across a membrane, which can drive protons across the membrane. Used by mitochondria and chloroplasts to power ATP synthesis via the mechanism of chemiosmosis.

proton pump A membrane protein that can hydrolyze ATP to power active transport of protons (H^+ ions) across a plasma membrane against an electrochemical gradient. Also called *H^+ ATPase.*

proto-oncogene Any gene that normally encourages cell division in a regulated manner, typically by triggering specific phases in the cell cycle. Mutation may convert it into an oncogene.

protostomes A major lineage of animals that share a pattern of embryological development, including spiral cleavage, formation of the mouth earlier than the anus, and formation of the coelom by splitting of a block of mesoderm. Includes arthropods, mollusks, and annelids. Compare with **deuterostomes.**

proximal tubule In the vertebrate kidney, the convoluted section of a nephron into which filtrate moves from Bowman's capsule. Involved in the largely unregulated reabsorption of electrolytes, nutrients, and water. Compare with **distal tubule.**

proximate causation In biology, the immediate, mechanistic cause of a phenomenon (how it happens), as opposed to why it evolved. Also called *proximate explanation.* Compare with **ultimate causation.**

pseudocoelomate An animal with an internal fluid-filled body cavity (coelom) that is lined with endoderm and mesoderm layers.

pseudogene A DNA sequence that closely resembles a functional gene but is not transcribed. Thought to have arisen by duplication of the functional gene followed by inactivation due to a mutation.

pseudopodium (plural: pseudopodia) A temporary bulge-like extension of certain cells used in cell crawling and ingestion of food.

puberty The various physical and emotional changes that an immature animal undergoes leading to reproductive maturity. Also the period when such changes occur.

pulmonary artery A short, thick-walled artery that carries oxygen-poor blood from the heart to the lungs.

pulmonary circulation The part of the circulatory system that sends oxygen-poor blood to the lungs. Is separate from the rest of the circulatory system (the systemic circulation) in mammals and birds.

pulmonary vein A short, thin-walled vein that carries oxygen-rich blood from the lungs to the heart.

pulse-chase experiment A type of experiment in which a population of cells or molecules at a particular moment in time is marked by means of a labeled molecule and then their fate is followed over time.

pump Any membrane protein that can hydrolyze ATP to power active transport of a specific ion or small molecule across a plasma membrane against its electrochemical gradient. See **proton pump.**

Punnett square A diagram that depicts the genotypes and phenotypes that should appear in offspring of a certain cross.

pupa (plural: pupae) A metamorphosing insect that is enclosed in a protective case.

pupation A developmental stage of many insects, in which the body metamorphoses from the larval form to the adult form while enclosed in a protective case.

pupil The hole in the center of the iris through which light enters a vertebrate or cephalopod eye.

pure line In animal or plant breeding, a strain of individuals that produce offspring identical to themselves when self-pollinated or crossed to another member of the same population. Pure lines are homozygous for most, if not all, genetic loci.

purines A class of small, nitrogen-containing, double-ringed bases (guanine, adenine) found in nucleotides. Compare with **pyrimidines.**

pyrimidines A class of small, nitrogen-containing, single-ringed bases (cytosine, uracil, thymine) found in nucleotides. Compare with **purines.**

pyruvate dehydrogenase A large enzyme complex, located in the inner mitochondrial membrane, that is responsible for conversion of pyruvate to acetyl CoA during cellular respiration.

quantitative trait A heritable feature that exhibits phenotypic variation along a smooth, continuous scale of measurement (e.g., human height), rather than the distinct forms characteristic of discrete traits.

quaternary structure The overall three-dimensional shape of a protein containing two or more polypeptide chains (subunits); determined by the number, relative positions, and interactions of the subunits. Compare with **primary, secondary,** and **tertiary structure.**

radial cleavage The pattern of embryonic cleavage seen in protostomes, in which cells divide at right angles to each other to form tiers. Compare with **spiral cleavage.**

radial symmetry An animal body pattern in which there are least two planes of symmetry. Typically, the body is in the form of a cylinder or disk, with body parts radiating from a central hub. Compare with **bilateral symmetry.**

radiation Transfer of heat between two bodies that are not in direct physical contact. More generally, the emission of electromagnetic energy of any wavelength.

radicle The root of a plant embryo.

radula A rasping feeding appendage in gastropods (snails, slugs).

rain shadow The dry region on the side of a mountain range away from the prevailing wind.

range The geographic distribution of a species.

Ras protein A type of G protein that is activated by binding of signaling molecules to receptor tyrosine kinases and then initiates a phosphorylation cascade, culminating in a cell response.

Rb protein A tumor-suppressor protein that helps regulate progression of a cell from the G_1 phase to the S phase of the cell cycle. Defects in Rb protein are found in many types of cancer.

reactant Any of the starting materials in a chemical reaction.

reaction center Centrally located component of a photosystem containing proteins and a pair of specialized chlorophyll molecules. Is surrounded by antenna complexes and receives excited electrons from them.

reactive oxygen intermediates (ROIs) Highly reactive oxygen-containing compounds that are used in plant and animal cells to kill infected cells and for other purposes.

reading frame The division of a sequence of DNA or RNA into a particular series of three-nucleotide codons. There are three possible reading frames for any sequence.

realized niche The ecological niche that a species occupies in the presence of competitors. Compare with **fundamental niche.**

receptor-mediated endocytosis Uptake by a cell of certain extracellular macromolecules, bound to specific receptors in the plasma membrane, by pinching off the membrane to form small membrane-bound vesicles.

receptor tyrosine kinase (RTK) Any of a class of cell-surface signal receptors that undergo phosphorylation after binding a signaling molecule. The activated, phosphorylated receptor then triggers a signal-transduction pathway inside the cell.

recessive Referring to an allele whose phenotypic effect is observed only in homozygous individuals. Compare with **dominant.**

reciprocal altruism Altruistic behavior that is exchanged between a pair of individuals at different points in time (i.e., sometimes individual A helps individual B, and sometimes B helps A).

reciprocal cross A breeding experiment in which the mother's and father's phenotypes are the reverse of that examined in a previous breeding experiment.

recombinant Possessing a new combination of alleles. May refer to a single chromosome or DNA molecule, or to an entire organism.

recombinant DNA technology A variety of techniques for isolating specific DNA fragments and introducing them into different regions of DNA and/or a different host organism.

recombination See **genetic recombination.**

rectal gland A salt-excreting gland in the digestive system of sharks, skates, and rays.

rectum The last portion of the digestive tract where feces are held until they are expelled.

red blood cell A hemoglobin-containing cell that circulates in the blood and delivers oxygen from the lungs to the tissues. Also called *erythrocyte.*

redox reaction Any chemical reaction that involves the transfer of one or more electrons from one reactant to another. Also called *reduction-oxidation reaction.*

reduction An atom's gain of electrons during a redox reaction, either by acceptance of an electron from another atom or by the electrons in covalent bonds moving closer to the atomic nucleus.

reduction-oxidation reaction See **redox reaction.**

reflex An involuntary response to environmental stimulation. May involve the brain (e.g., conditioned reflex) or not (e.g., spinal reflex).

refractory No longer responding to stimuli that previously elicited a response. For example, the tendency of voltage-gated sodium channels to remain closed immediately after an action potential.

regeneration Growth of a new body part to replace a lost body part.

regulatory cascade In embryonic development, a progressive series of interactions among genes and/or cytoplasmic determinants that organizes the body plan of the embryo.

regulatory sequence, DNA Any segment of DNA that is involved in controlling transcription of a specific gene by binding certain proteins.

regulatory site A site on an enzyme to which a regulatory molecule can bind and affect the enzyme's activity; separate from the active site where catalysis occurs.

regulatory transcription factor General term for proteins that bind to DNA regulatory sequences (eukaryotic enhancers, silencers, and promoter-proximal elements), but not to the promoter itself, leading to an increase or decrease in transcription of specific genes. Compare with **basal transcription factor.**

reinforcement In evolutionary biology, the natural selection for traits that prevent interbreeding between recently diverged species.

release factors Proteins that can trigger termination of RNA translation when a ribosome reaches a stop codon.

releaser See **sign stimulus.**

renal corpuscle In the vertebrate kidney, the ball-like structure at the beginning of a nephron, consisting of a glomerulus and the surrounding Bowman's capsule. Acts as a filtration device.

replacement mutation See **missense mutation.**

replacement rate The number of offspring each female must produce over her entire life to "replace" herself and her mate, resulting in zero population growth. The actual number is slightly more than 2 because some offspring die before reproducing.

replica plating A method of identifying bacterial colonies that have certain mutations by transferring cells from each colony on a master plate to a second (replica) plate and observing their growth when exposed to different conditions.

replication fork The Y-shaped site at which a double-stranded molecule of DNA is separated into two single strands for replication.

repolarization Return to a normal membrane potential after it has changed; a normal phase in an action potential.

repressor Any regulatory protein that inhibits transcription.

reproduction The ability of an organism to make an exact or nearly exact copy of itself.

reptiles One of the two lineages of amniotes (vertebrates that produce amniotic eggs) distinguished by adaptations for reproduction on land. Includes turtles, snakes and lizards, crocodiles and alligators, and birds. Except for birds, all are ectotherms.

reservoir In biogeochemical cycles, a location in the environment where elements are stored for a time.

residues In a polymer, the individual units derived from the monomers that covalently bind to form the polymer. Proteins contain amino acid residues; nucleic acids, nucleotide residues; and polysaccharides, sugar residues.

resilience, community A measure of how quickly a community recovers following a disturbance.

resistance, community A measure of how much a community is affected by a disturbance.

resistance (*R*) loci Genes in plants encoding proteins involved in sensing the presence of pathogens and mounting a defensive response. Compare with **avirulence (*avr*) loci.**

respiration See **cellular respiration.**

respiratory distress syndrome A syndrome in which premature infants can suffocate due to insufficient surfactant in their lungs.

respiratory system The collection of cells, tissues, and organs responsible for gas exchange between an animal and its environment.

resting potential The membrane potential of a cell in its resting, or normal, state.

restriction endonucleases Bacterial enzymes that cut DNA at a specific base-pair sequence (restriction site). Also called *restriction enzymes.*

restriction site A specific short sequence in a DNA molecule that is recognized and cleaved by a particular restriction endonuclease. Also called *restriction endonuclease recognition site.*

retina A thin layer of light-sensitive cells (rods and cones) and neurons at the back of a camera-type eye, such as that of cephalopods and vertebrates.

retinal A light-absorbing pigment, derived from vitamin A, that is linked to the protein opsin in rods and cones of the vertebrate eye.

retrovirus A virus with an RNA genome that reproduces by transcribing its RNA into a DNA sequence and then inserting that DNA into the host's genome for replication.

reverse transcriptase A enzyme of retroviruses (RNA viruses) that can synthesize double-stranded DNA from a single-stranded RNA template.

Rh factor A protein present on the surface of red blood cells in some but not all humans. Clumping may occur when blood from an Rh^+ individual is mixed with that from an Rh^- individual.

rhizobia (singular: rhizobium) Members of the bacterial genus *Rhizobia*; nitrogen-fixing bacteria that live in root nodules of members of the pea family (legumes).

rhizoid The hairlike structure that anchors a bryophyte (nonvascular plant) to the substrate.

rhizome A modified stem that runs horizontally underground and produces new plants at the nodes (a form of asexual reproduction). Compare with **stolon.**

rhodopsin A transmembrane complex that is instrumental in detection of light by rods and cones of the vertebrate eye. Is composed of the transmembrane protein opsin covalently linked to retinal, a light-absorbing pigment.

ribonucleic acid (RNA) A nucleic acid composed of ribonucleotides that usually is single stranded and functions as structural components of ribosomes (rRNA), transporters of amino acids (tRNA), and translators of the message of the DNA code (mRNA).

ribonucleotide See **nucleotide.**

ribosomal RNA (rRNA) A RNA molecule that forms part of the structure of a ribosome.

ribosome A large complex structure that synthesizes proteins by using the genetic information encoded in messenger RNA strands. Consists of two subunits, each composed of ribosomal RNA and proteins.

ribosome binding site In a bacterial mRNA molecule, the sequence just upstream of the start codon to which a ribosome binds to initiate translation. Also called the *Shine-Dalgarno sequence.*

ribozyme Any RNA molecule that can act as a catalyst, that is, speed up a chemical reaction.

ribulose bisphosphate (RuBP) A five-carbon compound that combines with CO_2 in the first step of the Calvin cycle during photosynthesis.

RNA See **ribonucleic acid.**

RNA interference (RNAi) Degradation of an mRNA molecule or inhibition of its translation following its binding by a short RNA (microRNA) whose sequence is complementary to a portion of the mRNA.

RNA polymerase One of a class of enzymes that catalyze synthesis of RNA from ribonucleotides using a DNA template. Also called *RNA pol.*

RNA processing In eukaryotes, the changes that a primary RNA transcript undergoes in the nucleus to become a mature mRNA molecule, which is exported to the cytoplasm. Includes the addition of a 5′ cap and poly(A) tail and splicing to remove introns.

RNA replicase A viral enzyme that can synthesize RNA from an RNA template.

rod cell A photoreceptor cell with a rod-shaped outer portion that is particularly sensitive to dim

light, but not used to distinguish colors. Also called simply *rod*. Compare with **cone cell.**

root (1) An underground part of a plant that anchors the plant and absorbs water and nutrients. (2) In a phylogenetic tree, the bottom, most ancient node.

root apical meristem (RAM) A group of undifferentiated plant cells at the tip of a plant root that can differentiate into mature root tissue.

root cap A small group of cells that covers and protects the tip of a plant root. Senses gravity and determines the direction of root growth.

root hair A long, thin outgrowth of the epidermal cells of plant roots, providing increased surface area for absorption of water and nutrients.

root pressure Positive (upward) pressure of xylem sap in the vascular tissue of roots. Is generated during the night as a result of the accumulation of ions from the soil and subsequent osmotic movement of water into the xylem.

root system The belowground part of a plant.

rotifers Members of the phylum Rotifera. Distinguished by a cluster of cilia (corona) at the anterior end and a pseudocoelom. Rotifers belong to the lophotrochozoan branch of the protostomes.

rough endoplasmic reticulum (rough ER) The portion of the endoplasmic reticulum that is dotted with ribosomes. Involved in synthesis of plasma membrane proteins, secreted proteins, and proteins localized to the ER, Golgi apparatus, and lysosomes. Compare with **smooth endoplasmic reticulum.**

roundworms Members of the phylum Nematoda. Distinguished by an unsegmented body with a pseudocoelom and no appendages. Roundworms belong to the ecdysozoan branch of the protostomes. Also called *nematodes*.

rRNA See **ribosomal RNA.**

rubisco The enzyme that catalyzes the first step of the Calvin cycle during photosynthesis: the addition of a molecule of CO_2 to ribulose bisphosphate. Also called *ribulose 1,5-bisphosphate carboxylase/oxygenase*.

ruminants A group of hoofed mammals (e.g., cattle, sheep, deer) that have a four-chambered stomach specialized for digestion of plant cellulose. Ruminants regurgitate the cud, a mixture of partially digested food and cellulose-digesting bacteria, from the largest chamber (the rumen) for further chewing.

sac fungus A member of a monophyletic lineage of fungi (Ascomycota) that produce large, often cup-shaped reproductive structures that contain asci. Also called *cup fungus* and *ascomycete*.

salicylic acid A compound produced by plants that may play a role in systemic acquired resistance (SAR) against pathogens; a component of aspirin.

salivary glands Vertebrate glands that secrete saliva (a mixture of water, mucus-forming glycoproteins, and digestive enzymes) into the mouth.

sampling error The accidental selection of a nonrepresentative sample from some larger population, due to chance.

saprophyte An organism that feeds primarily on dead plant material.

sapwood The younger xylem in the outer layer of wood of a stem or root, functioning primarily in water transport.

sarcomere The repeating contractile unit of a skeletal muscle cell; the portion of a myofibril located between adjacent Z disks.

sarcoplasmic reticulum Sheets of smooth endoplasmic reticulum in a muscle cell. Contains high concentrations of calcium, which can be released into the cytoplasm to trigger contraction.

saturated Referring to fats and fatty acids in which all the carbon-carbon bonds are single bonds. Such fats have relatively high melting points. Compare with **unsaturated.**

scanning electron microscope (SEM) A microscope that produces images of the surfaces of objects by reflecting electrons from a specimen coated with a layer of metal atoms. Compare with **transmission electron microscope.**

scarify To scrape, rasp, cut, or otherwise damage the coat of a seed. Necessary in some species to trigger germination.

Schwann cell A type of glial cell that wraps around axons of some neurons outside the brain and spinal cord, forming a myelin sheath that provides electrical insulation. Compare with **oligodendrocyte.**

sclereid In plants, a type of sclerenchyma cell that usually functions in protection, such as in seed coats and nutshells. Compare with **fiber.**

sclerenchyma cell In plants, a cell that has a thick secondary cell wall and provides support; typically contains the tough structural polymer lignin and usually is dead at maturity. Includes fibers and sclereids. Compare with **collenchyma cell** and **parenchyma cell.**

screen See **genetic screen.**

scrotum A sac of skin, containing the testes, suspended just outside the abdominal body cavity of many male mammals.

secondary cell wall The inner layer of a plant cell wall formed by certain cells as they mature. Provides support or protection.

secondary consumer A carnivore; an organism that eats herbivores. Compare with **primary consumer.**

secondary growth In plants, an increase in the width of stems and roots due to the activity of lateral meristems. Compare with **primary growth.**

secondary immune response The acquired immune response to a pathogen that the immune system has encountered before. Compare with **primary immune response.**

secondary production The total amount of new body tissue produced by animals that eat plants. May involve growth and/or reproduction.

secondary spermatocyte A cell produced by meiosis I of a primary spermatocyte in the testis. Can undergo meiosis II to produce spermatids.

secondary structure In proteins, localized folding of a polypeptide chain into regular structures (e.g., α-helix and β-pleated sheet) stabilized by hydrogen bonding between atoms of the backbone. In nucleic acids, elements of structure (e.g., helices and hairpins) stabilized by hydrogen bonding and other interactions between complementary bases. Compare with **primary, tertiary,** and **quaternary structure.**

secondary succession Gradual colonization of a habitat after an environmental disturbance (e.g., fire, windstorm, logging) that removes some or all previous organisms but leaves the soil intact. Compare with **primary succession.**

second law of thermodynamics The principle of physics that the entropy of the universe or any closed system increases during any spontaneous process.

second-male advantage The reproductive advantage of a male who mates with a female last, after other males have mated with her.

second messenger A nonprotein signaling molecule produced or activated inside a cell in response to stimulation at the cell surface. Commonly used to relay the message of a hormone or other extracellular signaling molecule.

secretin A peptide hormone produced by cells in the small intestine in response to the arrival of food from the stomach. Stimulates secretion of bicarbonate (HCO_3^-) from the pancreas.

sedimentary rock A type of rock formed by gradual accumulation of sediment, as in riverbeds and on the ocean floor. Most fossils are found in sedimentary rocks.

seed A plant reproductive structure consisting of an embryo, associated nutritive tissue (endosperm), and an outer protective layer (seed coat). In angiosperms, develops from the fertilized ovule of a flower.

seed coat A protective layer around a seed that encases both the embryo and the endosperm.

seed plants Members of several phyla of green plants that have vascular tissue and make seeds. Include **angiosperms** and **gymnosperms.**

seedless vascular plants Members of several phyla of green plants that have vascular tissue but do not make seeds. Include horsetails, ferns, lycophytes, and whisk ferns.

segment A well-defined region of the body along the anterior-posterior body axis, containing similar structures as other, nearby segments.

segmentation Division of the body or a part of it into a series of similar structures; exemplified by the body segments of insects and worms and by the somites of vertebrates.

segmentation genes A group of genes that affect body segmentation in embryonic development. Includes gap genes, pair-rule genes, and segment polarity genes.

segmented worms See **annelids.**

segregation, principle of The concept that each pair of hereditary elements (alleles of the same gene) separate from each other during the formation of offspring (i.e., during meiosis). One of Mendel's two principles of genetics.

selective adhesion The tendency of cells of one tissue type to adhere to other cells of the same type.

selectively permeable membrane Any membrane across which some solutes can move more readily than others.

selective permeability The property of a membrane that allows some substances to diffuse across it much more readily than other substances.

self Property of a molecule or cell such that immune system cells do not attack it, due to certain molecular similarities to other body cells.

self-fertilization In plants, the fusion of two gametes from the same individual to form a diploid offspring. Also called *selfing*.

self-incompatible Incapable of self-fertilization.

semen The combination of sperm and accessory fluids that is released by male mammals and reptiles during ejaculation.

semiconservative replication The mechanism of replication used by cells to copy DNA. Results in each daughter DNA molecule containing one old strand and one new strand.

seminal vesicles In male mammals, paired reproductive glands that secrete a sugar-containing fluid into semen, which provides energy for sperm movement. In other vertebrates and invertebrates, often stores sperm.

senescence The process of aging.

sensitive period A short time period in a young animal's life during which learning of certain critical behaviors can occur. Also called the *critical period.*

sensor Any cell, organ, or structure with which an animal can sense some aspect of the external or internal environment. Usually functions, along with an integrator and effector, as part of a homeostatic system.

sensory neuron A nerve cell that carries signals from sensory receptors to the central nervous system. Compare with **interneuron** and **motor neuron.**

sepal One of the protective leaflike organs enclosing a flower bud and later supporting the blooming flower.

septum (plural: septa) Any wall-like structure. In fungi, septa divide the filaments (hyphae) of mycelia into cell-like compartments.

serotonin A neurotransmitter involved in many brain functions, including sleep, pleasure, and mood.

serum The liquid that remains when cells and clot material are removed from clotted blood. Contains water, dissolved gases, growth factors, nutrients, and other soluble substances. Compare with **plasma.**

sessile Permanently attached to a substrate; not capable of moving to another location.

set point A normal or target value for a regulated internal variable, such as body heat or blood pH.

severe combined immunodeficiency disease (SCID) A human disease characterized by an extremely high vulnerability to infectious disease. Caused by a genetic defect in the immune system.

sex chromosome Any chromosome carrying genes involved in determining the sex of an individual. Compare with **autosome.**

sex-linked inheritance Inheritance patterns observed in genes carried on sex chromosomes, so females and males have different numbers of alleles of a gene and may pass its trait only to one sex of offspring. Also called *sex-linkage.*

sexual dimorphism Any trait that differs between males and females.

sexual reproduction Any form of reproduction in which genes from two parents are combined via fusion of gametes, producing offspring that are genetically distinct from both parents. Compare with **asexual reproduction.**

sexual selection A pattern of natural selection that favors individuals with traits that increase their ability to obtain mates. Acts more strongly on males than females.

shell A hard protective outer structure. In protists, also called a *test.*

Shine-Dalgarno sequence See **ribosome binding sequence.**

shoot apical meristem (SAM) A group of undifferentiated plant cells at the tip of a plant stem that can differentiate into mature shoot tissues.

shoot system The aboveground part of a plant comprising stems, leaves, and flowers (in angiosperms).

short-day plant A plant that blooms in response to long nights (usually in late summer or fall in the northern hemisphere). Compare with **day-neutral** and **long-day plant.**

short interspersed nuclear elements See **SINES.**

shotgun sequencing A method of sequencing genomes that is based on breaking the genome into small pieces, sequencing each piece separately, and then figuring out how the pieces are connected.

sieve plate In plants, a pore-containing structure at one end of a sieve-tube member in phloem.

sieve-tube member In plants, an elongated sugar-conducting cell in phloem that has sieve plates at both ends, allowing sap to flow to adjacent cells.

signal In behavioral ecology, any information-containing behavior.

signal receptor Any cellular protein that binds to a particular signaling molecule (e.g., a hormone or neurotransmitter) and triggers a response by the cell. Receptors for water-soluble signals are transmembrane proteins in the plasma membrane; those for many lipid-soluble signals (e.g., steroid hormones) are located inside the cell.

signal recognition particle (SRP) A RNA-protein complex that binds to the ER signal sequence in a polypeptide as it emerges from a ribosome and transports the ribosome-polypeptide complex to the ER membrane where synthesis of the polypeptide is completed.

signal transducers and activators of transcription (STATs) In mammals, a group of regulatory transcription factors that, upon phosphorylation, can activate transcription of certain genes.

signal transduction The process by which a stimulus (e.g., a hormone, a neurotransmitter, or sensory information) outside a cell is amplified and converted into a response by the cell. Usually involves a specific sequence of molecular events, or signal transduction pathway.

signal transduction cascade See **phosphorylation cascade.**

sign stimulus A simple stimulus that elicits an invariant, stereotyped behavioral response (fixed action pattern) from an animal. Also called a *releaser.*

silencer A regulatory sequence in eukaryotic DNA to which repressor proteins can bind, inhibiting transcription of certain genes.

silent mutation A mutation that does not detectably affect the phenotype of the organism.

simple eye An eye with only one light-collecting apparatus (e.g., one lens), as in vertebrates. Compare with **compound eye.**

simple fruit A fruit (e.g., apricot) that develops from a single flower that has a single carpel or several fused carpels. Compare with **aggregate** and **multiple fruit.**

simple sequence repeat See **microsatellite.**

SINEs (short interspersed nuclear elements) The second most abundant class of transposable elements in human genomes; can create copies of itself and insert them elsewhere in the genome. Compare with **LINEs.**

single nucleotide polymorphism (SNP) A site on a chromosome where individuals in a population have different nucleotides. Can be used as a genetic marker to help track the inheritance of nearby genes.

single-strand DNA-binding proteins (SSBPs) A class of proteins that attach to separated strands of DNA during replication or transcription, preventing them from re-forming a double helix.

sink Any tissue, site, or location where an element or a molecule is consumed or taken out of circulation (e.g., in plants, a tissue where sugar exits the phloem). Compare with **source.**

sinoatrial (SA) node A cluster of cardiac muscle cells, in the right atrium of the vertebrate heart, that initiates the heartbeat and determines the heart rate. Compare with **atrioventricular (AV) node.**

siphon A tubelike appendage of many molluscs, that is often used for feeding or propulsion.

sister chromatids The paired strands of a recently replicated chromosome, which are connected at the centromere and eventually separate during anaphase of mitosis and meiosis II. Compare with **non-sister chromatids.**

sister groups Closely related taxa, which occupy adjacent branches in a phylogenetic tree. Also called *sister taxa.*

skeletal muscle The muscle tissue attached to the bones of the vertebrate skeleton. Consists of long, unbranched muscle fibers with a characteristic striped (striated) appearance; controlled voluntarily. Also called *striated muscle.* Compare with **cardiac** and **smooth muscle.**

sliding-filament model The hypothesis that thin (actin) filaments and thick (myosin) filaments slide past each other, thereby shortening the sarcomere. Shortening of all the sarcomeres in a myofibril results in contraction of the entire myofibril.

slug (1) A member of a certain lineage of terrestrial gastropods, closely related to snails but lacking a shell. (2) A mobile aggregation of cells of a cellular slime mold.

small intestine The portion of the digestive tract between the stomach and the large intestine. The site of the final stages of digestion and of most nutrient absorption.

small nuclear ribonucleoproteins See **snRNPs.**

smooth endoplasmic reticulum (smooth ER) The portion of the endoplasmic reticulum that does not have ribosomes attached to it. Involved in synthesis and secretion of lipids. Compare with **rough endoplasmic reticulum.**

smooth muscle The unstriated muscle tissue that lines the intestine, blood vessels, and some other organs. Consists of tapered, unbranched cells that can sustain long contractions. Not voluntarily controlled. Compare with **cardiac** and **skeletal muscle.**

snRNPs (small nuclear ribonucleoproteins) Complexes of proteins and small RNA molecules that function in splicing (removal of introns from primary RNA transcripts) as components of spliceosomes.

sodium-potassium pump A transmembrane protein that uses the energy of ATP to move sodium ions out of the cell and potassium ions in. Also called Na^+/K^+*-ATPase.*

solute Any substance that is dissolved in a liquid.

solute potential (ψ_S) A component of the potential energy of water caused by a difference in solute concentrations at two locations. Also called *osmotic potential*. Compare with **pressure potential (ψ_P)**.

solution A liquid containing one or more dissolved solids or gases in a homogeneous mixture.

solvent Any liquid in which one or more solids or gases can dissolve.

soma See **cell body.**

somatic cell Any type of cell in a multicellular organism except eggs, sperm, and their precursor cells. Also called *body cells*.

somatic nervous system The part of the peripheral nervous system (outside the brain and spinal cord) that controls skeletal muscles and is under voluntary control. Compare with **autonomic nervous system.**

somatostatin A hormone secreted by the pancreas and hypothalamus that inhibits the release of several other hormones.

somites Paired blocks of mesoderm on both sides of the developing spinal cord in a vertebrate embryo. Give rise to muscle tissue, vertebrae, ribs, limbs, etc.

soredium (plural: soredia) In lichens, a small reproductive structure that consists of fungal hyphae surrounding a cluster of green algae.

source Any tissue, site, or location where a substance is produced or enters circulation (e.g., in plants, the tissue where sugar enters the phloem). Compare with **sink.**

Southern blotting A technique for identifying specific DNA fragments separated by gel electrophoresis by transferring them to filter paper, separating the strands, and hybridizing with a labeled probe complementary to the fragment of interest. Compare with **Northern** and **Western blotting.**

speciation The evolution of two or more distinct species from a single ancestral species.

species A distinct, identifiable group of populations that is thought to be evolutionarily independent of other populations and whose members can interbreed. Generally distinct from other species in appearance, behavior, habitat, ecology, genetic characteristics, etc.

species–area relationship The mathematical relationship between the area of a certain habitat and the number of species that it can support.

species diversity The variety and relative abundance of the species present in a given ecological community.

species richness The number of species present in a given ecological community.

specific heat The amount of energy required to raise the temperature of 1 gram of a substance by 1°C; a measure of the capacity of a substance to absorb energy.

spectral karyotyping See **chromosome painting.**

spectrophotometer An instrument used to measure the wavelengths of light that are absorbed by a particular pigment.

sperm A mature male gamete; smaller and more mobile than the female gamete.

spermatid An immature sperm cell.

spermatogenesis The production of sperm. Occurs continuously in a testis.

spermatogonia (singular: spermatogonium) The diploid cells in a testis that can give rise to primary spermatocytes.

spermatophore A gelatinous package of sperm cells that is produced by males of species that have internal fertilization without copulation.

sphincter A muscular valve that can close off a tube, as in a blood vessel or a part of the digestive tract.

spicule Stiff spike of silica or calcium carbonate found in the body of many sponges.

spindle fibers Groups of microtubules that attach to chromosomes and push and pull them during mitosis and meiosis.

spiracle In insects, a small opening that connects air-filled tracheae to the external environment, allowing for gas exchange.

spiral cleavage The pattern of embryonic cleavage seen in deuterostomes, in which cells divide at oblique angles to form a spiral coil of cells. Compare with **radial cleavage.**

spleen A dark red organ, found near the stomach of most vertebrates, that filters blood, stores extra red blood cells in case of emergency, and plays a role in immunity.

spliceosome In eukaryotes, a large, complex assembly of snRNPs (small nuclear ribonucleoproteins) that catalyzes removal of introns from primary RNA transcripts.

splicing The process by which introns are removed from primary RNA transcripts and the remaining exons are connected together.

sporangium (plural: sporangia) A spore-producing structure found in seed plants, some protists, and some fungi (e.g., chytrids).

spore (1) In bacteria, a dormant form that generally is resistant to extreme conditions. (2) In eukaryotes, a single cell produced by mitosis or meiosis (not by fusion of gametes) that is capable of developing into an adult organism.

sporophyte In organisms undergoing alternation of generations, the multicellular diploid form that arises from two fused gametes and produces haploid spores. Compare with **gametophyte.**

sporopollenin A watertight material that encases spores and pollen of modern land plants.

stabilizing selection A pattern of natural selection that favors phenotypes near the middle of the range of phenotypic variation. Reduces overall genetic variation in a population. Compare with **disruptive selection.**

stamen The male reproductive structure of a flower. Consists of an anther, in which pollen grains are produced, and a filament, which supports the anther. Compare with **carpel.**

standing defense See **constitutive defense.**

stapes The last of three small bones (ossicles) in the middle ear of vertebrates. Receives vibrations from the tympanic membrane and by vibrating against the oval window passes them to the cochlea.

starch A mixture of two storage polysaccharides, amylose and amylopectin, both formed from α-glucose monomers. Amylopectin is branched, and amylose is unbranched. The major form of stored carbohydrate in plants.

start codon The AUG triplet in mRNA at which protein synthesis begins; codes for the amino acid methionine.

statocyst A sensory organ of many arthropods that detects the animal's orientation in space (i.e., whether the animal is flipped upside down).

statolith A tiny stone or dense particle found in specialized gravity-sensing organs in some animals such as lobsters.

statolith hypothesis The hypothesis that amyloplasts (dense, starch-storing plant organelles) serve as statoliths in gravity detection by plants.

STATs See **signal transducers and activators of transcription.**

stem cell Any relatively undifferentiated cell that can divide to produce daughter cells identical to itself or more specialized daughter cells, which differentiate further into specific cell types.

stereocilium (plural: stereocilia) One of many stiff outgrowths from the surface of a hair cell that are involved in detection of sound by terrestrial vertebrates or of waterborne vibrations by fishes.

steroid A class of lipid with a characteristic four-ring structure.

steroid-hormone receptor One of a family of intracellular receptors that bind to various steroid hormones, forming a hormone-receptor complex that acts as a regulatory transcription factor and activates transcription of specific target genes.

sticky end The short, single-stranded ends of a DNA molecule cut by a restriction endonuclease. Tend to form hydrogen bonds with other sticky ends that have complementary sequences.

stigma The moist tip at the end of a flower carpel to which pollen grains adhere.

stolon A modified stem that runs horizontally over the soil surface and produces new plants at the nodes (a form of asexual reproduction). Compare with **rhizome.**

stoma (plural: stomata) Generally, a pore or opening. In plants, a microscopic pore on the surface of a leaf or stem through which gas exchange occurs.

stomach A tough, muscular pouch in the vertebrate digestive tract between the esophagus and small intestine. Physically breaks up food and begins digestion of proteins.

stop codon One of three mRNA triplets (UAG, UGA, or UAA) that cause termination of protein synthesis. Also called a *termination codon*.

strain A population of genetically similar or identical individuals.

stream A body of water that moves constantly in one direction.

striated muscle See **skeletal muscle.**

stroma The fluid matrix of a chloroplast in which the thylakoids are embedded. Site where the Calvin cycle reactions occur.

structural formula A two-dimensional notation in which the chemical symbols for the constituent atoms are joined by straight lines representing single (—), double (=), or triple (≡) covalent bonds. Compare with **molecular formula.**

structural gene A stretch of DNA that codes for a functional protein or functional RNA molecule, not including any regulatory sequences (e.g., a promoter, enhancer).

structural homology Similarities in organismal structures (e.g., limbs, shells,

flowers) that are due to inheritance from a common ancestor.

structural isomer A molecule that shares the same molecular formula as another molecule but differs in the order in which covalently bonded atoms are attached. Compare with **geometric** and **optical isomer.**

style The slender stalk of a flower carpel connecting the stigma and the ovary.

subspecies A population that has distinctive traits and some genetic differences relative to other populations of the same species but that is not distinct enough to be classified as a separate species.

substrate (1) A reactant that interacts with an enzyme in a chemical reaction. (2) A surface on which a cell or organism sits.

substrate-level phosphorylation Production of ATP by transfer of a phosphate group from an intermediate substrate directly to ADP. Occurs in glycolysis and in the Krebs cycle.

succession In ecology, the gradual colonization of a habitat after an environmental disturbance (e.g., fire, flood), usually by a series of species. See **primary** and **secondary succession.**

sucrose A disaccharide formed from glucose and fructose. One of the two main products of photosynthesis.

sulfate reducer A prokaryote that produces hydrogen sulfide (H_2S) as a by-product of cellular respiration.

summation The additive effect of different postsynaptic potentials at a nerve or muscle cell, such that several subthreshold stimulations can cause an action potential.

supernatant The liquid above a layer of solid particles (the pellet) in a tube after centrifugation.

surface tension The cohesive force that causes molecules at the surface of a liquid to stick together, thereby resisting deformation of the liquid's surface and minimizing its surface area.

surfactant A mixture of phospholipids and proteins produced by lung cells that reduces surface tension, allowing the lungs to expand more.

survivorship curve A graph depicting the percentage of a population that survives to different ages.

suspension culture A population of cells grown in a flask containing a liquid nutrient medium. The flask is rotated continuously to keep the cells suspended and the nutrients mixed.

suspension feeder Any organism that obtains food by filtering small particles or small organisms out of water or air. Also called *filter feeder.*

sustainability The planned use of environmental resources at a rate no faster than the rate at which they are naturally replaced.

sustainable agriculture Agricultural techniques that are designed to maintain long-term soil quality and productivity.

swim bladder A gas-filled organ of many ray-finned fishes that regulates buoyancy.

swamp A wetland that has a steady rate of water flow and is dominated by trees and shrubs.

symbiosis (adjective: symbiotic) Any close and prolonged physical relationship between individuals of two different species. See **commensalism, mutualism,** and **parasitism.**

symmetric competition Ecological competition between two species in which both suffer similar declines in fitness. Compare with **asymmetric competition.**

sympathetic nervous system The part of the autonomic nervous system that stimulates fight-or-flight responses, such as increased heart rate, increased blood pressure, and decreased digestion. Compare with **parasympathetic nervous system.**

sympatric speciation The divergence of populations living within the same geographic area into different species as the result of their genetic (not physical) isolation. Compare with **allopatric speciation.**

sympatry Condition in which two or more populations live in the same geographic area, or close enough to permit interbreeding. Compare with **allopatry.**

symplast In plant roots, a continuous pathway through which water can flow through the cytoplasm of adjacent cells that are connected by plasmodesmata. Compare with **apoplast.**

symporter A carrier protein that allows an ion to diffuse down an electrochemical gradient, using the energy of that process to transport a different substance in the same direction *against* its concentration gradient. Compare with **antiporter.**

synapomorphy A shared, derived trait found in two or more taxa that is present in their most recent common ancestor but is missing in more distant ancestors. Useful for inferring evolutionary relationships.

synapse The interface between two neurons or between a neuron and an effector cell.

synapsis The physical pairing of two homologous chromosomes during prophase I of meiosis. Crossing over occurs during synapsis.

synaptic cleft The space between two communicating nerve cells (or between a neuron and effector cell) at a synapse, across which neurotransmitters diffuse.

synaptic plasticity Long-term changes in the responsiveness or physical structure of a synapse that can occur after particular stimulation patterns. Thought to be the basis of learning and memory.

synaptic vesicle A small neurotransmitter-containing vesicle at the end of an axon that releases neurotransmitter into the synaptic cleft by exocytosis.

synaptonemal complex A network of proteins that holds non-sister chromatids together during synapsis in meiosis I.

synthesis (S) phase The phase of the cell cycle during which DNA is synthesized and chromosomes are replicated.

system In biology, a more complex organization resulting from the combination of various components, such as a group of organs that work together to perform a physiological function.

systemic acquired resistance (SAR) A slow, widespread response of plants to a localized infection that protects healthy tissue from invasion by pathogens. Compare with **hypersensitive response.**

systemic circulation The part of the circulatory system that sends oxygen-rich blood from the lungs out to the rest of the body. Is separate from the pulmonary circulation in mammals and birds.

systemin A peptide hormone, produced by plant cells damaged by herbivores, that initiates a protective response in undamaged cells.

systole The portion of the heartbeat cycle during which the heart muscles are contracting. Compare with **diastole.**

systolic blood pressure The force exerted by blood against artery walls during contraction of the heart's left ventricle. Compare with **diastolic blood pressure.**

taiga A vast forest biome throughout subarctic regions, consisting primarily of short conifer trees. Characterized by intensely cold winters, short summers, and high annual variation in temperature.

taproot A large vertical main root of a plant.

taste bud Sensory structure, found chiefly in the mammalian tongue, containing spindle-shaped cells that respond to chemical stimuli.

TATA-binding protein (TBP) A protein that binds to the TATA box in eukaryotic promoters and is a component of the basal transcription complex.

TATA box A short DNA sequence in many eukaryotic promoters about 30 base pairs upstream from the transcription start site.

taxis Movement toward or away from some external cue.

taxon (plural: taxa) Any named group of organisms at any level of a classification system.

taxonomy The branch of biology concerned with the classification and naming of organisms.

TBP See **TATA-binding protein.**

T cell A type of leukocyte that matures in the thymus and, with B cells, is responsible for acquired immunity. Involved in activation of B cells ($CD4^+$ helper T cells) and destruction of infected cells ($CD8^+$ cytotoxic T cells). Also called *T lymphocytes.*

T-cell receptor (TCR) A transmembrane protein found on T cells that can bind to antigens displayed on the surfaces of other cells. Composed of two polypeptides called the alpha chain and beta chain. See **antigen presentation.**

tectorial membrane A membrane in the vertebrate cochlea that takes part in the transduction of sound by bending the stereocilia of hair cells in response to sonic vibrations.

telomerase An enzyme that replicates the ends of chromosome (telomeres) by catalyzing DNA synthesis from an RNA template that is part of the enzyme.

telomere The region at the end of a linear chromosome.

telophase The final stage in mitosis or meiosis during which sister chromatids (replicated chromosomes in meiosis I) separate and new nuclear envelopes begin to form around each set of daughter chromosomes.

temperate Having a climate with pronounced annual fluctuations in temperature (i.e., warm summers and cold winters) but typically neither as hot as the tropics nor as cold as the poles.

temperature A measurement of thermal energy present in an object or substance, reflecting how much the constituent molecules are moving.

template strand (1) The strand of DNA that is transcribed by RNA polymerase to create RNA. (2) An original strand of RNA used to make a complementary strand of RNA.

tendon A band of tough, fibrous connective tissue that connects a muscle to a bone.

tentacle A long, thin, muscular appendage of gastropod molluscs.

termination (1) In enzyme-catalyzed reactions, the final stage in which the enzyme returns to its original conformation and products are released. (2) In DNA transcription, the dissociation of RNA polymerase from DNA when it reaches a termination signal sequence. (3) In RNA translation, the dissociation of a ribosome from mRNA when it reaches a stop codon.

territory An area that is actively defended by an animal from others of its species.

tertiary structure The overall three-dimensional shape of a single polypeptide chain, resulting from multiple interactions among the amino acid side chains and the peptide backbone. Compare with **primary, secondary,** and **quaternary structure.**

test A hard protective outer structure seen in some protists. Also called a *shell.*

testcross The breeding of an individual of unknown genotype with an individual having only recessive alleles for the traits of interest in order to infer the unknown genotype from the phenotypic ratios seen in offspring.

testis (plural: testes) The sperm-producing organ of a male animal.

testosterone A steroid hormone, produced and secreted by the testes, that stimulates sperm production and various male traits and reproductive behaviors.

tetrapod Any member of the taxon Tetrapoda, which includes all vertebrates with two pairs of limbs (amphibians, mammals, birds, and other reptiles).

theory A proposed explanation for a broad class of phenomena or observations.

thermal energy The kinetic energy of molecular motion.

thermocline A gradient (cline) in environmental temperature across a large geographic area.

thermophile A bacterium or archaean that thrives in very hot environments.

thermoreceptor A sensory cell or an organ specialized for detection of changes in temperature.

thermoregulation Regulation of body temperature.

thick filament A filament composed of bundles of the motor protein myosin; anchored to the center of the sarcomere. Compare with **thin filament.**

thigmotropism Growth or movement of an organism in response to contact with a solid object.

thin filament A filament composed of two coiled chains of actin and associated regulatory proteins; anchored at the Z disk of the sarcomere. Compare with **thick filament.**

thorn A modified plant stem shaped as a sharp protective structure. Helps protect a plant against feeding by herbivores.

threshold potential The membrane potential that will trigger an action potential in a neuron or other excitable cell. Also called simply *threshold.*

thylakoid A flattened, membrane-bound vesicle inside a plant chloroplast that functions in converting light energy to chemical energy. A stack of thylakoids is a granum.

thymus An organ, located in the anterior chest or neck of vertebrates, in which immature T cells generated in the bone marrow undergo maturation.

thyroid gland A gland in the neck that releases thyroid hormone (which increases metabolic rate) and calcitonin (which lowers blood calcium).

thyroid-stimulating hormone (TSH) A peptide hormone, produced and secreted by the anterior pituitary, that stimulates release of thyroid hormones from the thyroid gland.

thyroxine (T_4) A peptide hormone containing four iodine atoms that is produced and secreted by the thyroid gland. Acts primarily to increase cellular metabolism. In mammals, T_4 is converted to the more active hormone triiodothyronine (T_3) in the liver.

tight junction A type of cell-cell attachment structure that links the plasma membranes of adjacent animal cells, forming a barrier that restricts movement of substances in the space between the cells. Most abundant in epithelia (e.g., the intestinal lining). Compare with **desmosome** and **gap junction.**

tip The end of a branch on a phylogenetic tree. Represents a specific species or larger taxon that has not (yet) produced descendants—either a group living today or a group that ended in extinction. Also called *terminal node.*

Ti plasmid A plasmid carried by *Agrobacterium* (a bacterium that infects plants) that can integrate into a plant cell's chromosomes and induce formation of a gall.

tissue A group of similar cells that function as a unit, such as muscle tissue or epithelial tissue.

tolerance In ecological succession, the phenomenon in which early-arriving species do not affect the probability that subsequent species will become established. Compare with **facilitation** and **inhibition.**

tonoplast The membrane surrounding a plant vacuole.

top-down control hypothesis The hypothesis that the size of herbivore populations is limited by predation or disease rather than by limited or toxic nutritional resources.

topoisomerase An enzyme that cuts and rejoins DNA downstream of the replication fork, to ease the twisting that would otherwise occur as the DNA "unzips."

torpor An energy-conserving physiological state, marked by a decrease in metabolic rate, body temperature, and activity, that lasts for a short period (overnight to a few days or weeks). Occurs in some small mammals when the ambient temperature drops significantly. Compare with **hibernation.**

totipotent Capable of dividing and developing to form a complete, mature organism.

trachea (plural: tracheae) (1) In insects, one of the small air-filled tubes that extend throughout the body and function in gas exchange. (2) In terrestrial vertebrates, the airway connecting the larynx to the bronchi. Also called *windpipe.*

tracheid In vascular plants, a long, thin water-conducting cell that has gaps in its secondary cell wall, allowing water movement between adjacent cells. Compare with **vessel element.**

trade-off In evolutionary biology, an inescapable compromise between two traits that cannot be optimized simultaneously. Also called *fitness trade-off.*

trait Any heritable characteristic of an individual.

transcription The process by which RNA is made from a DNA template.

transcriptional control Regulation of gene expression by various mechanisms that change the rate at which genes are transcribed to form messenger RNA. In negative control, binding of a regulatory protein to DNA represses transcription; in positive control binding of a regulatory protein to DNA promotes transcription.

transcriptome The complete set of genes transcribed in a particular cell.

transduction Conversion of information from one mode to another. For example, the process by which a stimulus outside a cell is converted into a response by the cell.

transfer cell In land plants, a cell that transfers nutrients from a parent plant to a developing plant seed.

transfer RNA (tRNA) One of a class of RNA molecules that have an anticodon at one end and an amino acid binding site at the other. Each tRNA picks up a specific amino acid and binds to the corresponding codon in messenger RNA during translation.

transformation (1) Incorporation of external DNA into the genome. Occurs naturally in some bacteria; can be induced in the laboratory by certain processes. (2) Conversion of a normal cell to a cancerous one.

transgenic Referring to an individual plant or animal whose genome contains DNA introduced from another individual, either from the same or a different species.

transitional form A fossil species or population with traits that are intermediate between older and younger species.

transition state A high-energy intermediate state of the reactants during a chemical reaction that must be achieved for the reaction to proceed. Compare with **activation energy.**

transition state facilitation The second stage (after initiation) in enzyme-catalyzed reactions, in which the enzyme enables formation of the transition state.

translation The process by which proteins and peptides are synthesized from messenger RNA.

translational control Regulation of gene expression by various mechanisms that alter the life span of messenger RNA or the efficiency of translation.

translocation (1) In plants, the movement of sugars and other organic nutrients through the phloem by bulk flow. (2) A type of mutation in which a piece of a chromosome moves to a nonhomologous chromosome. (3) The process by which a ribosome moves down a messenger RNA molecule during translation.

transmembrane protein Any membrane protein that spans the entire lipid bilayer. Also called *integral membrane protein.*

transmission The passage or transfer (1) of a disease from one individual to another or (2) of electrical impulses from one neuron to another.

transmission electron microscope (TEM) A microscope that forms an image from electrons that pass through a specimen. Compare with **scanning electron microscope.**

transpiration Water loss from aboveground plant parts. Occurs primarily through stomata.

transporter See **carrier protein.**

transport protein Collective term for any membrane protein that enables a specific ion or small molecule to cross a plasma membrane. Includes carrier proteins and channel proteins, which carry out passive transport (facilitated diffusion), and pumps, which carry out active transport.

transposable elements Any of several kinds of DNA sequences that are capable of moving themselves, or copies of themselves, to other locations in the genome. Include LINEs and SINEs.

tree of life A diagram depicting the genealogical relationships of all living organisms on Earth, with a single ancestral species at the base.

triacylglycerol See **fat.**

trichome A hairlike appendage that grows from epidermal cells of some plants. Trichomes exhibit a variety of shapes, sizes, and functions depending on species.

triglyceride See **fat.**

triiodothyronine (T_3) A peptide hormone containing three iodine atoms that is produced and secreted by the thyroid gland. Acts primarily to increase cellular metabolism. In mammals, T_3 has a stronger effect than does the related hormone thyroxine (T_4).

triose A monosaccharide (simple sugar) containing three carbon atoms.

triplet code A code in which a "word" of three letters encodes one piece of information. The genetic code is a triplet code because a codon is three nucleotides long and encodes one amino acid.

triploblast (adjective: triploblastic) An animal whose body develops from three basic embryonic cell layers: ectoderm, mesoderm, and endoderm. Compare with **diploblast.**

trisomy The state of having three copies of one particular type of chromosome.

tRNA See **transfer RNA.**

trochophore A larva with a ring of cilia around its middle that is found in some lophotrochozoans.

trophic level A feeding level in an ecosystem.

tropomyosin A regulatory protein present in thin (actin) filaments that blocks the myosin-binding sites on these filaments, thereby preventing muscle contraction.

troponin A regulatory protein, present in thin (actin) filaments, that can move tropomyosin off the myosin-binding sites on these filaments, thereby triggering muscle contraction. Activated by high intracellular calcium.

true navigation The type of navigation by which an animal can reach a specific point on Earth's surface.

trypsin A protein-digesting enzyme present in the small intestine that activates several other protein-digesting enzymes.

trypsinogen The precursor of protein-digesting enzyme trypsin. Secreted by the pancreas and activated by the intestinal enzyme enterokinase.

T tubules Membranous tubes that extend into the interior of muscle cells. Propagate action potentials throughout a muscle cell and trigger release of calcium from the sarcoplasmic reticulum.

tube foot One of the many small, mobile, fluid-filled extensions of the water vascular system of echinoderms; the part extending outside the body is called a podium. Used in locomotion and feeding.

tuber A modified plant rhizome that functions in storage of carbohydrates.

tumor A mass of cells formed by uncontrolled cell division. Can be benign or malignant.

tumor suppressor A gene (e.g., *p53* and *Rb*) or the protein it encodes that prevents cell division, particularly when the cell has DNA damage. Mutated forms are associated with cancer.

tundra The treeless biome in polar and alpine regions, characterized by short, slow-growing vegetation, permafrost, and a climate of long, intensely cold winters and very short summers.

turgid Swollen and firm as a result of high internal pressure (e.g., a plant cell containing enough water for the cytoplasm to press against the cell wall). Compare with **flaccid.**

turgor pressure The outward pressure exerted by the fluid contents of a plant cell against its cell wall.

Turner syndrome A human genetic disorder caused by the presence of only one X chromosome and no Y chromosome ("XO"). Individuals with this condition are female but sterile.

turnover In lake ecology, the complete mixing of upper and lower layers of water that occurs each spring and fall in temperate-zone lakes.

twofold rotational symmetry See **dyad symmetry.**

tympanic membrane The membrane separating the middle ear from the outer ear in terrestrial vertebrates, or similar structures in insects. Also called the *eardrum.*

ubiquinone See **coenzyme Q.**

ultimate causation In biology, the reason that a trait or phenomenon is thought to have evolved; the adaptive advantage of that trait. Also called *ultimate explanation.* Compare with **proximate causation.**

umami The taste of glutamate, responsible for the "meaty" taste of most proteins and of monosodium glutamate.

umbilical cord The cord that connects a developing mammalian embryo or fetus to the placenta and through which the embryo or fetus receives oxygen and nutrients.

unequal crossover An error in crossing over during meiosis I in which the two non-sister chromatids match up at different sites. Results in gene duplication in one chromatid and gene loss in the other.

unsaturated Referring to fats and fatty acids in which at least one carbon-carbon bond is a double bond. Double bonds produce kinks in the fatty acid chains and decrease the compound's melting point. Compare with **saturated.**

upstream In genetics, opposite to the direction in which RNA polymerase moves along a DNA strand. Compare with **downstream.**

urea A water-soluble excretory product of mammals and sharks. Used to remove from the body excess nitrogen derived from the breakdown of amino acids. Compare with **uric acid.**

ureter In vertebrates, a tube that transports urine from one kidney to the bladder.

urethra The tube that drains urine from the bladder to the outside environment. In male vertebrates, also used for passage of sperm during ejaculation.

uric acid A whitish excretory product of birds, reptiles, and terrestrial arthropods. Used to remove from the body excess nitrogen derived from the breakdown of amino acids. Compare with **urea.**

urochordates One of the three major chordate lineages (Urochordata), comprising sessile, filter-feeding animals that have a polysaccharide exoskeleton (tunic) and two siphons through which water enters and leaves; also called tunicates or sea squirts. Compare with **cephalochordates** and **vertebrates.**

uterus The organ in which developing embryos are housed in those vertebrates that give live birth. Common in most mammals and in some lizards, sharks, and other vertebrates.

vaccination The introduction into an individual of weakened, killed, or altered pathogens to stimulate development of acquired immunity against those pathogens.

vaccine A preparation designed to stimulate an immune response against a particular pathogen without causing illness. Vaccines consist of inactivated (killed) pathogens, live but weakened (attenuated) pathogens, or portions of a viral capsid (subunit vaccine).

vacuole A large organelle in plant and fungal cells that usually is used for bulk storage of water, pigments, oils, or other substances. Some vacuoles contain enzymes and have a digestive function similar to lysosomes in animal cells.

vagina The birth canal of female mammals; a muscular tube that extends from the uterus through the pelvis to the exterior.

valence The number of unpaired electrons in the outermost electron shell of an atom; determines how many covalent bonds the atom can form.

valence electron An electron in the outermost electron shell, the valence shell, of an atom. Valence electrons tend to be involved in chemical bonding.

valves In circulatory systems, flaps of tissue that prevent backward flow of blood, particularly in veins and between the chambers of the heart.

van der Waals interactions A weak electrical attraction between two hydrophobic side chains. Often contributes to tertiary structure in proteins.

variable number tandem repeat See **minisatellite.**

variable (V) region The portion of an antibody's light chains or heavy chains that has a highly variable amino acid sequence and forms part of the antigen-binding site. Compare with **constant (C) region.**

vasa recta In the vertebrate kidney, a network of blood vessels that runs alongside the loop of Henle of a nephron. Functions in reabsorption of water and solutes from the filtrate.

vascular bundle A cluster of xylem and phloem strands in a plant stem.

vascular cambium One of two types of lateral meristem, consisting of a ring of undifferentiated plant cells inside the cork cambium of woody plants; produces secondary xylem (wood) and secondary phloem. Compare with **cork cambium.**

vascular tissue system In plants, any tissue that is involved in conducting water or solutes from one part of a plant to another. Also called simply *vascular tissue.* See **phloem** and **xylem.**

vas deferens A pair of muscular tubes that store and transport semen from the epididymis to the ejaculatory duct. In nonhuman animals, called the *ductus deferens.*

vector A biting insect or other organism that transfers pathogens from one species to another. See also **cloning vector.**

vegetative organs The nonreproductive parts of a plant including roots, leaves, and stems.

vein Any blood vessel that carries blood (oxygenated or not) under relatively low pressure from the tissues toward the heart. Compare with **artery.**

vena cava (plural: vena cavae) A large vein that returns oxygen-poor blood to the heart.

ventral Toward an animal's belly and away from its back. The opposite of dorsal.

ventricle (1) A thick-walled chamber of the heart that receives blood from an atrium and pumps it to the body or to the lungs. (2) One of several small fluid-filled chambers in the vertebrate brain.

vertebra (plural: vertebrae) One of the cartilaginous or bony elements that form the spine of vertebrate animals.

vertebrates One of the three major chordate lineages (Vertebrata), comprising animals with a dorsal column of cartilaginous or bony structures (vertebrae) and a skull enclosing the brain. Includes fishes, amphibians, mammals, reptiles, and birds. Compare with **cephalochordates** and **urochordates.**

vessel element In vascular plants, a short, wide water-conducting cell that has gaps through both the primary and secondary cell walls, allowing unimpeded passage of water between adjacent cells. Compare with **tracheid.**

vestigial trait Any rudimentary structure of unknown or minimal function that is homologous to functioning structures in other species. Vestigial traits are thought to reflect evolutionary history.

vicariance The physical splitting of a population into smaller, isolated populations by a geographic barrier.

villi (singular: villus) Small, fingerlike projections (1) of the lining of the small intestine or (2) of the fetal portion of the placenta adjacent to maternal arteries. Function to increase the surface area available for absorption of nutrients and gas exchange (in the placenta).

virion A single mature virus particle.

virulence The ability of a pathogen or parasite to cause disease and death.

virulent Referring to pathogens that can cause severe disease in susceptible hosts.

virus A tiny intracellular parasite that uses host cell enzymes to replicate; consists of a DNA or RNA genome enclosed within a protein shell (capsid). In enveloped viruses, the capsid is surrounded by a phospholipid bilayer derived from the host cell plasma membrane, whereas nonenveloped viruses lack this protective covering.

visceral mass One of the three main parts of the mollusc body; contains most of the internal organs and external gill.

visible light The range of wavelengths of electromagnetic radiation that humans can see, from about 400 to 700 nanometers.

vitamin An organic micronutrient that usually functions as a coenzyme.

vitelline envelope A fibrous sheet of glycoproteins that surrounds mature egg cells in many vertebrates. Surrounded by a thick gelatinous matrix (the jelly layer) in some species. In mammals, called the *zona pellucida.*

viviparous Producing live young (instead of eggs) that develop within the body of the mother before birth. Compare with **oviparous** and **ovoviviparous.**

volt (V) A unit of electrical potential (voltage).

voltage Potential energy created by a separation of electric charges between two points. Also called *electrical potential.*

voltage clamping A technique for imposing a constant membrane potential on a cell. Widely used to investigate ion channels.

voltage-gated channel An ion channel that opens or closes in response to changes in membrane voltage. Compare with **ligand-gated channel.**

wall pressure The inward pressure exerted by a cell wall against the fluid contents of a plant cell.

water cycle, global The movement of water among terrestrial ecosystems, the oceans, and the atmosphere.

water potential (ψ) The potential energy of water in a certain environment compared with the potential energy of pure water at room temperature and atmospheric pressure. In living organisms, ψ equals the solute potential (ψ_S) plus the pressure potential (ψ_P).

water potential gradient A difference in water potential in one region compared with that in another region. Determines the direction that water moves, always from regions of higher water potential to regions of lower water potential.

watershed The area drained by a single stream or river.

water table The upper limit of the underground layer of soil that is saturated with water.

water vascular system In echinoderms, a system of fluid-filled tubes and chambers that functions as a hydrostatic skeleton.

Watson-Crick pairing See **complementary base-pairing.**

wavelength The distance between two successive crests in any regular wave, such as light waves, sound waves, or waves in water.

wax A class of lipid with extremely long hydrocarbon tails, usually combinations of long-chain alcohols with fatty acids. Harder and less greasy than fats.

weather The specific short-term atmospheric conditions of temperature, moisture, sunlight, and wind in a certain area.

weathering The gradual wearing down of large rocks by rain, running water, and wind; one of the processes that transform rocks into soil.

weed Any plant that is adapted for growth in disturbed soils.

Western blotting A technique for identifying specific proteins separated by gel electrophoresis by transferring them to filter paper and exposing them to a labeled antibody that binds to the protein of interest. Compare with **Northern blotting** and **Southern blotting.**

wetland A shallow-water habitat where the soil is saturated with water for at least part of the year.

white blood cells See **leukocytes.**

wild type The most common phenotype seen in a population; especially the most common phenotype in wild populations compared with inbred strains of the same species.

wildlife corridor Strips of wildlife habitat connecting populations that otherwise would be isolated by man-made development.

wilt To lose turgor pressure in a plant tissue.

wobble hypothesis The hypothesis that some tRNA molecules can pair with more than one mRNA codon, tolerating some variation in the third base, as long as the first and second bases are correctly matched.

wood Xylem resulting from secondary growth. Also called *secondary xylem.*

xeroderma pigmentosum A human disease characterized by extreme sensitivity to ultraviolet light. Caused by an autosomal recessive allele that results in a defective DNA repair system.

X-linked inheritance Inheritance patterns for genes located on the mammalian X chromosome. Also called *X-linkage.*

X-ray crystallography A technique for determining the three-dimensional structure of large molecules, including proteins and nucleic acids, by analysis of the diffraction patterns produced by X-rays beamed at crystals of the molecule.

xylem A plant vascular tissue that conducts water and ions; contains tracheids and/or vessel elements. Primary xylem develops from the procambium of apical meristems; secondary xylem, or wood, from the vascular cambium of lateral meristems. Compare with **phloem.**

xylem sap The watery fluid found in the xylem of plants.

yeast Any fungus growing as a single-celled form. Also, a specific lineage of ascomycetes.

Y-linked inheritance Inheritance patterns for genes located on the mammalian Y chromosome. Also called *Y-linkage.*

yolk The nutrient-rich cytoplasm inside an egg cell; used as food for the growing embryo.

Z disk The structure that forms each end of a sarcomere. Contains a protein that binds tightly to actin, thereby anchoring thin filaments.

zero population growth (ZPG) A state of stable population size due to fertility staying at the replacement rate for at least one generation.

zona pellucida The gelatinous layer around a mammalian egg cell. In other vertebrates, called the *vitelline envelope.*

zone of (cellular) division In plant roots, a group of apical meristematic cells just behind the root cap where cells are actively dividing.

zone of (cellular) elongation In plant roots, a group of young cells, located behind the apical meristem, that are increasing in length.

zone of (cellular) maturation In plant roots, a group of plant cells, located several centimeters behind the root cap, that are differentiating into mature tissues.

Z scheme Path of electron flow in which electrons pass from photosystem II to photosystem I and ultimately to $NADP^+$ during the light-dependent reactions of photosynthesis. Also called *noncyclic electron flow.*

zygomycete A member of a paraphyletic group of fungi (Zygomycota) characterized by a durable, thick-walled zygosporangium that forms from yoked hyphae of different mating types.

zygosporangium (plural: zygosporangia) The spore-producing structure in fungi that are members of the Zygomycota.

zygote The diploid cell formed by the union of two haploid gametes; a fertilized egg. Capable of undergoing embryological development to form an adult.
