Bosutinib 500 mg daily was compared to imatinib 400 mg daily in a phase III randomized trial of 502 patients in newly diagnosed CP CML.[43] Although the primary end point of complete cytogenetic response rate at 12 months (70% with bosutinib vs 68% with imatinib) was not significantly different observed, the rate of major molecular response was significantly higher in the bosutinib group (41% vs 27%, *P*<0.001). The incidence of adverse events was similar between the groups with the exception that bosutinib had a higher incidence of diarrhea (68% vs 21%) and imatinib had a higher incidence of edema (38% vs 11%).

Ponatinib is considered a third-generation TKI that contains a novel triple-bond linkage in its chemical structure that avoids the steric hindrance caused by the bulky isoleucine residue at position 315 in T315I *BCR-ABL* binding site cleft, providing clinical activity against this resistance phenotype.[44] In the combined phase I and II trials, 147 patients had a T315I mutated *BCR-ABL* CML in either CP, AP, BC or Ph positive ALL, the maximum tolerated dose of ponatinib was 45 mg with dose-limiting toxicities identified as pancreatitis and myelosuppression.[44,45] Of the 76 patients with CP CML, 72% achieved a complete cytogenetic response and 61% a major molecular response. Of the 45 patients with AP or BC CML, the rate of major hematologic response was 58% and 27%, respectively.[44,45] Hepatotoxicity including reports of liver failure, vascular occlusion, heart failure, and death are also included in the black box warning, several of which occurred within 1 week of starting therapy. The manufacturer recommends specific dose modifications for myelosuppression, hepatotoxicity, and elevated lipase. Due to these toxicities, the FDA requires a Risk Evaluation and Mitigation Strategy (REMS) prescribing program in patients with CML and a T315I mutation or in patients in whom no other TKI therapy is indicated.[46]

Tables 135-4 and 135-5 summarize dosing, drug interactions, adverse drug reactions, and monitoring of advanced-generation TKIs. Edema and plural effusions can be managed by dasatinib drug holiday, diuretics, or short courses of steroids. Nilotinib can be associated with indirect bilirubin elevations in 10% to 15% of patients.[38,39] Nilotinib may prolong the QTc interval (black box warning) and patients should have an electrocardiogram at baseline, at 7 days following initiation of therapy, and periodically thereafter. Based on early clinical trial data, bosutinib appears to have similar rates of adverse events of diarrhea, nausea and vomiting, rash, and abdominal discomfort.[41] Like imatinib, advanced-generation TKIs are metabolized by cytochrome P450 (CYP) 3A4. Clinicians need to be aware of possible drug interactions with inducers and inhibitors of the CYP3A4 pathway such as phenytoin, azole antifungals, or macrolide antibiotics.

Clinical **Controversy...**

The controversy of whether to use imatinib or a second-generation TKI therapy as first-line treatment for patients is ongoing. In the first-line setting, a higher proportion of patients treated with nilotinib or dasatinib achieved a major cytogenetic response and *BCR-ABL* transcripts of less than 10% at 3 and 6 months than those on imatinb. The achievement of a major molecular response, especially early in therapy, is associated with long-term disease control. However, the five-year progression-free and overall survival are not significantly different between imatinib and second-generation tyrosine kinase therapy. A generic formulation of imatinib is available that may provide cost savings for payers and patients. The NCCN guidelines currently support that either imatinib, nilotinib, or dasatinib may be used in the first line setting.[12]

Omacetaxine

Omacetaxine was approved by the FDA in October 2012 for treatment of CP or AP CML with resistance or intolerance to two or more TKIs. Omacetaxine is a first-in-class cephalotaxine ester that inhibits protein synthesis independent of direct *BCR-ABL* binding. The putative mechanism is the reduction of *BCR-ABL* oncoproteins and Mcl-1, an anti-apoptotic Bcl-2 family member, via binding to A-site cleft in the peptidyl-transferase center of the large ribosomal subunits. Efficacy with omacetaxine has been demonstrated in two patients groups: CP or AP CML resistant to two or more TKIs and

patients previously treated with imatinib harboring the T315I mutation. The former group was evaluated in a combined analysis of two phase II studies for CP and AP CML. Omacetaxine was administered at 1.25 mg/m^2 subcutaneously twice daily for 14 consecutive days every 28 days then for 7 days every 28 days as maintenance.[47] Of the 122 patients enrolled, 81 had CP CML of which 20% achieved a major cytogenetic response, 10% achieved a complete cytogenetic response, with a median overall survival of 34 months.

A phase II trial of omacetaxine was conducted in 62 CP CML patients with a history of the T315I mutation.[48] Patients were treated with the induction regimen as above and transitioned to maintenance when the patient achieved a hematologic response. Hematologic response was achieved in 77%, complete cytogenetic response in 16%, and major cytogenetic response in 23% of patients. The median duration of complete hematologic response was 9.1 months, and major cytogenetic response was 6.6 months. The majority of grade 3/4 toxicities reported in these trials were myelosuppression with occasional reports of myalgias and arthralgias and gastrointestinal toxicity.

Hematopoietic Stem Cell Transplantation

5 Allogeneic HSCT remains the only therapy proven to cure patients with CML, with many patients alive and disease-free decades after transplant. Patients undergoing allogeneic HSCT from a human leukocyte antigen (HLA)-matched sibling donor have 5-year survival rates ranging from 60% to 80% and long-term survival of about 50%.[49,50] In most long-term survivors, the *BCR-ABL* translocation is absent in all diagnostic tests including RT-PCR. Prognostic risk factors associated with survival outcomes include age, phase of disease, and disease duration. Increasing age is associated with poorer prognosis, with higher transplant-related mortality in patients older than age 50 years. Patients with CP who receive allogeneic HSCT have better outcomes than those in AP or BC. The time from diagnosis to transplantation also affects outcomes. Patients who undergo matched-sibling allogeneic HSCT within the first year of diagnosis have a better 5-year survival rate than those who undergo transplantation more than 1 year after their diagnosis (70%-80% vs 50%-60%).[49,50] These data were reported prior to the use of imatinib as first-line therapy for CML.

The major limitation for broad application of HSCT is that fewer than 30% of patients who are transplant-eligible will have an HLA-matched sibling donor. The most practical approach is to use an HLA-matched unrelated donor, if available. Matched unrelated donor HSCT has an overall 5-year survival reported to be 40% to 70%, which approaches overall survival data results reported for matched-sibling donor HSCT.[7,12,49,50] The advent of TKI therapy has resulted in fewer transplants for CML. Data collected to date appear to show that imatinib use prior to transplantation does not negatively affect transplant-related mortality.[51]

Treatment options in patients who relapse after HSCT are limited. Graft-versus-leukemia (GVL) effect, TKIs, omacetaxine, IFN-α, or a clinical trial are reasonable options. The infusion of donor lymphocytes functions as a form of adoptive immunotherapy that can induce a GVL effect. In relapsed CML, donor lymphocytes induce durable responses and these responses strongly correlate with the development of graft-versus-host disease (GVHD).[52] Tumor burden also predicts the likelihood of response to donor lymphocyte infusion in relapsed CML. The optimal method of administering donor lymphocytes remains unclear, but these data suggest it may be possible to partially separate the GVL effect from GVHD.

Imatinib has been used in patients who have residual disease after allogeneic HSCT. Most patients respond to imatinib with complete molecular response of 70%.[53] Use of imatinib or other TKI therapies require further study to determine the magnitude of benefit when applied in the post-HSCT setting.[54] The role of nonmyeloablative transplants in CML is evolving, but preliminary results suggest comparable outcomes to myeloablative transplants. Data from a German registry suggest that 17% of all transplants for CML use a reduced-intensity conditioning regimen.[55]

Personalized Pharmacotherapy

Personalized treatment of CML is mostly directed following initiation of second-line therapy. Mutational analysis of binding sites that confer resistance to TKIs should be evaluated if initial response is inadequate, or the milestones of complete cytogenetic response or major molecular response are lost, or if any signs of disease progression in the form of AP or BC are noted.[12,13] The results of this analysis will guide selection of the appropriate TKI as second-line therapy.[12,13,56] In addition, with the advent of omacetaxine and ponatinib, two agents are now available that are active against the T315I mutation that confers resistance to the rest of the TKIs.

Preliminary data support the role of therapeutic drug monitoring of TKIs in CML. Trough imatinib levels of ≥1 μmol/L have been associated in patients with a higher response than those with <1 μmol/L.[57] Data on nilotinib and dasatinib are more limited. The clinical applicability of therapeutic drug monitoring is still to be determined because the drug assays are not yet commercially available.

Evaluation of Therapeutic Outcomes

Current standard of care is for patients with newly diagnosed CP CML to receive imatinib or one of the second-generation TKIs. The goal of disease monitoring in CML is to differentiate patients who have optimally responded to an initial course of TKI therapy from those at high risk for treatment failure. With imatinib, nilotinib, and dasatinib as appropriate options for frontline therapy for newly diagnosed CP CML, and bosutinib, ponatinib, and omacetaxine approved for salvage therapy, clinicians have a large number of treatment options to consider before allogeneic HSCT. Future research opportunities will focus on how to select second-, third-, and fourth-line therapies and whether combination therapy provides additional long-term benefit.

CHRONIC LYMPHOCYTIC LEUKEMIA

Epidemiology and Etiology

Chronic lymphocytic leukemia is a lymphoproliferative disorder characterized by accumulation of functionally incompetent clonal B lymphocytes.[58] Chronic lymphocytic leukemia is the most common form of leukemia in the United States, but is rare in other countries, such as Japan and China. It is estimated that 18,960 new cases of CLL will be diagnosed in the United States in 2016.[1] Occasional family clusters have been recognized, and first-degree relatives of patients with CLL are at three times the risk of developing a lymphoid malignancy as compared with the general population. Chronic lymphocytic leukemia is a disease of the elderly, with a median age of 71 years, although 20% to 30% of CLL occurs in patients who are younger than 55 years of age. Male sex, white race, family history, and advanced age are known risk factors for the disease.

Pathophysiology

Chronic lymphocytic leukemia cells are comprised of a neoplastic clone of CD5$^+$ cells, which express low levels of surface-membrane immunoglobulin M (IgM) and immunoglobulin D (IgD) compared to normal peripheral blood B cells. Normal CD5$^+$ B lymphocytes are present in the lymph nodes and in the blood. Neoplastic CD5$^+$ cells accumulate in the lymph nodes and spleen because of the loss of apoptosis by either the overexpression of an oncogene, such as *bcl-1* or *2*, or loss of a tumor suppressor gene, such as *RB1*.[58] The bcl-2 protein is a major regulator of apoptosis or programmed cell death.

Evidence is emerging that antigenic stimulation and cytokines drive the proliferation of the CLL cells.

Although CLL lacks a common genetic target as observed in CML, B-cell-receptor signaling has emerged as a driving factor for CLL tumor survival. Bruton's tyrosine kinase (BTK), a member of the Tec family of kinases, is essential for the activation of several constitutively active pathways for CLL cell survival. Bruton's tyrosine kinase leads to activation of the Akt, extracellular signal-regulated kinase (ERK), and nuclear factor kappa light-chain enhancer of active B-cells (NF-κβ) pathways.[59] Additionally, BTK is required for B-cell chemokine-mediated homing and adhesion. Phosphatidylinosital 3-Kinase (PI3K) is a lipid kinas that has a catalytic subunit with four different isoforms: α, β, γ, and δ. When PI3K is activated, it generates phospholipid messengers on the cell membrane that recruit and activate various intracellular enzymes that regulate cell motility, survival, and proliferation.[60] The δ isoform plays a critical role in normal B-cell development, function, and transducing signals from receptors. The PI3Kδ signaling pathway is hyperactive in CLL and other B-cell cancers.

A monoclonal population of B cells with a similar surface antigen phenotype as CLL cells has been recently identified in patients up to several years prior to diagnosis of the disease.[61] This phenomenon, termed monoclonal B-cell lymphocytosis (MBL) appears to predict whether a patient is at risk for developing CLL over time. In a cohort of 77,000 patients enrolled in a cancer screening trial, 45 patients were diagnosed with CLL throughout the duration of the study. Baseline blood samples collected on enrollment of the screening trial were analyzed for the patients who developed CLL. MBL was present in 44 of 45 of the patients by either flow cytometric or molecular analysis (ie, RT-PCR assay) and confirmed in 41 of 45 of these patients by both methods. Samples predated the diagnosis of CLL in a time period ranging from 6 months to 6.4 years. This finding could lead to potentially earlier diagnosis and intervention for CLL.

Cytogenetic abnormalities correlate with disease progression in CLL. About 80% of patients with CLL have a karyotypic abnormality. The chromosomes that are most frequently involved include chromosomes 11, 12, 13, and 17.[62] Additional cytogenetic abnormalities may be acquired during therapy, particularly with deletions of chromosome 17, which have an adverse effect on survival.[63] Somatic point mutations have been identified in a cohort of 91 patients yielding nine mutated genes: *TP53*, *ATM*, *MYD88*, *NOTCH1*, *SF3B1*, *ZMYM3*, *MAPK1*, *FBXW7*, and *DDX3X*.[64] These mutations were associated with cell-cycle and DNA repair pathways, intracellular signaling, inflammatory pathways, and RNA splicing and processing. A correlation was identified with *SF3B1* and chromosome 11 deletions providing insight into how these mutations may impact clinical outcomes.

About 4% of patients with CLL will undergo transformation of their disease to an aggressive non-Hodgkin lymphoma (diffuse large B cell), which is termed as *Richter's syndrome*. Richter's syndrome may be triggered by accumulation of additional cytogenetic abnormalities in the malignant clone of lymphocytes or by viral infections, such as Epstein-Barr's virus.[65]

CLINICAL PRESENTATION — Chronic Lymphocytic Leukemia

Constitutional Symptoms

- Fever, fatigue, weight loss

Physical Examination

- Lymphadenopathy (87%)
- Splenomegaly (54%)
- Hepatomegaly (14%)

Laboratory Tests

- Peripheral blood
  - Lymphocytosis
  - Coombs-positive autoimmune hemolytic anemia
  - Hyper- or hypogammaglobulinemia
  - Monoclonal gammopathy
  - Anemia
  - Thrombocytopenia
- Bone marrow
  - Hypercellular
  - Increased mature lymphocytes
  - Increased megakaryocytes
- Molecular markers
  - Cytogenetics (17p-)
  - ZAP-70 mutations

Staging and Prognosis

Survival times for patients with CLL are widely variable, with some patients succumbing to disease within 3 years and others living into a second decade from the time of diagnosis. The Rai and the Binet staging systems are commonly used in CLL with the Rai being favored in the United States and the Binet in Europe. The Rai staging system has been combined into a risk classification scheme: low risk (stage 0), intermediate risk (stages I and II), and high risk (stages III and IV) with median survivals of greater than 10 years, 7 years, and 2 to 4 years, respectively.[58,66]

The disease course for CLL varies within each stage such that one patient may have an indolent course with long survival time, while another patient may have more aggressive disease and a relatively short survival time. The Rai and Binet staging systems incompletely predict for individual patients who may experience more rapid disease progression. Patients with Richter's syndrome will have a rapidly advancing disease course that mimics diffuse large B-cell non-Hodgkin lymphoma. However, successful treatment of the diffuse large B-cell non-Hodgkin lymphoma with combination chemotherapy will not eradicate the underlying clone of CLL cells and patients will ultimately relapse.[65]

Biomarkers, such as CD38 expression and ζ-associated protein 70 (ZAP-70) expression, have been explored as prognostic factors for CLL. CD38 is a cell-surface antigen that is associated with early progression, significantly shorter overall survival, and a poor response to fludarabine.[58,67,68] ZAP-70 is an intracellular protein with tyrosine kinase activity. Once considered as simply a surrogate marker for the unmutated variable region of the immunoglobulin heavy chain gene (IGHV), elevated ZAP-70 expression appears to predict for rapid CLL disease progression and independently correlates with prognosis.[66,68]

Cytogenetic changes such as deletion of the short arm of chromosome 17 (17p-), which corresponds to p53 silencing, can be biomarkers of poor response to therapy. A prospective study showed that newly diagnosed patients with 17p- had a median time-to-progression following first-line therapy with either fludarabine or

fludarabine and cyclophosphamide of 10 to 12 months.[63] Patients with chromosomal abnormalities of 11, 12, 13, and 17 have reported median survivals of 133 months, 114 months, 79 months, and 32 months, respectively.[62]

TREATMENT
Chronic Lymphocytic Leukemia

Desired Outcomes

6 The primary goals of treatment for CLL are to achieve and maintain remission duration with minimal treatment-related toxicity. The management of patients with CLL is highly individualized with some patients receiving therapy on diagnosis, while other patients with early-stage disease are managed expectantly. Indications for starting treatment include disease-related symptoms (fatigue, night sweats, weight loss, and fever), threatened end-organ function, bulky disease, doubling of lymphocyte doubling time in less than 6 months, progressive anemia, and platelet count less than 100,000/mm^3 (100×10^9/L).[70,71] Consideration of initial treatment options is based on several factors including patient age, disease stage, and high-risk prognostic factors, such as deletion 17p- or 11q.

Most stage 0 patients do not require treatment and can be managed with observation. In patients with stage I disease, treatment is controversial. A consistent survival benefit from early therapy has not been reported in asymptomatic patients.[70,71] Cytotoxic chemotherapy in early stage CLL is usually reserved for patients who have disease characteristics consistent with a more aggressive course, such as short lymphocyte doubling times and presence of biologic markers such as ZAP-70 or high-risk cytogenetics. In stages II through IV disease, treatment is required, with the goal of achieving a partial or complete remission. Table 135-6 shows the regimens used to treat newly diagnosed and previously treated CLL.[69-71]

TABLE 135-6 Treatment for Newly Diagnosed and Previously Treated Chronic Lymphocytic Leukemia

Treatment	Overall Response (%)	Complete Response (%)
Chlorambucil		
Untreated	37	4
Fludarabine alone		
Untreated	60-80	20-30
Previously treated	13-59	3-37
Fludarabine + cyclophosphamide		
Untreated	80-90	25-40
Previously treated	60-70	10-15
Rituximab alone		
Untreated	50-60	10-20
Previously treated	80-90	20-40
Fludarabine + rituximab		
Untreated	80-100	30-50
Previously treated	80-90	20-40
Fludarabine + cyclophosphamide + rituximab		
Untreated	95	70
Previously treated	73	25
Alemtuzumab alone		
Untreated	80-90	20-30
Previously treated	30-50	0-20
Alemtuzumab + fludarabine		
Previously treated	83	17-30
Bendamustine + rituximab		
Untreated	97	38
Previously treated	60	9
Ofatumumab + chlorambucil		
Untreated	82	12

Previously treated	71	5
Idelalisib + rituximab		
Previously treated	81	0

Cytotoxic Chemotherapy

Orally administered alkylating agents such as chlorambucil and cyclophosphamide, given either alone or with corticosteroids, historically have been used as primary treatment for CLL. Results from a meta-analysis involving 2,048 patients from six randomized controlled studies evaluated low-dose alkylating agents in CLL.[72] That analysis showed that delayed treatment with alkylating agents in asymptomatic patients did not adversely affect 10-year survival. More importantly, if only deaths caused by CLL were considered, significantly longer survival was observed when treatment was deferred. Chlorambucil continues to be used in elderly, symptomatic patients as initial treatment for CLL, but its use is based on a small number of studies with no demonstrable survival advantage.[71,72] Commonly used dosing schedules for chlorambucil are intermittent pulse dosing of 15 to 40 mg/m^2 orally every 28 days or daily doses of 4 to 8 mg/m^2/day.[71] The dose of chlorambucil is often titrated to circumvent myelosuppression.

Cyclophosphamide produces a similar response rate as chlorambucil (overall response rate: 40%-60%; complete response: 4%) and can be used in patients who cannot tolerate chlorambucil or in whom response is not optimal. Some patients who do not respond to chlorambucil will respond to single-agent cyclophosphamide. Cyclophosphamide is typically given orally at a daily dose of 1 to 3 mg/kg. Oral cyclophosphamide is less commonly used than chlorambucil because of the risk of hemorrhagic cystitis and bladder cancer with prolonged treatment.

Fludarabine-based therapy is a common initial treatment in CLL. It is particularly useful in younger patients and in those patients who can tolerate immunosuppressive chemotherapy. Fludarabine, along with the other purine analogs, 2-chlorodeoxyadenosine (cladribine) and 2-deoxycoformycin (pentostatin), are highly active in CLL, with fludarabine being the most widely studied agent in the class in the treatment of CLL.[70-73] Most patients receive fludarabine 25 to 30 mg/m^2 IV daily for 5 days when used as a single agent. Cladribine and pentostatin have similar activity, although head-to-head trials comparing these three nucleosides have not been conducted.[73-75]

Fludarabine was initially studied in CLL patients who were refractory to chlorambucil. Several trials reported overall response rates to fludarabine in previously treated patients ranging from 13% to 59% and complete response rates of 3% to 37%.[74-77] Fludarabine has higher overall response and complete remission rates than alkylating-based therapies in the frontline setting. In one of the randomized studies that compared fludarabine to chlorambucil in chemotherapy-naïve patients, fludarabine-treated patients had a higher complete remission rate as compared with chlorambucil (20% vs 5%).[75] However, the higher complete remission rate did not translate into a significant difference in overall survival and patients treated with fludarabine had a higher rate of severe neutropenia and infection. The study allowed chlorambucil failures to cross over to fludarabine, which may have hampered the ability to show a survival advantage in the fludarabine arm. A recent review of younger patients enrolled in a large phase III trial showed that 33% of patients receiving fludarabine or fludarabine-based therapy had infectious complications.[76] An increase in *Pneumocystis* infections was not observed, but a 6% increase in herpes and varicella zoster

infection was documented. Dose reductions occurred frequently as a result of the infectious episodes. Based on the increased risk of infectious complications, some practitioners recommend antiviral and antibacterial prophylaxis with treatment.[72,76,77]

Bendamustine is an alkylating agent that contains a purine-derivative benzimidazole ring in its chemical structure that yields a compound that is non–cross-resistant with other alkylating agents. Bendamustine induces cell death via single and double-stranded cross-links.[78] The efficacy of bendamustine was established as first-line agent in Binet stage B or C CLL in a phase III trial that randomized 319 patients to bendamustine or chlorambucil.[79,80] Complete response rates of 31% versus 2% and an overall response rate for 68% versus 31% were observed for bendamustine and chlorambucil, respectively. The median progression-free survival was 21.2 versus 8.8 months favoring bendamustine ($P<0.0001$). The median overall survival was not reached in the bendamustine group and was 78.8 months in the chlorambucil group. Adverse events reported for bendamustine include hematologic toxicity in about 25% of patients, and gastrointestinal and cutaneous toxicity.

Biologic Therapy

Monoclonal antibodies, such as rituximab and alemtuzumab, are increasingly being used in the treatment of CLL. Rituximab is a chimeric monoclonal antibody that targets the CD20 antigen expressed on B lymphocytes. Rituximab was initially approved for patients with indolent non-Hodgkin lymphoma and later for aggressive non-Hodgkin lymphoma. Rituximab received FDA approval for the treatment of CD20-positive CLL in 2010. CLL cells have less prominent CD20 expression on their surface as compared to non-Hodgkin lymphoma, which may explain the lower clinical response. Efficacy with rituximab as a single agent in CLL is moderate with a 58% overall response rate reported with 9% complete responses.[70,71] Subsequent studies have used higher rituximab doses (up to 500 mg/m^2 per cycle) when given in combination with other agents.

7 Alemtuzumab is a monoclonal antibody that targets the CD52 antigen found on both B and T lymphocytes (Fig. 135-2). This agent was initially FDA approved in 2001 for the treatment of patients with CLL who had been treated with alkylating agents and had failed fludarabine therapy and is now approved as a single agent for both frontline and salvage treatment of CLL. Alemtuzumab is titrated to a maintenance dose of 30 mg IV or subcutaneously given 3 times a week for 12 weeks. As a single agent, alemtuzumab has produced response rates from 33% to 53% in patients with refractory disease, but complete responses are infrequent.[81-83]

Results from a randomized phase III trial comparing alemtuzumab to chlorambucil in chemotherapy-naïve patients with symptomatic CLL showed higher complete response rates with alemtuzumab than with chlorambucil, 24% versus 2%, respectively.[81] These differences in response rate translated into a significant difference in progression-free survival (hazard ratio, 0.58; 95% confidence interval, 0.43-0.77, $P<0.0001$).

Infusion-related reactions are one of the most frequently reported toxicities with alemtuzumab. The reactions experienced with IV administration include fever, rigors, and hypotension.[82] Alemtuzumab is associated with serious, potentially life-threatening toxicities, including pancytopenia, infusion reactions, and opportunistic infections. Because of alemtuzumab's profound immunosuppression, the 2015 NCCN guidelines recommend antibacterial and antiviral prophylaxis to prevent *Cytomegalovirus* reactivation and *Pneumocystis* infections.[71] Prophylaxis with trimethoprim-sulfamethoxazole and famciclovir or valacyclovir is recommended with the use of alemtuzumab.[71,82] Alemtuzumab is FDA-approved for IV administration, although the use of subcutaneous alemtuzumab has been evaluated to reduce the frequency of these reactions. In a study by Lundin et al. 41 patients received 30 mg of subcutaneous alemtuzumab three times a week for 12 weeks, which yielded a response rate of 87%.[83] Major adverse event were grades 1 and 2 skin reactions in 90% of patients; fever, rigors, and hypotension were infrequent. About 10% of patients had reactivation of *Cytomegalovirus* and required ganciclovir treatment. Similar to IV administration, antiviral and antibacterial prophylaxis is warranted when alemtuzumab is given via the subcutaneous route.[83]

Ofatumumab is a fully human monoclonal antibody to CD20 that was approved as single-agent therapy in 2009 for patients with CLL that is refractory to fludarabine and alemtuzumab. Ofatumumab is administered as an IV infusion with an initial dose of 300 mg then four weekly doses followed by four monthly doses of 2,000 mg. An overall response rate of 58% in patients with fludarabine and alemtuzumab refractory disease and 47% in bulky fludarabine refractory disease was reported.[84] Median time-to-progression was 5.7 and 5.9 months and median overall survival 13.7 and 15.4 months in the fludarabine, alemtuzumab refractory patients and bulky fludarabine

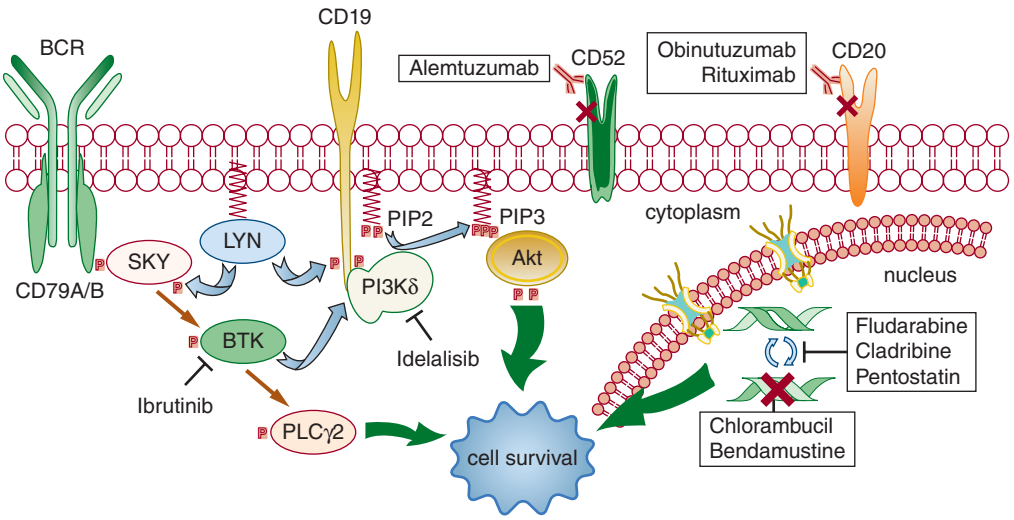

FIGURE 135-2 Current treatments and their molecular targets in chronic lymphocytic leukemia *(Reprinted with permission from Manman W, Wang X, Song Z, et al. Targeting PI3Kδ: Emerging Therapy for Chronic Lymphocytic Leukemia and Beyond. Med Res Rev 2015;35:720-752. Copyright © 2015 John Wiley and Sons. All rights reserved.)*

refractory disease patients, respectively. Adverse events reported in greater than 10% of patients included infection and neutropenia. Infusion-related events were reported in about 60% of patients, 40% during the first infusion, and 25% with the second infusion. Serious toxicities such as fatal infections, progressive multifocal leukoencephalopathy, and hepatitis B reactivation have been reported.

The efficacy of first-line ofatumumab was studied in a phase III trial of 447 patients with previously untreated CLL.[85] Median progression-free survival was significantly longer in the ofatumumab and chlorambucil group versus the chlorambucil alone group (22.4 vs 13.1 months). Grade III toxicity including neutropenia and infusion-related events were reported more frequently in the combination arm although the overall infection rate was similar in both treatment arms. These results led to the approval of ofatumumab in combination with chlorambucil in previously untreated CLL for whom fludarabine-based therapy is considered inappropriate.

Combination Therapy

The single-agent activity of fludarabine has led to incorporation of fludarabine in combination regimens in patients with CLL. The most widely studied combination is fludarabine with cyclophosphamide, which produces complete response rates between 25% and 40% in treatment-naïve patients as compared with 20% to 30% for single-agent fludarabine.[70-75] Although improved response rates and progression-free survival have been reported with fludarabine and cyclophosphamide combinations compared with fludarabine alone, no benefit in overall survival has been observed.

8 The combination of fludarabine and rituximab has promising activity. In vitro studies suggest that rituximab is synergistic with fludarabine and cyclophosphamide and has led investigators to evaluate this combination in clinical trials. Results from an uncontrolled trial of fludarabine, cyclophosphamide, and rituximab (FCR) reported a complete remission rate of 70% in previously untreated CLL patients.[86] FCR has documented a complete remission rate of 25% in previous treated patients. Results of two phase III trials comparing FCR with fludarabine and cyclophosphamide documented a progression-free survival benefit (30 vs 20 months) in patients treated with FCR in patients with refractory disease and an overall survival benefit (87.2% vs 82.5%) in patients with newly diagnosed disease.[87,88] The results of these phase III trials led to FDA approval of rituximab with fludarabine and cyclophosphamide in CLL.

Bendamustine and rituximab (BR) have been combined in two phase II studies in patients with CLL, in the frontline and relapsed setting.[89,90] In the frontline setting, 117 patients were treated with bendamustine 90 mg/m^2 days 1 and 2 and rituximab 375 mg/m^2 IV on day 0 for cycle 1 and then 500 mg/m^2 IV on day 1 for subsequent cycles.[89] Overall, 88% of patients had a clinical response with 23% being complete responses. The median EFS was 34 months with 90% of patients reported being alive at the median follow-up time point of 27 months. Patients with 17p- responded less well, with a 37.5% overall response rate. Grade 3/4 myelosuppression was observed in about 20% of patients. BR is currently being compared to FCR in previously untreated fit patients with CLL. An interim analysis showed overall response rates of 97.8% for both regimens, but the FCR group had a higher complete response rate (47.4% vs 38.1%, P=0.031) and 2-year progression-free survival (85% vs 78.2%, P=0.041).[90] The advantages of FCR need to be balanced by a higher risk of severe adverse events, in particular neutropenia (81.7% vs 56.8%; P<0.001) and infections (39% vs 25.4%; P<0.001) associated with FCR. Based on these results no firm recommendations of FCR or BR can be made in the first-line setting. The risks and benefits of FCR and BR should be discussed with the patient because no overall survival advantage has been reported.

In the relapsed setting, BR was administered as above with the exception of a lower bendamustine dose of 70 mg/m^2 in 78 patients who had received a median of two prior treatments.[91] The overall response rate was 59%, with 9% of patients having a complete response. With a median follow-up of 24 months, the EFS was 14.7 months with a median overall survival of 34 months. About 25% of patients experienced grade 3/4 myelosuppression with three treatment-related deaths related to infection.

Obinutuzumab is a glycoengineered type II anti-CD20 monoclonal antibody that does not induce translocation of CD20 monoclonal antibody complexes or complement-dependent cytotoxicity, but rather stimulates direct cell death via actin reorganization and homotypic adehesion.[91] Obinutuzumab was FDA approved in 2013 in combination with chorlambucil in patients with previously untreated CLL. A Phase III trial randomized 781 patients to one of three groups: 1) chlorambucil 0.5 mg/kg on days 1 to 15; 2) obinutuzumab 1,000 mg on days 1, 8, 15, of cycle 1 and day 1 on cycles 2 through 6 plus chlorambucil; 3) rituximab 375 mg/m^2 on day 1 of cycle 1 then 500 mg/m^2 on day 1 of cycles 2 through 6 plus chlorambucil. Progression-free survival was increased with obinutuzumab and chlorambucil (26.7 months) compared to rituximab and chlorambucil (16.3 months) or chlorambucil (11.1 months).[92] Overall survival favored obinutuzumab and chlorambucil compared to chlorambucil monotherapy (hazard ratio 0.41; 95% CI 0.23-0.74; P=0.002). Treatment with obinutuzumab and chlorambucil versus rituximab and chlorambucil resulted in longer progression-free survival (hazard ratio 0.39; 95% CI 0.31-0.49; P<0.001) and higher rates of complete response (70% vs 20.7%). Infusion-related reactions and neutropenia were more common with the obinutuzumab group than rituximab, but the risk of infection was similar.

9 Targeted Therapy

Ibrutinib is an orally administered compound that covalently binds to the cysteine-481 amino acid of the BTK enzyme and inhibits signaling of ERK, NF-κB, and cytosine phosphate-guanine mediated tumor cell proliferation and migration.[59] Ibrutinib was FDA approved in 2014 for the treatment of CLL. In the phase Ib/II trial, 85 patients with relapsed or refractory CLL received ibrutinib at 420 mg or 840 mg by mouth daily.[59] The overall response rate was 71% for both groups with a partial response observed in 20% and 15%, respectively. In a phase III trial, ibrutinib was compared to ofatumumab in patients with relapsed or refractory CLL with a primary endpoint of progression-free survival.[93] Median progression-free survival in the ibrutinib groups was not reached as compared to 8.1 months in the ofatumumab group (hazard ratio 0.22, 95% CI 0.15-0.32; P<0.001). The overall response rate was significantly higher in the ibrutinib group at 42.6% versus 4.1% with ofatumumab (P<0.001). Overall survival at 12 months also favored ibrutinib, 90% versus 81%. The response rate among patients with a 17p-deletion was 68%, including one complete response, highlighting the ability of ibruitnib to overcome resistance associated with purine analogues and alkylating agents. The most frequent nonhematologic adverse events were diarrhea, fatigue, fever, and nausea. A toxicity unique to ibrutinib is lymphocytosis (69%) secondary to tumor cell mobilization to the peripheral blood. This lymphocytosis is not an indicator of disease progression and ibrutinib should be continued at the standard dose.

Idelalisib is a small-molecule inhibitor of PI3Kδ and interferes with the PI3Kδ-AKT signaling pathway leading to increased apoptosis.[60] Idelalisib 150 mg taken orally twice a day plus rituximab was compared to rituximab plus placebo in a randomized phase III trial in patients with relapsed CLL who had comorbidities that precluded them from being treated with standard chemotherapy.[60] Patients may not have been eligible for systemic chemotherapy for the following reasons: severe neutropenia or thrombocytopenia, an estimated glomular filtration rate of less than 60 mL/min/1.73 m^2, or a score of 6 or more on the Cumulative Illness Rating Scale. The primary endpoint of progression-free survival was not reached in the idelalisib

group compared to 5.5 months in the rituximab monotherapy group ($P<0.001$). The overall response rate also favored the idelalisib group, 81% versus 13% ($P<0.001$) as did the 12 months overall survival, 92% versus 80% ($P=0.02$). Black box warnings include hepatic dysfunction, severe diarrhea, colitis, intestinal perforation, and pneumonitis. Patients should have complete blood counts and hepatic function monitored prior to initiation and throughout treatment.

It should be noted that both ibrutinib and idelalisib are metabolized by cytochrome P450 (CYP) 3A4. Therefore, clinicians need to be aware of possible drug interactions with inducers and inhibitors of the CYP3A4 pathway such as phenytoin, azole antifungals, or macrolide antibiotics.

Clinical **Controversy...**

Certain molecular and cellular markers have been identified that may predict CLL disease progression. ZAP-70 expression, CD38 expression, IGHV mutations, and 17p- are associated with a more aggressive clinical course of CLL. Controversy surrounds whether or not treatment should be based on these biologic markers alone. 17p- is the most consistent poor prognostic marker and results in a loss of the tumor suppressor gene, p53. Consensus guidelines delineate treatment options for patients based on the presence of 17p-. If a patient has 17p- more aggressive regimens that contain immunotherapy and purine analogs (eg, fludarabine, cyclophosphamide, and rituximab) are potential first-line treatments. Given that ibrutinib is active against CLL with 17p- it is also a potential first line treatment option. Head-to-head comparisons of ibrutinib versus chemoimmunotherpay in the first line setting are lacking and require further evaluation.[71]

Hematopoietic Stem Cell Transplantation

The experience with the use of HSCT in CLL is limited. Patients treated with allogeneic HSCT achieve higher remission rates and appear to have a longer disease-free survival, but is associated with high treatment-related mortality, which approaches 40%. Contrary to the high mortality reported in most studies, a randomized phase II study of high-risk CLL patients comparing allogeneic and autologous HSCT reported 100-day mortality of 4% in both arms. After 6 years of follow-up, no difference in overall survival (58% autologous and 55% allogeneic) was observed.[93] This low early mortality must be interpreted carefully, given that only 25 carefully selected patients received allogeneic HSCT as compared with 137 who received autologous HSCT. T-cell depletion was performed on the allogeneic grafts, which may reduce 100-day mortality at the cost of increased relapse, infectious complications, or posttransplant lymphoproliferative disorders as a consequence of reduced GVL effect.[94]

Although allogeneic HSCT may offer the potential of cure in CLL, the advanced age of most patients, limited donor availability, and the high treatment-related mortality precludes the routine application in the management of this disease. Allogeneic HSCT is a more viable option for younger patients with aggressive disease. Older patients who are not candidates for full-intensity allogeneic HSCT may be candidates for nonmyeloablative allogeneic HSCT.

Immunotherapy

The use of immunotherapy in CLL had been considered as a potential treatment strategy because of the presence of tumor specific antigens such as CD19. The modification of autologous T cells expressing an anti-CD19 chimeric antigen receptor (CART19) has been explored in patients with refractory CLL.[95] Autologous T cells are collected via leukapheresis and treated with a self-inactivating lentiviral vector to express the CD19 specific chimeric antigen receptor concurrently with the costimulatory CD137 signaling domain. Modified cells are kept for about two weeks for expansion and then harvested for infusion. Patients receive a preparative regimen of standard CLL-directed chemotherapy with the goal of lymphodepleting the patients and enhancing the proliferation of the infused T-cells. A cell dose of about 3×10^8 autologous transduced-T cells is administered within several days of completion of chemotherapy.

In the largest single-center experience, 45 highly refractory CLL patients have been treated with this approach.[95] Overall response rate was reported to be 45% with small numbers of patients having documented persistence of the genetically-modified T-cell population lasting beyond 3 years. Toxicity with the procedure is notable for the expected toxicities of the chemotherapy preparative treatment, cytokine release syndrome, hypogammaglobinemia and B-cell aplasia. Cytokine release syndrome is believed to be an interleukin-6 mediated event characterized by escalating fevers (>40°C), myalgias, nausea, vomiting and diarrhea. Severe cases of cytokine release syndrome can progress to hypotension, capillary leak, and hypoxia requiring critical care level support.

Personalized Pharmacotherapy

Molecular biomarkers are important as predictors for disease time to progression, decision making for initiation of treatment, and prognosis. The most important are cytogenetic abnormalities such as deletion 17p- and 11q, which are associated with more aggressive disease that is less responsive to treatment. Unmutated status of the immunoglobulin heavy chain variable gene locus and overexpression of ZAP-70 and CD38 expression are also predictive of poor prognosis.

The 2015 NCCN guidelines recommend treatment options based on the presence of deletion 17p- or 11q, age older or younger than 70 years, and first- and second-line regimens.[71] Preferred first-line therapy options for patients younger than 70 years without poor-risk cytogenetics or significant comorbidities are aggressive chemoimmunotherapy regimens such as bendamustine, rituximab; fludarabine, cyclophosphamide, rituximab; fludarabine, rituximab; and pentostatin, cyclophosphamide, and rituximab. In patients who are older than 70 years without poor-risk cytogenetics preferred chemotherapy options include: obinutuzumab, chlorambucil; ofatumumab, chlorambucil; rituximab, chlorambucil; or bendamustine, rituximab. In frail patients or those with significant comorbidities and unable to tolerate purine analogs preference of first line therapy may include: obinutuzumab, chlorambucil; ofatumumab, chlorambucil; or rituximab, chlorambucil. The current standard of care for relapsed or refractory CLL is ibrutinib monotherapy and idelalisib plus rituximab.[70,71] For patients who have poor-risk cytogenetics such as 17p- deletion, first-line therapy options consist primarily of more aggressive chemoimmunotherapy treatment options (FCR; fludarabine and rituximab; high-dose methylprednisolone and rituximab) or targeted therapy with ibrutinib. Preferred second-line regimens include ibrutinib or idelalisib plus rituximab regardless of age or comorbidities.[70,71]

Evaluation of Therapeutic Outcomes

Chronic lymphocytic leukemia is an incurable disease and the goal of therapy is to optimize remission duration while minimizing the burden of treatment-related adverse effects. Supportive care for patients undergoing active treatment for CLL is crucial for ensuring a successful outcome. Patients may become hypogammaglobinemic as a consequence of disease progression or treatment will need routine monitoring of serum IgG. If the serum IgG falls below 500 mg/dL (5 g/L), then monthly replacement doses of 300 to 500 mg/kg of IV immune globulin is warranted. Antibiotic prophylaxis for patients

receiving fludarabine-based regimens or chemoimmunotherapy should be considered for herpes virus and *Pneumocystis*. Patients who are treated with alemtuzumab will require monitoring for cytomegalovirus (CMV) antigen every 1 to 2 weeks while on therapy and for 2 months after or be given prophylaxis with valganciclovir.

ABBREVIATIONS

ABL	Abelson proto-oncogene
ALL	acute lymphoblastic leukemia
AP	accelerated phase
ATP	adenosine triphosphate
BC	blast crisis
BCR	breakpoint cluster region
BTK	Bruton's tyrosine kinase
CHOP	cyclophosphamide, hydroxydaunorubicin, vincristine, prednisone
CLL	chronic lymphocytic leukemia
CML	chronic myelogenous leukemia
CMV	cytomegalovirus
CNS	central nervous system
CP	chronic phase
CYP	cytochrome P450
EFS	event-free survival
ERK	extracellular signal-regulated kinase
FCR	fludarabine, cyclophosphamide, rituximab
FDA	Food and Drug Administration
FISH	fluorescence in situ hybridization
GVHD	graft-versus-host disease
GVL	graft-versus-leukemia (effect)
HLA	human leukocyte antigen
HSCT	hematopoietic stem cell transplantation
Ig	immunoglobulin M
IGHV	immunoglobulin heavy chain gene
IFN-α	interferon alpha
IRIS	International Randomized study of Interferon vs STI571 trial
MBL	monoclonal B-cell lymphocytosis
mRNA	messenger ribonucleic acid
NCCN	National Comprehensive Cancer Network
PDGFR	platelet-derived growth factor receptor
Ph	Philadelphia chromosome
PI3K	phosphatidylinositol 3-kinase
REMS	Risk Evaluation and Mitigation Strategy
RT-PCR	reverse-transcription polymerase chain reaction
STI	signal transduction inhibitor
TKI	tyrosine kinase inhibitor
WBC	white blood cell
WHO	World Health Organization
ZAP-70	ζ-associated protein 70

Multiple Myeloma

Kamakshi V. Rao and Amy M. Pick

KEY CONCEPTS

1. Multiple myeloma (MM) is a cancer that develops in plasma cells, leading to excessive production of a monoclonal immunoglobulin.
2. Most patients have skeletal involvement at the time of diagnosis with associated bone pain and fractures. Anemia, hypercalcemia, and renal failure may also be present. A bone marrow biopsy with 10% or more plasma cells and a M-protein spike on plasma or urine electrophoresis confirms the diagnosis.
3. Cytogenetics may play an important role when selecting the appropriate initial therapy for patients with a new MM diagnosis and tools such as the Mayo Stratification for Myeloma and Risk-adapted Therapy (mSMART) approach are available.
4. Induction treatment is based on patients' eligibility for autologous stem cell transplantation. Novel agents such as thalidomide, lenalidomide, pomalidomide, bortezomib, and carfilzomib have gained popularity over traditional chemotherapy because of higher response rates and survival. The increased response rate is at the expense of significant grade 3 and 4 toxicity, which can include myelosuppression, venous thromboembolism (VTE), and neuropathy depending on the regimen used.
5. Thalidomide, lenalidomide, and pomalidomide are immunomodulatory agents that have antiangiogenic and anti-inflammatory activity. Thalidomide's dose limiting toxicity is neuropathy. Lenalidomide is less neurotoxic, but can cause significant myelosuppression. Pomalidomide, the newest of this class, is currently only used in relapsed/refractory MM.
6. The proteasome inhibitors, bortezomib and carfilzomib, are highly active in the treatment of MM, particularly those with high-risk cytogenetics.
7. Autologous hematopoietic stem cell transplantation (HSCT) is used after induction in patients with reasonably good performance status to maximize complete remissions and prolong survival. Combining autologous HSCT with allogeneic HSCT is investigational and should be performed within a clinical trial.
8. Maintenance therapies may be used in both transplant-eligible and ineligible patients. Current regimens typically include lenalidomide or bortezomib with the intent of increasing response rates and progression-free survival.
9. Bisphosphonates are used to treat bone disease associated with MM, which results in decreased pain and skeletal-related events and improved quality of life.
10. Salvage therapy for patients with relapsed or refractory MM can include any of the prior listed therapies and depends on patient's performance status, risk category, and prior treatments used for induction.

INTRODUCTION

1 Multiple myeloma (MM) is a malignancy of plasma cells or immunoglobulin-producing B lymphocytes.[1,2] The cancer is characterized by clonal proliferation and accumulation of a monoclonal immunoglobulin secreted from the plasma cell that can be measured in the plasma or urine. Patients with MM often have osteolytic bone lesions at the time of diagnosis, which is probably related to various bone-mobilizing cytokines secreted from the MM clone and bone marrow stromal cells. Other clinical manifestations include end-organ damage such as renal insufficiency, hypercalcemia, and anemia. The treatment of MM often consists of two or three drug combinations incorporating a proteasome inhibitor and immunomodulator. These regimens have improved response rates and outcomes compared to conventional chemotherapeutic agents. Although therapy is not currently curative, MM continues to be a remarkable example of bench-to-bedside translation in new drug development.

EPIDEMIOLOGY AND ETIOLOGY

In the United States, it was estimated that 30,330 cases of MM were diagnosed in 2016, with 12,650 deaths.[3] It is a disease that affects older adults with a median age of 69 years at diagnosis.[4] MM occurs more frequently in men and African Americans. Familial clusters of MM have been reported with emerging evidence suggesting a genetic predisposition toward the disease.[5]

Certain environmental factors have been implicated with MM. Radiation exposure has been historically linked to the development of MM with atomic bomb survivors having a five times higher risk of MM than nonexposed controls. Data suggest that low levels of radiation may also be a risk factor. MM has been associated with exposure to various chemicals including pesticides, aromatic hydrocarbons, and petroleum products used in farming, cleaning works, mining, and other occupational groups working with these chemicals. Alcohol and tobacco use have not been strongly associated with an increased risk of MM and the association of MM with an infectious etiology has been inconclusive.[6]

Although the pathogenesis of MM has not been fully elucidated, multiple genetic mutations have been identified and our understanding of these cellular events has improved. Decades of research and improved scientific techniques have enabled closer examination of the changes that occur during the development of normal and abnormal B cells.

PATHOPHYSIOLOGY

MM is a genetically heterogeneous disease that is characterized by abnormal clonal plasma cell infiltration in the bone marrow. Monoclonal gammopathy of undetermined significance (MGUS) and

smoldering MM may precede active MM. MGUS is associated with monoclonal immunoglobulin in the blood (≤ 3 g/dL [≤ 30 g/L]) without clinical manifestations of the complications of MM (eg, end-organ damage).[7,8] The conversion rate of MGUS to MM is about 1% per year. The molecular changes associated with the conversion of MGUS to MM are not clear, but genome-wide studies have identified several candidate genes associated with disease progression.[2,8,9] Smoldering MM is an advanced premalignant stage that is clinically distinct from MGUS with criteria including high monoclonal immunoglobulin in the blood (≥ 3 g/dL [≥ 30 g/L]) without clinical manifestations of the complications of MM. Although patients with smoldering MM have asymptomatic disease, the risk of progression to MM is about 10% per year for the first 5 years after diagnosis, about 3% per year for the next 5 years, and about 1% per year for the next 10 years.[10,11] Certain cytogenetic characteristics appear to be associated with a higher risk of transformation to active MM including a translocation of 4 and 14.[10] Multiple genetic changes may occur over time leading to more symptomatic disease. Numerous genetic mutations are associated with transformation, with one report of four patients who transformed from smoldering MM to MM acquiring an average of 433 mutations.[9] The molecular mechanisms leading to these mutations remain to be fully elucidated.

MM is characterized by the accumulation of malignant plasma cells in the bone marrow. Both MM and normal plasma cells are produced from differentiated B cells after antigen stimulation. Normal plasma cells will die within days to weeks after differentiation, whereas MM plasma cells are immortalized.[1,6] The malignant plasma cell is involved in the unregulated production of a monoclonal antibody referred to as *M protein*. MM cells are seldom seen in large quantities in the peripheral blood because of their close interaction with bone marrow stromal cells. MM cells are supported by a nurturing bone marrow microenvironment which promotes the further expansion of myeloma clones. Molecules such as interleukin-6 (IL-6), vascular endothelial growth factor (VEGF), insulin-like growth factor 1 (IGF-1), and the transcriptional regulator nuclear factor kappa B (NF-*κB*) are part of the microenvironment and stimulate clonal growth, disease progression, and promote resistance to therapy.[9] The disruption of the microenvironment is an important strategy for therapy.[12] Figure 136-1 shows several of the factors involved in disease pathogenesis and progression and potential mechanisms of action of thalidomide, lenalidomide, pomalidomide, bortezomib, and carfilzomib.

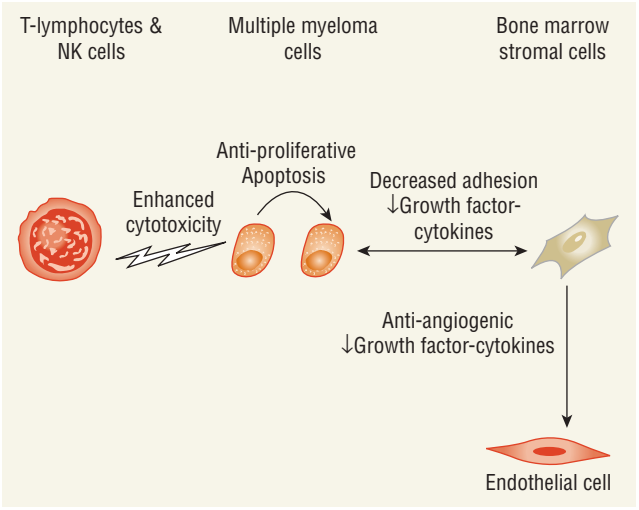

FIGURE 136-1 Proposed mechanisms of action of immunomodulatory drugs.

CLINICAL PRESENTATION

The clinical manifestations are related to the effects of the myeloma cell on the bone microenvironment and the unregulated production of the M protein. 2 Most patients with MM present with complaints of bone pain and fatigue at diagnosis.[6] Initial laboratory evaluation often reveals hypercalcemia, renal insufficiency, anemia, and other abnormalities including β_2-microglobulin that measures tumor burden. Skeletal evaluation shows gross abnormalities in most patients. Bone scans show abnormalities that often include lytic lesions, osteoporosis, and fractures. This group of findings (hyper**c**alcemia, **r**enal insufficiency, **a**nemia, and **b**one lesions) is often referred by the acronym *CRAB* and suggests end-organ damage.[6,7] A confirmed diagnosis is defined by a bone marrow biopsy with 10% or more plasma cells and an M-protein spike on plasma or urine electrophoresis.[7,13] Both the National Comprehensive Cancer Network (NCCN) and International Myeloma Working Group (IMWG) have described criteria to diagnose MM.[13,14]

Following the diagnosis of MM, further workup involves analyzing the isotype of M protein. Serum protein electrophoresis and serum and urine immunofixation identify the M-protein isotype being secreted. In a minority of patients, M protein may not be detected in

CLINICAL PRESENTATION — Multiple Myeloma

General Criteria

- 80% of patients present with symptomatic disease

Signs and Symptoms

- Bone pain (fractures, lytic lesions)
- Fatigue (anemia)
- Infection (reduced polyclonal response)
- Neurologic symptoms (nerve compression)
- Polyuria (hypercalcemia)
- Nausea and vomiting (hypercalcemia)

Laboratory Parameters

- Elevated M protein
  - Plasma electrophoresis
  - Urine electrophoresis
  - Immunofixation
- Elevated serum creatinine
- Hypercalcemia
- Low hemoglobin
- Low albumin
- Elevated β_2-microglobulin
- Elevated C-reactive protein

Bone Marrow

- More than or equal to 10% plasma cells

Cytogenetics

- Chromosome 13 deletion
- Translocations of t(4;14), t(11;14) and t(14;16)
- Del (17p)
- Chromosome 1 amplification

the plasma but found in the urine, requiring the urine to be examined as part of a complete diagnostic workup. About 60% of patients have intact monoclonal immunoglobulin G (IgG), 20% have monoclonal IgA, and the remaining 20% secrete only monoclonal light chains. Antibodies are composed of two light chains where antigen binds and two heavy chains. Light-chain immunoglobulins, called Bence Jones proteins, can be secreted by the MM clone and excreted in the urine due to their low molecular weight. Bence Jones proteins are primarily responsible for MM-associated renal failure.[1,6] Serum-free light chains (SFC) may also be measured and these results may provide valuable information on the likelihood of disease progression.[15]

Most patients have bone involvement at the time of diagnosis.[6,7] The effects of MM on the bone result from the abnormal production of cytokines, including IL-1, IL-6, tumor necrosis factor-α (TNF-α), and the receptor for activation of NF-κB ligand (RANK-L). Bone involvement is the net effect of the activation of osteoclasts and inhibition of osteoblastogenesis.[16] This leads to bone destruction and resorption predisposing one to pathologic fractures and lytic lesions. Patients with MM are frequently anemic due to infiltration of the bone marrow with the MM clone and poor erythropoietin response. Patients can have clinically important hypercalcemia, which results from calcium mobilization due to bone resorption. Renal failure can occur as a result of high protein load from the monoclonal protein secretion as well as dehydration.

STAGING AND PROGNOSTIC FACTORS

Two clinical staging systems for MM have been developed. The newer International Staging System (ISS) uses serum β_2-microglobulin and albumin concentrations to stage patients.[17] These two routine laboratory tests predict survival in patients treated with either conventional treatment or autologous hematopoietic stem cell transplantation (HSCT). It does not consider cytogenetics or molecular markers. An older staging system, Durie-Salmon, may also be used. It uses hemoglobin, serum calcium, bone involvement, and M protein to categorize patients into one of three stages.[13] The Durie-Salmon system has variable accuracy in patients undergoing HSCT and with newer novel therapies.[6] Table 136-1 describes the ISS and median survival times for each stage.

3 Certain cytogenetic abnormalities have been identified as important prognostic factors. Shortened overall survival has been demonstrated in patients with chromosomal 13 deletion (del 13), translocation of 4 and 14 (t(4;14)), and deletion of 17p (del (17p)).[6,13] Recent data suggest that the translocation of 11 and 14 may be associated with increased survival. The Mayo Clinic developed a risk-adapted approach, known as the mSMART (Mayo Stratification for Myeloma and Risk-adapted Therapy), that categorizes patients into three risk groups based on cytogenetics and gene expression profiling: high, intermediate, and standard risk.[18] Therapeutic options and treatment length is then provided for each risk group. Additional prognostic factors generally represent the underlying pathologic changes associated with MM, including proinflammatory biomarkers (elevated C-reactive protein), tumor load (increased β_2-microglobulin), and dysregulated cellular growth (labeling index and marrow microvessel density).

TABLE 136-1 The International Staging System for Multiple Myeloma

Stage	Characteristics	Median Survival (mo)
I	Serum β_2-microglobulin <3.5 mcg/mL (mg/L) Serum albumin ≥3.5 g/dL (≥35 g/L)	62
II	Not stage I or stage III	44
III	Serum β_2-microglobulin ≥5.5 mcg/mL (mg/L)	29

TREATMENT

Desired Outcomes

The primary goal in the treatment of MM is to prolong the patient's survival and improve quality of life. The different phases of treatment also have specific goals. The goal of induction therapy in newly diagnosed MM patients is to obtain at least a major response.[6,7] Induction therapy is followed by various treatment phases including transplant, consolidation, and maintenance therapy. The goals of these subsequent phases are to further improve response rates. With the integration of novel agents into therapy, progression-free survival and overall survival have steadily improved, and responses have increased in frequency, depth, and duration. Unfortunately, there is no convincing evidence that patients are cured of their disease.

General Approach

The decision to initiate treatment depends on whether the patient is experiencing symptoms of the disease. Watchful waiting is the most common practice for patients with smoldering MM and is currently recommended by the NCCN guidelines.[13] However, this treatment paradigm is evolving with the availability of novel agents. Several small published studies suggest that early treatment with novel agents in patients with high-risk smoldering MM may improve overall survival and delay time to progression.[9] The challenge remains identifying patients with high-risk smoldering MM and developing criteria to assess a treatment response.[9]

4 Initial management of symptomatic MM (refer to "Clinical Presentation") depends on whether patients are candidates for autologous HSCT (Fig. 136-2). Transplant consideration factors include patient age, renal function, performance status, and comorbidities. The determination of transplant eligibility guides further treatment decisions. All patients with symptomatic MM are treated with initial induction therapy, with the selected regimen based on transplant eligibility. Therapies that may compromise stem cell reserve are avoided in transplant-eligible patients and the selected regimen will often be composed of various novel agents. Doublet or triplet combination regimens such as dexamethasone combined with bortezomib and lenalidomide or thalidomide have become common.

Induction therapy is usually continued until the desired response is achieved. Patients who are candidates for autologous HSCT will often receive two to four cycles of therapy and then will proceed to hematopoietic stem cell collection. Most patients undergo autologous HSCT immediately following collection, but some patients may decide to delay the transplant until first relapse. Patients who are not candidates for autologous HSCT usually receive several cycles of consolidation therapy, although the optimal duration of therapy after desired response is achieved is unknown. Single-agent maintenance therapy may be given in both transplant-eligible and ineligible patients. The use of guidelines may assist the clinician with drug therapy selection. Clinicians may be guided by the NCCN and IMWG Guidelines and mSMART treatment recommendations, which are discussed later in the "Initial Therapy" section.

The IMWG has developed uniform response criteria for MM.[19] Clinical response to therapy is generally defined by a reduction in M protein in the blood and urine. Numerous response types have been defined and the depth-of-response correlates with improved outcomes. A complete response (CR) is defined as elimination of the M protein as measured by immunofixation and plasma cells (≤5%) in the bone marrow. A CR is desirable because it is associated with improved overall survival.[20] A stringent complete response (sCR) is a CR with normal free light chain and absence of clonal cells in bone marrow. Lesser responses include partial response (PR), near complete response (nCR), and very good partial response (VGPR). These lesser responses are important because they may also correlate with

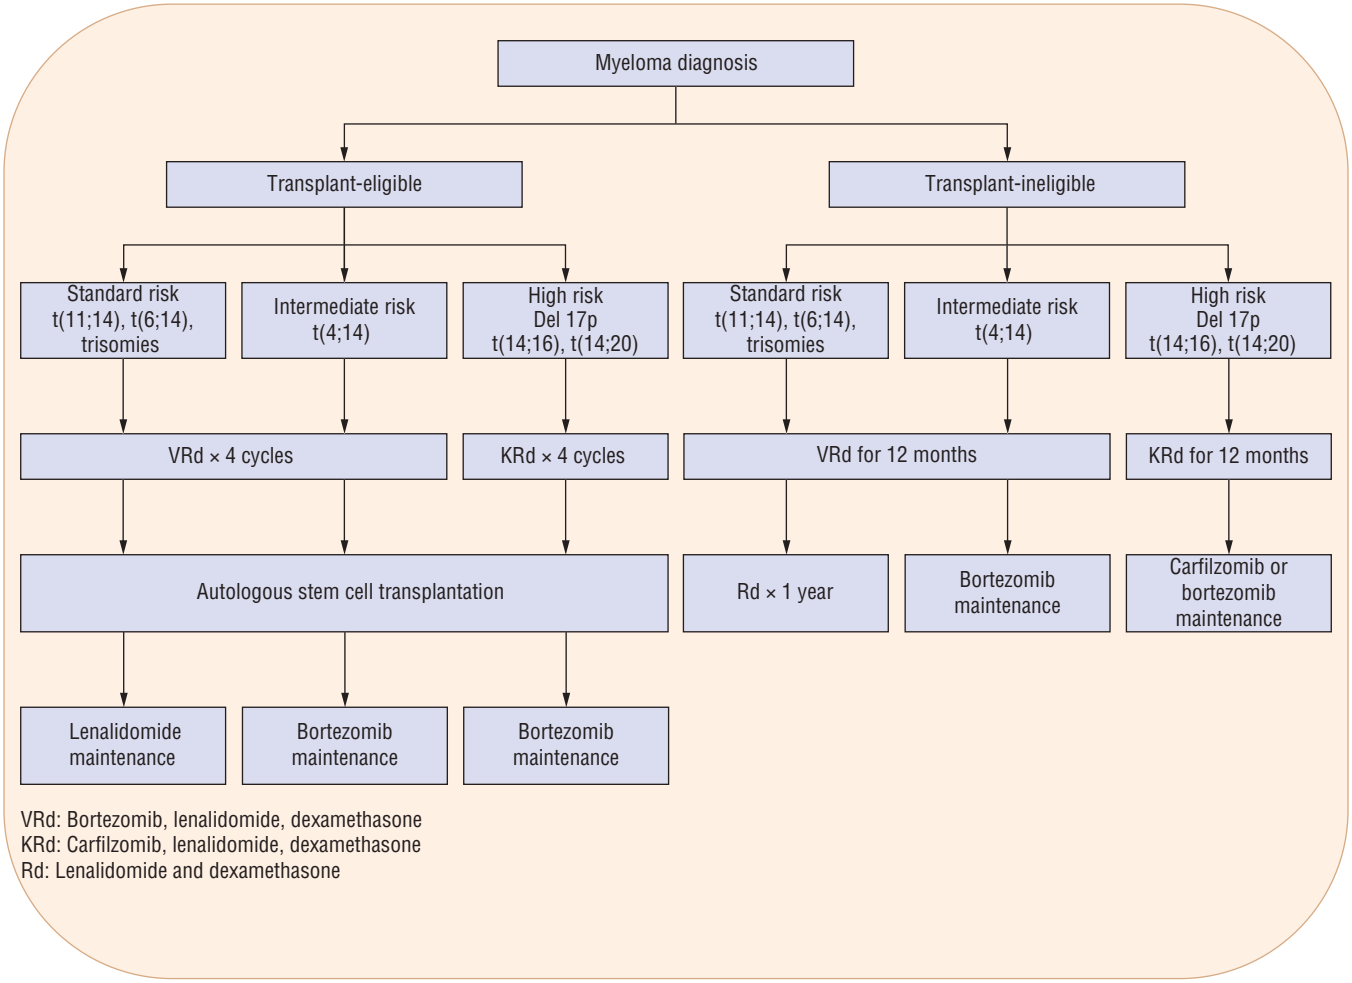

FIGURE 136-2 Risk adapted treatment of multiple myeloma based on eligibility for hematopoietic stem cell transplantation. *Adapted from Mayo Clinic mSMART classification.*

improved survival. Table 136-2 describes the most common types of responses that are used clinically.[13]

Pharmacotherapy of Multiple Myeloma

The current treatment of MM is based on novel agents from two classes of drugs, the immunomodulators and proteasome inhibitors. A three-drug regimen is commonly used in the treatment of MM and often incorporates dexamethasone and a drug from each class.

TABLE 136-2 Definition of Clinical Response in Multiple Myeloma

Type of Response	Definition[a]
PR	• ≥50% decrease in serum M protein • Reduction in 24-hour urine light chain by ≥90%
VGPR	• Serum and urine M protein detected on immunofixation but not electrophoresis
CR	• Negative immunofixation on serum and urine • No soft tissue plasmacytomas
sCR	• <5% plasma cells in the bone marrow • CR definition • Normal free light chain ratio • Absence of clonal cells in the bone marrow

CR, complete remission; PR, partial response; sCR, stringent complete response; VGPR, very good partial remission.

[a]Maintained for a minimum of 6 weeks.

Adapted from Mayo Clinic mSMART classification. Mayo Stratification for Myeloma and Risk-adapted Therapy: Newly Diagnosed Myeloma.

The optimal regimen is not clear because of the lack of head-to-head comparative trials.[6,7] Several highly active combination regimens are available. These regimens have improved response rates and survival with acceptable but different toxicity profiles compared to conventional regimens previously used in MM. Tables 136-3 and 136-4 show dosing and monitoring parameters for the newer agents used in the treatment of MM. Dose reductions in elderly patients and in patients with adverse events are often required.[13,20]

Conventional Chemotherapy

Conventional chemotherapy incorporating a corticosteroid was once the mainstay for the treatment of MM. Today, these conventional drugs may be combined with a novel agent to improve overall survival. Two of the common conventional chemotherapy regimens used historically to treat MM were melphalan plus prednisone (MP) and vincristine, doxorubicin, and dexamethasone (VAD).[6,21] The two drug regimen MP is no longer preferred because of inferior overall survival compared with newer regimens and is now often combined with a novel agent.[6,7,20] Melphalan is only recommended in the transplant-ineligible patients because of the adverse effects it has on stem cell mobilization and subsequent autologous HSCT.[6] Melphalan has also been associated with the development of myelodysplastic syndromes which is why the use of VAD chemotherapy as initial treatment became more common.[22] VAD has also been replaced with novel therapies.[13]

Corticosteroids are the cornerstone in MM therapy. Dexamethasone has been used alone as initial therapy and is believed to account for most of the antimyeloma activity of VAD (Table 136-5).

TABLE 136-3 Dosing of Novel Agents in Multiple Myeloma

Drug (Brand Name)	Initial Dose	Usual Dose	Special Population
Thalidomide (Thalidomide®)	50-100 mg/day	200 mg/day	Start low in elderly adults; increase dose every 1-3 weeks
Lenalidomide (Revlimid®)	10-25 mg/day Days 1-21 (28-day cycle) Days 1-28 (35 day cycle)	25 mg/day	Adjust dose in renal impairment: 30-60 mL/min (0.5-1.0 mL/s) (10 mg every 24 h) <30 mL/min (<0.5 mL/s) (15 mg every 48 h) <30 mL/min (<0.5 mL/s) (dialysis) (5 mg every 24 h)
Bortezomib (Velcade®)	1.3 mg/m² Days 1, 4, 8, and 11 Every 21 days		Reduce initial dose in hepatic impairment (serum bilirubin >1.5 × ULN) to 0.7 mg/m²
Carfilzomib (Kyprolis®)	20/m² given on days 1, 2, 8, 9, 15, and 16 of a 28-day cycle	27 mg/m²	
Pomalidomide (Pomalyst®)	4 mg/day for 21 days (28-day cycle)		

ULN, upper limit of the normal range.

TABLE 136-5 Initial Therapies for Multiple Myeloma

Regimen	Type of Response (%) OR	CR	CR/nCR/ VgPR
Melphalan + prednisone	40-50		5-10
Dexamethasone	40-50		
Thalidomide	34-40		
Thalidomide + dexamethasone	50-70	5-10	20-30
Melphalan, prednisone, and thalidomide	50-80	5-25	20-50
VAD chemotherapy	50-60		
Doxorubicin combinations + thalidomide	70-90		40-50
Single autoHSCT	80-90		40-50
Tandem autoHSCT	80-90		30-50
AutoHSCT followed by RI-alloHSCT	80-90		60
Bortezomib	40-50		12
Bortezomib + dexamethasone	80-90		20-30
Bortezomib + chemotherapy	80-98	10–30	43
Bortezomib + thalidomide + dexamethasone	85-95	20–35	50-60
Bortezomib + lenalidomide + dexamethasone	100		50-74
Lenalidomide + LD dexamethasone	70		40
Lenalidomide + high-dose dexamethasone	80		50
Clarithromycin + lenalidomide + dexamethasone	93	43	68
Lenalidomide + chemotherapy	80	15-25	
Carfilzomib + Lenalidomide + LD dexamethasone	98	42 (sCR)	81

alloHSCT, allogeneic hematopoietic stem cell transplantation; autoHSCT, autologous hematopoietic stem cell transplantation; CR, complete response; LD, low dose; OR, overall response (at least partial response); RI, reduced intensity; sCR, stringent complete response; VAD, vincristine, doxorubicin, and dexamethasone.

High-dose dexamethasone is associated with a higher rate of infection and central nervous system toxicity compared to MP which led investigators to conclude that high-dose dexamethasone should be used with caution as initial therapy, particularly in older patients.[23] In current regimens, newer agents (thalidomide, bortezomib, lenalidomide, carfilzomib) are combined with dexamethasone or the MP backbone to maximize initial response rates.[6,7,24] Doxorubicin or liposomal doxorubicin are also combined with various novel agents to improve response rates.

Immunomodulatory Drugs (IMiD)

Thalidomide (Thalomid®) Thalidomide was first used clinically in Europe in the late 1950s as a sedative and antiemetic but its use was largely abandoned when teratogenicity was reported. Its immunomodulatory effects became evident in the treatment of Hansen disease (leprosy), and it continues to be used for this rare indication. These clinical benefits are thought to be related to the anti-TNF activity of thalidomide. Recognizing that TNF may be involved in the pathophysiology of MM led researchers to study thalidomide as a treatment for refractory MM in 1999. The observation that thalidomide had activity against myeloma rejuvenated it as an important therapeutic agent.[6]

TABLE 136-4 Adverse Reactions and Monitoring Parameters for Novel Agents in Multiple Myeloma

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Thalidomide	Neuropathy, sedations, constipation, VTE, rash, neutropenia, teratogenicity	Neurologic examination, active bowel sounds, CBC, STEPS Program	Evening dose to ↓ sedation Laxatives VTE prophylaxis
Lenalidomide	Myelosuppression, rash	CBC, renal function, REMS	Adjust dose in renal impairment VTE prophylaxis
Pomalidomide	Myelosuppression, rash, VTE, teratogenicity	CBC, REMS	
Bortezomib	Myelosuppression, neuropathy, infection gastrointestinal	CBC, neurologic examination	VZV prophylaxis
Carfilzomib	Myelosuppression, infection	CBC, fluid status, serum chemistries	Hydration to reduce risk of renal toxicity and TLS Dexamethasone premedication for infusion reactions VZV prophylaxis

CBC, complete blood count; STEPS, System for Thalidomide Education and Prescribing Safety; REMS, Risk Evaluation and Mitigation Strategy; TLS, tumor lysis syndrome; VTE, venous thromboembolism; VZV, varicella zoster.

5 Thalidomide and other IMiDs have complex immune effects and appear to block several pathways that are involved in disease progression in MM.[6,7,25] While not fully understood, IMiDs have anti-angiogenic and anti-inflammatory properties which may directly or indirectly affect the myeloma cell. IMiDs decrease the production of cytokines and growth factors such as IL-6, TNF-*α,* and VEGF which are believed to have a role in the pathogenesis of the disease. IMiDs may also inhibit nuclear factor-*κB* (NF-*κB*) activation, either directly or indirectly via TNF, which results in increased apoptosis of the MM clone.[6] Further discussion of NF-*κB* can be found in the proteasome inhibitors treatment section. Thalidomide and other IMiDs induce IL-2 mediated T-cell proliferation including natural killer cell activity. Figure 136-1 shows the proposed effects of thalidomide on the myeloma cell.

Thalidomide activity has been demonstrated in numerous trials. Initially, single-agent thalidomide was evaluated in refractory MM and produced overall response rates (including minor responses) in about 30% of patients.[26] Although minor and partial responses were the most common types of responses, these end points were associated with improved survival.[27]

With the activity of thalidomide in refractory MM established, subsequent studies evaluated its activity in newly diagnosed transplant-eligible and -ineligible patients. These studies evaluated thalidomide in combination with other therapies, including dexamethasone, bortezomib, and chemotherapy. PR rates with thalidomide monotherapy in untreated patients were about 30% to 40%.[6] When dexamethasone was added to thalidomide in untreated patients, response rates (≥ PR) increased to about 70% to 80%.[28] In vitro results suggest there may be synergism and reversal of resistance when used in combination.[6] The higher response rate with the combination of thalidomide plus dexamethasone has made this an attractive combination for initial therapy. The addition of bortezomib to the combination of thalidomide and dexamethasone (VTD) has been investigated in transplant-eligible patients. The triple drug regimen was associated with higher overall response rates (CR, vCR, and VGPR) compared to the combination of thalidomide and dexamethasone (TD) following first and second HSCT.[13,29] For this reason, the combination of thalidomide, bortezomib, and dexamethasone is a first-line option for transplant-eligible patients. Clinicians should recognize the higher rate of venous thromboembolism (VTE) with this combination (15%-20%) and consider VTE prophylaxis when used in patients with MM.[6,13]

The addition of thalidomide to chemotherapy also increases response rates (Table 136-5). Three randomized controlled trials evaluated the addition of thalidomide to MP in newly diagnosed MM.[30-32] Two of the three trials showed improvement in progression-free survival and overall survival with melphalan, prednisone, and thalidomide (MPT) compared with MP. The other trial demonstrated only an improvement in progression-free survival but not overall survival. Based on these results, MPT is an option for transplant-ineligible patients including older patients with MM.[13] Clinicians should be aware that the increased response rate of MPT is at the expense of higher rates of grades 3 and 4 toxicity, particularly VTE, peripheral neuropathy, and infection.[31,32]

Thalidomide dose correlates with response and toxicity. When thalidomide is combined with chemotherapy, thalidomide doses of 100 mg/day are associated with high CR rates.[30] Neuropathy is one of the important dose-limiting toxicities and may correlate with cumulative thalidomide doses. Thalidomide-induced neuropathy is usually, but not always, reversible and is associated with demyelinating changes in peripheral neurons. About 10% to 20% of patients are unable to tolerate thalidomide with neuropathy being the toxicity most often associated with discontinuation of therapy.[6,32]

Other common toxicities associated with thalidomide include constipation, sedation, fatigue, and rash. Although these toxicities can be problematic, they rarely require discontinuation of thalidomide treatment and can be therapeutically managed. Stimulant laxatives can be used to prevent severe constipation. The severity of constipation and sedation declines over time in many patients.[33]

The rate of VTE with single-agent thalidomide is relatively low (< 5%) and may not exceed the baseline incidence for MM patients. For this reason, VTE prophylaxis is not recommended in patients receiving single-agent thalidomide.[33] When thalidomide is combined with dexamethasone or chemotherapy, the risk of thrombosis is elevated, with rates reported between 10% and 30%.[30-32] The underlying mechanism for thrombosis in these patients is unknown, however, appears to be multifactorial. The American Society of Clinical Oncology (ASCO) and the IMWG have guidelines for VTE prevention. The ASCO guidelines suggest that patients should receive prophylactic aspirin or low molecular weight heparin (LMWH), depending on VTE risk.[34] The IMWG guidelines include therapeutic doses of warfarin, fixed-dose warfarin, LMWH, or aspirin depending on the patient's risk for VTE.[35] A randomized trial has compared the use of fixed-dose warfarin (1.25 mg/day), aspirin (100 mg/day), or LMWH (enoxaparin 40 mg/day) in MM patients receiving thalidomide combinations. Fixed-dose warfarin and aspirin showed similar efficacy to LMWH based on a composite measure of VTE and cardiac events. However, when only grade 3 to 4 VTEs were evaluated, aspirin prophylaxis was similar to LMWH, but fixed-dose warfarin was inferior.[36] The evidence suggests low-dose aspirin is effective prophylaxis, but should be reserved for patients in whom LMWH is not feasible and in whom there is a low-to-moderate risk of developing VTE.[36]

Lenalidomide (Revlimid®) 5 Lenalidomide is a potent thalidomide analog and shares a similar mechanism of action to other IMiDs by targeting the microenvironment. Lenalidomide is commonly used, due to an improved toxicity profile compared with thalidomide. In phase I studies, patients with relapsed, refractory MM were found to have a maximum tolerated dose of lenalidomide of 25 mg/day, with this dose being the most commonly used dose in subsequent phase II and III studies.[37] Lenalidomide is typically used in combination with low-dose dexamethasone or MP in the treatment of MM. The drug may be used in transplant-eligible or -ineligible patients, but clinicians should be aware that multiple cycles of lenalidomide therapy may impair stem cells, possibly affecting stem cell collection.[13]

Lenalidomide was FDA approved in 2006 for the treatment of relapsed or refractory MM based on the results of two randomized controlled trials. In both trials, patients were randomized to receive a combination of either lenalidomide (25 mg/day on days 1- 21 of a 28-day cycle) and high-dose dexamethasone or an identical lenalidomide placebo and high-dose dexamethasone. In one trial, patients receiving lenalidomide and dexamethasone group had overall response and CR rates of 61% and 14%, respectively, compared with 20% and 0.6% in the dexamethasone alone group (P<0.001).[38] These improved response rates translated into longer median overall survival time in the lenalidomide and dexamethasone group (29.6 vs 20.5 months). Similar results were reported in the second trial (Table 136-5).[39] Lenalidomide subsequently received FDA approval for the treatment of newly diagnosed patient with MM. In this setting, the doublet of lenalidomide and dexamethasone was compared with dexamethasone alone. The trial was halted when a planned interim analysis showed the combination to be more active than dexamethasone alone, with increased progression-free survival and overall response rate in the combination arm.[13]

The most appropriate dosing of dexamethasone with lenalidomide has also been evaluated. An open-label noninferiority phase III trial addressed this question in untreated patients with MM.[40] Patients were randomized to lenalidomide plus high-dose dexamethasone (40 mg on days 1-4, 9-12, and 17-20 of each 28 day cycle) compared with lenalidomide plus low-dose dexamethasone (40 mg/week). The

trial reported a superior 2-year overall survival rate in the lenalidomide plus low-dose dexamethasone group (87% vs 75%) and found that lenalidomide with low-dose dexamethasone was associated with higher overall survival and less toxicity than lenalidomide with high-dose dexamethasone. This trial was halted after a second interim analysis and patients were allowed to cross-over to the low-dose arm.[40] Results showed that the lenalidomide plus high-dose dexamethasone arm had a 26% incidence of VTE compared to a 12% rate in those randomized to the lenalidomide plus low-dose dexamethasone arm.[40] The improved survival in the low-dose dexamethasone arm is likely related to lower mortality from adverse events, particularly VTE. Deaths in the high-dose dexamethasone group usually occurred in the first 4 months and in elderly patients. The low risk of VTE in the lenalidomide plus low-dose dexamethasone arm may allow for VTE prophylaxis with low-dose aspirin, LWMH, or warfarin as needed.[40] Lenalidomide plus dexamethasone is considered a category 1 NCCN recommendation for the initial treatment of MM patients regardless of transplant eligibility (see Fig. 136-2).[13]

Lenalidomide is also commonly added to bortezomib-based regimens and chemotherapy. The triplet of bortezomib, lenalidomide, and dexamethasone has demonstrated activity in newly diagnosed and refractory or relapsed MM. It is an option for transplant-eligible MM patients, with ongoing studies to determine its role in this setting (see Fig. 136-2).[13] The triplet regimen of melphalan, prednisone, and lenalidomide (MPL) has been studied in transplant-ineligible patients. In a recent study, MPL was compared to MPT in newly diagnosed patients with MM. No differences in survival and response rates were observed, but MPT was associated with more grade 3 or higher overall toxicity (73% vs 58%; P=0.007).[41] Along with MPT, MPL is recognized by the NCCN as a first-line option for transplant-ineligible patients.[13]

Lenalidomide is considered less toxic than thalidomide. Lenalidomide causes less neurotoxicity, somnolence, and constipation but more myelosuppression than thalidomide.[6] When used as part of combination therapy, the risk of VTE with lenalidomide is similar to that observed with thalidomide, and VTE prophylaxis is recommended.[3,34] Multiple cycles of lenalidomide impair stem cell mobilization.[13,24] IMWG recommends that transplant-eligible patients receiving lenalidomide have stem cells collected within the first four cycles of therapy.[13]

Pomalidomide (Pomalyst®) 5 Pomalidomide is the newest IMiD used in the treatment of myeloma. It is FDA approved in relapsed MM in patients who have received at least two prior therapies including lenalidomide and bortezomib. A phase II trial showed that the combination of pomalidomide with dexamethasone produced a good overall response rate (35%) in heavily pretreated relapsed and refractory MM.[13] The toxicity profile was reasonable and consisted mainly of manageable myelosuppression. Pomalidomide has also been evaluated in phase III trials. An open-label phase III trial compared pomalidomide and low-dose dexamethasone to pomalidomide and high-dose dexamethasone in relapsed or refractory MM. The primary endpoint of progression-free survival was longer in the low-dose dexamethasone arm compared with the high-dose dexamethasone combination (4 vs 1.9 months).[42] Thus, the combination of pomalidomide and dexamethasone is an option for relapsed and refractory MM.

Proteasome Inhibitors

Bortezomib (Velcade®) Bortezomib was the first drug in the class of proteasome inhibitors. It is approved in newly diagnosed and relapsed or refractory MM. The mechanism of action is complex and involves inhibiting the proteasome and NF-κB activation. The proteasome is a protease complex responsible for degrading cytosolic proteins that are conjugated to ubiquitin. Ubiquitin is an 8.5-kD polypeptide that tags various proteins for destruction.[43] By reversibly binding to the chymotrypsin site in the catalytic core of the 26S proteasome, bortezomib inhibits the degradation of these targeted proteins.

As discussed earlier, NF-κB activity is increased in MM. In the cytosol, NF-κB is bound to and is inhibited by IκB. The proteasome degrades IκB. When the proteasome is inhibited with bortezomib, cytosolic concentrations of IκB remain high, and NF-κB is retained in the cytosol as an inactive complex. The resulting inhibition of the NF-κB signal leads to a reduction in cytokine production and growth inhibition of the MM clone. Other proteins involved in cell-cycle regulation and apoptotic signaling that may be affected by bortezomib include p53, JNK proteins, and caspase 3.[6,43]

Bortezomib was initially approved in 2003 under the FDA's accelerated approval process for relapsed or refractory MM in patients who had failed at least two prior therapies. The approval was based on a phase II trial in which refractory MM received 1.3 mg/m^2 of bortezomib twice weekly for 2 weeks followed by 1 week of rest. Patients received up to 8 cycles. The overall response rate was 35% (includes minor responses) with seven (3.6%) patients achieving a CR.[44] Subsequently, a large phase III study (Assessment of Proteasome Inhibition for Extending Remissions [APEX] trial) demonstrated that bortezomib had superior activity compared with high-dose dexamethasone in relapsed MM.[45] Bortezomib-treated patients had higher complete and partial response rates (38% vs 18%), longer median time-to-progression (6.2 vs 3.5 months), and improved 1-year overall survival (80% vs 66%) compared with patients receiving dexamethasone. The differences in each of these end points were statistically significant.[45] The results from this study led to expanded FDA approval in 2005 to include patients who had relapsed after one therapy.

Combination therapy with bortezomib has shown promising results in relapsed MM. The combination of bortezomib and corticosteroids has reported CR and nCR rates ranging between 5% and 15%.[46] 6 Bortezomib is often part of a three-drug combination and, in addition to dexamethasone, may include doxorubicin, melphalan, thalidomide, or lenalidomide. These regimens have reported CR and nCR rates of 10% to 50% in relapsed MM.[6,13,46]

Numerous studies have investigated bortezomib in newly diagnosed patients in both transplant-eligible and -ineligible patients (Table 136-5). The inclusion of bortezomib in three- or four-drug combinations produces CR and nCR rates of about 19% to 52% in newly diagnosed MM.[6] Commonly used regimens in the treatment of transplant-eligible patients include bortezomib-cyclophosphamide-dexamethasone, bortezomib-thalidomide-dexamethasone, and bortezomib-lenalidomide-dexamethasone.[13] Bortezomib is also part of a regimen known as MPB (melphalan, prednisone, and bortezomib) used in the treatment of transplant-ineligible patients. The most pivotal trial leading to FDA approval as front-line therapy was the VISTA (Velcade as Initial Standard Therapy in multiple myeloma) trial in which MPB was compared with MP. The overall response and CR rates, time-to-progression, and overall survival were significantly better in the MPB group.[13] An update of this study reported a continued survival benefit after 5 years of follow-up.[47] The NCCN guidelines recognize MPB as an option for transplant-ineligible patients.[13] A meta-analysis of phase III trials suggests that MPB may achieve better response rates, including higher CR and more rapid response than MPT. However, no overall survival and progression-free survival differences were demonstrated.[13] Bortezomib-based therapies may also be preferred in patients with higher risk disease. For example, bortezomib may be able to overcome certain cytogenetic abnormalities, including the t(4;14) translocation.[48]

Bortezomib can cause significant toxicity. The most common adverse effects are mild-to-moderate fatigue and gastrointestinal toxicities. Neuropathy occurs frequently and is the most common cause of discontinuation of therapy. Other important toxicities

include thrombocytopenia, fever, neutropenia, and infection. An increased risk of shingles has been reported in bortezomib-treated patients, and the NCCN guidelines recommend that herpes zoster prophylaxis be considered.[13] Bortezomib-based therapy is an attractive option for those patients with renal dysfunction since renal dose modifications are not required. Unlike melphalan and lenalidomide, bortezomib does not affect stem cell mobilization.

Neurotoxicity is a concern with bortezomib. The neurotoxicity may be decreased with modifying the route of administration and dosing schedule of bortezomib. In a phase III trial in relapsed MM, therapeutic equivalence was found between intravenous and subcutaneous routes of administration.[49] In addition, subcutaneous administration offers the potential advantage of administration in patients without IV access, convenience and improved safety profile, particularly less peripheral neuropathy. Dose schedules have also been modified to decrease toxicity-related treatment delays. Once-weekly bortezomib has been compared with twice-weekly dosing with similar overall response rates demonstrated (93% vs 88%), respectively.[13] The once-weekly schedule was associated with a reduced incidence of serious neuropathy and fewer dose reductions.[50]

Carfilzomib (Kyprolis®) Carfilzomib is a second-generation, irreversible proteasome inhibitor approved for patients with relapsed and refractory disease. Its mechanism, higher selectivity for the chymotryptic site of the 20S proteasome, and toxicity profile are distinct compared to bortezomib.[51] The dosing schedule is also different than bortezomib. Carfilzomib is more potent, yet tolerable, with two consecutive daily doses. Collectively, clinical trials have generally adopted the administration schedule of days 1, 2, 8, 9, 15, and 16 of a 28-day cycles with carfilzomib, starting at 20 mg/m^2 IV over 2 to 10 minutes on the first cycle/week and increasing to 27 mg/m^2 or more afterward depending on tolerability.[13,51]

Carfilzomib may be used as a single-agent as well as in combination therapy. The single-agent activity of carfilzomib is based on an open-label phase II study of 266 patients with relapsed and refractory MM who had received a median of five previous therapies.[52] Patients received carfilzomib 20 mg/m^2 IV over 2 to 10 minutes twice weekly on 2 consecutive days with dexamethasone premedication for 3 of 4 weeks in cycle 1 and then 27 mg/m^2 in subsequent cycles until disease progression, unacceptable toxicity, or completion of a maximum of 12 cycles. The primary endpoint of overall response rate (≥PR) was 23.7%, and the median duration of response was 7.8 months (95% confidence interval [CI] 5.6-9.2 months). In patients who were refractory or intolerant to both bortezomib and lenalidomide, 37% obtained clinical benefit. In patients refractory to both bortezomib and lenalidomide, the overall response rate (≥PR) was 15.4%. Moreover, unfavorable cytogenetic characteristics did not appear to adversely impact response rates. The median overall survival was 15.6 months compared with the median of 9 months typically seen in this setting.[52]

The activity of carfilzomib in combination regimens as first-line treatment is impressive. Two phase II trials have evaluated carfilzomib in combination with lenalidomide and low-dose dexamethasone and an additional trial has examined carfilzomib with cyclophosphamide and dexamethasone. The overall response rate (VGPR or higher) reported in these trials ranges from 74% to 88%.[13,53] The responses were rapid and increased in depth with additional cycles of therapy. The three-drug regimen containing lenalidomide did not adversely affect stem cell collection, but was associated with peripheral neuropathy, which was predominately grade 1 or 2 and observed in 23% of patients.[53] More data are required before carfilzomib-containing regimens are recommended for first-line therapy. The Endurance trial is currently comparing bortezomib-lenalidomide-dexamethasone versus carfilzomib-lenalidomide-dexamethasone.

Numerous trials of carfilzomib in relapsed myeloma are ongoing. The results from a recent interim analysis showed that the addition of carfilzomib to a lenalidomide-dexamethasone backbone improved progression-free survival (26.3 vs 17.6 months) and health-related qualify of life without any change in adverse effects.[51] Additional trials are examining the role of carfilzomib monotherapy compared with other regimens.

The most mature safety data for carfilzomib come from the compiled results of four phase II studies.[54] The most frequently reported adverse events included fatigue (55%), anemia (47%), nausea (45%), thrombocytopenia (36%), dyspnea (35%), diarrhea (33%), and pyrexia (30%). The most common grade 3 or greater adverse events were thrombocytopenia (23%), anemia (22%), lymphopenia (18%), pneumonia (11%), and neutropenia (10%). Most of these events were manageable. Peripheral neuropathy appears to be minimal with grade 3 or higher neuropathy reported in less than 1% in clinical trials.

Ixazomib (Ninlaro®) Ixazomib is the first oral proteasome inhibitor approved for the treatment of MM. It is a once-weekly medication that may be used as second-line therapy in combination with lenalidomide and dexamethasone. The approval is based on the TOURMALINE-MM1 trial which showed the addition of ixazomib to lenalidomide and dexamethasone extended progression-free survival in patients with relapsed or refractory MM compared with lenalidomide and dexamethasone alone (20.6 vs 14.7 months; HR 0.742; *P*=0.012). The safety profile was similar to the individual agents and included neutropenia, anemia, thrombocytopenia, pneumonia, diarrhea, cutaneous rash, and peripheral neuropathy. The approval of ixazomib is exciting because it allows for an orally administered triple-drug combination in the management of MM. Current studies are examining the role of ixazomib in other MM settings including induction and maintenance therapy.[55]

Monoclonal Antibodies

Two monoclonal antibodies have been recently FDA approved for the treatment of relapsed and refractory MM. Daratumumab (Darzalex®) is an IgG1-κ fully human monoclonal antibody that targets CD38, a glycoprotein highly expressed on MM cells. Accelerated FDA approval was granted after two open-label phase II trials of daratumumab showed single-agent activity (overall response rates of 29% and 36%).[57] Elotuzumab (Empliciti®) is another monoclonal antibody that is directed against signaling lymphocyte activation molecule family 7 (SLAMF7). Elotuzumab was evaluated in a phase III trial in combination with lenalidomide and dexamethasone.[57] The elotuzumab combination demonstrated improved progression-free survival and a higher overall response rate compared to lenalidomide.

Panobinostat (Farydak®)

Inhibitors of histone deacetylase enzymes such as panobinostat and vorinostat have shown activity in MM.[13] Panobinostat was evaluated in a recent phase III trial. Patients with refractory or relapsed MM who had received prior therapy with an IMiD and bortezomib were randomized to receive bortezomib, dexamethasone, and panobinostat or bortezomib, dexamethasone, and placebo.[56] The trial enrolled 768 patients and the primary endpoint of progression-free survival was statistically improved by 3.91 months (11.99 vs 8.08 months). No overall survival data were reported. There were serious adverse effects noted including thrombocytopenia, diarrhea, fatigue, and peripheral neuropathy. This trial led to the FDA approval of panobinostat in combination with bortezomib and dexamethasone in patients with refractory or relapsed MM.

Drugs in Development

There are numerous drugs in development for MM that target the MM microenvironment. Combination therapy incorporating traditional chemotherapeutic agents such as bendamustine are currently in clinical trials.[13] In addition, therapies that activate the immune system are also being explored. ImMucin is a 21-mer cancer vaccine that has demonstrated activity in a phase I/II trial.[58] The vaccine

targets the mucin 1, cell surface associated (MUC1) glycoprotein domain, which increases the bodies T cells and antibody response. The trial administered ImMucin along with human granulocyte-macrophage colony-stimulating factor to 15 MUC-1 positive patients with MM and found the vaccine to be well tolerated with 11 patients having stable disease or improvement. For this reason, ImMucin was granted orphan drug designation by the FDA for the treatment of MM.

Initial Therapy

Initial therapy is guided by the NCCN, IMWG, and mSMART recommendations.[13,18,35] These recommendations are based on transplant eligibility (see Fig. 136-2). In patients ineligible for autologous HSCT, thalidomide, lenalidomide, or bortezomib is often added to MP.[13,18,20,21,50] Bortezomib-containing regimens (ie, MPB) may be particularly useful in MM patients with high-risk cytogenetics (t(4;14), 17p-). Lenalidomide plus low-dose dexamethasonse is also an option. The preferred combination is currently unclear and will require randomized controlled comparisons of these combinations. Carfilzomib-based therapy has an important role in heavily pretreated refractory MM and is being evaluated in ongoing phase III trials as induction therapy for newly diagnosed MM patients.

If autologous HSCT is planned after induction therapy, melphalan should be avoided, and thalidomide, bortezomib, or lenalidomide can be added to dexamethasone or VAD-like chemotherapy.[13,20,21,50] The NCCN guidelines list several induction therapy options (see Fig. 136-2). Because there is no standard induction regimen, clinicians can select from a wide range of possible induction regimens.[13] Many clinicians recommend lenalidomide or bortezomib and dexamethasone as two-drug induction regimens or bortezomib, dexamethasone, and either cyclophosphamide, doxorubicin, or lenalidomide as three-drug regimens for patients who are autologous HSCT candidates.[20,21,50]

Some clinicians may choose therapies based on risk using the mSMART model.[18] Bortezomib-containing induction regimens are often utilized in patients with high-risk cytogenetics which is reflected in the mSMART model (see Fig. 136-2).[18] In this approach, high-risk patients receive the combination of bortezomib, lenalidomide, and dexamethasone as induction therapy. Intermediate- and standard-risk patients receive the combination of bortezomib, cyclophosphamide, and dexamethasone or lenalidomide and low-dose dexamethasone. These regimens are continued in transplant-eligible patients for four cycles then followed by transplant, but transplant can be delayed depending on patient preference. Transplant-ineligible patients will receive therapy for about 1 year and then possibly maintenance therapy.[18]

Clinical **Controversy...**

Novel agents, such as thalidomide, bortezomib, and lenalidomide, are routinely used in combination with dexamethasone or chemotherapy as induction therapy. There is no standard induction therapy, and decisions are made based on physician preference and individual characteristics of the patient. Some experts recommend a risk-adapted approach that tailors the treatment based on cytogenetics and gene expression profiling.

Autologous Hematopoietic Stem Cell Transplantation

Although MM is a chemosensitive tumor with significant response rates after treatment with conventional chemotherapy, response durations have been short. In an attempt to improve outcomes with chemotherapy, high-dose chemotherapy regimens with autologous stem cell support have been used after initial induction therapy. The intent of the induction therapy before transplant is to reduce tumor burden. With newer treatment regimens being used for induction, higher rates of quality responses (CR, VGPR, nCR) can be obtained. Recent data suggest that obtaining quality responses during induction improves the outcomes associated with autologous HSCT.[59]

7 Two pivotal, randomized, controlled trials have evaluated the role of high-dose chemotherapy followed by autologous HSCT. In these trials, previously untreated patients were randomized to induction therapy alone versus the same induction therapy followed by high-dose chemotherapy and autologous HSCT. In 1996, the Intergroupe Francophone du Myelome (IFM) reported results of a trial demonstrating a survival advantage for high-dose chemotherapy with autologous HSCT compared with conventional chemotherapy.[60] Since then, six other trials have compared autologous HSCT to conventional chemotherapy.[61-64] Four of the six trials showed improved progression-free survival, while three showed an increase in overall survival associated with the autologous transplant arms. It is worth noting that only one of these trials used newer myeloma induction regimens. The other trials used induction regimens that are rarely used in the modern era of therapy. Palumbo et al. evaluated an induction regimen of lenalidomide and dexamethasone followed by either chemotherapy (melphalan/prednisone/lenalidomide) or tandem melphalan-based autologous transplants.[64] Results of this trial showed a progression-free survival and overall survival benefit for the autologous transplant arm. Based on all available data, guidelines from the American Society of Blood and Marrow Transplantation (ASBMT) support high-dose chemotherapy and autologous HSCT as a level A recommendation.[65]

Induction regimens containing at least one of the novel agents may make a significant difference in response and survival outcomes after autologous HSCT.[66] A randomized phase III trial performed by the French group compared the combination of bortezomib and dexamethasone to VAD as induction before autologous HSCT.[67] Patients were randomized to one of four treatment arms, which included either bortezomib plus dexamethasone or VAD as induction therapy. All arms underwent autologous HSCT with melphalan preparation (200 mg/m^2). Postinduction CR and nCR rates were 15% in the bortezomib-containing arms compared to 6% in those receiving VAD. Progression-free survival was superior in the patients in whom autologous HSCT was preceded by bortezomib plus dexamethasone induction. Two other studies that used bortezomib-based induction before autologous HSCT showed similar benefit.[66]

The optimal timing of autologous HSCT (early vs late) in MM was investigated in three trials. In a landmark trial, patients were randomized to early (within 12 months of diagnosis, $n = 91$) or late transplantation (>12 months after diagnosis, $n = 94$), and no significant difference in 5-year overall survival was observed between the groups.[68] Event-free survival, however, was significantly longer in the early transplantation group (39 months vs 13 months). In an analysis that factors in the time without symptoms, treatment, or treatment toxicity (TWisTT), patients receiving early transplantation had a longer time in a state associated with a good quality of life (27.8 vs 22.3 months). The results of this study supported early autologous HSCT because of its effects on event-free survival and quality of life. Since then, two retrospective studies comparing early versus delayed autologous HSCT have been published.[69,70] These studies included MM patients who received either lenalidomide or thalidomide-based induction regimen, or another novel-therapy based induction regimens. Both trials demonstrated similar time-to-progression and overall survival in the early (within 12 months) and delayed transplant groups. The results of these two retrospective evaluations may support the idea that, in the setting of novel therapy, delaying transplant may be feasible, but the lack of rigorous, prospective, randomized data prevents the uniform recommendation to delay transplant. Enrollment in clinical trials is highly recommended for most patients when evaluating the appropriate timing of stem cell transplantation in MM.[13]

A specialized form of autologous HSCT, tandem transplantation, involves the use of two separate autologous HSCT procedures separated by a rest period of several months. It was theorized that this more intensive approach would lead to improvements in therapeutic outcomes. Since the initial evaluation showing a benefit to the tandem transplant approach, a number of trials have investigated this approach to therapy. Two large meta-analyses evaluated single versus tandem autologous HSCT in the setting of MM.[71,72] Combined, these meta-analyses included nine individual trials in their evaluations. Both analyses concluded that the use of tandem autologous HSCT was associated with an improvement in response rate but did not result in improvements in event-free survival or overall survival. Further, it was noted that the improvement in response rates may have come at the expense of a significant increase in transplant-associated mortality with the use of tandem transplantation.

The primary conclusion from the current data on autologous HSCT as consolidation therapy in MM is that it should be used in younger patients with good performance status. Before transplant, all patients should receive induction therapy to reduce tumor burden. Because of higher transplant-related mortality, a second autologous HSCT is not currently recommended for patients with a diagnosis of MM. There is controversy surrounding the potential value of upfront autologous HSCT in an era of novel induction therapy. Some experts recommend a risk-adapted approach to treatment that included autologous HSCT in the algorithm. For example, the Mayo Clinic offers autologous HSCT to transplant-eligible intermediate- and high-risk patients after bortezomib-based induction therapy. Standard-risk patients are given the option of autologous HSCT followed by maintenance therapy or induction followed by maintenance therapy.[18]

Maintenance Therapy

8 Even with the advances in induction therapy and autologous HSCT, most patients eventually progress within 3 to 5 years, suggesting that effective maintenance therapy is needed to control or delay disease progression. The International Myeloma Working Group has published a consensus document on maintenance therapy in MM.[73]

Historically, variable efficacy and high toxicities have been reported with interferon-α (IFN-α) and dexamethasone maintenance, and neither drug can be recommended outside of a clinical trial.[23] IFN-α at one time was considered to be the maintenance drug of choice after autologous HSCT based on data from a randomized trial showing superior progression-free survival and overall survival following autologous HSCT.[74] A meta-analysis supports the benefit of IFN-α maintenance, but the benefit is limited by high toxicity and intolerance.[75] A randomized trial conducted by the Southwest Oncology Group evaluated the benefit of prednisone maintenance therapy in 125 patients.[76] Patients who received high-dose steroids had significantly longer progression-free survival and overall survival at the expense of high toxicity. Although IFN-α or corticosteroid maintenance has not been widely adopted because of toxicity profile, these therapies served as proof of principle for maintenance therapy and led to trials evaluating thalidomide, lenalidomide, and bortezomib in this setting.

Thalidomide has been studied as maintenance after autologous HSCT. Six trials have evaluated the role of thalidomide maintenance therapy.[21] In all six trials, treatment with thalidomide was associated with improvements in overall response rate, progression-free survival, and event-free survival. Overall survival was improved in three of the six trials.[21] Toxicity assessments showed that patients receiving thalidomide experienced significantly higher rates of clinically significant toxicities, leading to discontinuation of maintenance therapy in a large number of patients. Of note, three of these studies found that in patients who relapsed after transplant, survival after relapse was shorter if they had received prior thalidomide therapy. Additionally, follow up from the MRC Myeloma IX trial demonstrated that in patients with adverse-risk cytogenetics, use of maintenance thalidomide resulted in shorter overall survival.[77]

Overall, the evidence demonstrates that thalidomide maintenance significantly reduces disease progression and prolongs event-free survival, but the effect on overall survival is unclear. The toxicities associated with thalidomide also make it a less than optimal choice in the maintenance setting.

Lenalidomide has largely replaced thalidomide as maintenance therapy because of its more favorable toxicity profile. Two pivotal, randomized phase III trials have investigated the use of lenalidomide maintenance after autologous HSCT.[78] In the CALGB 100104 study, 460 patients with myeloma underwent autologous HSCT, after which subjects were randomized to receive placebo or lenalidomide maintenance. Interim analysis of the data showed significant improvement in time-to-progression in the lenalidomide arm, which led to the study being unblinded. Upon unblinding, 86 of 128 patients receiving placebo crossed over to active treatment with lenalidomide. Despite this large crossover, time-to-progression and overall survival were still improved in the lenalidomide group. In the IFM-2005 trial, patients after autologous HSCT received two cycles of lenalidomide consolidation, followed by randomization to either further lenalidomide maintenance or placebo. In this trial, lenalidomide treatment was associated with an improvement in progression-free survival, but overall survival was similar between groups.[79,80] One unique adverse effect noted in these trials was second primary malignancy, including solid tumors, hematologic malignancies, and non-melanoma skin cancers, associated with lenalidomide treatment. In both trials, these second malignancies occurred at significantly higher rate compared to placebo or control arms. Based on the data, the FDA issued a safety announcement to be added to the warning section of the lenalidomide drug labeling, detailing this increased risk. Given the risk, some practitioners have advocated limiting the use of maintenance lenalidomide to 2 years after transplant in order to minimize risk.[78]

Bortezomib maintenance after autologous HSCT has been evaluated in three separate studies.[20,21] Unfortunately, there is significant variability in the regimens used in these studies, and most included bortezomib in both the induction and maintenance setting, making it difficult to clearly define the clinical benefit of bortezomib in the maintenance setting. In the largest of these trials, 827 patients with newly diagnosed myeloma were randomized to receive induction therapy with vincristine/doxorubicin/dexamethasone (VAD) or bortezomib/doxorubicin/dexamethasone (PAD) followed by autologous HSCT.[81] Maintenance for the VAD group consisted of thalidomide, while maintenance for the PAD group consisted of bortezomib. After 2 years of maintenance, CR rates and progression-free survival were improved in the PAD group. Twelve months after randomization, progression-free survival and overall survival were improved for the PAD arm. Although data supports the activity of bortezomib, the exact role, dose, schedule, and duration of therapy remains unclear.

Given the available data, NCCN and ASBMT do not recommend the use of dexamethasone or IFN-α in the maintenance setting.[13,65] Both thalidomide and lenalidomide are recommended maintenance agents by both NCCN and ASBMT (category 1, grade A). ASBMT guidelines note that in most cases, lenalidomide is the preferred agent. Bortezomib is also a feasible maintenance option, though data are limited. NCCN lists bortezomib as a maintenance option with a category 2A recommendation. ASBMT guidelines identify bortezomib as a grade D recommendation for maintenance therapy, with potential utility in those with cytogenetic high risk disease. The decision to use any of these agents in the maintenance setting must include careful consideration of the benefits and risks.

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic HSCT uses a stem cell source other than the patient and is therefore a transplant across immunologic barriers. Unlike autologous HSCT, which is simply a method of increasing the dose intensity of chemotherapy, allogeneic HSCT is a form of immune therapy. The interest in allogeneic transplantation for MM exists from the notion of using a disease-free stem cell source which may potentially offer longer disease control and possible cure. The major post-transplant complications associated with allogeneic transplant are acute and chronic graft-versus-host disease (GVHD). GVHD may be accompanied by graft-versus-myeloma effect. The graft-versus-myeloma effect, which is mediated by antitumor effector cells from the GVHD reaction, reduces relapse risk and may offer the patient the best chance for long-term disease-free survival.[82]

Myeloablative allogeneic HSCT has traditionally been associated with a high rate of morbidity and mortality, between 20 and 50%.[83] Historically, allogeneic transplant has been used after patients have received and progressed after an autologous HSCT. Several trials have compared tandem autologous transplants to autologous followed by allogeneic stem cell transplant, although there is wide variability in trial design patient selection, and protocols for the prevention and treatment of GVHD).[65] In all trials to date, there have been no consistent findings of improvements in overall survival or progression-free survival. Meta-analyses have shown that the use of allogeneic HSCT may confer a higher CR rate, but this comes at the cost of a higher rate of transplant-related mortality.[84,85]

Allogeneic HSCT may have a role in the management of patients with high risk disease. Ongoing clinical trials are evaluating the role of allogeneic HSCT in patients with MM who have high risk cytogenetic characteristics, who are likely to either respond poorly to upfront therapy or who relapse quickly after upfront therapy or autologous HSCT. There is increasing interest in the use of reduced intensity conditioning regimens. With the current available data, upfront myeloablative allogeneic HSCT is not routinely recommended.

Supportive Care

Bone-Modifying Agents

9 Along with anti-MM therapy, supportive care measures are aggressively used to stabilize skeletal abnormalities. Patients with MM have a high rate of bone involvement of their disease. The mechanism of MM-associated bone disease is thought to be mediated through a number of pathways, including IL-6, IL-1, and TNF-α, but the most targeted pathway is that involving receptor activator factor kappa B ligand (RANK-L) and osteoprotegerin (OPG).[16] In normal bone, RANK-L and OPG are both produced by osteoblasts. RANK-L binds to RANK receptors on osteoclasts, to stimulate bone resorption, and to OPG, a "decoy receptor," to inhibit bone resorption and stimulate bone formation. A balance between RANK-L and OPG is the basis for normal bone remodeling. In MM, an imbalance in normal bone homeostasis leads to increased osteoclast activity and the formation of osteolytic bone lesions which can lead to clinically significant skeletal-related events, including fracture, hypercalcemia, and bone pain.

Bone-modifying agents are frequently used in the treatment of bone-related complications associated with MM. Bisphosphonates are the most studied and used of these agents. Bisphosphonates bind to crystalline calcium in the bone, and are then phagocytized by osteoclasts, leading to osteoclast apoptosis.[86,87] In addition to osteoclast inhibition, bisphosphonates may also promote apoptosis in MM cells. This effect may result from the inhibition of the mevalonic acid pathway, which produces several molecules required for growth of the MM clone.[88] In addition, other potential antimyeloma effects of bisphosphonates may include modifying the cytokine microenvironment, inhibiting the adhesion of MM cells to bone marrow matrix cells, and inhibiting angiogenesis.[89] Although it is possible that bisphosphonates have an antimyeloma effect, there is little direct clinical evidence to support this activity.

The use of bisphosphonates in MM is based on the results of several large, randomized, controlled trials. In the first published study of pamidronate in myeloma, the drug was compared with placebo in a group of MM patients undergoing their first or second course of chemotherapy.[90] Several clinical end points were found to be positively impacted by pamidronate therapy. The investigators reported that patients in the pamidronate group had a lower risk of skeletal-related events, lower pain scores, and improved quality of life. Importantly, a survival advantage was observed in the pamidronate-treated patients who had already received one or more courses of antimyeloma chemotherapy. This finding of improved survival in subgroup analysis is part of the circumstantial evidence to propose an antimyeloma effect for the bisphosphonates.

In 2003, the long-term follow-up results of a trial comparing zoledronic acid to pamidronate were published.[91] This trial included a total of 1,648 patients, although only 194 of these patients had a diagnosis of MM. Patients were randomized to receive zoledronic acid 8 mg (reduced to 4 mg), zoledronic acid 4 mg, or pamidronate 90 mg every 4 weeks for 24 months. With 25 months of follow-up, results showed that zoledronic acid reduced the proportion of patients overall with skeletal-related events, and decreased skeletal morbidity. These findings were less pronounced in the MM subgroup, where time to first skeletal-related event was similar amongst the groups.

Other randomized, controlled trials have been conducted, and the results of these trials were pooled in a recent systematic review.[92] Twenty randomized trials were included, which accounted for 6,692 MM patients. The risk of vertebral fractures and pain was significantly lower in the bisphosphonate-treated patients, and there was no difference between zoledronic acid or pamidronate. Given that the aggregate data in the systematic review agreed with the large controlled studies described earlier, the effect on vertebral fractures and pain are well-supported benefits of bisphosphonate therapy. An overall survival benefit associated with bisphosphonate use in MM patients remains unclear, but this meta-analysis reported that zoledronic acid improved overall survival compared with placebo.

Of interest, a study sponsored by the Myeloma Research Council was published in 2010, comparing zoledronic acid to clodronate in 1,960 patients with newly diagnosed MM. The results of this trial demonstrated a 16% reduction in mortality associated with zoledronic acid. Median overall survival was also significantly extended in the zoledronic acid arm. These results have provided further interest in the potential that bisphosphonate therapy may have some direct anti-myeloma activity, although the mechanism of this activity is largely unknown.[93]

Pamidronate and zoledronic acid, the two most commonly used bisphosphonates in MM, are usually well tolerated. Flu-like symptoms can occur after the administration of bisphosphonates. Acute renal impairment can occur with both agents and is related to both infusion time and dose. For zoledronic acid, the risk of acute renal impairment is higher with the 8 mg dose (vs 4 mg) and when the duration of infusion is 5 minutes (vs 15 minutes). Patients with moderate renal impairment (creatinine clearance: 30-60 mL/min [0.5-1.0 mL/s]) should have their dose of zoledronic acid adjusted downward by 25% (3 mg). This recommendation is included in the zoledronic acid package insert and is based on a greater renal toxicity in patients with preexisting renal impairment.[94] Randomized studies suggest that renal effects are similar between pamidronate and zoledronic acid, and patients on bisphosphonate therapy should have serum creatinine measured at baseline and then periodically thereafter.[95]

Osteonecrosis of the jaw (ONJ) is characterized by an area of exposed necrotic bone and often affects the mandible and the maxilla, but it can also affect the soft palate. Treatment of ONJ involves surgical debridement and antimicrobial therapy and is often suboptimal.[96] The development of ONJ may be related to dental disease and tooth extraction and appears to be more common with IV bisphosphonates compared with oral, and more common with zoledronic acid than with pamidronate. The incidence of ONJ is unknown but may be as high as 10% in MM patients receiving zoledronic acid for extended periods of time. A strong recommendation on a preferred bisphosphonate based on ONJ incidence is likely not warranted. A recent meta-analysis found no difference between the bisphosphonate used and the risk of ONJ.[92]

Recommendations for the treatment of MM-related bone disease were published by the International Myeloma Working Group in 2013.[97] These guidelines recommend that bisphosphonate therapy be initiated in patients with or without bone lesions at diagnosis, and should continue for 1 to 2 years. After 2 years, patients who have achieved a CR or VGPR may consider discontinuing therapy because of the increased risk of ONJ. In addition to recommendations regarding bisphosphonate therapy, this publication also provides guidance for nonpharmacologic interventions to optimize bone health, including radiation, surgery, and kyphoplasty or vertebroplasty.

More recently, a new class of bone-modifying agents has emerged. Denosumab is a first-in class monoclonal antibody directed towards RANK-L. By binding to RANK-L, denosumab prevents binding of RANK-L to RANK, reducing osteoclast activity and allowing bone formation and osteoblast function to predominate. A phase III trial evaluated the efficacy and safety of denosumab compared to zoledronic acid in patients with MM and other cancers.[98] Initial results from this study showed denosumab to be noninferior to zoledronic acid in delaying time to first skeletal-related event. Rates of overall survival, disease progression, and ONJ were similar between groups. Of note, renal adverse effects occurred at a higher rate with zoledronic acid. Denosumab does not require dose adjustments for those with impaired renal function. In a subset analysis of patients with MM, the hazard ratio for death was 2.26 for patients receiving zoledronic acid. While the exact reason for this increase in mortality associated with denosumab is unknown, it is not recommended to routinely use denosumab in place of a bisphosphonate for patients with MM.

Clinical **Controversy...**

Although bisphosphonates are indicated in MM patients with bone disease, controversies surrounding the selection of the best agent and duration of therapy remain. Because of the risk of ONJ in MM patients, a cautious approach on bisphosphonate use is prudent. Some experts recommend that the duration of bisphosphonate therapy should be limited to 2 years. The preference of pamidronate over zoledronic acid is also controversial given that ONJ has also been reported with pamidronate, and the higher risk of ONJ with zoledronic acid is based on observational studies rather than head-to-head randomized comparisons.

Relapsed or Refractory Disease

10 A variety of factors must be considered when determining the most appropriate therapy for an individual who suffers relapses, including the type and duration of previous therapies, whether the patient received a transplant, presence or absence of adverse prognostic factors, toxicity of prior therapies (eg, peripheral neuropathy), organ dysfunction (eg, renal impairment), and how much time has elapsed from initial response to relapse.[13,20,21] The same drugs used to treat MM initially can also be used as salvage therapy in patients who have relapsed. Patients who suffer relapse more than 6 months after initial induction therapy may have same induction therapy repeated.[13] The treatment of patients with relapsed or refractory MM can be with active agents in combination or single agents used sequentially. With the growing number of highly active agents, combination salvage therapy has become predominant. The NCCN has five category 1 recommendations and lists many other additional regimens.[13] Bortezomib is widely used in relapsed and refractory MM. One reason is that bortezomib has activity in patients with high-risk cytogenetics and high-risk patients are more likely to suffer relapse and require salvage therapy. Bortezomib may be used as a single agent or in combination therapy. The addition of dexamethasone, liposomal doxorubicin, panobinostat, lenalidomide, or thalidomide to patients who progress on single-agent bortezomib has been shown to improved response.[50] Interestingly, prior use of IMiDs or high-dose chemotherapy does not appear to affect bortezomib activity in relapsed MM. A phase III trial reported that bortezomib with or without dexamethasone had activity in relapsed or refractory disease despite prior thalidomide therapy or autologous HSCT.[99] Several IMiD combination regimens may also be used in relapsed and refractory MM. Lenalidomide is the IMiD most commonly utilized and has received a category 1 recommendation in relapsed or refractory patients when combined with dexamethasone alone or in combination with carfilzomib and dexamethasone.[13,50]

Treatment decisions for individual patients with relapsed disease may potentially be improved by taking into account patient-specific information such as the type of previous therapies, adverse cytogenetics, and end-organ dysfunction. For example, in patients with relapsed MM, combined bortezomib and liposomal doxorubicin has shown improved time-to-progression compared with bortezomib alone, including in patients who had received prior anthracyclines, lenalidomide, and thalidomide.[50] In contrast, treatment with lenalidomide and dexamethasone resulted in a significantly shorter time-to-progression in patients who had previously been treated with thalidomide compared with thalidomide-naïve patients.[38,39] Despite clear progress, most salvage therapies produce less than a 50% response rate, and new drugs and drug combinations are needed.

Questions remain on the optimal timing for autologous HSCT. For patients who are eligible for autologous HSCT and did not receive transplant as part of initial therapy, it is appropriate to offer autologous HSCT at first relapse. It is important to emphasize that although higher quality of life was realized when autologous HSCT was used as consolidation therapy, there was no difference in overall survival based on timing of transplant. The use of salvage autologous HSCT in patients who received a prior autologous HSCT seemed to be most beneficial in patients who had a response of greater than 24 months after initial autologous HSCT.[100] In patients with relapsed or refractory MM, autologous HSCT followed by nonmyeloablative allogeneic HSCT has potential benefit but at the expense of increased transplant-related mortality requiring treatment only be performed as part of a clinical protocol.

PERSONALIZED PHARMACOTHERAPY

Therapy for MM is personalized based on staging (eg, ISS), cytogenetics, gene expression profiling, performance status of the patient, age of the patient, and preexisting risk for drug toxicity. Personalized therapy has been driven by the explosion of new treatment options in MM and a better understanding of the MM biology and therapeutic targets. As described previously, the Mayo Clinic recommends a risk-adapted approach that tailors therapy based on risk category (eg, high, intermediate, or standard).

The use of a risk-adapted approach is reasonable in newly diagnosed patients (see Fig. 136-2). MM is currently not curable, and the disease will evolve as the disease progresses, which will require evaluation of biomarkers at times of relapse and progression to tailor therapy in each stage of the disease.

In addition to molecular characteristics of the tumor, a number of patient-related factors guide personalized treatment. For example, older patients with poor performance status would not be candidates for autologous HSCT. Patients with preexisting severe peripheral neuropathy would be less likely to receive thalidomide or bortezomib because of neurotoxicity. Patients with risk factors for VTE would be more likely to receive bortezomib-containing combinations because the risk of VTE is lower compared with thalidomide or lenalidomide combinations. Patients with preexisting renal failure may be less likely to receive lenalidomide because it requires dose adjustment based on renal function. With personalized therapy, patients will have the opportunity to benefit from the use of novel agents.

EVALUATION OF THERAPEUTIC OUTCOMES

As MM is currently an incurable disease, the goals of therapy are to prolong survival and to improve quality of life. Patients with asymptomatic MM are usually followed and not treated. Asymptomatic patients are assessed every 3 to 6 months for disease progression, which would then warrant therapy. Assessment involves measurement of M protein in blood and urine and laboratory tests that include complete blood count, serum creatinine, and calcium. Patients are treated as the disease produces symptoms. Disease response is defined by a decline in M protein. After completion of the initial course of therapy and once a response is obtained, patients should be monitored every 3 months. Bone surveys are performed yearly or as required because of changes in symptoms. Various other tests, including bone marrow biopsy, magnetic resonance imaging, and positron emission tomography, or computed tomography scan, are performed on an as-needed basis to evaluate disease status.

ABBREVIATIONS

ASBMT	American Society of Bone Marrow Transplant
ASCO	American Society of Clinical Oncology
CI	confidence interval
CR	complete remission
IκB	inhibitory factor kappa B
IFN	interferon
IGF-1	insulin-like growth factor
IL	interleukin
IL-6	interleukin-6
IMiD	immunomodulatory drug
HSCT	hematopoietic stem cell transplantation
IFM	Intergroupe Francophone du Myelome

Myelodysplastic Syndromes

e137

Kristen B. McCullough and Julianna A. Merten

KEY CONCEPTS

1. Myelodysplastic syndromes (MDS) primarily affect elderly adults, with median age at diagnosis of 76 years.
2. MDS are associated with environmental, occupational, and therapeutic exposures to chemicals or radiation.
3. The clonal population of cells manifested as MDS results from enhanced self-renewal of a hematopoietic stem cell or acquisition of self-renewal in a progenitor cell, increased proliferative capacity in the abnormal clone, impaired cell differentiation, evasion of immune regulation, and antiapoptotic mechanisms in the disease-sustaining cell.
4. Most patients with MDS present with fatigue and lethargy or symptoms related to anemia-induced tissue hypoxia.
5. The prognosis of patients with MDS is variable. Overall survival time ranges from a few months to several years and is most accurately estimated with the International Prognostic Scoring System—Revised (IPSS-R).
6. The primary goal of therapy is hematologic improvement for lower-risk patients and alteration in the natural course of the disease for higher-risk patients. Palliation of symptoms and improvement in quality of life are goals of therapy for all patients.
7. Current guidelines recommend erythropoietin (EPO) or darbepoetin with or without filgrastim for management of anemia in patients with lower-risk MDS.
8. Hypomethylating agents are appropriate for patients with lower-risk MDS with clinically significant neutropenia or thrombocytopenia, patients with anemia who are unlikely to respond to or have not responded to a trial of EPO or immunosuppressive therapy.
9. Antithymocyte globulin is appropriate treatment for patients with lower risk, HLA DR15 positive expressing MDS who have symptomatic anemia that is unlikely to respond to erythropoietic agents.
10. Lenalidomide is recommended for initial treatment of lower-risk 5q- syndrome accompanied by symptomatic anemia.
11. Allogeneic hematopoietic stem cell transplantation offers potentially curative therapy to patients with MDS who have a donor and are healthy enough for the procedure.

INTRODUCTION

Myelodysplastic syndromes (MDS) are myeloid clonal, heterogeneous, stem cell disorders characterized by predominantly hypercellular bone marrows, anemia, thrombocytopenia, leukopenia, and an inherent predisposition toward evolution to acute myeloid leukemia (AML).[1,2] The diagnostic hallmark for MDS is the presence of bone marrow dysplasia in at least 10% of cells of a single myeloid lineage.[1] The clinical course of patients with MDS varies from a slowly progressing indolent disease to more aggressive disease characterized by excess bone marrow blasts and rapid progression to AML in up to 30% of cases.[3,4]

Our understanding of the molecular genetics behind MDS has advanced in recent years, but few targeted treatments have been approved in MDS. Aberrations in epigenetic regulator genes, spliceosome component pathways, DNA damage response genes, and genes regulating transcription factors have redefined the molecular landscape in MDS and several additional chromosomal abnormalities have been incorporated into prognostic models predicting survival and leukemic transformation.[5,6] Between 2004 and 2006, three medications (azacitidine, decitabine, and lenalidomide) were approved by the FDA for the treatment of MDS with both azacitidine and lenalidomide improving survival in MDS.[7,8] Despite progress in disease classification, identification of over 40 recurrently mutated genes, improvement in risk stratification, and development of new treatment options in the past two decades, the ability to provide patient specific, targeted therapy remains elusive.

EPIDEMIOLOGY

1 MDS primarily affect elderly adults, with a median age at diagnosis of 76 years and a slight male predominance, with an estimated male-to-female ratio of about 1.75 to 1.[9,10] An estimated 3 to 12 cases of MDS are diagnosed per 100,000 persons per year. The risk of MDS increases with age; in patients older than 65 to 70 years, an estimated 27 to 75 new cases occur per 100,000 persons per year.[10-12] The Surveillance, Epidemiology and End Results (SEER) Program estimates about 19,600 new cases of MDS are diagnosed in the United States each year.[10] Recent reports suggest that the incidence of MDS has been grossly underestimated, with analyses of Medicare claims databases indicating it could be as high as 45,000 per year.[12,13] Many experts predict that the incidence of MDS will increase as the population of the United States ages and clinicians become more aware of MDS.[9]

Renal Cell Carcinoma

Christine M. Walko and Daniel J. Crona

e138

KEY CONCEPTS

1. Renal cell carcinoma (RCC) predominantly occurs later in life, with about 70% of all cases diagnosed between the ages of 55 and 84 years.
2. Established risk factors for RCC include smoking, obesity, hypertension, and inherited susceptibility.
3. Inactivation of the von Hippel-Lindau tumor suppressor gene is the hallmark of the most common type of RCC, the clear cell histologic subtype.
4. More than 50% of RCC cases are diagnosed by incidental findings on routine imaging for unrelated reasons.
5. The Memorial Sloan-Kettering Cancer Center Prognostic Factors Model for Survival classifies patients into low-, intermediate-, and high-risk groups based on five clinical factors and can predict survival among both untreated patients and those treated with immunotherapy and/or targeted agents.
6. Surgical excision of the primary tumor, either by radical or partial nephrectomy, is the preferred treatment modality for patients with stage I-III RCC, but some patients with stage IV disease may also benefit from surgery.
7. Historically, immunotherapy (interleukin [IL]-2 and interferon [IFN]-*α*) was considered the preferred first-line therapy for metastatic RCC (mRCC) but has largely been replaced by targeted agents because of their improved efficacy and tolerability. Nivolumab is a new immunotherapy option for mRCC patients who have received prior targeted therapy.
8. Sunitinib, pazopanib, and axitinib are oral small molecule inhibitors of vascular endothelial growth factor (VEGF) and platelet-derived growth factor and are treatment options as first-line therapy for mRCC. Bevacizumab and IFN-α is also a first-line option.
9. The multikinase inhibitors sorafenib and cabozantinib, and the mammalian target of rapamycin (mTOR) inhibitor everolimus, are the oral agents used as second-line therapy options for mRCC patients who progress on a targeted therapy or cytokine-based therapy first-line regimen.
10. Temsirolimus is an IV administered mTOR inhibitor indicated for first-line therapy in patients with high-risk mRCC.

INTRODUCTION

Renal cell carcinoma (RCC) represents about 2% of all adult malignancies and is the most common type of malignancy of the kidney and renal pelvis. Until a decade ago, there were few treatment options, and those that were available had modest activity and were poorly tolerated by patients. However, treatment for the disease has been revolutionized by targeted agents that were developed based on an increased understanding of RCC pathophysiology. Clear cell is the predominant subtype of RCC (up to 75% of all cases), and is the result of inactivation of the von Hippel-Lindau (*VHL*) tumor suppressor gene located on chromosome 3p25. *VHL* inactivation leads to increased production of growth factors, such as vascular endothelial growth factor (VEGF), transforming growth factor (TGF), platelet-derived growth factor (PDGF), and others responsible for angiogenesis and cell growth.[1] Prior to 2005, the primary therapeutic option for patients with advanced or metastatic RCC (mRCC) after nephrectomy was immunotherapy, which induced few durable responses and caused high rates of severe toxicities. However, nine new drugs have been approved as first- or second-line therapy for RCC: sorafenib, sunitinib, temsirolimus, bevacizumab (in combination with interferon-*α* [IFN-*α*]), everolimus, pazopanib, axitinib, nivolumab, and cabozantinib.[2-9] Each drug is an example of targeted therapy against growth factors important in the pathophysiology of RCC and has yielded much needed progress in a disease with few therapeutic options. RCC serves as an example of rational development of targeted agents based on knowledge of tumor biology and molecular signaling pathways for the treatment of other malignancies.

EPIDEMIOLOGY

About 62,000 new cases of kidney and renal pelvis cancer are diagnosed each year in the United States, with two-thirds of these cases occurring in men. More than 13,000 people in the United States will die of kidney cancer each year. Kidney cancer is the seventh most common cancer in men, and the number of new cases diagnosed each year is similar to non-Hodgkin lymphoma and melanoma. In women, kidney cancer is the eighth most common cancer, occurring at a rate similar to the rates for ovarian and pancreatic cancers.[10] The incidence of RCC has increased over the past three decades. The rate has increased more rapidly in blacks than whites and in women than men. In the United States, between 2002 and 2006, the age-adjusted incidence rate in black men was 21.3, white men 19.2, black women 10.3, and white women 9.9 per 100,000 person years.[11] This increase may be related to improved imaging techniques and greater use of these imaging modalities, although the higher prevalence of some risk factors may also explain the increased incidence.

1 Kidney cancer is most commonly diagnosed between the ages of 40 and 70 years, with a peak in the sixth and seventh decades of life. Nearly 70% of all cases of kidney cancer are diagnosed in people between the ages of 55 and 84 years, with less than 3% of all cases diagnosed in patients younger than 34 years.[11]

Melanoma

Cindy L. O'Bryant and Jamie C. Poust

KEY CONCEPTS

1. Cutaneous melanoma is an increasingly common malignancy, but it is a cancer that can be cured if detected early. Public education about screening and early detection is one strategy to control the increase in incidence and the mortality associated with cutaneous melanoma.
2. Surgical resection can cure patients with early-stage melanoma.
3. Adjuvant therapy should be considered in patients with locally advanced disease; recommended options include IFN-α_{2b}, ipilimumab or participation in a clinical trial.
4. Single agent chemotherapy offers limited benefit in metastatic melanoma. Combination chemotherapy has not been shown to be superior to single-agent therapy.
5. Advances in immunotherapy with ipilimumab, pembrolizumab, and nivolumab have led to long durable responses in some patients with metastatic melanoma and have significantly impacted overall survival.
6. The immune-related toxicities associated with immunotherapy can be severe and life-threatening. Consequently, the use of these agents warrants appropriate patient selection, close monitoring and toxicity management by an experienced healthcare team.
7. As the biology of melanoma has been further delineated, a growing number of potential targets for drug therapy have been identified. BRAF mutations appear in up to 70% of melanoma patients. The use of BRAF inhibitors with or without MEK inhibitors has been shown to improve overall survival in patients with this mutation.
8. Treatment of melanoma is determined by many factors. As the number of treatment options for patients with metastatic melanoma grows, it will be important to consider disease- and patient-related aspects when determining appropriate therapy.

INTRODUCTION

Skin cancer is the most common malignancy worldwide and is associated with chronic ultraviolet (UV) exposure. The two types of skin cancer are nonmelanoma skin cancers (NMSCs) and melanoma. Although NMSCs are the most common malignancy of the skin, cutaneous melanoma accounts for up to 75% of all skin cancer-related deaths. Melanoma cases are increasing globally with the highest rates found in Australia, New Zealand, North America, and Northern Europe. Melanoma is the sixth most common cancer in the United States. The incidence of melanoma has steadily increased in the United States since the 1970s, and for the last decade, has raised an average of 1.4% each year.[1] When detected early, patients generally have a good prognosis. With the rise in the number of melanoma skin cancers and the associated mortality, it is essential to consider issues of care beyond that of disease treatment. Skin cancer prevention and screening have a major impact on public health, and on the success of treatment, for those individuals diagnosed with both NMSC and melanoma. Skin cancers tend to occur more frequently in older individuals with a median age of diagnosis 63 years old.[1] Therefore, as the population continues to age, effective strategies to prevent, detect, and treat individuals with these cancers are necessary. An understanding of the biology of melanoma has led to the development of targeted therapies toward somatic mutations and immunotherapies, which have shown improved outcomes in patients with advanced melanoma.

EPIDEMIOLOGY

In the United States, about one in every 50 individuals will be diagnosed with melanoma in their lifetime. The lifetime risk is greater in men than women, but rates are higher in women before the age of 50. Risk also varies with ethnicity, with the majority of melanoma occurring in non-Hispanic whites.[2,3] In 2016, it is estimated that 76,380 new cases of melanoma would be diagnosed in the United States.[3] Unfortunately, this estimate may not be accurate as many superficial, and in situ melanomas, are managed in facilities that do not routinely report their cases to cancer registries. Childhood and adolescent melanoma account for only 1% of new melanoma cases each year, but is the most common skin cancer in individuals younger than 20 years old. The incidence in this age group is increasing by 2% per year. Adolescents between the age of 15 and 19 years have the highest rates of melanoma (18%) compared to younger children, with the incidence in girls being higher than boys in all age ranges.[4]

The estimated number of individuals expected to die of melanoma in 2016 in the United States is 10,130.[3] Survival rates have gradually increased over the past four decades. The 5- and 10-year relative survival rates are 91% and 89%, respectively, but survival declines to 16% with more advanced disease.[1] Although the overall mortality rate has remained stable, those younger than 50 years of age had a 2.6% decrease from 2007 to 2011 while those over 50 years of age had a 0.6% increase.[3]

A number of patient-specific factors and environmental factors have been identified (Table 139-1), and it is likely these factors alone, or in combination, increase the risk of cutaneous melanomas.

Individual physical characteristics can determine responses to UV radiation. Caucasians with fair-colored hair (red or blond), light-colored eyes (blue or green), high degrees of freckling, and those who have a tendency to burn, and rarely tan with exposure to sunlight, appear to be especially at risk. Both UVB and UVA are known carcinogens and are related to the development of melanoma. Clinical and epidemiologic research shows a higher rate of

TABLE 139-1 Risk Factors for Melanoma

Patient-Specific Risk Factors
Adulthood (age older than 15 years)
History of cutaneous melanoma
Dysplastic nevi
High density of common nevi and atypical nevi
Cutaneous melanoma in first-degree relative
Immunodeficiency or immunosuppression
High degree of freckling
Sunburns easily or tans rarely
Blonde or red hair
Blue, green, or gray eyes
Socioeconomic status (higher > lower)
Race (Caucasians > Hispanics > African Americans)
External Risk Factors
Intense intermittent sun exposures
History of sunburn
More than four painful sunburns before age 15 years
Recreational sun exposure

melanoma in those who have extensive or repeated intense UV and sun exposure.[5] Intermittent intense sun exposure, blistering sunburns, the use of tanning beds, and the time of life when exposed to the sun are critical factors for development of cutaneous melanoma. Individuals with a history of these factors are at highest risk. The risk is lower in individuals who have had chronic sun exposure, without a history of burning, and those with occupational exposure. The risk with sunlight and UV radiation seems to be greatest during childhood and adolescence and is more hazardous than exposure during adult life.

An important risk factor for melanoma is the number and size of melanocytic nevi (pigmented lesions or moles) on the body. The formation of these nevi has been shown to be directly related to cumulative sun exposure. The relative risk of developing melanoma increases with the number of typical nevi an individual has. A second risk factor is the presence of atypical melanocytic nevi. Atypical nevi may progress from a normal nevus or be dysplastic from the onset. Up to 20% of melanomas develop from atypical nevi. Congenital melanocytic nevi may be present at birth or within the first few months after birth, and the associated risk of melanoma increases with size.

Immunocompromised patients are at an increased risk for development of cutaneous melanoma and these cases have been shown to have a poor prognosis.[6] Immunodeficiency includes individuals with chronic lymphocytic leukemia, Hodgkin lymphoma, and immunosuppression after organ transplant. Acquired immunodeficiency syndrome (AIDS) has been shown to increase the risk of developing cutaneous melanoma and the disease often is more aggressive. A personal history of NMSC or melanoma skin cancers is a risk factor for subsequent melanoma and may be associated with a poor prognosis. Xeroderma pigmentosum is a rare skin disorder associated with an increased risk for melanoma.

A number of genes have been implicated in melanoma development and progression, and molecular profiling studies have identified several distinct molecular subclasses of melanoma. Familial atypical multiple mole syndrome (FAMMS) or dysplastic nevus syndrome is a hereditary disease characterized by a predisposition to develop dysplastic nevi and cutaneous melanoma. It is estimated that up to 12% of cases of melanoma are associated with a family history or hereditary dysplastic nevus syndrome. FAMMS is associated with mutations in the *CDKN2A* gene located at chromosome 9p21. *CDKN2A* encodes two distinct proteins: inhibitor of cyclin-dependent kinase 4 (INK4A or $p16^{INK4a}$) and ARF (alternative reading frame; p14ARF). INK4A regulates cell cycle progression at the G_1/S checkpoint by inhibiting the G_1 cyclin-dependent kinases that phosphorylate and inactivate the retinoblastoma protein. ARF inhibits p53 degradation and loss of ARF inactivates p53. The frequencies of *CDKN2A* mutations vary in melanoma, but are more commonly found in individuals with familial inheritance patterns and are associated with multiple cases of melanoma in a family, young age at diagnosis, multiple primary melanomas among family members, and pancreatic cancer.[7]

ETIOLOGY

Melanoma arises from the melanocytes in the basal layer of the epidermis. DNA damage, most commonly a result of UV radiation, causes cellular mutations which transform the cell, allow uncontrolled proliferation, and lead to the formation of tumors. The identification of these genetic alterations has led to the recognition of molecular subgroups of melanoma, and more focused drug development for treatment. The first insights to the role of genetics were seen with the relationship of *CDKN2A* mutations and FAMMS.

One of the major signaling pathways found to be associated with the development of melanoma is the mitogen-activated protein kinase pathway (MAPK), which mediates receptor tyrosine kinases, resulting in activation of RAS and downstream BRAF. Activating *BRAF* mutations are the most common somatic genetic event in human melanoma, occurring in 25% to 70% of melanoma patients and primarily noted by a single point mutation (V600E). In the V600E mutation, a valine is substituted for glutamic acid at codon 600. *BRAF* is a somatic mutation and its high prevalence appears to be an epidemiologic link between UV radiation and melanoma. *BRAF* mutations are common in melanomas arising from skin with intermittent sun exposure.[8]

Upstream of BRAF, mutations in *NRAS* and c-*Kit* have also been found as molecular drivers in the development of melanoma. Mutations in *NRAS* are found in 15% to 20% of patients. These tumors are associated with more advanced disease at diagnosis, high growth rates, and shorter survival times than those with *BRAF* mutations.[8] c-*Kit* is a transmembrane receptor tyrosine kinase which, when activated, signals the MAPK andphosphatidyl-inosital-3-OH kinase (PI3K) pathways, resulting in transcription and cell proliferation. Mutations in c-*Kit* are commonly found in acral and mucosal melanomas.[8]

Other genetic alterations involved with the development of melanoma include *MITF* (microphthalmia-associated transcription factor), which is a gene important to the survival of melanocytes. When mutated, *MITF* acts as an oncogene.[9] The melanocortin 1 receptor gene (*MC1R*), is prevalent in individuals with melanoma and signals through the MITF pathway. It is involved in melanin synthesis and is associated with the red hair and fair skin phenotype. Variants in *MCIR* lead to a shift in the production from eumelanin (brown/black pigment) to pheomelanin (red/yellow pigment).[10]

PREVENTION AND DETECTION

1 Skin cancer is recognized as a major health problem in the United States. As a result, in 2014 the US Surgeon General released Call to Action to Prevent Skin Cancer. The Call to Action addresses the following goals to support skin cancer prevention: increase opportunities for sun protection in outdoor settings; provide individuals with the information they need to make informed, healthy choices about UV radiation exposure; promote policies to advance the national goal of preventing skin cancer; reduce harms from indoor tanning; and strengthen research, surveillance, monitoring, and evaluation related to skin cancer prevention.[11] As such, the mainstay of melanoma prevention remains strategies to protect individuals from the harmful effects of the sun (Table 139-2). There are three different strategies for melanoma chemoprevention: primary chemoprevention in healthy individuals; secondary chemoprevention to prevent

TABLE 139-2 Options for Sun Protection Sunscreens

premalignant melanoma precursors from becoming melanoma; and tertiary chemoprevention to prevent melanoma recurrence.

UV exposure plays a major role in melanoma development and is the most preventable cause of melanoma. For most people, the sun is the most common source of UV exposure and an important environmental factor in the pathogenesis of melanoma. The incidence of melanoma has been associated with latitude and the intensity of solar exposure among susceptible populations. Radiation in the UVB range (280-320 nm) is historically considered to be the critical factor linking sunlight and melanoma, although prolonged exposure to UVA radiation (320-400 nm) is also important.

Education, and reeducation, about the importance of sun protection have the potential to decrease the rising incidence of this disease. Strategies such as sun avoidance, especially during peak hours of sun intensity (10 AM-4 PM), and staying in the shade when outdoors, are important education concepts for individuals who are in the sun for prolonged periods or who are at high risk for burning. Skiers and winter sports enthusiasts should be cautioned about exposure to UV radiation because the reflection off snow and high altitude contribute to increased UV exposure. The use of protective clothing to minimize damage to the skin for individuals who spend time in the sun is also an option. Clothing and hats designed to protect an individual from sun exposure, but allow for physical activities, such as water sports and hiking, are widely available. In addition, the use of sunglasses, with both UVA and UVB protection, is important. The use of tanning beds has also been associated with development of melanoma. A recent meta-analysis reported that about 6,000 cases of melanoma may be related to indoor tanning in the United States each year.[12] In 2009, the World Health Organization International Agency for Research on Cancer declared UV light emitted from tanning beds was a human carcinogen.[13] To aid in the prevention of skin cancers here in the United States, the Food and Drug Administration (FDA) reclassified UV tanning devices to class II (moderate-to-high risk) devices.[14] Furthermore, regulations have been put in place to restrict minors' access to indoor tanning in 44 states, including 13 which prohibit the use of indoor tanning for anyone younger than 18 years of age.[11]

The use of sunscreens is another strategy to decrease UV exposure. Historically, people have been educated that the risk of skin cancer can be limited by the use of sunscreens with a sun protection factor (SPF) of 15 or greater. In 2011, the FDA mandated new testing and labeling regulations for sunscreen products. Under these regulations, sunscreens labeled as broad spectrum must protect against both UVA and UVB radiation. A product labeled as broad spectrum with a SPF of 15 or higher when used regularly, as directed, and with other sun protective measure, will help prevent sunburn and reduce the risk of skin cancer. Additionally, the regulations limit the SPF value on sunscreen labels to 50+ because of the lack of evidence to show that products with SPF values greater than 50 provide greater protection.[15]

It is important to counsel patients about the appropriate use of sunscreens to optimize benefits from these products. Sunscreens should be applied 30 minutes before going into the sun and should be reapplied every 2 hours, after swimming, and after perspiring heavily. About 1 oz (30 mL) of sunscreen (a "palmful") should be used to cover the arms, legs, neck, and face of the average adult. Sun protection must be used regularly and not merely limited to times of recreation or anticipated "prolonged" exposure. Times of season changes, when the potential for sun exposure can be perceived as erratic, are possible times for the "first-of-the-season sunburn."

Thickness and stage of the disease are inversely related to melanoma survival. Early detection can play a large part in the secondary and tertiary prevention of melanoma. Many healthcare organizations, and skin cancer groups, recommend monthly self-skin examination (SSE) to serve as a mechanism for recognizing moles or marks on the skin that may be melanoma. Patients with a strong family history should have additional clinical examinations, and in some cases, screening photography to document the size, shape, and location of moles. Both patients and clinicians need to be properly educated in the clinical features of the disease to ensure more appropriate diagnosis. Currently, there are no consistent recommendations for the screening and early detection of melanoma.

PATHOPHYSIOLOGY

Melanomas most often arise within epidermal melanocytes of the skin, although they can also arise from noncutaneous melanocytes. During fetal development, melanocytes migrate over a predictable route to a variety of sites within the body including the skin, uveal tract, meninges, and ectodermal mucosa. Primary melanoma can arise in any area of the body with melanocytes. The skin is the most frequent site of melanoma; cutaneous melanoma constitutes 90% of all melanomas. Primary melanoma can arise in the eye (ocular melanoma), the mucosa, and in some cases, as metastatic disease with unknown primary site.[16]

Melanocytes synthesize melanin to protect various tissues, such as the skin, from UV damage and reach the keratinocytes in the upper layers of the epidermis via dendrites. Tyrosinase is an essential enzyme within melanosomes that synthesizes melanin. They are resistant to severe UV radiation, unlike keratinocytes, and their survival leads to the proliferation of mutated genes.

The pathogenesis of human melanoma involves a series of morphologic stages: melanocytic atypia, atypical melanocytic hyperplasia, radial growth phase in which limited growth and radial expansion of the nevi may occur without metastatic competence, primary melanoma in the vertical growth phase with or without intransit metastasis, regional lymph node metastatic melanoma, and distant metastatic melanoma. Primary melanoma is characterized by radial growth and limited vertical thickness (less than 0.75 mm). Primary melanoma demonstrates little tendency to metastasize. Melanoma has a potential for metastasis formation with the onset of a vertical growth phase. Therefore, the thickness of a primary melanoma is an important prognostic factor and is used in the staging classification of cutaneous melanoma. Of note, melanomas can skip steps in this development pathway.

Melanoma cells secrete a variety of growth autocrine and paracrine factors which may facilitate proliferation. As disease progresses, melanoma cells increase production of certain growth factors and cytokines which, in turn, activate cellular growth and survival pathways. Understanding the biology of melanoma has provided potential targets for drug therapy. Pathways, such as MAPK and PI3K/AKT, have been targeted by RAF and MEK inhibitors and mammalian target of rapamycin (mTOR) inhibitors, respectively. As new pathways are identified and as agents that inhibit these pathways are developed, there is growing excitement about the opportunities to impact treatment of melanoma in new and effective ways.

The immune response appears to be more involved in the progression of melanoma than other solid tumors. Spontaneous cancer regressions are rare but are a well-documented phenomenon seen in melanoma and appear to be associated with host immunity.[17] Recombinant cytokines including interleukin-2 (IL-2) and interferons (IFNs) have been used in the treatment of melanoma to stimulate the immune system through T cell activation. Immune checkpoint receptors, such as cytotoxic T lymphocyte antigen 4 (CTLA-4) and programmed death-1 (PD-1), both found on the surface of activated T cells, appear to have an inhibitory effect on the cells. Blocking these receptors is an effective strategy for increasing the T-cell antitumor response. Vaccines against melanoma-associated antigens and the use of adoptive T cell therapy (ACT) and chimeric antigen receptors (CARs) T cell therapy are other immunotherapeutic approaches currently under investigation.[17,18]

HISTOLOGIC SUBTYPES

Cutaneous melanomas are categorized by growth patterns. Four major histologic subtypes, or growth patterns of primary cutaneous melanoma, have been identified: superficial spreading melanoma (SSM), nodular melanoma, lentigo maligna melanoma (LMM), and acral lentiginous melanoma (ALM). Clinical outcomes of the four major melanoma subtypes are similar if the comparison controls for depth of penetration or tumor thickness. Any of the four subtypes can present as an amelanotic variant. Amelanotic melanomas appear to be devoid of clinically apparent pigmentation. Desmoplastic melanoma is a less common subtype found in about 1% of cases. It is frequently seen in older individuals, and its clinical presentation is similar to that seen in NMSCs. If a biopsy of the lesion is not obtained, the disease may be mismanaged.

SSM is the most common morphologic type of cutaneous melanoma, accounting for about 75% of all melanomas and is associated with intense, intermittent sun exposure. Early in lesion development, SSM is flat, growing radially before vertically. SSM evolves slowly, typically over 1 to 5 years. As the lesion progresses it may become raised or ulcerated. The borders are often irregular and asymmetrical as the lesion progresses and may vary in color (blue, black, brown, pink, or other colors). SSMs may occur at any anatomic site on the body, but are more commonly seen on the back in men, and on the legs in women.[19] The average age of a diagnosis of SSM is 50 years old. These lesions can be linked to mutations in *BRAF*.

LMM represents 10% to 20% of melanomas and is commonly found on the head and neck. It is unique from other histologic subtypes; because of prolonged radial growth phase, it does not have the same propensity to metastasize. LMM arises on chronically sun-exposed sites in older individuals and presents as a freckle-like lesion. LMMs are generally large flat, tan-colored lesions with shades of brown and black. The lesions gradually grow, develop, and begin to change in color.[19] Evolution into invasive melanoma is characterized by nodular development within the flat lesion. Median age at diagnosis is 65 years old. These lesions can be linked to mutations in *KIT*.

Nodular melanoma is the second most common growth pattern of melanoma, occurring in 15% to 30% of patients. Since nodular melanoma is a pure vertical growth phase disease, it is more aggressive and develops more rapidly than other subtypes.[19] Nodular melanomas are dark blue–black and often uniform in color with a shiny surface, although a small percentage of nodular melanomas are amelanotic and have a fleshy appearance. Nodular melanomas are raised and often symmetric. Although they can occur at any age, they typically occur around 50 years of age, and are most common on the trunk, head, and neck. Nodular melanomas are more common in men.

ALM makes up about 5% of melanomas and is not related to UV exposure. It presents as three distinct clinical subtypes: melanoma on the palms of the hands or soles of the feet, subungual melanoma, and mucosal melanoma.[6] Most ALMs are located on the soles of the feet and appear as a large tan or brown stain. The lesions often have irregular convoluted borders and may be masked by thick skin on the feet. Suspicious lesions on the palms or soles of the feet should be evaluated. Subungual melanoma arises in the nail matrix or nail bed. The most common presentation is a brown or black line in the great toe or the thumbnail. Mucosal melanoma is rare but can occur on any mucosal surface. Mucosal melanoma occurs most commonly in the oropharyngeal mucosa followed by the anal and rectal, genital, and urinary mucosa. Unfortunately, mucosal melanoma often does not become clinically apparent until the mass is large or the lesion bleeds. ALM is the most common type of melanoma reported in individuals with a dark complexion (eg, African Americans, Asians, and Hispanics).[19] Similar to LMMs, this subtype is characterized by a protracted radial growth phase and are associated with mutations in *c-KIT*.

Uveal melanoma is currently considered a separate disease from cutaneous melanoma. It is the most common primary intraocular malignancy seen in adults but is an uncommon tumor. Unlike cutaneous melanoma, the frequency and mortality rates of uveal melanoma have remained steady. This melanoma arises from the pigmented epithelium of the choroid. Iris melanoma is a subset of uveal melanoma and tends to have a more benign course. The risk of metastasis varies with the histologic type and size of the tumor as well as the location in the eye and most frequently metastasizes to the liver but can spread to a variety of tissues.[20]

CLINICAL SUBTYPES

With the understanding of the role of genetic alterations in the treatment and outcomes of patients with melanoma, four distinctive clinical subtypes have emerged based on UV exposure and anatomic site. The four subtypes are divided into 1) nonchronic sun damage (non-CSD): melanomas on skin without chronic sun-induced damage; 2) CSD: melanomas on skin with chronic sun-induced damage characterized by the presence of solar elastosis; 3) acral; and 4) mucosal. A genomic analysis revealed differences in the activation of the MAPK and PI3K between the different clinical subtypes. The data showed *BRAF* mutations predominantly occur in non-CSD and less commonly in the other groups. About 10% to 20% of all the subtypes contain *NRAS* mutations and these mutations occur independent of BRAF.[21,22] Further studies showed *c-KIT* mutations are found in almost 40% of acral and mucosal subtypes, in almost a third of CSD melanomas and not at all in non-CSD melanomas.[21,22] This data further emphasizes the need for continued refinement of tumor classifications in melanoma based on genetic and biological features with the hope this will ultimately lead to more personalized treatment options and improved outcomes for patients.

CLINICAL PRESENTATION

Benign nevi often occur in sun-exposed areas and are typically 4 to 6 mm in diameter (about the size of a pencil eraser), raised or flat, uniform in color and round in shape. Dysplastic nevi, an intermediate between benign nevi and melanoma, tend to be larger than common nevi (greater than 5 mm), appear as flat macules with asymmetry, have a fuzzy or ill-defined shape, and vary in color.

The initial clinical presentation of melanoma is often a cutaneous lesion and depends on the histologic subtype and the stage of development of the lesion. The cardinal clinical feature of a cutaneous melanoma is a pigmented skin lesion which changes over a period of time. Any changes in the skin surrounding a nevus, including redness or swelling, are important clinical signs. Uncommonly, the lesion may become itchy or tender and painful. Friability of the

CLINICAL PRESENTATION

General

- Any lesion that changes in appearance over time

Local Signs and Symptoms

- The clinical features used to describe questionable lesions are highlighted with the mnemonic "ABCDE"
  - (A) Asymmetry: Melanoma lesions are often asymmetric
  - (B) Border: Melanoma lesions have irregular borders
  - (C) Color: Color is often variegated in a melanoma ranging from tan, blue-black, red, purple, or white
  - (D) Diameter: Melanoma lesions are frequently greater than 6 mm
  - (E) Enlargement or evolution: A sudden enlargement or change in lesion is concerning for melanoma
- Other signs of melanoma include a lesion that swells, bleeds, or oozes

Systemic Signs and Symptoms

- Palpable lymph nodes
- Depending on the site of metastasis, shortness of breath, abdominal pain, bone pain, headache, and mental status changes

Laboratory Tests

- In addition to a comprehensive metabolic panel, LDH should be evaluated

Other Diagnostic Tests

- Biopsy and pathology review for staging with molecular testing for BRAF and *c-Kit*
- When applicable, SLNB
- Systemic staging should include chest, abdomen, and pelvic CT scan or CT/PET bone scan, and brain MRI

CT, computed tomography; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PET, positron emission tomography; SLNB, sentinel lymph node biopsy.

lesion, resulting in bleeding or oozing, is a danger sign. Perhaps, the most important warning sign of danger is the evolution in any characteristic of a lesion. A biopsy of the lesion is critical to establish diagnosis of melanoma. Subsequent pathologic interpretation of the biopsy will help provide information on prognosis and treatment options. An excisional biopsy, with a 1- to 2-mm margin of normal-appearing skin, is recommended for a suspicious lesion and should include a portion of underlying subcutaneous fat for microstaging. For larger lesions, an incisional or punch biopsy can be performed, and should include a core of full-thickness skin and subcutaneous tissue. When excisional biopsies are not appropriate, as with the face or palmar surface of the hands, a full-thickness incisional or punch biopsy is preferred. A shave biopsy is never appropriate because it can underestimate the thickness of the lesion and may not fully remove the lesion. Additionally, scarring may mask the remaining tumor.

Evaluation of any individual with a suspected melanoma includes a complete history and total-body skin examination. The focus of the patient history is identifying potential risk factors including family history of melanoma, personal history of skin cancer or nevus excisions, sun exposure, and phenotype. A total dermatologic examination is necessary to determine melanoma risk factors (eg, mole pattern, mole type, or freckling) and for staging. Melanoma commonly spreads to the lymph nodes; therefore, individuals suspicious for advanced disease should be examined for lymphadenopathy. Lactate dehydrogenase (LDH) should be measured as elevated serum levels are an independent predictor of decreased survival.[23] In addition, any other signs or symptoms suggestive of metastatic disease should be completely evaluated.

1 Improved survival rates for melanoma have been attributed to the identification and treatment of disease at an early stage when the disease is limited and has not yet metastasized. It follows that one strategy to improve survival rates would be to increase efforts to identify early-stage melanoma. The cost-effectiveness of massive screening for all adults by a physician has never been demonstrated. However, routine examination of the skin by physicians is recommended for individuals, adults, and children who are at high risk. The entire cutaneous surface, including the scalp, should be examined.

It has been estimated that about 50% of the initial melanoma lesions found are discovered by self-examination. Therefore, one of the most direct strategies to improve early detection would be a method to increase effective SSE by the individual, the individual's partner, or a caregiver. Identification of early melanoma allows the opportunity to treat lesions when they are early stage and curable, thus lowering the mortality rate of the disease. Healthcare professionals who routinely work with the public, such as community pharmacists, have an opportunity to increase public awareness concerning the benefits and appropriate methods for SSE. Educational pamphlets describing SSE (Table 139-3) for the public are widely available through the American Cancer Society, American Academy of Dermatology, and Skin Cancer Foundation. If a newly discovered pigmented lesion is identified, or if a preexisting pigmented lesion changes, the individual should be evaluated by a physician immediately.

SSE is of special interest in elderly adults. As the population of older adults (greater than or equal to 65 years of age) increases, it is expected that the mortality rate from melanoma also will increase. Barriers to successful SSE in elderly adults, such as failing eyesight, lack of partners, and poor memory, impact older adults in detecting new or changing lesions. These barriers, coupled with the higher

TABLE 139-3 Self-Examination of Suspicious Moles

1. Examine your body front and back in the mirror and then the right and left sides with the arms raised
2. Bend the elbows and look carefully at the forearms and upper arms and palms
3. Look at the backs of the legs and feet. Look specifically in the spaces between toes and at the soles of the feet
4. Examine the back of the neck and scalp with the help of a hand-held mirror; part the hair (or use a blow dryer) to lift the hair and give yourself a closer look
5. Check the back and buttocks with a handheld mirror

incidence of melanoma in men, present challenges and opportunities for healthcare professionals to target education to this growing segment of our population.

STAGING AND PROGNOSTIC FACTORS

The size of a primary melanoma lesion is associated with the likelihood of metastasis. The Breslow tumor thickness of the primary melanoma lesion is commonly used as prognostic factor to determine predicted outcomes.[24] Tumor thickness is quantified to the nearest tenth of a millimeter with an ocular micrometer, measuring from the top of the granular layer of the overlying epidermis to the deepest contiguous invasive melanoma cell. The correlation between tumor thickness and probability of tumor metastasis is strong but does not include aspects such as tumor satellites, defined rather arbitrarily, as skin involvement within 2 cm of the primary lesion, and vascular invasion. Patients with satellitosis have a worse prognosis than patients with thick primary lesions (tumor thickness greater than 4 mm), and prognosis is more similar to that of patients with nodal metastasis. Mitotic rate, defined as the number of mitosis per square millimeter, is another important prognostic factor for developing metastatic disease. Increasing mitotic rate represents a more aggressive lesion and is associated with a poorer survival rate despite tumor size. The American Joint Committee on Cancer (AJCC) developed a staging system for melanoma which divides patients with localized melanoma into four stages according to microstaging criteria of Breslow, but data from large patient databases demonstrated that the different cut off values for primary thickness may better predict overall survival. Additionally, ulceration of the melanoma and satellite lesions of the primary tumor should be considered when making decisions about therapy. As a result, the AJCC revised the staging system for cutaneous melanoma which was updated in 2009.[23] It is important to carefully examine older clinical trials to determine which staging system was used to determine patient inclusion and exclusion criteria, as results may differ based on these patient criteria. Clinical staging includes microstaging of the primary melanoma with clinical, laboratory and radiologic evaluation. It is used after complete excision of the primary melanoma along with clinical assessment to determine regional and distant metastasis. Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional nodes after partial or complete lymphadenectomy. At this time, it appears that patients with very limited disease (in situ or stage 0) do not require pathologic evaluation of lymph nodes (Tables 139-4 and 139-5).[22]

As with other solid tumors, the presence of regional lymph node involvement is a powerful predictor of tumor burden and patient outcome. Sentinel lymph node biopsy (SLNB) is a minimally invasive procedure which determines if a patient is a candidate for a complete lymph node dissection. The rationale for lymphatic mapping and subsequent SLNB is based on the observation that regions of the skin have patterns of lymphatic drainage to specific lymph nodes in the regional lymphatic basin. The sentinel lymph node is believed to be the first node in the lymphatic basin into which the primary melanoma drains. Unlike other solid tumors, melanoma appears to progress in an orderly nodal distribution. SLNB allows for detection of micrometastases as a result of more thorough examination of a single sentinel node than is possible when examining multiple lymph nodes with a lymph node dissection, and may be most useful for melanomas located in ambiguous drainage sites such as the head and neck areas. SLNB is associated with low false-negative rates and low complication rates.[25] Detection of clinically undetectable disease in a lymph node basin not directly adjacent to the primary lesion, may allow for upstaging of patients who initially are believed to have node-negative disease. The American Society of Clinical Oncology and Society of Surgical Oncology joint clinical practice guidelines recommend SLNB for patient with any intermediate-thickness melanoma.[25]

TABLE 139-4 Melanoma Tumor (T), Node (N), Metastasis (M) Classification

T Classification	Thickness	Ulcerative Status
T_X	Primary tumor cannot be addressed (eg, shave biopsy)	
T_0	No evidence of primary tumor	
T_{is}	Melanoma in situ	
T_1	≤1 mm	A: No ulceration and mitosis <1/mm^2 B: With ulceration or mitosis ≥1/mm^2
T_2	1.01-2 mm	A: No ulceration B: With ulceration
T_3	2.01-4 mm	A: No ulceration B: With ulceration
T_4	>4 mm	A: No ulceration B: With ulceration
N Classification	**No. of Metastatic Nodes**	**Nodal Metastatic Mass[a]**
N_X	Regional lymph nodes cannot be assessed	
N_0	No regional lymph nodes	
N_1	1 node	A: Micrometastasis B: Macrometastasis
N_2	2-3 nodes	A: Micrometastasis B: Macrometastasis C: In-transit metastases or satellite(s) without metastatic nodes
N_3	≥4 metastatic lymph nodes or matted nodes or in-transit metastases or satellite(s) with metastatic node(s)	
M Classification	**Site**	**Serum Lactate Dehydrogenase**
M_X	Distant metastases cannot be assessed	
M_0	No detectable distant metastasis	
M_{1a}	Distant skin, subcutaneous tissue, or nodal metastatic disease	Normal
M_{1b}	Lung metastases	Normal
M_{1c}	All other visceral metastases Any distant metastasis	Normal Elevated

M, metastasis; N, node; T, tumor.

[a]Micrometastases are diagnosed after sentinel or elective lymphadenectomy. Macrometastases are defined as clinically detectable lymph node metastases confirmed by therapeutic lymphadenectomy or when any lymph node metastasis exhibits extracapsular extension.

Data from Balch CM, Gershenwald JE, Soong SJ, et al. Final version of 2009 AJCC melanoma staging and classification. J Clin Oncol 2009;27:6199-6206.

The stage of melanoma, based on tumor thickness, level of tumor invasion, and ulceration, at the time of diagnosis, is one of the primary indicators of the natural history of the disease and contributes to prognosis. Other factors such as tumor growth pattern, or histological subtype, mitotic rate, density of tumor infiltrating lymphocytes (TILs) in the tumor tissue, elevated LDH level, satellite lesions, angiolymphatic invasion, gender, and age also have been reported to influence survival (Table 139-6). The location of the primary tumor on the skin is also important as tumors of the extremities have an increased survival compared with those with axial, neck, head, and trunk tumors. In addition, a number of additional prognostic factors

have been identified in patients with advanced disease. The number of metastatic sites, disease involvement of the gastrointestinal tract, liver, pleura, or lung, Eastern Cooperative Oncology Group (ECOG) performance status of 1 or greater, male sex, and prior immunotherapy have been associated with poor prognosis.[26]

TREATMENT

Desired Outcomes

Treatment of cutaneous melanoma depends on the stage of disease. Local disease is managed, and often cured, with surgical ablation. Regional disease is treated with surgical resection of the primary lesion and, depending on the risk of recurrence, adjuvant therapy in an effort to eradicate any residual disease and cure the patient. The role of interferon-α (IFN-α) as adjuvant therapy after surgical resection remains controversial. Until recently, metastatic melanoma has been a difficult disease to treat. The treatment goals for metastatic disease are to slow tumor progression, prolong life, relieve acute symptoms, and improve quality of life. With the advent of new immunotherapy and molecular targeted therapy, the management of metastatic melanoma has drastically changed. After more than a decade of ineffective drug development, several new treatment options now exist for the treatment of metastatic melanoma such as CTLA-4 inhibitors, BRAF inhibitors, MEK inhibitors, and PD-1 inhibitors. Molecular targeted agents offer rapid and high response rates with prolonged time to disease progression, while immunotherapy can induce durable responses. These new treatment options have increased survival expectations to an all-time high in the history of melanoma treatment.

Surgery

Patients who present with a suspicious pigmented lesion should undergo a full-thickness excisional biopsy, if possible. A full-thickness incisional or punch biopsy is preferred, in cases where an excisional biopsy not possible, to provide microstaging and ultimately determine therapy.

2 Localized cutaneous melanoma can often be cured with surgical excision. The cure rates for melanomas smaller than 1 mm are as high as 98%. The extent of the excision margin is important in preventing local recurrence and ultimate survival. For melanoma in situ, excision of the visible lesion or biopsy site with a 0.5 to 1 cm border of clinically normal skin, and a layer of subcutaneous tissue with confirmation of histologically negative peripheral margins, is recommended. The recommended clinical margin for invasive melanoma depends on tumor thickness. Excision with a 1 cm margin of clinically normal skin, and underlying subcutaneous tissue, is recommended for invasive melanomas 1 mm thick or smaller. Current guidelines recommend a 1 to 2 cm margin for melanoma with tumor thickness of 1.01 to 2 mm.[22] Lesions which are 2 to 4 mm thick should be excised with a 2 cm margin. Primary tumors more than 4 mm thick require at least a 2 cm margin, whether a larger margin is beneficial is unclear. Surgical management of lentigo maligna melanoma is problematic as subclinical extension of atypical junctional melanocytic hyperplasia

may extend beyond the visible margins. Complete excision of these lesions is important.

When isolated regional lymph nodes are detected via physical examination, in the absence of distant disease, therapeutic lymphadenectomy is recommended. The extent of therapeutic lymph node dissection often is modified according to the anatomic area of the lymphadenopathy. Selective regional lymphadenectomy performed after scintigraphic and dye lymphographic identification of the affected sentinel draining lymph node(s), is the standard of care for melanomas more than 1 mm thick. If the sentinel node is found to have micrometastatic melanoma, regional dissection of the involved nodal basin is performed. If the lesion is 0.75 to 1 mm in thickness with ulceration or is Clark level IV or V, lymphatic mapping with SLNB may be considered based on patient characteristics, such as ulceration of the tumor.[27] The likelihood of detecting metastatic disease in the sentinel lymph node is about 1% in tumors which are smaller than 0.8 mm, but increases to more than 30% in tumors 4 mm thick.[27] Final results, with 10 years of follow-up, from the Multicenter Selective Lymphadenectomy Trial I showed no difference in disease-specific survival when SLNB was compared to the watch and wait approach (remove nodes once palpable).[28] These results support current clinical practice to remove microscopic metastasis before they become problematic. The Multicenter Selective Lymphadenectomy Trial II is currently enrolling patients to assess whether or not a complete lymph node dissection after a positive SLNB improves overall survival. SLNB results are important for accurate staging, therapeutic lymphadenectomy, and to aid in the decision to offer adjuvant treatment.[27]

One of the most important aspects of surgical management of cutaneous melanoma is the role of patient follow-up.[22] Postsurgical follow-up of patients who have had a melanoma excised is essential to monitor for undetected metastatic disease and the development of a second primary cutaneous melanoma or nonmelanoma primary malignancy. Scheduled screening, in addition to routine surgical follow-up, is required for any patient with a melanoma; the recommended frequency and duration depend on the stage of melanoma. The optimal duration of follow-up remains controversial. Most patients who develop recurrent disease do so in the first 5 years after treatment, but late recurrences, more than 10 years after surgery, have been observed. The increased lifetime risk of developing a second primary melanoma supports lifetime dermatologic surveillance for all patients.

A patient with stage III melanoma commonly has lymph node involvement and in-transit metastases may also occur. In-transit metastasis is the clinical manifestation of tumor which develops in lymphatics between the primary melanoma and the regional lymph node basin.[5] In-transit metastases are more than 2 cm from the original lesion. In-transit metastases are more common in individuals with thick, ulcerated lesions. Surgery is used for management of in-transit lesions, with the goal of complete resection. Unfortunately, subsequent recurrence in the same extremity often occurs after initial resection of in-transit metastasis.

The role of surgery beyond that of cure is less clear, although surgery may offer palliation for patients with isolated metastasis.[27] In these cases, surgery may extend survival time in select patients with metastatic disease. Patients whose metastasis can be completely resected may experience improved quality of life, improved overall survival, and occasionally long-term disease control.[27]

Brain metastasis is a frequent complication of advanced melanoma. About 20% to 50% of patients with stage IV disease develop clinically apparent central nervous system (CNS) involvement. Surgical resection, with or without radiation, has been used in select individuals. More recently, high control rates of brain metastasis have been achieved with focal radiation therapy such as linear accelerator-based stereotactic radiosurgery or gamma-knife technologies.[29] Melanoma in the gastrointestinal tract can lead to bowel obstruction. Appropriate resection or bypass may provide significant relief of symptoms. Despite the lack of controlled clinical trials, the impact on palliative surgery should be evaluated in the context of a patient's comfort and quality of life. The risk of relapse and death after resection of a local, or regional cutaneous melanoma, is the primary determinant for use of adjuvant therapy after primary resection. Adjuvant trials have focused on patients at intermediate or high risk for recurrence.

Adjuvant Therapy

3 Melanoma is considered one of the most immunogenic solid tumors, and it appears to interact with, and respond to, the immune system of the host in which it arises. Spontaneous regressions of melanoma suggest the importance of the immune system in disease modulation. Lymphoid infiltration into the primary melanoma also suggests that immunomodulation may impact the biology of melanoma. Early work has shown that nonspecific immunomodulators, such as levamisole and Bacillus Calmette-Guérin (BCG) for treatment of melanoma, were associated with some regression of the tumor, although many of these responses were limited and short-lived. Because melanoma is generally resistant to traditional treatment modalities such as radiation and chemotherapy, immunotherapy offers an avenue of treatment. In early trials, patients who showed the highest response to immunotherapy had minimal disease burden. The use of adjuvant immunotherapy to treat these patients has been investigated to prevent distant recurrence and improve long term survival.

Interferon

One of the oldest, and most controversial, immunotherapy approaches for the treatment of melanoma is the use of IFNs. The IFNs are a group of proteins with diverse immunomodulatory and antiangiogenic properties. A number of studies evaluated various doses and schedules of recombinant IFN for treatment of metastatic melanoma. Response rates in metastatic melanoma range from 10% to 30%, and overall response rates are about 15% for IFN-α. In clinical trials of IFN therapy for patients with metastatic melanoma, response rates were highest in patients with limited disease. Responses were seen at all sites of disease, but were most frequent in subcutaneous, lymph node, and pulmonary metastasis. The activity of IFN in patients with minimal disease encouraged investigators to evaluate the role of adjuvant IFN. A large, multicenter cooperative group trial (E1684) of adjuvant IFN-α_{2b} versus observation was designed for 287 patients with high-risk (stages IIB and III disease based on the 1997 AJCC staging criteria) melanoma after curative surgical resection. IFN-α_{2b} was given IV as an induction therapy at maximum tolerated doses of 20 million IU/m^2 per dose 5 days per week for 4 weeks; treatment was continued for 48 weeks with subcutaneous IFN-α_{2b} 10 million IU/m^2 per dose 3 times per week. This therapy now is often referred to as *high-dose interferon* (HDI). With a median follow-up period of 6.9 years, patients treated with HDI had significantly longer relapse-free and overall survival compared with patients who were observed after surgical resection (1.72 vs 0.98 years and 3.8 vs 2.8 years, respectively).[30] Both the 5-year relapse-free and overall survival rates were higher with HDI. This data led to the 1995 FDA approval of HDI as standard of care. With longer follow-up (median, 12.6 years), however, the difference in overall survival was no longer significant.[31] Further analysis showed that the greatest reduction in melanoma recurrence occurred during the first few months of treatment. Subgroup analysis of this study indicated that patients with large primary tumors and node-negative disease did not receive the same benefit from therapy, but the small number of patients in this group made it difficult to draw definite conclusions about the role of IFN for adjuvant therapy in this setting.

Pegylated IFN-α_{2b} has also been evaluated in the adjuvant setting with the hope for a better efficicy and toxicity profile. The European

Organization for Research and Treatment of Cancer (EORTC) 18991 trial evaluated 1,256 patients with resected stage III melanoma. Patients were randomized to observation or pegylated IFN. Pegylated IFN was given less frequently compared with nonpegylated IFN. Updated results demonstrated an improvement in relapse-free survival, but no difference in overall survival or distant metastasis-free survival.[32] Based on this data, the FDA approved pegylated IFN-α_{2b} as an option for adjuvant treatment.

HDI treatment is associated with multiple toxicities, including flu-like syndrome. Toxicities of IFN therapy in the adjuvant HDI trials were common and severe. About one-third of patients will need a dose modification during induction and only half of the patients are able to complete the year of therapy in an outpatient setting. One strategy for reducing toxicities associated with IFN is to modify the dose and duration. A subsequent ECOG trial (E1690) of low-dose IFN (3 million IU per dose given subcutaneously three times weekly *low-dose interferon* [LDI]) for 24 months compared with the HDI regimen described earlier versus observation did not demonstrate an overall survival advantage of HDI versus observation.[33] At a median follow-up period of 52 months, the 5-year estimated relapse-free survival rates for HDI, LDI, and observation were 44%, 40%, and 35%, respectively. With longer follow-up, however, the difference in relapse-free survival was no longer significant.[33] A significant overall survival benefit was not seen for HDI or LDI compared with observation, although the investigators speculated that this analysis of survival was affected by the number of patients in the observation arm who received IFN therapy after disease progression.[33]

The use of IFN in the adjuvant setting remains controversial. Although the HDI regimen is used in the United States, the LDI strategy remains standard in many European countries. In a pooled analysis of 713 patients who participated in two randomized controlled trials (E1684 and E1690), HDI was associated with a significant reduction in relapse-free survival compared with observation ($P < 0.006$).[31] No benefit in overall survival was observed in the pooled analysis. The results of nine randomized clinical trials of adjuvant HDI or LDI versus observation in melanoma were included in a systematic review. The systematic review observed a trend toward reduced risk of recurrence of melanoma and of death among the IFN-treated patients in nearly all studies.[34] Because of differences in dose, frequency, and duration of IFN-α treatment in the various trials, the review was not able to compare LDI versus HDI. Furthermore, the wide variability in number of patients enrolled, end points, patient selection, quality, type of therapy, duration of treatment, and follow-up precluded statistical analysis of the pooled results. Although the differences in overall survival have not always been statistically significant, HDI remains the only adjuvant treatment shown to prolong survival in prospective randomized trials. IFN-α_{2b} is approved by the FDA for treatment of patients with primary melanomas larger than 4 mm (stages IIB and IIC) and in patients with melanoma involving regional lymph nodes who are disease-free after lymph node dissection (stage III).

For patients who receive IFN, it is important to effectively prevent and manage treatment-related toxicities. A common syndrome seen with IFN-α therapy is a diverse group of side effects referred to as *constitutional symptoms*, which can include acute symptoms such as fever, chills, myalgia, and fatigue, and can encompass some of the more chronic toxicities such as fatigue, anorexia, and depression.[35] Acetaminophen can be used to prevent or minimize acute dose-related symptoms such as fever, myalgia, and chills. Opiates, such as meperidine, are often required when patients experience severe chills or rigors, most commonly during the initial month of the HDI induction phase. Nonsteroidal anti-inflammatory drugs (NSAIDs) have been used to manage IFN-related myalgia, but may have overlapping side effects with IFN, such as a decrease in renal blood flow. NSAIDs and acetaminophen may mask fevers which occur in patients who experience neutropenia while undergoing therapy. Additionally, NSAIDs may increase the risk of bleeding in the setting of thrombocytopenia caused by IFN. Fatigue is one of the most frequently observed dose-limiting toxicities seen with IFN therapy, occurring in 70% to 100% of patients.[35] IFN-induced fatigue appears to be dose related and may worsen with continued therapy. Pharmacologic (eg, methylphenidate) and nonpharmacologic (eg, exercise, psychosocial techniques, distraction, energy management, and dietary modifications) may improve IFN-related fatiguein patients. Depression is common and should be fully evaluated. Contributing factors such as IFN-induced hypothyroidism or concomitant IFN symptoms (eg, nausea and fatigue) should be evaluated concurrently with depression symptoms to optimize treatment decisions. Antidepressants, such as selective serotonin reuptake inhibitors, have been studied in IFN-induced depression with notable benefit.[35] Anorexia is reported in about 70% of patients receiving adjuvant IFN therapy for melanoma and is thought to be mediated through direct effects on hypothalamic neurons, modification of normal hypothalamic neurotransmitters or neuropeptides, or effects from stimulation of other cytokines.[35] Taste alterations may contribute to anorexia. Glucocorticoids should not be used for appetite stimulation or as part of an antiemetic therapy as they may adversely impact the immunomodulatory effects of IFN. Other toxicities, such as hematologic or hepatic toxicities, require monitoring and appropriate dose modification.

CTLA-4 Checkpoint Inhibitor

One of the major advances in the treatment of metastatic melanoma has come through targeting specific immune checkpoints. T-cells play a role in cell-mediated immunity and cancer immunotherapy. T-cells are activated when the T-cell receptor (TCR) interacts with its antigen followed by the interaction of CD28 on the T-cell with the co-stimulatory molecule, B7 on antigen presenting cells. To prevent over activation of T-cells receptors, such as CTLA-4, function as a co-inhibitory receptor for the co-stimulatory molecule B7. Crosslinking of CTLA-4 by B7 inhibits T-cell activation, transcription, translation, and transduction. CTLA-4 blockade overcomes this inhibition and results in activation and proliferation of Tcells.[17] Ipilimumab, a monoclonal antibody to CTLA-4, has demonstrated efficacy in the metastatic melanoma setting. More recently, the EORTC 18071 trial evaluated 475 patients treated with high-dose ipilimumab 10 mg/kg IV every 3 weeks × 4 doses, then every 3 months for up to 3 years, compared to placebo in the adjuvant setting. Recurrence-free survival was 26.1 months in patients treated with high-dose ipilimumab compared to 17.1 months in patients treated with a placebo ($P = 0.0013$).[36] The effect on overall survival remains to be determined.

CTLA-4 antibodies produce several immune-related adverse effects (irAEs) that are distinct and different than adverse events associated with conventional cancer treatments. CTLA-4 antibodies cause autoimmune-irAEs by promoting the activation of self-reactive T cells. The incidence of irAEs is as high as 60%, and up to 20% of patients experience Grade 3 or 4 irAEs.[37] The most common serious irAEs include dermatitis, enterocolitis, hepatitis, and endocrinopathies.[17] These adverse reactions are dose-related and follow a predictable pattern: skin related toxicities occur first after the first dose; colitis follows after the second dose; and hepatitis and endocrinopathies occur last, after third or fourth dose.[38] Most irAEs are reversible with treatment and resolve after 6 to 8 weeks, with the exception of endocrinopathies which may require lifelong hormonal treatment. Close monitoring for irAEs and participation in a risk evaluation and mitigation strategy (REMS) program while on therapy is necessary.[22] It is recommended that patients obtain a comprehensive metabolic panel (with liver function tests), complete blood count, and thyroid function tests at baseline, throughout treatment and for up to 6 months after treatment.[38] Ipilimumab therapy should be held for moderate-to-severe irAEs. High-dose systemic corticosteroids

should be initiated for patients who do not improve from withholding therapy or for grade 3 immune-related events. Ipilimumab can be restarted when adverse events improve to grade 0 or 1 and systemic corticosteroid doses have been minimized. In early studies, corticosteroids were discouraged for concern they would blunt the desired immune response. But studies show that the efficacy of ipilimumab is not compromised with steroid use.[39] For patients who are steroid refractory, defined as no response to high dose IV steroids within 48 to 72 hours of initiation, other immunosuppressive agents have been utilized. Agents such as infliximab and mycophenolate can be used for patients who develop steroid refractory colitis and hepatitis, respectively.[38] Due to its own hepatotoxicity potential, infliximab should be used with caution. Published guidelines for the treatment of irAEs are available.[38] In cases of severe or life-threatening irAEs, permanent discontinuation of therapy is recommended. In clinical studies reported to date, patients who experienced grade 3 or 4 autoimmune toxicities were also the most likely to exhibit tumor regression and increased time-to-relapse in the metastatic setting.[37] The most common adverse effects observed in the EORTC 18071 adjuvant trial were autoimmune colitis and autoimmune hepatitis, consistent with known adverse effects. Autoimmune endocrinopathies occurred at a higher frequency than in the metastatic disease trials. irAE led to the discontinuation of treatment in 52% of patients who were treated with ipilimumab. Of concern, five deaths were attributed to drug-related adverse effects.[36]

Although IFN is approved for the adjuvant setting, many experts continue to question its use given the considerable treatment toxicities and the uncertain overall survival advantage. High-dose ipilimumab provides a new treatment option for patients with high risk disease. Further evaluation is needed to determine its effect on overall survival. Given the significant toxicities associated with high-dose ipilimumab, the decision to treat a patient should be based on careful evaluation of the risk versus benefit. Patients who receive ipilimumab must be carefully monitored for irAEs. The National Comprehensive Cancer Network (NCCN) guidelines for melanoma list IFN-α and ipilimumab as treatment options in the adjuvant setting. Other options include observation, and most importantly, clinical trials.[22]

Clinical **Controversy...**

The role of ipilimumab in the adjuvant setting for high-risk patients after surgical resection of melanoma needs further investigation. In the adjuvant trial, ipilimumab was dosed at 10 mg/kg while the FDA approved dose in the metastatic setting remains 3 mg/kg. The optimal dose to balance efficacy and toxicity remains unknown.

Treatment of Metastatic Melanoma

Chemotherapy and Biochemotherapy

4 Although many drugs show in vitro activity against melanoma, only a few drugs have consistently shown a response rate greater than 10% in individuals with metastatic melanoma. Most clinical trials of new agents in melanoma measure antitumor activity in terms of response rates, which does not always correlate with survival, and do not evaluate benefit to the patient. Complete responses can be durable in a small number of patients.

Dacarbazine, a cytotoxic drug thought to exert its antitumor effect through alkylation, currently is the most effective chemotherapeutic agent for treatment of melanoma. Dacarbazine remains the only FDA-approved chemotherapeutic agent for treatment of metastatic melanoma in the United States. Prospective controlled clinical trials have observed response rates of 10% to 25%, with an average duration of response of 5 to 7 months.[40] Complete responses are uncommon, with fewer than 5% of patients treated with single-agent dacarbazine sustaining long-term complete responses. The optimum dose schedule of dacarbazine has never been determined; doses of 250 mg/m^2/day for 5 days or 800 to 1,000 mg/m^2 every 3 weeks are seen in practice. Common adverse effects of dacarbazine therapy include myelosuppression, severe nausea and vomiting, and flu-like symptoms after high doses. Nausea and vomiting can be prevented and managed with available antiemetics and are not a major complication.

Temozolomide is an oral prodrug of the active metabolite of dacarbazine and is less emetogenic than dacarbazine. Temozolomide appears to cross into the CNS and was initially thought to have benefit for patients with CNS metastasis. In a phase III trial of chemotherapy-naïve individuals with metastatic melanoma, temozolomide showed efficacy at least equivalent to that of dacarbazine in terms of objective response rates, time-to-progression, and overall and disease-free survival but appeared to be associated with improvement in some aspects of quality of life.[40]

Other chemotherapeutic agents such as *platinum analogues*, *taxanes*, and *nitrosureas* have been evaluated as single agents in the treatment of metastatic melanoma and have been found to exhibit minimal benefit. Of note, a phase III trial comparing *albumin-bound paclitaxel* with dacarbazine in chemotherapy-naïve melanoma patients reported an increase in progression-free survival and a trend in overall survival in patients receiving albumin-bound paclitaxel. Neuropathy and neutropenia were more common in the albumin-bound paclitaxel arm.[41] At this time, these agents are not routinely used as single-agent therapy for melanoma, but are being incorporated into multidrug strategies against metastatic melanoma.

In an attempt to improve the limited responses seen with single-agent chemotherapy, a variety of combination chemotherapy regimens have been evaluated in both small and large clinical trials. The combination of dacarbazine with other chemotherapy, most commonly cisplatin, increased response rates with minimal survival benefit. The initial reports with the cisplatin, vinblastine, and dacarbazine (CVD) regimen were exciting, with reported response rates greater than 50%, a 4% complete response rate, a median response duration of 9 months, and acceptable toxicities.[42] Subsequent reports showed no difference in response rates or survival.

The Dartmouth regimen is a combination which includes carmustine, dacarbazine, cisplatin, and tamoxifen. Initial reports with this regimen demonstrated high response rates of 20% to 50%, but few patients achieve long-term survival. A controlled clinical trial from the National Cancer Institute of Canada demonstrated no benefit in response or survival from tamoxifen in this combination.[43] Further trials showed no benefit of the Dartmouth regimen compared with single-agent dacarbazine.[40] Of concern, toxicities were higher with the combination study and included bone marrow suppression, nausea, vomiting, and fatigue.

Low overall response rates and toxicity have limited the routine use of chemotherapy alone in the management of metastatic disease. The strategy of a combination of chemotherapy (dacarbazine, platinum agents, or vinca alkaloids) and cytokines (aldesleukin or IFN) often termed *biochemotherapy*, has been a focus of investigation in the management of metastatic melanoma. The primary rationale for this combination is to increase overall activity and perhaps response rates based on preclinical trials which suggest potential synergistic interactions between cytokines and some chemotherapy agents. As with other treatment strategies in melanoma, results from initial trials suggested higher response rate with biochemotherapy than with either chemotherapy or biotherapy alone. Despite encouraging results with combination chemotherapy and combination biotherapy, the results of clinical studies have not demonstrated a clear advantage with biochemotherapy compared with chemotherapy alone. A meta-analysis of 18 randomized trials of chemotherapy versus biochemotherapy showed that biochemotherapy was associated

with a significantly higher response rate in treatment of metastatic melanoma but the higher response rate did not translate into a significant difference in overall survival.[44] Toxicities can be severe and are consistent with the individual agents in the regimen.

Biochemotherapy has also been evaluated in the adjuvant setting. Early published data was encouraging. Recently, results from larger phase III studies comparing biochemotherapy with IFN, as adjuvant therapy in high-risk stage III disease, were published. This trial demonstrated that biochemotherapy significantly improved relapse-free survival, but no difference in overall survival was observed.[45]

The role of chemotherapy and biochemotherapy in metastatic melanoma is limited because of low response rates and a lack of survival benefit. NCCN currently recommends these treatment approaches as second-line or subsequent treatment options for patients with metastatic melanoma.[22]

Immunotherapy

Significant attention has been given to immunotherapy as a treatment modality in metastatic melanoma due to its general resistance to traditional treatment modalities. Although complete response rates seen with biotherapy are relatively low, the responses can be durable. Over the past few years, advances in immunotherapy for the treatment of melanoma have significantly impacted survival in patients with metastatic melanoma.

Interleukin-2 Interleukin-2 is a glycoprotein produced by activated lymphocytes. IL-2 was first identified as a T-cell growth factor, but IL-2 is also a growth factor for a variety of cells, including lymphocytes and natural killer (NK) cells. IL-2 also may be immunosuppressive.

The precise mechanism of cytotoxicity of IL-2 is unknown. In vitro and in vivo, IL-2 stimulates the production and release of many secondary monocyte-derived and T-cell–derived cytokines, including IL-4, IL-5, IL-6, IL-8, tumor necrosis factor (TNF)-α, granulocyte-macrophage colony-stimulating factor, and IFN-γ, which may have direct or indirect antitumor activity. In addition, IL-2 stimulates the cytotoxic activities of NK cells, monocytes, lymphokine-activated killer (LAK) cells, and cytotoxic T lymphocytes (CTLs). IL-2 also appears to activate endothelial cells, which results in increased expression of adhesion molecules.[46]

High-dose aldesleukin was evaluated is a series of trials with objective response rates around 16%. Of significance, 6% of those patients produced a complete response which were durable (median response, 70 months).[46] Responses were seen at a number of metastatic sites such as the lung, liver, bone, lymph nodes, and subcutaneous tissue. The FDA approved high-dose aldesleukin regimen used for treatment of metastatic melanoma is 600,000 IU/kg per dose every 8 hours for 14 doses maximum in a 5-day period given for two cycles, with a 10- to 14-day rest period between cycles. At these doses, cytokine-induced capillary leak syndrome is a common problem and often is accompanied by significant hypotension, visceral edema, dyspnea, tachycardia, and arrhythmias. Increased permeability of capillary walls allows for a fluid shift from the intravascular space into tissue. As the patient becomes intravascularly dehydrated, hypotension may occur, resulting in reflex tachycardia and arrhythmias. In addition, the decrease in blood volume may result in decreased renal blood flow and urine output, manifesting as increases in blood urea nitrogen, serum creatinine, edema, and weight gain and a decrease in urine output (input greater than output). Visceral edema may result in pulmonary congestion, pleural effusions, and edema. The management of patients receiving high-dose aldesleukin requires extensive supportive care medications, careful monitoring, and staff trained in aspects of critical care such as hypotension management. Constitutional symptoms are a frequent complication of aldesleukin therapy and become more intense as therapy progresses. Additional side effects seen with aldesleukin include pruritus, eosinophilia, bone marrow suppression, increased liver function tests, neurologic disturbances, diarrhea, and nausea

Careful patient selection for aldesleukin therapy is important. Pretreatment factors such as performance status, site of metastasis, and LDH may predict who will respond. Based on reports of long-term responses (greater than 10 years) experienced by some patients, the benefit certainly exceeds the risk for those individuals. Unfortunately, at this time, it is difficult to determine which individuals will respond to aldesleukin therapy because no biologic or immunologic biomarkers have been found to correlate with response. The decision to treat an individual with high-dose aldesleukin should be based on an analysis of an individual patient's risk versus potential benefit. With newer agents now available on the market, and complexity of administration, the role of aldesleukin has diminished.

5 CTLA-4 Checkpoint Inhibitors CTLA-4 was the first immune checkpoint inhibitor identified as a target for anticancer therapies and ipilimumab was the first drug in this class of drugs to demonstrate efficacy in metastatic melanoma. Results from phase I and II trials with ipilimumab demonstrate up to 20% response rates in advanced disease.[47] In a phase III trial of 676 HLA-A*0201-positive patients with refractory metastatic melanoma, ipilimumab (3 mg/kg) plus a glycoprotein 100(gp100) peptide vaccine was compared with ipilimumab (3 mg/kg) alone or gp100 alone.[48] The median overall survival time was significantly longer in patients treated with ipilimumab, alone or combined with gp100, as compared with patients treated with gp100 alone (10.0 or 10.1 vs 6.4 months, hazard ratio [HR] 0.66, $P = 0.003$). Another phase III trial compared a higher dose of ipilimumab (10 mg/kg) plus dacarbazine with dacarbazine alone in patients previously untreated for metastatic melanoma.[49] Ipilimumab plus dacarbazine demonstrated significantly longer overall survival (11.2 vs 9.1 months, HR 0.72, $P < 0.001$) and higher survival rates at 1 year (47.3% vs 36.3%), 2 years (28.5% vs 17.9%), and 3 years (20.8% vs 12.2%) than dacarbazine alone. In 2011, ipilimumab, dosed at 3 mg/kg IV every 3 weeks × 4 doses, became the first FDA approved drug for the treatment of unresectable or metastatic melanoma with a survival benefit. With longer follow-up data, the survival benefit is maintained for patients who had an initial response to ipilimumab. Five-year follow-up data from clinical trials demonstrates survival rates of 13% to 23% with survival durations of 13 to 16 months.[50] It is also important to note that the 3-year survival mark is noteworthy for patients treated with ipilimumab. Up to 85% of the patients who were alive at 3 years were alive at 4 years, suggesting that the 3-year survival mark may be a useful surrogate endpoint.[51] After a period of time, it is felt that the balance between immune response and tumor growth can shift leading to disease relapse after an extended duration of response. Re-treatment can be an option for patients who had an initial clinical benefit and has been shown to re-induce a response; no additional toxicities have been observed with re-induction.[52]

One of the greatest lessons learned from early clinical trials with ipilimumab was the differing kinetics of response and how to evaluate response to treatment. Patients appeared to have no regression of disease for many weeks after treatment initiation. Even more alarming was around 10% of patients initially experienced a significant increase in tumor burden which suggested disease progression. This was then followed by a delayed response to the drug after 12 weeks of therapy; some patients continued to have a steady reduction in tumor burden over time which eventually produced a durable clinical benefit.[53] It is hypothesized that the delayed response is related to the time needed to stimulate the immune system.[50] Due to this phenomenon, the Response Evaluation Criteria in Solid Tumors (RECIST) developed immune-related response criteria (irRC) to evaluate immunotherapies. The most significant additions were the allowance of up to 25% increase in tumor volume and deferral of assessing response until 12 weeks from the start of therapy.[50]

TABLE 139-7 Management of Immune-Related Adverse Effects

Organ Toxicity	Signs/Symptoms	Management	Comments
Skin and Mucosa	Pruritus, rash, desquamation, mucositis	Grade 1 or 2 Topical corticosteroids (betamethasone 0.1%) Urea based creams Oral antipruritic as needed (diphenhydramine or hydroxyzine) Grade 3 or 4 Prednisone 1-2 mg/kg/day or equivalent	Rare cases of toxic epidermal necrosis and Stevens-Johnson syndrome have been reported with ipilimumab
Gastrointestinal	Diarrhea, hematochezia, abdominal cramping, nausea and vomiting	Grade 1 Oral hydration Electrolyte repletion Loperamide Grade 2 Diphenoxylate hydrochloride and atropine Budesonide 9 mg daily Grade 3 or 4 Methylprednisolone 125 mg IV once followed by prednisone 1-2 mg/kg/day or equivalent	Infliximab 5mg/kg IV every 2 weeks may be given if symptoms do not improve with 48-72 hours of high dose steroids. Bowel perforation and obstruction may occur in cases of severe colitis
Hepatic	Transaminitis, jaundice, sclera icterus	Grade 1 or 2 Hold therapy Grade 3 or 4 Prednisone 1-2 mg/kg/day or equivalent	Mycophenylate mofetil 500 mg IV/PO Q12 hours can be used in patients who do not respond to steroids within 48 hours
Neurologic	Muscle weakness, motor neuropathies, sensory neuropathies	Grade 1 Monitor Grade 2 Consider holding therapy Grade 3 or 4 Prednisone 1-2 mg/kg/day or equivalent	Rare case reports of Guillian-Barre' syndrome and myasthenia gravis have been reported with ipilimumab
Endocrine	Headache, weakness, visual changes, behavioral changes, electrolyte imbalances	Grade 1 or 2 Appropriate hormone replacement therapy Grade 3 or 4 Methylprednisolone 1-2 mg/kg IV then 1-2 mg/kg/day of oral prednisone or equivalent	Potential endocrinopathies include Addison's disease, panhypopituitarism, adrenal crisis and hypophysitis. These effects may be permanent
Ocular	Photophobia, eye dryness, blurred vision	Grade 1 or 2 Prednisolone acetate 1% topical Grade 3 or 4 Prednisone 1-2 mg/kg/day or equivalent	Rare cases of episcleritis and uveitis have been reported
Pulmonary	Dyspnea, new or worsened cough, chest pain, hemoptysis	Grade 2 Prednisone 1-2 mg/kg/day or equivalent Grade 3 or 4 Methylprednisolone 1-2 mg/kg IV then 1-2 mg/kg/day of oral prednisone or equivalent	Pneumonitis is more common with pembrolizumab and nivolumab than ipilimumab

*Hold immunotherapy for grade 3 or 4 irAEs. Data from references 53 and 56.

6 The greatest challenge with the use of ipilimumab is management of irAEs. Patients must be thoroughly educated on signs and symptoms of irAEs and when to seek medical attention. Providers should be familiar with the differing type, timing and appropriate management of irAEs (Table 139-7). As previously discussed, management of irAEs should follow established treatment guidelines.[38]

5 **PD-1 and PD-L1 Checkpoint Inhibitors** PD1 protein is an immune checkpoint upregulated on activated T-cells in response to inflammation. Antibodies directed against PD-1 block the binding of program death-ligand 1 (PD-L1) and 2 (PD-L2) to the receptor on tumor cells, thus allowing Tcells to remain stimulated and the immune response to continue.[8] Pembrolizumab (formerly known as lambrolizumab) and nivolumab are two monoclonal antibodies directed against PD-1. These agents have demonstrated response rates of 30% with long term clinical benefit in early phase I trials.[54] Most notably from these trials, PD-1 inhibitors had a more favorable safety profile with significantly fewer irAEs compared to ipilimumab. Additionally, benefits were seen in patients who had been previously treated with ipilimumab with no difference in response rates. The KEYNOTE-001 trial evaluated the efficacy of pembrolizumab in patients who were previously treated with ipilimumab. The trial reported that overall response rate was 26%, progression-free survival at 24 weeks was 45%, and 1-year overall survival was 58%.[55] Treatment was well tolerated with grade 3 or 4 adverse effects only occurring in 12% of patients. In the randomized controlled trial of patients previously treated with ipilimumab, nivolumab produced higher response rates (32% vs 11%) with fewer irAEs when compared to chemotherapy.[56] An important observation from these studies is the lack of cross resistance between ipilimumab and PD-1 inhibitors. As with ipilimumab, if patients are able to achieve a response to these agents, that response can be maintained for an extended duration. In 2014, the FDA approved both pembrolizumab at 2 mg/kg IV every 3 weeks and nivolumab 3 mg/kg IV every 2 weeks for the treatment of patients with advanced or unresectable melanoma who progressed on previous ipilimumab therapy and, if applicable, a BRAF inhibitor.

6 Like ipilimumab, the response to PD-1 inhibitors is delayed. One notable difference is response to the PD-1 inhibitors may be slightly faster than with ipilimumab. The most common adverse effects of pembrolizumab and nivolumab are fatigue, cough, nausea, pruritis, rash, decreased appetite, constipation, arthralgias and diarrhea.[55,56] The risk of grade 3 or 4 irAEs is significantly lower compared to ipilimumab. The incidence of grade 3 or 4 diarrhea/colitis with PD-1 inhibitors is dramatically lower and occurs in only1% to 2% of patients. A higher incidence of autoimmune pneumonitis (1%-2%) is seen with nivolumab and pembrolizumab compared to ipilimumab.[38] Patients should be counseled to notify a provider if they notice new or worsening cough,

chest pain or shortness of breath. Treatment of irAEs follows the same established treatment algorithms as ipilimumab (Table 139-7).

First line therapy with PD-1 inhibitors has been evaluated for the treatment of unresectable or metastatic melanoma. In the KEYNOTE-006 trial, pembrolizumab was compared directly to ipilimumab for first line treatment. In this trial, 834 patients with unresectable or metastatic melanoma were randomized to receive 10 mg/kg every 2 weeks or every 3 weeks or ipilimumab 3 mg/kg every 3 weeks for 4 doses. One-year overall survival rates were 75% for the pembrolizumab every 2 weeks (HR 0.63, $P=0.005$), 68.4% for the pembrolizumab every 3 weeks (HR 0.69, $P=0.0036$) and 58.2% for ipilimumab.[57] Treatment-related grade 3 or 4 adverse effects were lower in both the pembrolizumab arms. With better efficacy and less toxicity compared to ipilimumab, the FDA has approved pembrolizumab 2 mg/kg IV every 3 weeks as a first line treatment option for metastatic melanoma. Similarly, in a randomized controlled trial, nivolumab produced significantly better 1-year overall survival rates (73% vs 42%, HR 0.42, $P<0.001$), median progression-free survival (5.1 vs 2.2 months, HR 0.43, $P<0.001$), and overall response rates (40% vs 14%) when compared to dacarbazine in the first line treatment of *BRAF* wild-type metastatic melanoma.[58] The NCCN Guidelines recommend both pembrolizumab and nivolumab as first-line treatment options for patients with unresectable or metastatic disease.

5 Combination CTLA-4 and PD-1 Checkpoint Inhibitors The mechanism of inhibition of CTLA-4 and PD-1 is complementary. A combination of a CTLA-4 inhibitor, which exerts its immune inhibition at the central level in the priming phase of activated T cells, and a PD-1 inhibitor, which acts in the peripheral phase within the tumor microenvironment, can result in synergistic activity. Impressive survival rates of 90% at 1-year and greater than 80% at 2-years are unprecedented in the treatment of metastatic melanoma in early trials.[37] This combination was studied in 945 previously untreated patients with unresectable stage III or IV melanoma. Patients were randomized to nivolumab alone, nivolumab plus ipilimumab, or ipilimumab alone. The median progression-free survival was 11.5 months with nivolumab plus ipilimumab, compared with 2.9 months with ipilimumab (HR 0.42, $P<0.001$).[59] **6** One of the most significant concerns of combining two immune checkpoint inhibitors is the safety profile. Grade 3 and 4 treatment-related adverse effects are significantly higher with the combination arm-compared to the ipilimumab arm (55% vs 27.3%). The risk of hepatotoxicity was higher in the combination arm. A second trial, CheckMate-069 trial confirmed the benefits of this combination. In this double-blind trial, 142 untreated melanoma patients were randomized to receive ipilimumab 3 mg/kg and nivolumab 1 mg/kg or the same dose of ipilimumab with placebo once every 3 weeks for 4 doses. Ipilimumab was then discontinued and patients received nivolumab or placebo at the same dose every 2 weeks until disease progression or unacceptable toxicity.[60] Objective response rate was 61% for patients receiving the combination versus 11% for patients receiving ipilimumab alone ($P<0.001$). Complete responses were seen in 22% of the combination arm and none in the ipilimumab arm. Responses were seen regardless of BRAF mutational status. Median progression-free survival was significantly longer in the combination arm (HR 0.40, $P<0.001$). As with previous studies, the responses appeared to be durable, with 82% of responding patients in the combination arm maintaining their response. The higher response rate with combinations of immune checkpoint inhibitors comes at the cost of greater toxicity. The risk of grade 3 or 4 drug-related adverse reactions was higher in the combination arm (54% vs 24%). As a result of data from these two trials, the FDA granted approval of combination therapy with nivolumab and ipilimumab inpatients with *BRAF* V600 wild-type unresectable or metastatic melanoma. While this combination offers higher response rates, some of which can be durable, judicious monitoring and aggressive management of toxicities are important.

Clinical **Controversy...**

The combination of ipilimumab and nivolumab leads to higher response rates compared to ipilimumab alone. Autoimmune toxicities with the combination are significantly higher and must be aggressively managed. Future trials are needed to evaluate if ipilimumab and nivolumab produce higher responses compared to nivolumab alone.

With the rapid advances in immunotherapy, the treatment of melanoma with these new therapies offers new hope to patients. Improved survival has been seen with both CTLA-4 and PD-1 inhibition. While pembrolizumab and nivolumab have better efficacy with less toxicity, ipilimumab is still effective and irAEs can be managed. The combination of ipilimumab and nivolumab has significantly higher responses compared to ipilimumab alone, but the risk of irAEs is also significantly higher. The NCCN guidelines list all of these regimens as potential treatment options for metastatic melanoma.

Despite advances in the treatment of melanoma, several questions still surround the use of immunotherapy. First, who is the best treatment candidate for immunotherapy? Some clinicians are hesitant to treat elderly patients with ipilimumab because of concern for toxicity. Similarly, patients with existing autoimmune conditions have been excluded from treatment with ipilimumab. These unique patient populations require further investigation. Second, what are the biomarkers of response to immunotherapy? Immunologic markers as well as biomarkers have been investigated without success to help identify patients who respond to ipilimumab.[37] Tumors that express PD-L1, regardless of the cancer, have demonstrated higher responses to PD-1/PD-L1 blockade. However, patients with tumors that do not express PD-1/PD-L1 do benefit and should not be excluded from this treatment option. Additionally, it remains unclear as to the best approach for assessing PD-L1 expression, definition of positivity in the assay, and clinical application.[54] Lastly, what is the optimal sequencing of immunotherapeutic agents and with immunotherapy and other therapeutic options? Studies are ongoing looking at sequencing of CTLA-4 inhibitors, PD-L/PD-L1 inhibitors, BRAF/MEK inhibitors, chemotherapy and other investigational agents.

Clinical **Controversy...**

Treatment with immunotherapy is expensive. The projected cost of combination therapy with ipilimumab and nivolumab is $250,000 the first year of therapy and $150,000 per year thereafter. Further analysis is needed to assess the cost-effectiveness of these therapies and the economic burden on patients and society.

Other Immunotherapy Approaches *Vaccine therapy* has been investigated for over a decade in metastatic melanoma. The rationale for vaccination is that antigens expressed on the surface of tumor cells differ from normal cells and vaccines have the ability to induce effective tumor-specific immune responses with less toxicity than conventional chemotherapy or other immunotherapies.

A variety of melanoma vaccines, based on whole tumor cells, peptides, and proteins have been evaluated for treatment of patients with metastatic disease and for intermediate- and high-risk patients after surgical resection of disease and to date none have shown a survival advantage.[17] Occasional clinical responses have been observed in clinical trials of melanoma vaccines, which demonstrate their potential. Vaccines in combination with other biologic therapies have

TABLE 139-8 Dosing of Oral Targeted Therapies

Drug	Brand Name	Dose	Food–Drug Interactions	Drug–Drug Interactions
Trametinib	Mekinist	2 mg Daily Store in the refrigerator (36-46°F)	Administration with a high-fat, high-calorie meal may decrease AUC Take 1 hour before or 2 hours after a meal	Trametinib may enhance the adverse effect of dabrafenib
Cobimetinib	Cotellic	60 mg daily on days 1-21 of 28	Take with or without meal Avoid grapefruit and grapefruit juice	CYP3A4 inducers may decrease cobimetinib drug levels CPY3A4 inhibitors may increase cobimetinib drug levels
Vemurafenib	Zelboraf	960 mg twice daily A missed dose may be take up to 4 hours prior to the next dose	Take with or without meal Avoid grapefruit and grapefruit juice	Vemurafenib may increased drug levels of CYP1A2 and Pg-P substrates CYP3A4 inhibitors may increase vemurafenib drug levels CYP3A4 inducers may decrease vemurafenib drug levels Monitor closely if vemurafenib is use concurrently with other drugs known the prolong QT interval
Dabrafenib	Tafinlar	150 mg twice daily A missed dose may be take up to 6 hours prior to the next dose	Take 1 hour before or 2 hours after a meal High-fat meals decrease Cmax and AUC Avoid grapefruit and grapefruit juice	Dabrafenib may decrease drug levels of CYP2B6, CYP2C19, CYP2C8, CYP2C9, and CYP3A4 substrates CYP2C8 and CYP3A4 inhibitors may increase dabrafenib drug levels CYP2C8 and CYP3A4 inducers may decrease dabrafenib drug levels Concurrent use with antacids, H2-Antagonists and proton pump inhibitors may decrease dabrafenib concentrations

AUC, area-under-the-curve; CYP, cytochrome P450.

been evaluated. Although tumor responses with some of these combination approaches have been observed in phase I and II trials, none of the vaccine responses or improvement in survival have been confirmed in phase III trials.[17] Clinical trials looking at way to incorporate vaccines into currently approved immunotherapeutic treatments are ongoing.

Oncolytic immunotherapy is currently being investigated for the treatment of metastatic melanoma. Talimogene laherparepvec (T-VEC) is a genetically modified oncolytic immunotherapy derived from herpes simplex-1. T-VEC works by two distinct mechanisms: 1) modification of attenuated HSV-1 to selectively replicate within the tumor environment causing death while sparing other cells and 2) secretion of GM-CSF to attract dendritic cells to the site to start the process of antigen presentation and T cells activation. Activated T cells can then target the cancer cells systemically. In a phase III study, T-VEC demonstrated better response rates (including complete responses) and a trend toward improved survival compared to GM-CSF alone.[61] It was well tolerated with fatigue, chills, and fever being the most common adverse effect with few severe adverse effects reported. T-VEC was recently FDA approved for the local treatment of unresectable cutaneous, subcutaneous, and nodal lesions in patients with recurrent melanoma after initial surgery. T-VEC is administered intratumorally (injected directly into the tumor) and as such patients with internal visceral disease are not appropriate candidates for treatment. With its favorable toxicity profile, ongoing studies are evaluating T-VEC in combination with other immune-directed treatments.

Targeted Therapy

7 Protein kinase inhibitors have emerged as standard therapy for malignancies such as renal cell carcinoma, chronic myelogenous leukemia, subsets of lung cancer and gastrointestinal stromal tumors. As our understanding of the biology of melanoma grows, there is increasing interest in targeted therapies against molecular targets involved in the development and progression of melanoma. Several orally administered targeted therapies are FDA approved for treatment of melanoma (Tables 139-8 and 139-9).

The MAPK and PI3K/AKT pathways are involved in tumor cell growth and differentiation and are activated in melanoma. BRAF is downstream in the MAPK pathway. *BRAF* mutations have been described in melanoma cell lines, and it appears that up to 70% of melanomas exhibit BRAF alteration.[8] In a phase I/II trial, vemurafenib, an orally available inhibitor of mutated BRAF, showed activity in patients with melanoma that had *BRAF* with the V600E mutation. In a phase III trial comparing vemurafenib with dacarbazine in patients with unresectable, previously untreated stage IIIC or IV melanoma with a *BRAF* V600E mutation, vemurafenib significantly improved response rate (48% vs 5%) and overall survival.[62] Patients treated with vemurafenib had longer median progression-free survival (5.3 vs 1.6 months) and a higher overall survival rate at 6 months (84% vs 64%). The median time-to-response was also shorter with vemurafenib than dacarbazine (1.45 vs 2.7 months). Dabrafenib, another oral selective BRAF inhibitor, demonstrated similar activity to vemurafenib in early stage clinical trials in patients with previously untreated *BRAF* V600E mutated melanoma. In a phase III study, dabrafenib 150 mg orally twice daily was compared to dacarbazine in patients with untreated stage IV or unresectable stage III melanoma. Patients in the dabrafenib arm had longer median progression-free survival (5.1 vs 2.7 months, HR 0.30, $P < 0.0001$).[63] A follow-up analysis showed that overall survival at 12 months was 70% with dabrafenib as compared to 63% with dacarbazine.[63] Both vemurafenib and dabrafenib have been studied in melanoma patients with CNS metastasis with some activity. Other drugs targeted toward mutated *BRAF*, such as sorafenib, have not reported encouraging results.

BRAF inhibitors are generally well tolerated (Table 139-9). Skin complications comprising of cutaneous squamous cell carcinoma or keratoacanthoma and photosensitivity reactions, are a major

TABLE 139-9 Monitoring of Oral Targeted Therapies

Drug	Adverse Reaction	Monitoring Parameters	Comments
Trametinib	Common: • Hypertension • Skin toxicity (most commonly puritis, acneiform rash, erythema, skin rash) • Hypoalbuminermia • Diarrhea • Stomatitis • Anemia • Lymphedema • Hyperglycemia • Increased liver function tests • Fever Rare but serious: • Cardiomyopathy • Hemorrhage • Rhabdomyolysis • Interstitial lung disease • Serious febrile events • Retinal detachment • Retinal vein occlusion • Basal cell carcinoma, squamous cell carcinoma or primary melanoma	• CBC at baseline and periodically for myelosuppression • CMP at baseline and periodically for hepatotoxicity and hyperglycemia • LVEF at baseline, 1 month after therapy initiation, then at 2- to 3-month intervals for cardiomyopathy • Ophthalmological evaluation periodically especially if patients report visual disturbances • Evaluate for signs/symptoms of pulmonary toxicity (eg, cough, dyspnea, hypoxia, pleural effusions, infiltrates) • Blood pressure • Signs and symptoms of bleeding concerning for hemorrhage • Dermatologic exams when used with dabrafenib at baseline, every 2 months during treatment, then 6 months after discontinuation for secondary skin malignancies	• Hospitalization may be required for severe skin toxicities • Intracranial hemorrhage reported to be fatal • The risk of adverse effects increases when trametinib is used in combination with dabrafenib
Cobimetinib	Common: • Nausea/vomiting/diarrhea • Hypertension • Photosensitivity • Electrolyte disturbances • Hypoalbuminemia • Lymphocytopenia • Anemia • Increased liver function tests • Increased CPK • Increase in serum creatinine • Fever Rare but serious: • Cardiomyopathy • Hemorrhage (GI and cerebral) • Secondary skin malignancies (cutaneous squamous cell carcinoma or keratoacathoma, basal cell carcinoma or secondary primary melanoma) • Retinal vein occlusion/Retinopathy • Hepatotoxicity • Rhabdomyolysis	• CMP at baseline and monthly during treatment for hepatotoxicity, renal dysfunction and electrolyte replacement • CPK at baseline and periodically during treatment for rhabdomyolysis • LVEF at baseline, 1 month after initiation of therapy, and every 3 months for cardiomyopathy • Dermatologic exams at baseline, every 2 months during treatment, then 6 months after discontinuationfor secondary skin malignancies • Ophthalmological evaluation periodically especially if patients reports visual disturbances • Signs and symptoms of hemorrhage and rhabdomyolysis	
Vemurafenib	Common • Nausea/vomiting/diarrhea • Skin toxicity (most commonly rash, photosensitivity, pruritus) • Headache • Alopecia • Peripheral edema • Arthralgias/myalgias • Hyperkeratosis • Fever • Decreased appetite Rare but serious: • Renal failure • Prolonged QT interval • SJS/TEN • Hepatotoxicity • Secondary skin malignancies (squamous cell carcinoma, basal cell carcinoma or keratocanthoma) • Hypersensitivity • Uveitis	• CMP at baseline and monthly or as clinically indicated for hepatotoxicity and renal failure • LVEF at baseline, 1 month after initiation of therapy, and every 3months for cardiomyopathy • Dermatologic exams at baseline, every 2 months during treatment, then 6 months after discontinuation for secondary skin malignancies • Eye pain, photophobia or vision changes	• Off label indication for *BRAF* V600K mutation

(*continued*)

TABLE 139-9 Monitoring of Oral Targeted Therapies (*Continued*)

Drug	Adverse Reaction	Monitoring Parameters	Comments
Dabrafenib	Common • Nausea/vomiting/diarrhea • Skin rash pruritus • Hyperkeratosis • Fever • Hypophosphatemia • Peripheral edema • Headache • Alopecia • Palmar-plantar erythrodysesthesia • Increased liver function tests • Hyperglycemia • Hemolytic anemia • Arthralgias Rare but serious: • Interstitial nephritis • Pancreatitis • Secondary skin malignancies (squamous cell carcinoma, basal cell carcinoma or keratocanthoma) • Uveitis • Hypersensitivity • Hemorrhage • Serious febrile event	• CMP with electrolytes for hypophosphatemia, hyperglycemia, and hepatotoxicity • CBC for myelosuppression • Dermatologic exams at baseline, every 2 months during treatment, then 6 months after discontinuation for secondary skin malignancies • Eye pain, photophobia or vision changes for uvetitis	• The risk of secondary skin malignancies decreases when used in combination with a MEK inhibitor • Assess LEVF when used in combination with a MEK inhibitor • Patients with G6PD deficiency are at risk for hemolytic anemia

concern with the use of these agents. In clinical trials, the incidence of cutaneous squamous cell carcinoma or keratoacanthoma with vemurafenib is 18% and 6% with dabrafenib.[22] The development of these lesions is thought to result from activation of the MAPK pathway in healthy skin cells lacking *BRAF* alterations. As a result, patients receiving a BRAF inhibitor should have dermatologic evaluations prior to starting therapy, every 2 months while on therapy and for up to 6 months following discontinuation of therapy. Cutaneous complications can be effectively managed by surgical resection, and treatment with the BRAF inhibitor can continue without dose adjustment.[64]

Unfortunately, patients develop resistance to BRAF inhibitors, typically after 5 to 6 months of therapy. Resistance is potentially caused by mutations in *MEK,* dependency on MEK/ERK antiapoptotic signaling, PI3K/AKT pathway involvement, *NRAS* mutation, or MAPK pathway reactivation. The use of MEK inhibitors in combination BRAF inhibitors has been found to delay the development of acquired resistance.[62,64]

7 MEK inhibitors have been studied in the treatment of metastatic melanoma and have shown modest activity as monotherapy. Trametinib is an inhibitor of MEK1/2. Compared with chemotherapy (dacarbazine or paclitaxel) in *BRAF*-mutated patients in a phase II trial, patients treated with trametinib had improved progression-free survival, overall survival, and response rates. These results were confirmed in a phase III trial that compared trametinib to chemotherapy (dacarbazine or paclitaxel). In this trial, median progression-free survival was 4.8 months versus 1.5 months in the trametinib and chemotherapy arms respectively (HR 0.45, $P<0.001$). Overall survival at 6 months was 81% for trametinib and 67% for chemotherapy (HR 0.54, $P=0.01$), even with crossover at progression. Common adverse events seen with trametinib were rash, diarrhea, and peripheral edema. Interestingly, secondary skin neoplasms were not observed in this trial.[65]

In addition to delaying drug resistance, the combination of a MEK inhibitor and a BRAF inhibitor has shown efficacy in the treatment of melanoma. The combination of trametinib 2 mg orally once daily and dabrafenib 150 mg orally twice daily received accelerated approval for the treatment in patients with unresectable or metastatic melanoma with *BRAF* mutations based on higher objective response rates compared to either agent alone. Additional trials with this combination compared to a BRAF inhibitors in the same patient population confirmed early findings and led to a full FDA approval. In a clinical trial that compared the combination to dabrafenib alone, patients randomized to the combination had longer median progression-free survival (9.3 vs 8.8 months, HR 0.75, $P=0.03$), overall survival at 6 months (93% vs 85%, HR 0.63, $P=0.02$) and higher overall response rates (66% vs 51%) as compared with dabrafenib alone.[66] In another phase III trial, the combination of dabrafenib and trametinib showed significantly longer median overall survival (not reached vs 17.2 months, HR 0.69, $P=0.005$) and higher overall survival at 12 months (72% vs 65%). Median progression-free survival was also significantly longer (11.4 vs 7.3 months, HR 0.56, $P<0.001$) and overall response rate was higher (64% vs 51%, $P<0.001$) in patients treated with the combination.[67] The safety profile with the combination was similar to that observed with either drug given alone, with the notable exception of deceased incidence of skin complications in the combination arms.

Cobimetinib is another inhibitor of MEK1/2 which was recently FDA approved for the treatment of patients with unresectable or metastatic melanoma with a *BRAF* mutation in combination with vemurafenib. The recommended dosing with this regimen is vemurafenib 960 mg orally twice daily on days 1 to 28 and cobimetinib 60 mg orally once daily on days 1 to 21 of a 28 day cycle. In a phase III trial, median progression-free survival was significantly improved with the combined regimen of cobimetinib and vemurafenib versus vemurafenib alone (9.9 vs 6.2 months, HR 0.51, $P<0.001$). Longer follow-up is needed to evaluate overall survival. Overall response rates were 68% and 45% for the combination and single agent arms, respectively. Adverse events were similar across the two groups and similar to the other MEK and BRAF combination, the number of secondary cutaneous cancer was decreased.[68]

Another agent of interest is imatinib mesylate, an oral agent that inhibits *c-KIT* and platelet-derived growth factor receptor. *c-KIT* is expressed primarily on acral and mucosal melanomas. Imatinib suppressed melanoma cell growth in preclinical studies. In clinical trials with unselected patients, imatinib is not active in metastatic melanoma despite downregulation of phosphorylated *c-KIT*.[22] However, a phase II trial of imatinib in patients with *c-KIT* mutations reported

that 23% had a partial response, 30% had stable disease, and progression-free survival was 3.5 months.[8] Reponses in these patients were short similar to what is seen with BRAF inhibitors.

Other important potential molecular targets in the treatment of melanoma include vascular endothelial growth factor (VEGF) and cyclin-dependent kinases. Studies with drugs that inhibit these pathways are currently ongoing. With the success of immunotherapy, combining targeted agents with immunotherapeutic agents is another area of research interest. Reports from a phase I trial combining vemurafenib and ipilimumab showed significant hepatotoxicity, which shows the importance of patient selection to identify the best candidates for combined modality therapy.[69]

Other Approaches

Radiation The role of radiation in the adjuvant treatment of melanoma is being investigated based on retrospective data that suggests patients treated with therapeutic lymphadenectomy for lymph node field relapse benefit from postoperative radiation to the nodal basins. Overall, these data demonstrate improvement in locoregional control with reasonable toxicity, but with no impact on overall survival. Results of a phase III trial indicated adjuvant radiotherapy reduced the risk of lymph node field relapse in patients who had undergone therapeutic lymphadenectomy for metastatic melanoma in regional lymph nodes.[70] No difference in relapse-free survival was observed. Radiation can be used patients with in-transit metastasis or for extranodal tumor extension. For patients with metastatic melanoma, radiation is palliative to symptomatic areas of disease progression. Adjuvant whole brain radiation after resection of brain lesions is controversial and is currently being investigated.[71]

Limb Perfusion and Limb Infusion Isolated limb perfusion is a surgical procedure involving regional intravascular delivery of chemotherapy or biotherapy (or both) into an extremity with cutaneous melanoma.[72] When in-transit metastasis occur in extremities, local therapy with isolated limb perfusion or isolated limb infusion has been used. Isolated limb perfusion is a method for escalating the dose of chemotherapeutic drugs to a specific region of the body while limiting the systemic toxicities of the agent. Most perfusions can be performed with drug exposures of less than 2%. The most significant side effect of isolated limb perfusion are regional toxicity because the skin, subcutaneous tissue, and tissue of the extremity receives the same dose and is subjected to the same perfusion conditions as the tumor located within the extremity. After regional perfusions, objective response rates greater than 50% in treated limbs have been reported, with overall response rates possibly as high as 80%. The role of hyperthermia (38.9°C-40°C [102°F-104°F]) with regional isolated perfusion is not clearly defined. Although most clinical trials have used melphalan, it is not known whether the combination of melphalan with other agents may improve results.[73] Agents that have been combined with melphalan include actinomycin D, nitrogen mustard, thiotepa, and cisplatin. Work with biologic response modifiers, such as TNF-α, has been encouraging.[74] A simplified form of isolated limb perfusion, called isolated limb infusion, is a low-flow isolated limb perfusion performed under hypoxic conditions via small-caliber arterial and venous catheters. It has been proposed that the hypoxia that develops during isolated limb infusion may be beneficial with certain cytotoxic agents such as melphalan.

PERSONALIZED PHARMACOTHERAPY

Treatment of cutaneous melanoma is determined by both disease-related and patient-related issues. Treatment recommendations are based on stage of disease. Treatment of localized disease is surgical excision, with the extent of excision based on the tumor size. Wide excision is recommended for in situ melanoma and wide excision with SLNB for stage IA, IB, and II disease.

The role of adjuvant therapy in the management of individuals at high risk for recurrence remains controversial. One controversy is to identify which patients are appropriate candidates for treatment after resection of the primary tumor. Another controversy with adjuvant therapy is the choice of therapy. HDI has the most evidence supporting its use and is FDA approved for this indication. The challenges with this therapy have been discussed and its use has limited worldwide acceptance. Based on positive clinical trial results, ipilimumab is now an acceptable option in the adjuvant setting. Patient selection must be carefully considered given the irAEs. New therapies and combinations must be evaluated to answer the remaining questions about adjuvant therapy in melanoma. The most appropriate option at this time is a clinical trial, if available.

8 Due to the rapid influx of effective therapies, the management of metastatic melanoma has become complex. The NCCN guidelines list a variety of preferred systemic therapies for advanced or metastatic melanoma, including ipilimumab, pembrolizumab, nivolumab, dabrafenib with or without trametinib, vemurafenib with or without cobimetinib, high-dose aldesleukin, and clinical trial. Dacarbazine, temozolomide, combination chemotherapy, or biochemotherapy are also included as treatment options.[22] The choice of drug therapy should be based on *BRAF* mutational status, the aggressiveness of the disease, and disease-related symptoms. Patients with a more indolent clinical picture may respond better to immunotherapy. Pembrolizumab or nivolumab are now recommended as first line treatment in *BRAF* wild-type melanoma over ipilimumab. Patients with a documented *BRAF* mutation are candidates for treatment with a BRAF inhibitor with or without a MEK inhibitor. These agents may be particularly beneficial in patients with *BRAF* mutations who are symptomatic from their disease because of the rapid response rates that are seen with their use. In patients who harbor the *c-KIT* mutation, imatinib can be offered as first-line therapy.[22] Combination chemotherapy or biochemotherapy should be reserved for patients who do not respond to immunotherapy or targeted therapy upfront. These modalities may be beneficial in stabilizing disease in patients who are *BRAF* wild-type with rapid disease progression. Best supportive care is also an option in some individuals. Data suggest that surgical treatment of metastatic melanoma should be considered in select individuals based on the extent and location of disease and performance status.

In patients who develop brain metastasis, treatment of CNS disease is independent of systemic therapy. Depending on the size and location of metastasis, surgical resection can be offered as the first-line treatment modality in patients with a favorable prognosis. Stereotactic radiosurgery is an acceptable alternative for patients who are unable to undergo resection. Whole-brain radiotherapy is generally reserved for patients with a large volume of metastasis because of the concern of cognitive decline.[75] In many cases, after brain metastasis have been treated, patients can continue with their systemic treatment. The role of targeted treatments and immunotherapy in patients with brain metastasis is ongoing. Early trials with ipilimumab excluded patients with active brain metastasis. Recently, several case reports have described activity in this patient population.[76] An important consideration for treatment of melanoma is the clinical presentation of the disease. As discussed, treatment of melanoma isolated to the limb may be most appropriately treated with regional therapy. Treatment options for metastatic uveal melanoma include strategies for managing hepatic metastasis.

EVALUATION OF THERAPEUTIC OUTCOMES

The outcome of patients treated with melanoma depends on the stage of disease at presentation. The prognosis of patients with thin tumors (less than 1 mm in thickness) and localized disease is good

with long-term survival in more than 90% of patients. The risk of regional nodal involvement rises with increasing tumor thickness and survival rates decrease in patients with nodal involvement. Long-term survival in patients with distant metastasis is even lower. Therefore, early diagnosis and appropriate treatment of early disease are essential. Patients with suspicious pigmented lesions should be evaluated and the lesion excised whenever possible. Treatment is determined by patient factors and stage of disease.

Clinical practice guidelines published by the NCCN and European Society of Clinical Oncology (ESMO) provide guidance for treatment and follow-up of patients with melanoma.[22,77] Intensive surveillance has the benefit of early detection of recurrent disease, which may lead to better options of surgical resection. Emphasis on evaluation of locoregional areas is important. For patients with in situ melanoma, periodic skin examinations for life are recommended, with frequency determined based on patient risk factors. Local recurrence is associated with aggressive tumor biology and frequently is a manifestation of an aggressive primary tumor. If a local recurrence occurs after inadequate primary disease management, the patient should undergo a workup based on the lesion thickness of the original melanoma. Patients with nodal recurrence should be evaluated for lymph node metastasis. Patients with systemic recurrence should be evaluated and treated in a fashion similar to patients presenting with systemic disease.

ABBREVIATIONS

Hematopoietic Stem Cell Transplantation

140

Susanne Liewer and Janelle Perkins

KEY CONCEPTS

1. Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a donor into a recipient, after the administration of chemotherapy with or without radiation. The rationale is to increase tumor cell kill by increasing the dose of chemotherapy. Immune-mediated effects also contribute to the tumor cell kill observed after allogeneic HSCT.
2. Hematopoietic stem cells used for transplantation can come from the recipient (autologous) or from a related or unrelated donor (allogeneic). If the related donor is a twin, the transplant is referred to as a syngeneic transplant.
3. Human leukocyte antigen (HLA) mismatching of allogeneic donor–recipient pairs at either class I or class II loci increases the risk of graft failure, graft-versus-host disease (GVHD), and worsens survival. The ideal donor is one that is matched at HLA-A,B,C, DRB1, and DQ.
4. Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood. Because of the rarity and similarity to other cells, hematopoietic stem cells are difficult to isolate and measure. These stem cells express the CD34 antigen, and measurement of the number of $CD34^+$ cells is a clinically useful measure of the number of hematopoietic stem cells.
5. Because of clinical and economic advantages, peripheral blood has replaced bone marrow as the source of hematopoietic stem cells in the autologous and adult allogeneic HSCT setting.
6. The purpose of the preparative (or conditioning) regimen in traditional myeloablative transplants is twofold: (a) maximal tumor cell kill and (b) immunosuppression of the recipient to reduce the risk of graft rejection (allogeneic HSCT only).
7. Reduced-intensity conditioning regimens (including those that are nonmyeloablative) have been developed in order to reduce early posttransplant morbidity and mortality while maximizing the graft-versus-malignancy (GVM) effect. The advantage to this approach is that patients who would otherwise not be eligible for allogeneic HSCT can now be offered a potentially curative therapy.
8. Transplant-related mortality associated with allogeneic HSCT ranges from 10% to 80% depending mostly on age, donor, and disease status. Major causes of death include infection, organ toxicity, and GVHD. The most common cause of death after autologous HSCT is disease relapse; transplant-related mortality is usually less than 5%, depending on the conditioning regimen, age, and disease status.
9. Patients undergoing allogeneic HSCT are given prophylactic immunosuppressive therapy, which inhibits T-cell activation, proliferation, or both. The most commonly used GVHD prophylaxis regimens are cyclosporine or tacrolimus and methotrexate. Sirolimus or mycophenolate mofetil are often substituted for methotrexate.
10. Initial treatment of both acute and chronic GVHD consists of prednisone, either alone or combined with cyclosporine or tacrolimus. Treatment of patients with steroid-refractory GVHD is unsatisfactory.

INTRODUCTION

1 Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a compatible donor into a recipient, usually after administration of high-dose chemotherapy with or without radiation (called conditioning or preparative regimens). The original rationale for HSCT for treatment of malignant disease is based on studies showing that most anticancer drugs have a steep dose–response relationship and that myelosuppression limits the chemotherapy dosage that can be safely administered. Although standard-dose chemotherapy can prolong survival in many cancer patients, most patients are not cured of their disease with this strategy alone. Infusion of hematopoietic stem cells allows administration of very high doses of chemotherapy (as much as 10-fold higher) by reestablishing hematopoiesis. If tumor cells that are resistant to standard doses are sensitive to higher doses of chemotherapy, then tumor cell kill will be greatly increased, and the likelihood of cure would be higher with HSCT compared with standard dose chemotherapy. However, the chemotherapy dose cannot be escalated indefinitely because of the risk for death caused by nonhematologic toxicity (Fig. 140-1).

HSCT is an important modality for treatment of a variety of malignant and nonmalignant diseases. More than 18,000 transplants were performed in the United States in 2012, primarily for malignant diseases.[1] The most common malignancies treated with HSCT are multiple myeloma, lymphomas, and leukemias. The number of transplants has grown steadily over the past decade because of an increase in the number of patients receiving alternative donor transplants and an increase in the number of patients older than 60 years undergoing transplantation.

Although HSCT is most commonly used for treatment of malignant diseases, many nonmalignant hematologic disorders, including aplastic anemia, thalassemia, and sickle cell anemia; immunodeficiency disorders; and other genetic disorders are also potentially curable with allogeneic HSCT. Transplantation is also being investigated as a treatment modality for patients with life-threatening autoimmune diseases, such as rheumatoid arthritis, systemic and multiple sclerosis, and systemic lupus erythematosus.

This chapter summarizes the procedures involved in HSCT and the common complications associated with HSCT. More detailed information on HSCT can be found in published reviews and books.[2-5] Information on HSCT also can be found on several

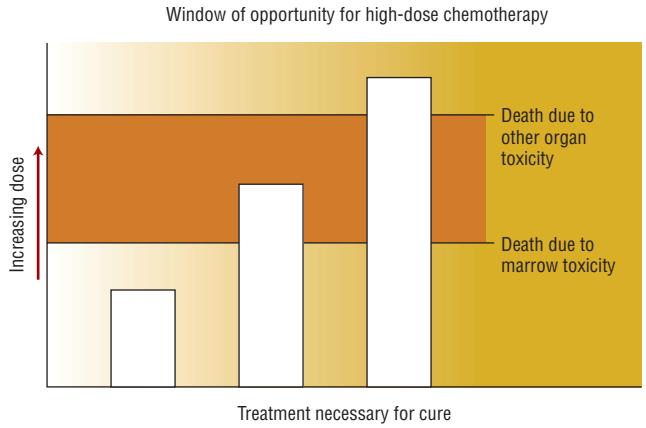

FIGURE 140-1 Patients represented by the middle column are the best candidates for hematopoietic stem cell transplantation because the technique allows for administration of chemotherapy or radiation in doses that otherwise would be intolerable because of severe myelosuppression.

websites, including *http://www.cibmtr.org* (Center for International Blood and Marrow Transplant Research [CIBMTR]) and *https://bethematch.org/* (National Marrow Donor Program [NMDP]).

HISTOCOMPATIBILITY TESTING AND DONOR SELECTION

2 Different types of donors are used in HSCT. The choice of donor depends on the diagnosis and disease status of the recipient as well as his or her age and comorbidities. The role and indications for HSCT are discussed in detail within individual disease chapters of this text. In *autologous* transplants, patients receive their own hematopoietic stem cells, which were collected and stored before administration of the transplant conditioning regimen. In *syngeneic* transplants, an identical twin serves as the donor. In *allogeneic* transplants, the donor is genetically not identical to the recipient but shares some common cell surface antigens called human leukocyte antigens (HLAs). These antigens are encoded by the major histocompatibility complex (MHC), a cluster of genes located on the sixth chromosome.[6] The MHC contains three distinct regions designated as class I, class II, and class III. Class I and class II genes encode for HLA; products of class III genes have other important roles in the immune system. Class I and class II HLA antigens differ in their tissue distribution, structure, and function. Their primary function is to aid the immune system in recognizing cells or tissues as "self" or "nonself." The genes (and the corresponding antigens they encode for) important in HSCT are the class I antigens, HLA-A, HLA-B, and HLA-C and the class II antigen, HLA-DRB1. Because of the polymorphism of the HLA system, there are many different HLA antigens within each different class of HLA. To reduce the chance of graft rejection and graft-versus-host disease (GVHD), a donor is chosen based on how many of these HLA antigens are the same as those of the recipient. Thus, an ideally matched donor would be a "8/8" match, matching at each of the HLA loci mentioned above.

To identify a suitable allogeneic donor, both the recipient and potential donors are HLA typed (ie, specific HLA antigens are identified); the potential donor who is most closely matched is generally chosen to be the transplant donor. HLA typing is accomplished by DNA-based techniques that use polymerase chain reaction (PCR) amplification of specific HLA genes from genomic DNA. DNA typing methods are categorized by the level of discrimination they provide in defining the sequence of an HLA gene.[6] Low-resolution methods provide limited sequence information about a particular HLA gene and are typically used to identify sibling donors. However, low-resolution techniques cannot distinguish the extremely polymorphic nature of many of the HLA antigens. HLA antigens are characterized by thousands of genetic variations (alleles), and each allele may correspond to a unique HLA molecule. Different alleles can be distinguished only by high-resolution typing techniques; high-resolution methods are used to identify suitable unrelated donors.

3 The degree of HLA mismatching correlates with the risk of graft rejection, GVHD, and survival.[6] Mismatches at HLA-A, HLA-B, HLA-C, and HLA-DRB1 are similarly associated with increased risk of GVHD and mortality.[7] HLA-DQ mismatching is less predictive of negative outcomes suggesting an 8/8 match is as beneficial as a 10/10 match. As the number of mismatches increase, the risk of GVHD and transplant-related mortality also increases. In the search for an allogeneic donor, the patient's siblings are typed first. The odds that any one full sibling will match a patient are one in four. About 30% of Americans have an HLA-identical sibling. In an effort to offer allogeneic HSCT to patients who lack an HLA-identical sibling donor, alternative donors are being used. The most common type of alternative donor is an individual unrelated to the recipient who is fully or closely HLA matched. To facilitate identification of these donors, the NMDP (https://bethematch.org) was started in 1986 with initial funding from a US Navy contract. To date, the NMDP has registered more than 16 million donors in the United States and has facilitated more than 60,000 unrelated donor transplants. Donors outside the United States can also be accessed by the NMDP through agreements with international cooperative registries. About one-third of the allogeneic HSCTs performed worldwide are from unrelated donors.[1] The NMDP currently requires that the recipient be typed by high-resolution methodology at HLA-A,B,C, and DRB1. Although it is the transplant center's responsibility to select the donor, the NMDP recommends that selected donor and recipient be matched at HLA-A,B,C, and DRB1 by high-resolution typing when possible for bone marrow or peripheral blood HSCT.[8] If more than one suitable HLA-matched unrelated donor is identified, other factors can be used to select the donor, such as younger age, being male or a nulliparous female, and negative cytomegalovirus (CMV) serostatus.

The likelihood of a recipient finding an HLA-matched unrelated donor ranges from one in 100 to one in 1,000,000 depending on the prevalence of the recipient's HLA type, race, and ethnic background. With the current size and racial make-up of the NMDP registry, the matching likelihood is higher for whites than for patients from other racial or ethnic groups. Agreements between NMDP and international registries may improve the likelihood of finding donors for these patients and NMDP has launched a major effort to promote participation among nonwhite volunteers. Another limitation is the time needed to search for a potential donor. While searches are generally done in an expeditious manner, some donor searches may take up to 3 to 4 months, and patients with acute leukemia can relapse while waiting for completion of the search. With improved HLA typing techniques and better supportive care, most reported outcomes with matched unrelated donors are no longer significantly different than those reported with related sibling donors.[9]

Unfortunately, not every patient who could benefit from an allogeneic donor transplant will have a matched related or unrelated donor available. This has sparked interest in evaluating the use of alternative donor options such as umbilical cord blood (discussed in the next section), mismatched unrelated donors or related haploidentical donors.[10] Potentially useful HLA-mismatched unrelated donors are those who are mismatched at one or, at most, two HLA loci. By allowing for minimal mismatching, the chance of finding an unrelated donor increases significantly. Although mismatched unrelated donor transplants are inferior with respect to GVHD, transplant-related mortality and overall survival when compared to matched unrelated donors, these transplants do offer a curative

therapeutic option in select populations.[11] Research is being focused on evaluating the relative effect of mismatches at specific loci to determine if some are less detrimental (permissive) than others in order to improve outcomes. In addition, NMDP recommends testing the recipient for donor-specific HLA antibodies as graft failure is more common when the antibodies are present.[6]

Related haploidentical donors are those that are a complete half mismatch to the recipient; the donor and recipient are matched at 3 of 6 or 4 of 8 HLA loci. Donors can be parents, children or siblings of the recipients. Historically, haploidentical allogeneic transplants (Haplo-HSCT) generated poor outcomes related to high rates of graft failure and GVHD. Strategies to reduce the incidence of graft failure and GVHD have included various methods of T-cell depletion including administration of anti-thymocyte globulin (ATG), alemtuzumab, or posttransplant cyclophosphamide.[11,12] The use of high dose post-transplant cyclophosphamide (PTCy) on days 3 and 4 after infusion of stem cells has provided encouraging results. Three observational studies have compared outcomes after Haplo-HSCT and PTCy to traditional matched related and unrelated donor transplants and have shown that GVHD and survival outcomes were similar.[12] Two parallel prospective studies with identical objectives, eligibility criteria and clinical endpoints were conducted with reduced-intensity conditioning regimens in either Haplo-HSCT with PTCy or umbilical cord blood transplant (UCBT).[13] While the trials were not designed for results to be compared directly, patients receiving Haplo-HSCT had higher rates of engraftment, lower incidence of acute and chronic GVHD and less nonrelapse mortality than reported in the UCBT trial. However, relapse rates were lower after UCBT leading to similar progression-free and overall survival between the two studies. These trials reproduce promising single-center results with Haplo-HSCT or UCBT and suggest that survival rates with these alternative donor sources are comparable to those observed after matched unrelated donors. Based on these results, a phase III study comparing the two alternative stem cell sources is currently underway (BMT-CTN 1101, NCT01597778). Until the results of that trial and other randomized controlled trials are available, choosing an alternative donor in the absence of a HLA-matched sibling or unrelated donor will remain controversial and depends on patient characteristics, physician preference and center experience.

HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells serve as "mother" cells for all blood cells, including erythrocytes, leukocytes, and platelets (see Chapter e86). Stem cells have varying degrees of "stemness." True pluripotent stem cells are capable of replicating indefinitely and can give rise to stem and progenitor cells of all tissues. Multipotent stem cells, such as hematopoietic stem cells, have the capacity for self-renewal and can differentiate into more than one cell type in a particular tissue lineage. Because of their capacity for self-renewal, hematopoietic stem cells are capable of repopulating the recipient's marrow, which has been "emptied" by administration of high-dose chemotherapy, either alone or combined with radiation.

4 Hematopoietic stem cells are rare cells, comprising less than 0.01% of all bone marrow cells. Isolation and quantitative measurement of hematopoietic stem cells are extremely difficult because of their rarity and their similar appearance to other cells. For these reasons, surrogate markers are used to measure the number of stem cells. CD34 is an antigen expressed on hematopoietic stem cells and other early progenitor cells. Determination of the number of cells expressing the CD34 antigen ($CD34^+$ cells), as determined by flow cytometry, has become the standard method of measuring hematopoietic stem cell content.

Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood (UCB). Hematopoietic stem cells from the bone marrow are obtained by multiple aspirations from the anterior and posterior iliac crests while the donor is under general anesthesia. The procedure takes about 1 hour and yields 200 to 1,500 mL, depending on the size of the donor. In allogeneic bone marrow transplantation (BMT), the marrow stem cells are given to the recipient 12 to 24 hours after harvest. In autologous BMT, the marrow is frozen and stored until needed. After intravenous infusion, the marrow stem cells enter the systemic circulation and find their way to the bone marrow cavity, where they reseed and grow in the bone marrow microenvironment. Although the donor experiences local soreness for a few days, the procedure usually is well tolerated, with no delayed complications resulting from the marrow aspiration. The major risk of serving as a marrow donor is the risk of undergoing general anesthesia.

Hematopoietic stem cells in peripheral blood (peripheral blood stem cells [PBSCs]) are found in the mononuclear fraction of white blood cells (lymphocytes and monocytes) and are collected by a procedure called leukapheresis (or apheresis). This is an outpatient procedure that involves withdrawal of blood from a vein (through a specialized IV catheter), selective removal of mononuclear cells (containing the hematopoietic stem cells) by an apheresis machine, and reinfusion of the unneeded blood components back to the patient. During this process, about 10 to 15 L of blood is processed over several hours during each daily apheresis session. Most of the blood cells are returned to the donor, and each apheresis yields about 200 mL of cells. Leukapheresis is continued daily until a target number of $CD34^+$ cells (which include hematopoietic stem cells) are collected.

The number of hematopoietic stem cells that circulate in peripheral blood normally is too low for apheresis to be technically feasible. Without mobilization techniques, at least six aphereses are usually required to collect a sufficient number of PBSCs. Several methods have been used clinically to "mobilize" hematopoietic stem cells from the bone marrow into peripheral blood for use in autologous transplantation. Figure 140-2 shows representative schemas for mobilization and collection of PBSCs. The most commonly used mobilization method in both donor populations (healthy donors and autologous donors) is administration of a recombinant hematopoietic growth factor such as granulocyte colony-stimulating factor (G-CSF [filgrastim]) or granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]). Both agents are approved by the Food and Drug Administration (FDA) for this indication, but filgrastim is more commonly used. Head-to-head comparisons report superior outcomes with filgrastim in terms of number of stem cells collected, and posttransplant patient outcomes such as hematopoietic recovery, transfusion and antibiotic support.[14] Chemotherapy followed by a hematopoietic growth factor in the autologous transplant population increases the number of PBSCs to a greater extent than growth factor alone. This approach is more expensive and is

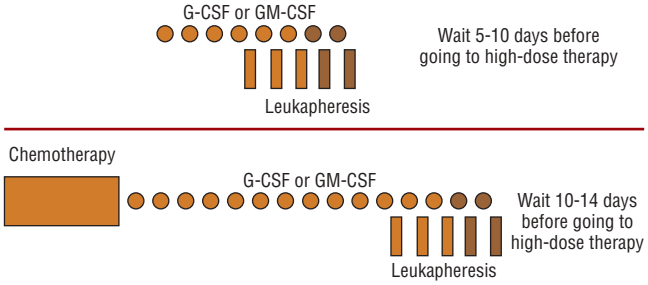

FIGURE 140-2 Schema for collection of peripheral blood progenitor cells after hematopoietic growth factor administration (top) or after chemotherapy and hematopoietic growth factor administration (bottom). Symbols with darker shading represent procedures performed only if adequate numbers of $CD34^+$ cells have not been collected. (G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.)

associated with more adverse effects, but the number of aphereses is reduced, and the additional chemotherapy may further reduce the tumor burden before transplant. However, these benefits have not translated into improved transplant outcomes so this approach is generally not used.[14] Pegfilgrastim (pegylated filgrastim) has also been evaluated in the mobilization setting, either alone or after chemotherapy (6 and 12 mg doses). Its prolonged half-life of 33 hours allows for single-dose administration, increasing patient convenience. Studies of single agent pegfilgrastim are limited by small numbers and report varying degrees of success.[14] The combination of pegfilgrastim and chemotherapy mobilization has resulted in similar $CD34^+$ cell collections and transplant-related outcomes to chemotherapy and filgrastim mobilization.[14]

An ongoing area of controversy is the use of biosimilar filgrastim agents during stem cell mobilization. Most of the data to support the use of biosimilars is in the setting of chemotherapy-induced neutropenia. A meta-analysis summarized the results in over 900 subjects that included healthy donors and patients with hematologic malignancies who used biosimilar agents to collect PBSCs. Mobilization with biosimilars resulted in expected $CD34^+$ stem cell yields with similar posttransplant engraftment and side effects to filgrastim, which suggests that biosimilars may be an acceptable option in mobilization.[15] The European Bone Marrow Transplantation Association (EBMT), World Marrow Donor Association (WMDA), as well as American Society for Blood and Marrow Transplantation (ASBMT) recommend that filgrastim biosimilars only be used within the context of a clinical trial until further information is available.[16,17]

Plerixafor is a novel inhibitor of the CXCR4 chemokine receptor that is FDA approved as a mobilizing agent in combination with filgrastim in autologous transplant candidates. Two phase III trials of plerixafor combined with filgrastim reported the combination was associated with higher $CD34^+$ cell yields, fewer apheresis sessions, increased likelihood of achieving $CD34^+$ target yields, and lower graft failure rates compared to single-agent filgrastim.[18,19] Based on the results of these trials, plerixafor is being routinely used to mobilize stem cells in autologous HSCT patients. However, because most patients are able to mobilize efficiently with filgrastim alone and plerixafor is expensive, transplant centers generally use a risk-adapted or preemptive approach to identify which patients are appropriate candidates for plerixafor. One approach is to give plerixafor to patients with certain characteristics that have been associated with a high risk of poor mobilization (ie, risk-adapted approach). These characteristics include older age, diagnosis of non-Hodgkin lymphoma (NHL), extensive chemotherapy history, previous radiation therapy, previous exposure to lenalidomide or purine analogs, previous mobilization failure and low preapheresis circulating peripheral blood $CD34^+$(PBCD34^+) cell counts.[14] However, these characteristics lack sensitivity and specificity in predicting poor mobilization outcomes and thus patients may be either over or under treated.[20] Another approach is often referred to as a preemptive strategy, which identifies poor mobilizers based on PB ("PBCD") $CD34^+$ cell counts on day 4 or 5 of filgrastim administration or on the first apheresis collection. Low numbers of $CD34^+$ cells after filgrastim administration have been associated with mobilization failure. Patients who do not have a minimal number of $CD34^+$ cells receive plerixafor.[14] Many transplant centers use these preemptive approaches to guide their mobilization strategies thereby limiting plerixafor use to patients at high risk for not obtaining the target $CD34^+$ yield. These algorithms have been reported to improve initial mobilization rates while efficiently managing resources.[14]

In about 20% to 30% of autologous transplant candidates, an optimal number of $CD34^+$ cells will not be obtained after the first attempt with standard mobilization regimens.[14] Several strategies for overcoming the obstacle of poor mobilization have been evaluated, including remobilization with the same or higher doses of the same hematopoietic growth factor, a combination of hematopoietic growth factors (ie, filgrastim and sargramostim), or a combination of chemotherapy and a hematopoietic growth factor. Each of these remobilization strategies has been used with varying success. Unfortunately these strategies are associated with failure rates that exceed 70%.[14] Bone marrow harvest is also an option if other strategies fail.

Current consensus guidelines suggest that plerixafor be used in remobilization regimens for patients failing primary mobilization attempts, regardless of whether it was used in the primary mobilization.[14] When combined with filgrastim, plerixafor is associated with failure rates of less than 30%, which compares favorably with other secondary mobilization strategies but is also more costly, especially if multiple doses of plerixafor are required.[21] The use of plerixafor combined with chemotherapy and filgrastim may a promising strategy, but further data are needed to better understand the appropriate timing and use of this regimen. The selection of a secondary mobilization regimen should be based on patient-specific factors and clinician judgment.

Several studies show that the number of $CD34^+$ cells infused correlates significantly with the rate of neutrophil and platelet recovery after high-dose chemotherapy.[14] Rapid neutrophil recovery usually is observed in patients who receive at least 2×10^6 $CD34^+$ cells/kg (body weight of recipient). More rapid platelet recovery is observed when at least 5×10^6 $CD34^+$ cells/kg is transplanted compared with lower cell doses. As a result, consensus guidelines recommend 2×10^6 $CD34^+$ cells/kg as a minimum number to collect for autologous transplant, with an optimal target of 5×10^6 $CD34^+$ cells/kg.[14] The decision to use a collection yield of less than 2×10^6 $CD34^+$ cells/kg should be limited to those cases in which the potential benefit of a HSCT outweighs the risks of infusing a suboptimal $CD34^+$ cell dose. For patients with multiple myeloma undergoing tandem transplants, cells for both transplants are collected before the first transplant. A minimum of 4×10^6 $CD34^+$ cells/kg is required, and generally the entire cell dose collected is divided into two equal aliquots, one for each transplant.

5 Use of peripheral blood instead of bone marrow as a source of hematopoietic stem cells offers several clinical and economic advantages. For autologous transplant patients the most clinically important advantage is that patients who receive mobilized PBSCs experience more rapid hematopoietic engraftment. Although engraftment of all lineages is more rapid when PBSCs are used, the most significant effect is observed with platelet recovery. Patients who receive mobilized PBSCs experience platelet recovery as much as 2 to 3 weeks earlier and require fewer platelet transfusions than those who receive bone marrow stem cells. As a result, patients usually are discharged earlier from the hospital, so the overall cost of autologous HSCT is reduced with the use of PBSCs. PBSCs may be less likely to be contaminated with malignant cells compared with marrow stem cells. Finally, because PBSCs are collected from the mononuclear cell fraction, a fraction that also contains immunocompetent cells (eg, natural killer [NK] cells and T lymphocytes), some investigators believe that infusion of PBSCs represents a form of "adoptive immunotherapy." In this model, NK cells and lymphocytes targeted against tumor cells help to kill residual tumor cells. As a result of these clinical and economic advantages, peripheral blood has replaced bone marrow as the source of stem cells in the autologous setting.

Peripheral blood has also become the predominant source of hematopoietic stem cells in adult allogeneic HSCT.[22] About two-thirds of allogeneic HSCTs performed in adults currently come from PBSCs harvested from normal donors receiving filgrastim mobilization. Filgrastim is generally well tolerated in the normal donor population. Short-term effects are similar to those seen in cancer patients receiving filgrastim (eg, bone pain, headache, fever, arthralgias, malaise). Although there are concerns about increased risk of acute myelogenous leukemia (AML) in healthy subjects given

filgrastim, no higher risk has been observed thus far.[23] Because of the long latent period of drug-related AML and the very low incidence of AML in the general population, longer follow-up of thousands of healthy donors will be required to definitively rule out an association between filgrastim and AML.

Randomized controlled trials and meta-analyses have shown that the stem cell source can influence posttransplant outcomes in allogeneic HSCT. Traditionally, matched related PBSCT have been associated with a more rapid hematopoietic recovery and required fewer transfusions compared with patients receiving bone marrow.[24] The difference in the rate of engraftment may be related to the threefold higher numbers of $CD34^+$ cells infused in recipients of PBSC transplants. Although increased risk of acute GVHD or transplant-related mortality in patients receiving allogeneic PBSC transplants has not been reported, a higher risk of chronic GVHD has been observed in many retrospective studies and meta-analyses.[24] The Blood and Marrow Transplant Clinical Trials Network (CTN) reported results from a trial that randomized 551 patients to allogeneic PBSC or bone marrow from matched unrelated donors.[25] Two years after transplant, there were no differences in overall survival, relapse, acute GVHD or mortality not related to relapse. However, a higher incidence of chronic GVHD was reported in patients who received PBSC transplants. Two-year survival is an early outcome, and further follow-up will need to be done to determine if these results are maintained over time. The published reports describing the impact of stem cell source on transplant related outcomes has focused primarily on transplants using myeloablative conditioning (discussed below). The CIBMTR reported retrospective data of patients with hematologic malignancies who received reduced intensity unrelated donor transplant with either PBSCs or bone marrow. Time-to-engraftment, risks of acute or chronic GVHD, relapse, non-relapse morality and overall survival were not significantly different between the two groups. Subgroup analysis suggests that GVHD prophylaxis may impact survival in this patient population and warrants further evaluation.[26] Selection of the optimal source of hematopoietic stem cells for an individual patient should be based on the risk of relapse, chronic GVHD, graft failure, and donor preference.

Hematopoietic stem cells found in UCB are an attractive source for several reasons.[27] Because the stem cells are collected from placental blood, there is a very low risk of transmissible infectious diseases, no risk to the mother or the baby, and the cells are immediately available. UCB initially was obtained from siblings, but now recipients of transplants from unrelated donors account for almost all patients who receive UCB transplants. More than 600,000 UCB grafts are available in more than 100 UCB banks, and more than 30,000 unrelated UCB transplants have been performed worldwide.[27]

Recipients of UCB transplants usually receive a $CD34^+$ cell dose more than 1 log lower than that given to recipients of BMT, and this difference in $CD34^+$ cell dose may explain the delayed engraftment in recipients of UCB transplants. The number of infused total nucleated and $CD34^+$ cells correlates with outcomes after UCB transplantation. The CIBMTR compared outcomes for adults with acute leukemia who were transplanted with unrelated bone marrow or PBSC versus UCB. Overall and leukemia-free survival were similar in all transplant groups. The risk of acute and chronic GVHD was lower in UCB recipients compared with PBSC, and the risk of chronic GVHD was lower in UCB compared with bone marrow. However, transplant-related mortality was higher after UCB as compared with other stem cell sources. These data support the use of UBCs as a source of stem cells when matched PBSCs or bone marrow are not immediately available.[28]

A major limitation of UCB transplants is the small volume of blood collected, usually 60 to 150 mL with resultant low numbers of $CD34^+$ cells. The relatively low numbers of hematopoietic cells may limit its use for larger recipients. This has led to "pooling" 2 or more units of UCB for one recipient (referred to as double cord transplant). The Seattle and Minnesota groups published their experience in more than 500 patients older than 10 years of age who received a matched related donor, matched unrelated donor, mismatched unrelated donor, or double cord transplant. Leukemia-free survival was similar in all groups, but the double cord transplant recipients had a higher risk of transplant-related mortality.[11] The Blood and Marrow Transplant CTN conducted a phase II trial in which a reduced-intensity conditioning regimen was administered with subsequent unrelated double cord transplant.[13] At 1 year posttransplant, the nonrelapse mortality remained high compared to alternative donor sources. Although the role of double cord transplantation has not yet been fully defined, these results suggest that pooled UCB units may provide an option for patients in which no other appropriate donors are available.

Initially, Haplo-HSCT generated poor outcomes related to high rates of graft failure and GVHD.[12] The use of PTCy on days 3 and 4 after infusion of stem cells has provided some encouraging results. Three observational studies have compared outcomes between Haplo-HSCT with PTCy to traditional matched related and unrelated donors and reported similar transplant outcomes. Two parallel prospective studies of reduced intensity conditioning regimens in Haplo-HSCT with PTCy or UCBT reported higher rates of engraftment and lower rates of acute and chronic GVHD and nonrelapse mortality in the Haplo-HSCT group. However, relapse rates were lower after UCBT leading to similar progression-free survival and overall survival between the two studies.[13] Based on these results, a phase III study comparing the two alternative stem cell sources is currently underway.

Clinical **Controversy...**

For patients that do not have a fully matched related or unrelated donor, the optimal alternative stem cell source, such as umbilical cord blood, mismatched unrelated, or HLA-haploidentical donors, is not clear. An ongoing phase III trial will directly compare two of these stem cell sources and may provide more definitive recommendations.

APPROACHES TO ERADICATE MALIGNANT CELLS

Conditioning Regimens

6 The purpose of the pretransplant conditioning regimen (also called the preparative regimen) depends on the type of transplant and the indication for its use. In the autologous setting, conditioning is used to eradicate malignant cells.[29] This is also the case in allogeneic HSCT for malignant diseases, but the conditioning regimen also serves a dual purpose to suppress the recipient's immune system to allow for donor cell engraftment. Two types of conditioning regimens are used, myeloablative and reduced intensity. Myeloablative conditioning (MAC) regimens contain very high doses of chemotherapy with or without radiation that would lead to life-threatening or fatal myelosuppression if hematopoietic stem cells were not infused.[30] Patients undergoing autologous HSCT receive only MAC regimens. Reduced-intensity conditioning (RIC) regimens are only used in allogeneic HSCT and consist of lower doses or different types of chemotherapy or lower doses of radiation than used in MAC regimens. RIC regimens were developed after the observation was made that some of the antitumor effect of the allogeneic transplant was mediated by a reaction between the donor's immune system and the recipient's cancer cells. This meant that very high doses of chemotherapy, radiation, or both may not be needed. Because RIC regimens use lower doses of chemotherapy or radiation or less toxic

TABLE 140-1 Dose-Limiting Nonhematologic Toxicities for Selected Chemotherapeutic Agents Included in Myeloablative Conditioning Regimens in Hematopoietic Stem Cell Transplantation

Drug	Conventional Dose[a] (mg/m²)	HSCT Dose (mg/m²)	Dose-Limiting Toxicity
Busulfan (oral)	2	450	Hepatic
Carboplatin	400	2,000	Hepatic, renal
Carmustine	200	1,200	Pulmonary, hepatic
Cisplatin	100	200	Renal, peripheral neuropathy
Cyclophosphamide	1,000	7,500	Cardiomyopathy
Etoposide	300-600	2,400	Mucositis
Ifosfamide	5,000	18,000	Renal
Melphalan	40	225	Mucositis
Thiotepa	20-50	1,125	Mucositis, central nervous system

HSCT, hematopoietic stem cell transplantation.

[a]Doses are approximate and are for drugs used as single agents. When combinations are used, doses may need to be decreased.

drugs, older patients and those with comorbidities are now able to undergo allogeneic transplant. Both types of regimens are discussed in detail below.

Myeloablative Conditioning Regimens

MAC regimens usually include at least one anticancer drug with a relatively steep dose-response curve and myelosuppression as their dose-limiting toxicity, such as alkylating agents. Cyclophosphamide, melphalan, busulfan, and carmustine are examples of chemotherapy agents commonly used in MAC regimens. Other agents are usually added that have additive or synergistic effects with these alkylating agents in specific types of cancers; other alkylating agents have also been used. Table 140-1 lists chemotherapeutic agents that are frequently used in MAC regimens as well as the doses used and their dose-limiting toxicity in the transplant setting.

Total-body irradiation (TBI) is also used in some pretransplant conditioning regimens. In patients with malignant disease, the rationale of TBI is to eradicate malignant cells located in areas inaccessible to the systemic circulation and thus to the chemotherapeutic agents (eg, CNS and testicles). TBI also has significant immunosuppressive activity. TBI doses for MAC regimens range from 10 to 15 Gy (1,000-1,500 rads or cGy), which is more than twice the lethal myelosuppressive dose of radiation for a normal person. TBI in these doses is typically fractionated (split over several days, once or twice a day) rather than given as a single-dose. Fractionated TBI has an improved therapeutic ratio compared with single-dose administration, that is, destruction of more leukemic cells and marrow stem cells while sparing other normal tissues. The acute toxicities of TBI consist of fever, nausea, vomiting, diarrhea, mucositis, and tender swelling of the parotid gland. Long-term complications of TBI-containing regimens include cataract formation, growth retardation, carcinogenesis, permanent reproductive sterility, and secondary malignancies.

Based on its immunomodulatory and antineoplastic effects, cyclophosphamide (60 mg/kg/day for 2 days) is commonly combined with TBI (CyTBI). Other chemotherapy agents have been used with TBI but there is no evidence to suggest that any of these combinations are more effective than CyTBI.[31] Due to the toxicities seen with high dose TBI, chemotherapy only regimens also have been developed. Many of these regimens contain busulfan due to its activity against a variety of malignancies. Busulfan can either be given IV or orally. The use of IV busulfan-containing regimens has been associated with improved survival compared to TBI containing regimens in patients with myeloid malignancies.[32] At some transplant centers, plasma busulfan concentrations are monitored and doses adjusted as systemic exposure has been shown to correlate with both efficacy and toxicity and use of a preparative regimen with targeted busulfan may improve patient outcomes.[31,33] Busulfan was originally combined with cyclophosphamide (BuCy) but more recently has been combined with fludarabine (BuFlu) to increase regimen tolerability when used in the allogeneic transplant setting.

Several studies, both prospective and retrospective, have been done evaluating differences between allogeneic transplant MAC regimens.[31,32] In general, there is no definitive data showing the superiority of one regimen over another, such that the choice of regimens before allogeneic HSCT generally is based on the experience of the transplant center, patient characteristics, diagnosis, and disease status.

Conditioning regimens used in autologous HSCT are exclusively myeloablative and generally include at least one alkylating agent with other agents added that may have specific activity against the tumor type being treated.[29,31] TBI usually is not commonly used and is not included in the conditioning regimen in patients who have received prior radiotherapy. MAC regimens used in patients with lymphoma generally include different combinations of cyclophosphamide, carmustine, etoposide, and cytarabine. Rituximab is commonly added in patients with CD20-positive lymphomas, although randomized controlled studies supporting the use of rituximab in this setting are lacking.[29] The Blood and Marrow Transplant CTN conducted a prospective comparative trial randomizing patients with diffuse large B cell lymphoma to receive high-dose chemotherapy with rituximab or iodine-131 tositumomab followed by autologous HSCT.[29] Progression-free survival and overall survival were not significantly different between the two groups, and thus anti-CD20 radiolabeled monoclonal antibodies are not used routinely as part of conditioning for patients with NHL undergoing autologous HSCT. Single-agent melphalan (200 mg/m²) is the standard conditioning regimen for patients undergoing autologous HSCT for myeloma. The addition of other agents to melphalan has not been proven to be superior to melphalan alone.[29]

Reduced-Intensity Conditioning Regimens

7 Donor T cells contribute to the tumor cell kill and prevention of relapse observed after allogeneic HSCT, an effect referred to as the graft-versus-malignancy (GVM) effect. Evidence for the GVM effect is based on retrospective studies showing that patients who developed GVHD had a lower risk of leukemic relapse than those who did not develop GVHD. However, the overall survival rate was not different because of the increased nonrelapse mortality associated with GVHD. Other anecdotal evidence supporting a T cell-mediated GVM effect includes the increased risk of relapse found with T cell-depleted

transplants compared with unmodified transplants and the efficacy of donor lymphocyte infusions (DLIs) in producing responses in patients who have relapsed after allogeneic HSCT.[31]

RIC regimens containing lower doses of chemotherapy or radiation or less toxic agents were developed to take advantage of the GVM effect but with a lower incidence of regimen-related toxicity than that of MAC regimens. Animal data demonstrated that MAC was not required for engraftment of donor cells (the other important role of conditioning in allogeneic HSCT), thus paving the way for the evaluation of RIC in humans.[31] The major advantage of RIC is that potentially curative transplants can be offered to patients who typically would not be considered for allogeneic HSCT because of their unacceptably high risk of transplant-related complications due to increased age or moderately compromised organ function. Use of RIC regimens has steadily increased in patients aged 50 and older.[1] In addition, because of the lower rate of toxicity, allogeneic HSCT with RIC can be offered to patients who have relapsed after traditional myeloablative autologous or allogeneic transplants, provided they are healthy enough to tolerate a second transplant. Because RIC regimens may not be completely myeloablative, host hematopoiesis can persist and lead to mixed chimerism (blood cells from both donor and recipient are present) (Fig. 140-3).[34] Several studies have reported significant correlations between donor T-cell chimerism levels and the risk of graft rejection, GVHD, and relapse. For example, a low percentage of donor T and NK cells present on day 14 has been associated with graft rejection, but high T-cell donor chimerism on day 28 has been associated with acute GVHD. Achievement of full donor chimerism was associated with better GVM effect and longer progression-free survival. These data suggest that monitoring donor chimerism after transplant may allow early interventions to prevent graft rejection or relapse.[34]

A number of RIC regimens that vary in their cytotoxic, myelosuppressive, and immunosuppressive activity have been developed.[31] Most regimens include fludarabine (125-240 mg/m^2) because of its potent immunosuppressive activity, combined with either low-dose TBI (at doses up to 8 Gy [800 rad]) or an alkylating agent, such as cyclophosphamide (2-3.6 g/m^2 or 120-200 mg/kg), busulfan (up to 10 mg/kg), or melphalan (up to 180 mg/m^2). ATG or alemtuzumab is sometimes given for additional immunosuppression, and other purine analogs (eg, pentostatin or clofarabine) are sometimes used instead of fludarabine. Rituximab has also been included in patients with CD20-positive lymphoid malignancies. Many of these regimens are myeloablative but are defined as RIC because of the reduced doses of chemotherapy.[30]

Some RIC regimens are considered nonmyeloablative because they result in little to no myelosuppression and do not require hematopoietic cell support for recovery of hematopoiesis. Nonmyeloablative regimens are associated with very little regimen-related toxicity but, similar to other RIC regimens, are immunosuppressive enough to result in full engraftment of important donor immune effector cells.[30] Two of the most common nonmyeloablative regimens are fludarabine (25 mg/m^2/day for 3-5 days) combined with cyclophosphamide (60 mg/kg/day × 2 days) or with TBI (less than or equal to 2 Gy [less than or equal to 200 rad]). Although these regimens are clearly nonmyeloablative, the distinction may be more difficult with other regimens as definitions remain somewhat arbitrary.

Progression-free and overall survival varies depending on the specific RIC regimen, disease type and status at the time of transplant, donor type, and patient age and comorbidities. Patients with indolent lymphoid malignancies generally have the lowest relapse rate after RIC transplants; those with advanced myeloid and lymphoid malignancies have higher relapse rates.[35] Several large retrospective registry-based studies have reported the results of RIC regimens.[35] In general, regimen-related toxicity and nonrelapse mortality have been reported to be lower than that of historical or concurrent control participants receiving MAC regimens in nonrandomized comparisons. This is remarkable considering the older age and higher incidence of comorbidities in patients receiving RIC transplants. Of concern, however, has been an increased rate of relapse in patients receiving RIC regimens, resulting in similar overall survival. One randomized trial has been published to date comparing RIC (FluTBI) versus MAC (CyTBI) regimens in patients 18 to 60 years of age with AML in first complete remission.[36] The two groups were well matched for age, cytogenetic abnormalities and donor type. The trial was stopped early due to slow accrual. Overall and progression-free survival were similar between the groups but, because the study was closed early, it likely lacked power to show a difference in the primary endpoints. The Blood and Marrow Transplant CTN performed a large randomized trial comparing RIC versus MAC in patients with AML or MDS. Eligibility criteria included age less than or equal to 65, disease in complete remission and

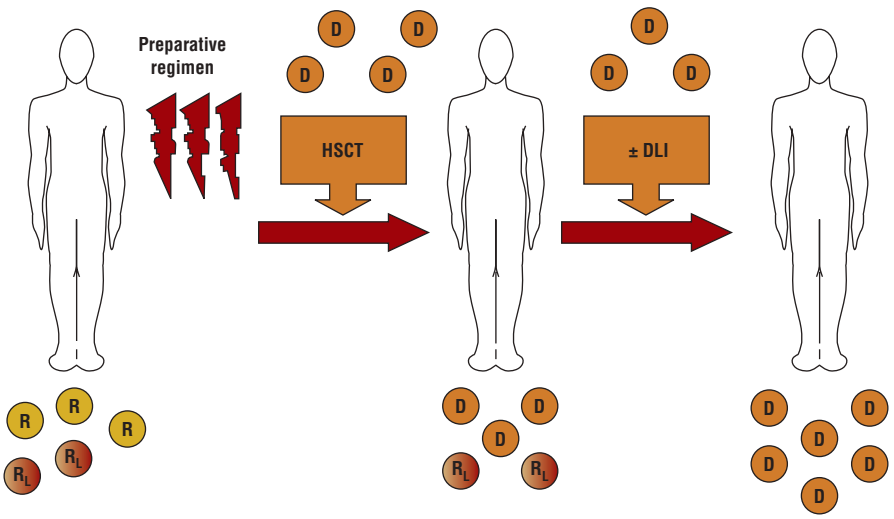

FIGURE 140-3 Schema for nonmyeloablative transplantation for hematologic malignancy. Recipients (R) receive a reduced-intensity conditioning regimen and an allogeneic hematopoietic stem cell transplant (HSCT). Initially, mixed chimerism is present with the coexistence of donor (D) cells and recipient-derived normal and leukemia/lymphoma (R_L) cells. Donor-derived T cells mediate a graft-versus-host hematopoietic effect that eradicates residual recipient-derived normal and malignant hematopoietic cells. Donor lymphocyte infusions (DLIs) can be administered to enhance graft-versus-malignancy effects.

minimal comorbidities. This trial was halted prematurely because a benefit in the MAC arm of the study was observed. The results, when published in a peer-reviewed journal, will assist clinicians in selecting the appropriate choice of regimen for the population represented in the study.[31] For other populations, clinicians will consider patient and disease characteristics as well as donor type when choosing an appropriate conditioning regimen until more evidence is available.

Clinical **Controversy...**

Although RIC regimens reduce transplant-related mortality, whether this approach results in improved survival compared with MAC regimens is not clear. Direct comparison of the results of RIC versus MAC transplants is difficult because patients undergoing RIC transplants tend to be older and have more comorbidities. Randomized controlled trials addressing these questions are ongoing, and the results of these studies should better define the role of RIC transplants.

Posttransplant Therapy

Relapse of primary disease remains the most common cause of death for both allogeneic and autologous HSCT patients. As a result, much research has been directed at both preventing and treating posttransplant relapse or progression of disease.[37-40] The use of therapy posttransplant can be categorized either as "maintenance (or consolidation) therapy" or "salvage therapy." Maintenance/consolidation therapy is used to prevent relapse whereas salvage therapy is given to treat active relapse. Methods of identifying relapsed disease for many transplantable malignant diseases have become quite sensitive, and often disease can be detected at the molecular level (ie, minimal residual disease) and used to direct posttransplant therapy. Several posttransplant therapies have been evaluated both in the maintenance and salvage settings, including immunotherapy, conventional chemotherapy, and targeted therapy. Relapse after autologous transplant can often be treated with standard doses of chemotherapy, a second autologous transplant, or even an allogeneic transplant, depending on the diagnosis, disease status, side effects, response, and duration of response to the first transplant. Treatment options for most patients who relapse after allogeneic HSCT are more limited, and prognosis is generally poor. Disease-specific chemotherapy and immunotherapy can be considered for some patients. A second allogeneic HSCT may be considered but is associated with a mortality rate of up to 45%.[38]

Immunotherapy

The rationale for posttransplant immunotherapy after allogeneic HSCT is based on the GVM effect. To take advantage of the GVM effect in patients who relapse after allogeneic HSCT, immunosuppressive therapy being used for GVHD is withdrawn as quickly as possible without inducing a serious GVHD flare. In rare cases, this is enough to reinduce a remission, but further therapy is usually required. In addition, this is not a viable option in patients with active GVHD. Induction of the GVM effect has been investigated with several immunostimulatory drugs including interleukin-2, cyclosporine, interferon-gamma, and interleukin-1. None of the randomized trials done with these agents showed survival benefit.[40] Other posttransplant immune strategies include DLI and monoclonal antibodies.

Donor Lymphocyte Infusion Perhaps the most commonly used form of posttransplant immunotherapy is DLI.[41,42] Lymphocytes are collected from the same donor who provided hematopoietic stem cells for the original allogeneic transplant, thus limiting this option to patients with available donors. Response to DLI is disease specific. More than 80% of patients with CML who are in cytogenetic or molecular relapse respond to DLI. The response rate of patients in more advanced phases is about 15% to 30%. Although the time to response is delayed (median, 3-4 months), patients often have a durable molecular remission to DLI. Response rates to DLI of patients with other myeloid malignancies, such as AML and myelodysplasia, are generally lower (25%-30%) than the rates of patients with CML. This may be related to the rapid proliferation of acute leukemia within the often prolonged time to response after DLI. Patients with relapsed AML after HSCT are more likely to achieve a complete response to DLI if they had a longer remission period after transplant and have some GVHD after the DLI; low tumor burden, remission at the time of DLI, and good-risk cytogenetics have also been shown to be favorable characteristics. Administration of induction chemotherapy or therapeutic agents with novel mechanisms of action (eg, 5-azacitidine, lenalidomide, and bortezomib) before DLI administration may improve the antitumor activity of DLI in patients with AML or other rapidly proliferating malignancies, but this method has not been tested in a randomized study.[38] DLI has been shown to have limited benefit in patients with relapsed acute lymphocytic leukemia (ALL) after transplant.

DLI appears to be effective in patients with multiple myeloma who relapse after allogeneic HSCT, with reported response rates of 40% to 50%. Chemotherapy followed by DLI may induce a GVM effect in patients with relapsed lymphoma. The highest response rates were reported in patients with indolent NHL while more aggressive malignancies had lower response rates.

The most serious complications of DLI are pancytopenia and GVHD, and DLI is not usually given to patients with active GVHD. The cytopenias generally are transient and can be treated with hematopoietic growth factors. Some patients may have a more prolonged course of aplasia with associated risk of infection, bleeding, and anemia and these patients may benefit from another infusion of donor hematopoietic stem cells.

New strategies being evaluated to improve outcomes with DLI include priming the donor with filgrastim, infusion of selected subsets of T-lymphocytes to promote GVM, preemptive use of DLI based on the presence of minimal residual disease or evidence of molecular/cytogenetic relapse, or prophylactic DLI in patients who are at high risk of relapse.[41]

Monoclonal Antibodies Although earlier studies showed potential benefit of rituximab as maintenance therapy for certain types of NHL patients after autologous HSCT, more recent randomized controlled trials with mature follow up have not consistently demonstrated benefit.[29,40] Therefore, routine use of rituximab maintenance is not recommended. Rituximab may be useful in combination with other active agents for salvage therapy of posttransplant relapse.

Brentuximab vedotin (anti-CD30 antibody conjugated to monomethyl auristatin E, a microtubule-disrupting agent) was evaluated as maintenance therapy in a randomized placebo-controlled study in patients with Hodgkin lymphoma after autologous HSCT.[43] Progression-free survival was significantly improved in patients randomized to brentuximab (hazard ratio 0.57, 95% confidence interval 0.4-0.81). Consistent benefit was seen across all subgroups that were analyzed. The most frequent adverse events in the brentuximab group were peripheral sensory neuropathy and neutropenia. No difference in overall survival was seen, likely because patients receiving placebo were allowed to crossover to brentuximab treatment at the time of progression. These results are encouraging given the generally poor prognosis of patients with relapsed/refractory Hodgkin lymphoma.

Chemotherapy or Targeted Therapy

Tyrosine kinase inhibitors (TKIs), such as imatinib, dasatinib, and nilotinib have been shown to be effective in the prevention and

treatment of relapse after allogeneic HSCT in patients with CML and Philadelphia chromosome–positive (Ph+) ALL.[44] In patients with CML who experience hematologic relapse (presence of leukemic blasts in blood or bone marrow) after allogeneic HSCT, imatinib has been reported to induce complete hematologic responses (disappearance of leukemic blasts) and complete cytogenetic responses (disappearance of cytogenetic markers of disease) in a majority of these patients. Outcomes in patients with Ph+ ALL have also been encouraging. TKIs are also given soon after transplant to prevent relapse.[44,45] Patients with Ph+ ALL and CML without evidence of disease after transplant who are treated with TKIs to prevent relapse appear to have sustained cytogenetic remissions (without evidence of cytogenetic markers of disease). In a study of patients with Ph+ ALL, 50% of patients who had minimal residual disease detected after stem cell transplant had a complete response to TKI therapy.[45] TKIs are generally well tolerated after transplant. Commonly reported side effects include neutropenia, thrombocytopenia, liver function abnormalities, edema, and muscle pain, which may require dosage reductions or discontinuation. Larger comparative studies will be required to clearly define the benefit of TKIs after transplant, as well as the optimal dosing, timing, and duration of therapy.

Based on its activity in AML and MDS, 5-azacitidine is being evaluated in the posttransplant setting to prevent or treat relapse in patients with these diagnoses. Investigators at the MD Anderson Cancer Center performed a dose and schedule finding study with 5-azacitidine maintenance therapy in patients who were in a complete remission after HSCT. The dose-limiting toxicity was thrombocytopenia, and the optimal dose was 32 mg/m^2 given subcutaneously for 5 days for 4 cycles. This study demonstrated that low-dose 5-azacitidine may be administered in this population safely, and it may prolong event-free survival and overall survival, justifying further studies to confirm these preliminary findings.[40,46] 5-azacitidine maintenance therapy has also been associated with a reduction in GVHD and increasing donor chimerism which delayed disease relapse.[39] Retrospective analyses of 5-azacitidine used to treat posttransplant relapse of AML have reported a response rate of 50% to 75% but overall survival remains poor (15%-20% at 2 years) and toxicity is substantial.[47] Improved results have been seen when DLI is given after 5-azacitidine.[39] Other therapies being investigated as maintenance therapy after allogeneic HSCT include panobinostat (deacetylase inhibitor) and the FLT3 tyrosine kinase inhibitors (sorafinib, quizartinib, and midostaurin).[39] Posttransplant therapy is also being evaluated in patients with multiple myeloma. Previous studies showed a potential benefit of thalidomide to prevent relapse after autologous transplant, but its use is limited by neurotoxicity and other bothersome adverse effects. When given after autologous transplant in patients with nonprogressing disease, lenalidomide has been shown to prolong progression-free survival compared with patients receiving placebo.[40] However, a small but significant increased incidence of second primary cancers was reported in the lenalidomide-treated patients. Further study is needed to better define the risk of second malignancies. Patients should be aware of this potential safety issue when discussing treatment with lenalidomide after autologous HSCT. Bortezomib maintenance therapy after autologous HSCT has also been associated with prolonged progression-free survival.[40]

TRANSPLANT-RELATED COMPLICATIONS

8 Although many patients with cancer who are treated with high-dose chemotherapy and autologous or allogeneic HSCT experience long-term survival and cure of their disease, this modality is associated with many serious and potentially life-threatening complications.[29,32] In spite of the availability of improved broad-spectrum anti-infective agents, immunosuppressive drugs, and hematopoietic growth factors which has improved survival over the last four decades, the transplant-related mortality rate after allogeneic HSCT with HLA-matched sibling and unrelated donors is 20% to 30%. The mortality rate is generally lower with the use of RIC regimens but higher when alternative donors are used. Causes of nonrelapse-related death are a result of transplant-related organ toxicity, GVHD, or immunosuppression. The risk of transplant-related mortality after autologous HSCT generally is less than 5%, depending on patient population and conditioning regimen.[29] The mortality rate is lower with autologous transplants because of the lack of GVHD and associated complications of immunosuppression. Transplant-related mortality in autologous HSCT usually is caused by regimen-related toxicity or infection.

Table 140-1 lists the dose-limiting nonhematologic toxicities for several drugs that are commonly included in MAC regimens. These toxicities may be uncommon or rare with administration of conventional doses of specific drugs. When these agents are given in high doses, the toxicities seen with conventional doses (eg, mucositis, enteritis, nausea, vomiting, and hematuria) can be more frequent or severe. Several unusual and severe manifestations of regimen-related toxicities are discussed in this section.

Sinusoidal Obstruction Syndrome

Sinusoidal obstruction syndrome (SOS), formerly known as hepatic venoocclusive disease (VOD), occurs as a result of chemotherapy-induced damage to the sinusoidal endothelial cells of the liver, which leads to release of proinflammatory cytokines and further damage to the endothelium. Gaps develop between the endothelial cells allowing cellular debris to accumulate, causing the sinusoids to narrow and eventually become occluded. In addition, injury to the endothelial cells produces fibrin deposition and clot formation, further narrowing the sinusoids.[48] These histologic changes can lead to obstruction of sinusoidal flow, reduced hepatic venous outflow, portal hypertension, and hepatic failure. Clinical signs of SOS include fluid retention (resulting in sudden weight gain and ascites), hepatomegaly (sometimes painful), and hyperbilirubinemia or jaundice. SOS usually occurs within the first 4 weeks after transplant, and the incidence of SOS ranges from 5% to 20% in most published series. Severe SOS is fatal in 50% to 75% of cases. Factors that have been reported to increase the risk of SOS include use of TBI-containing conditioning regimens (dose dependent), use of sirolimus for the prevention of GVHD, increased systemic exposure to busulfan, oral administration of busulfan, individual variability in cyclophosphamide metabolism, chronic viral hepatitis, and elevated liver function test results before transplant. Pretransplant exposure to gemtuzumab ozogamicin (Mylotarg®) has been implicated in the development of SOS in patients undergoing allogeneic HSCT, especially when given within a few months of transplant.[48]

Prostaglandin E_1, unfractionated low-molecular-weight heparin, and ursodiol have all been studied in prevention of SOS.[32,48] Ursodiol has been found to not only reduce the risk of SOS in patients undergoing MAC allogeneic transplants but has also been associated with reduced transplant-related mortality and GVHD. Defibrotide, a polydisperse oligonucleotide with fibrinolytic properties, is another agent that has been used successfully in the prophylaxis of SOS. It is being routinely used in some European transplant centers in patients at high risk for SOS.[48]

Treatment of SOS is generally supportive, including fluid and electrolyte management. Hepato- and nephrotoxic drugs should be avoided. Mild-to-moderate disease generally resolves without specific therapy. Recombinant tissue plasminogen activator has been given to patients with severe SOS because of the possible role of the coagulation cascade in the pathogenesis of SOS. Responses have been reported, but patients also experienced a higher risk of bleeding.[48] Mounting evidence supports the use of defibrotide in the treatment

of patients with severe SOS, demonstrating improved response rates and lower mortality compared with historical control participants.[48] Defibrotide (Defitelio®) was recently approved by the FDA in 2016 and its role in the treatment of SOS is still being defined.

Pulmonary Complications

Pulmonary complications after HSCT can be categorized as infectious and noninfectious (infectious complications are discussed in Chapter 122). Noninfectious complications can be caused by direct damage to the pulmonary tissue by chemotherapy or radiation used in the conditioning regimen, immune effects of the graft, or other causes not clearly understood. Early complications include diffuse alveolar hemorrhage, periengraftment respiratory distress syndrome, and idiopathic interstitial pneumonitis.[49] Diffuse alveolar hemorrhage is characterized by dyspnea, hypoxia, dry cough, and fever; chest radiography usually shows diffuse infiltrates in an alveolar pattern. Diffuse alveolar hemorrhage is diagnosed by examination of bronchoalveolar lavage fluid via bronchoscopy, which reveals progressively bloodier fluid with each instilled aliquot and negative findings on microbiologic analysis. Although the condition can be life-threatening or fatal, prompt treatment with high doses of corticosteroids is sometimes beneficial.[49]

Periengraftment respiratory distress syndrome is characterized by fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema can occur during neutrophil recovery after HSCT.[49] The incidence of engraftment syndrome is not known because of the lack of uniform diagnostic criteria, although some series report that about 10% of patients who receive autologous HSCT develop the syndrome. This syndrome can progress to life-threatening respiratory failure with or without multiple organ failure. Corticosteroids are effective in some patients.

Idiopathic interstitial pneumonitis (also called idiopathic pneumonia syndrome) is defined as widespread alveolar injury in the absence of active lower respiratory tract infection after HSCT.[50] Patients with idiopathic interstitial pneumonitis are clinically indistinguishable from patients with interstitial pneumonitis related to infection. Idiopathic interstitial pneumonitis is postulated to have a multifactorial etiology, including toxic effects of MAC, immunologic cell-mediated injury, inflammatory cytokine-induced lung damage, and occult pulmonary infections. The risk is similar in recipients of autologous or allogeneic HSCT but appears to be higher in patients who are conditioned with a TBI-containing regimen or who have acute GVHD. A mortality rate as high as 70% has been reported, and treatment consists of supportive care only as the efficacy of corticosteroids is not well described. Etanercept may be beneficial in some patients with idiopathic interstitial pneumonitis.[51]

Late pulmonary complications cover a wide spectrum of disorders and include both obstructive and restrictive lung diseases.[49,52] The best described of these disorders is bronchiolitis obliterans with or without organizing pneumonia. Although bronchiolitis obliterans is thought to be a result of chronic GVHD affecting the lungs, its pathogenesis has not been completely elucidated. Therapy consists of corticosteroids, which are about 50% effective. Patients with mild-to-moderate airflow impairment appear to have the best response. The survival rate at 5 years from diagnosis of bronchiolitis obliterans is less than 20%.

Graft Failure

Initial engraftment of hematopoietic cells after high-dose chemotherapy conditioning regimens usually occurs in the first 2 to 4 weeks after transplant. Engraftment is evidenced by rising peripheral blood counts and the presence of hematopoietic precursor cells in the marrow. In allogeneic HSCT, the presence of donor cells (ie, chimerism) is confirmed by PCR-based analysis of polymorphic DNA sequences of cells from the bone marrow and peripheral T cells. Full chimerism is defined as greater than 95% of cells of donor origin. In most patients, engraftment is sustained with complete recovery of hematopoiesis.

However, graft failure (loss of bone marrow function with resultant loss in peripheral blood counts) can occur after both allogeneic and autologous HSCT. It can be the result of heavy pretreatment with chemotherapy or radiation therapy (or both); infusion of insufficient numbers of hematopoietic stem cells; viral infection; recurrence of primary hematologic malignancy; drug reaction (eg, to ganciclovir); development of a secondary myelodysplasia; or in the allogeneic setting, an immunologic reaction between the donor and recipient caused by inadequate immunosuppression of the recipient (ie, graft rejection). Two syndromes have been observed. Whereas early graft failure occurs when the rate of hematopoietic recovery is delayed or does not occur at all (primary graft failure or delayed engraftment), late graft failure is characterized by a decline in peripheral blood counts after initial engraftment (secondary graft failure). With widespread use of PBSCs and posttransplant growth factors, primary graft failure is rare after autologous and HLA-matched allogeneic HSCT but is not uncommon after UCBT. Graft failure that occurs after allogeneic HSCT, characterized by regrowth of immunocompetent recipient cells and a simultaneous loss of donor cells, is referred to as *graft rejection*. Graft rejection occurs rarely after HLA-matched allogeneic HSCT. An increased risk of graft rejection has been observed in recipients of hematopoietic stem cells from HLA-mismatched donors, recipients of T cell-depleted marrow, and patients with severe aplastic anemia. In a large retrospective analysis of over 20,000 patients undergoing myeloablative allogeneic HSCT the incidence of primary graft failure was reported was 5.5%.[53] In this analysis, risk factors for primary graft failure included bone marrow (vs peripheral blood) grafts, diagnosis of a myeloproliferative disorder, HLA mismatched transplants, ABO incompatibility, and BuCy conditioning. The long-term prognosis of patients with graft failure is poor. Despite supportive care and treatment with hematopoietic growth factors, death may result from infection or bleeding. In some patients with an allogeneic donor, a second infusion of stem cells can be attempted.[32]

Hematopoietic growth factors usually are given after transplant to patients who receive autologous HSCT, based on several benefits associated with their use including fewer antibiotic days and decreased length of stay. Decreasing resource utilization after transplant (total antibiotic days and length of stay) can help justify the cost of growth factors in this patient population. Growth factors can be initiated the day of, the day after, or as late as 7 days after the infusion of stem cells and are continued until neutrophil recovery to greater than an arbitrary number of neutrophils (500-1,000 cells/mm^3 [0.5-1.0 × 10^9/L]). Pegfilgrastim appears to be equally efficacious to filgrastim in this setting.

Hematopoietic growth factors also accelerate the rate of neutrophil recovery in patients undergoing allogeneic HSCT. However, filgrastim does not reduce infection rates, antibiotic days or length of stay. The decision to whether or not to use filgrastim must be made by each institution and may be reserved for use in patients who are at risk for a prolonged rate of neutrophil recovery (eg, UCB transplants).

Results of studies with platelet growth factors, such as thrombopoietin and interleukin-11 (IL-11), given posttransplant have been disappointing. Platelet transfusions remain the standard of care in patients with thrombocytopenia below a given threshold (eg, 10,000 cells/mm^3 [10 × 10^9/L]) and in patients with significant bleeding.

Anemia may be problematic in the posttransplant setting, especially in patients receiving allogeneic HSCT. The etiology is unclear and most likely is multifactorial. Although erythropoietin administration may be useful in reducing the need for red blood

cell transfusions, its use in cancer patients is associated with an increased risk of adverse events and is limited by FDA warnings and restrictions.

Graft-Versus-Host Disease

GVHD is caused by immunocompetent allogeneic donor T cells reacting against recipient/host antigens on the surface of antigen-presenting cells (APCs). In that setting, donor T cells recognize unmatched major or minor histocompatibility antigens of the host as genetically foreign, become activated, proliferate, and attack recipient tissue, thereby producing the clinical syndrome of GVHD.

Two different clinical syndromes of GVHD (acute and chronic) are recognized, each with two subcategories. Classic acute GVHD occurs within 100 days after transplant or DLI while persistent, recurrent or late-onset acute GVHD occurs beyond 100 days after transplant, withdrawal of immunosuppression or DLI.[54] Both subcategories of acute GVHD occur in the absence of chronic GVHD. Classic chronic GVHD usually occurs after day 100, with only clinical manifestations that can be attributed to chronic GVHD. Chronic GVHD may occur after resolution of acute GVHD or de novo (no prior acute GVHD). Acute and chronic overlap syndrome is a newly defined entity in which features of both acute are chronic GVHD appear together. Chronic GVHD usually develops before resolution of acute GVHD (also called progressive onset). The clinical manifestations of GVHD are distinct. Whereas acute GVHD usually is limited to the gastrointestinal tract, skin, and liver, signs and symptoms of chronic GVHD resemble an autoimmune disorder and can affect many organ systems.

A "hyperacute" form of GVHD may occur in patients with multiple HLA mismatches and in patients who receive T cell–replete transplants without adequate GVHD prophylaxis, especially after MAC regimens.[55] Descriptions of hyperacute GVHD vary but usually include fever, generalized erythroderma, desquamation, and edema. More severe forms with accompanying organ failure have been seen in haploidentical donors. Hyperacute GVHD typically occurs about 1 week after transplant before engraftment of neutrophils. The response rate to first-line therapy appears to be lower in patients with hyperacute GVHD compared with patients who develop GVHD later after transplant, but no difference in survival has been observed.

Acute Graft-Versus-Host Disease

The pathophysiology of acute GVHD has been described as a three-step process.[56] In step 1, the conditioning regimen causes damage to the intestinal mucosa, leading to release of lipopolysaccharides into the systemic circulation. This stimulates secretion of inflammatory cytokines such as IL-1 and tumor necrosis factor-α (TNF-α). These cytokines upregulate MHC gene products and host APCs such as dendritic cells, which play a critical role in this immune response. In step 2, donor T cells are activated, and secretion of other cytokines (IL-2 and interferon-γ) by activated T cells results in recruitment of macrophages and alteration of target cells in the gastrointestinal tract and skin so that they are more susceptible to damage. In step 3, multiple cytotoxic effector cells (T cells and macrophages) are generated and contribute to target tissue injury by secreting more inflammatory cytokines that cause target cell apoptosis. The term "cytokine storm" is sometimes used to describe the critical role of inflammatory cytokines in this process. Three general approaches have been used to prevent GVHD in humans. The first is to reduce host tissue damage with the use of RIC regimens. The second and most widely used approach is to modulate donor T cells by reducing T-cell numbers (T-cell depletion), activation (most immunosuppressive agents), or proliferation (antiproliferative agents). The third approach is to block inflammatory stimulation and effectors (eg, TNF-α inhibition, IL-1 receptor blockade).

The principal target organs in acute GVHD are the skin, liver, and gastrointestinal tract.[56] Acute GVHD is classified into four grades, depending on the number of organs involved and the degree of involvement of each organ (Table 140-2). Grade I disease involves only the skin. Grades II through IV involve the skin and the liver, gastrointestinal tract, or both. Acute skin GVHD usually is manifested as a generalized maculopapular rash that initially involves the face, ears, palms, soles, and upper trunk. The skin rash can spread to the rest of the body and, if untreated or refractory to treatment, will progress to bullae formation and desquamation similar to a burn injury. Gastrointestinal GVHD presents as a secretory diarrhea but may progress to abdominal pain or cramping and ileus; hemorrhage may also occur. GVHD of the upper intestinal tract appears as persistent nausea, vomiting, anorexia, and dyspepsia. The diagnosis of gastrointestinal GVHD should be made by biopsy of the intestinal

TABLE 140-2 Consensus Grading of Acute Graft-versus-Host Disease

Organ/Extent of Involvement			
	Skin	**Liver**	**Intestinal Tract**
Stage			
1	Rash on <25% of skin[a]	Bilirubin 2-3 mg/dL (34.2-51.3 µmol/L)[b]	Diarrhea >500 mL/day[c] or persistent nausea[d]
2	Rash on 25%-50% of skin	Bilirubin 3-6 mg/dL (51.3-102.6 µmol/L)	Diarrhea >1,000 mL/day
3	Rash on >50% of skin	Bilirubin 6-15 mg/dL (102.6-256.5 µmol/L)	Diarrhea >1,500 mL/day
4	Generalized erythroderma with bulla formation	Bilirubin >15 mg/dL (>256.5 µmol/L)	Severe abdominal pain with or without ileus
Grade			
0	None	None	None
I	Stage 1-2	None	None
II	Stage 3	or Stage 1	or Stage 1
III	—	Stage 2-3	or Stage 2-4
IV[e]	Stage 4	or Stage 4	—

[a]Use the "rule of nines" to determine body surface area involvement.

[b]Range given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin has been documented.

[c]Volume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area.

[d]Persistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.

[e]Grade IV may include lesser organ involvement but with extreme decrease in performance status.

tract (stomach, duodenum, or rectum). Hepatic GVHD usually is asymptomatic, consisting of hyperbilirubinemia and elevated alkaline phosphatase levels; increases in serum transaminases occur less consistently. The diagnosis can be made by biopsy, if possible.

The overall incidence of moderate-to-severe (grades II-IV) acute GVHD ranges from 20% to more than 80%.[57] Mortality directly attributable to acute GVHD or its treatment occurs in about 20% of patients. The incidence of GVHD is related to the degree of histocompatibility, number of T cells in the graft, donor and recipient age and gender, intensity of the conditioning regimen, source of hematopoietic cells (bone marrow vs peripheral blood), and prophylactic regimen. The most severe acute GVHD is observed in allogeneic HSCT with non-HLA-identical donors. In this setting, the incidence of grades II to IV acute GVHD can exceed 50% despite aggressive GVHD prophylaxis. Severe acute GVHD is a major cause of mortality with the risk of death increasing as the grade of GVHD increases. This risk is further increased if initial therapy is not effective.

Multiorgan acute GVHD and the drugs given to prevent or treat the disease are associated with delayed immunologic recovery and increased susceptibility to infections. Infection is often the primary cause of death in patients with GVHD. Patients with GVHD treated with an immunosuppressive regimen should receive prophylactic antiviral, antibacterial, and antifungal therapy and be monitored routinely for the occurrence of these infections.

Prevention of Acute Graft-Versus-Host Disease 9 Because treatment of established acute GVHD often is unsatisfactory, aggressive preventive measures usually are taken. The most common strategy used to prevent acute GVHD is to block the activation of T cells by administration of immunosuppressive agents.[56,57] Several immunosuppressive agents have been used, including methotrexate (MTX), cyclosporine (CSA), tacrolimus (TAC), sirolimus, mycophenolate mofetil, ATG, corticosteroids, and monoclonal antibodies directed at T cells. **Table 140-3** shows the doses, toxicities, and monitoring of immunosuppressive agents used to prevent or treat GVHD. Most GVHD prophylaxis regimens combine immunosuppressive agents that affect different stages of T-cell activation. The most commonly used GVHD prophylaxis regimens are CSA or TAC and MTX. Another strategy is removing or depleting most T cells from donor bone marrow ex vivo before transplant by physical separation or by treatment with monoclonal antibodies directed at T cells.

Initially, acute GVHD prophylaxis was single agent MTX administered on days 1, 3, 6, and 11 after transplant and then weekly. However, when a short course of MTX was combined with CSA, the two agents showed synergy and a survival benefit. The addition of a third agent, such as prednisone, to the CSA/MTX combination failed to improve overall outcomes. TAC, another calcineurin inhibitor, was shown to have similar results to CSA when combined with a short course of MTX. The combination of a calcineurin inhibitor with MTX remains a standard immunosuppressive regimen used today. Intravenous CSA or TAC is usually started a few days before or on the day of transplant. Patients are converted to oral formulations when they can be tolerated. CSA or TAC typically are given at full doses until days 50 to 100, gradually tapered in the absence of GVHD, and discontinued by day 180. MTX is still given IV on days 1, 3, 6, and 11 after transplant. About 70% of patients are able to receive all four doses of MTX. Elimination of one or more MTX doses may be associated with an increased risk of GVHD. However, toxicities such as severe mucositis, hepatotoxicity or the development of conditions that may prolong MTX systemic exposure (eg, renal failure or third spacing) are common reasons to omit the day 11 dose of MTX. For patients who experience significant toxicity from MTX, monitoring of MTX levels with leucovorin rescue may be warranted.

Despite standard prophylaxis with CSA or TAC and MTX, grade II to IV acute GVHD still occurs in 30% to 50% in matched related donor transplants and 40% to 70% in matched unrelated donor transplants. Because of the gastrointestinal and hematologic toxicities of MTX, and in an effort to improve prevention, other prophylactic regimens have been evaluated. Sirolimus, an mTOR inhibitor, has been successfully used for the prevention of rejection in solid organ transplant patients and has theoretical advantages when used as GVHD prophylaxis. This agent has been reported to promote immune tolerance through generation of regulatory T cells, has antiviral properties (CMV and Epstein-Barr virus), and has antitumor activity against some hematologic malignancies.[58] Several studies have shown encouraging results with sirolimus when combined with a calcineurin inhibitor (TAC or CSA) in the prevention of GVHD, and many clinicians believe that the combination of TAC and sirolimus is less toxic and more efficacious than CSA and sirolimus. A phase III randomized trial was conducted by the Blood and Marrow CTN that compared TAC and sirolimus with TAC and MTX as GVHD prophylaxis.[59] The primary endpoint, grade II to IV acute GVHD-free survival at day 114, and the incidence of grade II to IV GVHD were similar between the two groups (67% vs 62%, P=0.38; 26% vs 34%, P=0.48). Neutrophil and platelet engraftment were more rapid in the TAC and sirolimus group by two and three days, respectively. Toxicities were similar between the two groups, except that oropharyngeal mucositis was less severe in the TAC and sirolimus arm. Chronic GVHD, disease relapse and overall survival at 2 years from transplantation were not different between groups. Based on similar long-term outcomes and shorter time-to-engraftment, TAC and sirolimus can be considered as an alternative to TAC and MTX.

Other MTX-sparing strategies have been evaluated for GVHD prophylaxis. Mycophenolate mofetil through its metabolite, mycophenolic acid, inhibits proliferation of lymphocytes and is synergistic with calcineurin inhibitors. Mycophenolate mofetil with TAC was compared with TAC and MTX in recipients of matched related and unrelated donors. The results of two small randomized trials have shown less toxicity with mycophenolate mofetil with similar rates of acute GVHD or overall survival.[60,61]

Single-agent PTCy is another GVHD prophylaxis strategy which does not include a calcineurin inhibitor. Its immunosuppressive activity is related to its antiproliferative effects on rapidly dividing alloreactive T cells. Hematopoietic stem cells have high levels of aldehyde dehydrogenase, thus sparing them from the antiproliferative activity of Cy. In patients receiving MAC with single-agent Cy posttransplant prophylaxis, 43% developed grade II to IV GVHD, and 10% had grade III to IV GVHD. The incidence of chronic GVHD was 10% at 26 months.[62] The use of posttransplant Cy combined with other immunosuppressive agents such as mycophenolate mofetil and a calcineurin inhibitor has shown to be effective immunosuppression for Haplo-HSCT patients.

Other novel agents, such are bortezomib, and pentostatin have shown activity in preventing GVHD. The addition of bortezomib, given on days 1, 4, and 7 after transplant, to standard TAC and MTX in RIC mismatched unrelated donor transplants showed an incidence of grade II to IV GVHD that was comparable to patients who received HLA-matched transplants.[63] Pentostatin 1.5 mg/m^2 weekly for 4 weeks combined with a calcineurin inhibitor and MTX increased the proportion of patients alive without GVHD at day 100 compared with control participants.[64] Although the addition of these novel agents is intriguing, the role of these agents in GVHD prophylaxis is not clear. The Blood and Marrow CTN is conducting a phase II trial evaluating the activity of several novel three-drug GVHD prophylaxis regimens: bortezomib or maraviroc added to TAC and MTX; and PTCy added to TAC and mycophenolate mofetil (BMT-CTN 1203, NCT02208037).

TABLE 140-3 Immunosuppression for the Prevention and Treatment of GVHD

Agent	Dose	Drug Monitoring
Prevention		
Tacrolimus[54]	0.02-0.03 mg/kg/day IV beginning 1-3 days before transplant; change to PO when able to tolerate	Check serum levels ~72 hours after start and then 2-3 times/wk until stable (trough serum levels, 5-15 mcg/L [6.2-18.6 nmol/L]); serum creatinine for renal toxicity, CBC for hematologic toxicity, blood pressure for hypertension, and BMP for electrolyte abnormalities
Cyclosporine[54]	3-5 mg/kg/day IV beginning 1-3 days before transplant; change to PO when able to tolerate	Check blood levels ~72 hours after start and then 2-3 times/wk until stable (trough blood levels, 150-450 mcg/L [125-374 nmol/L]); serum creatinine for renal toxicity, CBC for hematologic toxicity, blood pressure for hypertension, and BMP for electrolyte abnormalities
Sirolimus[58]	Loading dose 12 mg PO on day +1 followed by 4 mg PO daily starting on day +2	Check serum levels ~24 hours after start and then 2-3 times/wk until stable (trough serum levels, 3-12 mcg/L [3-13 nmol/L]); serum creatinine for renal toxicity and CBC for hematologic toxicity
Methotrexate[54]	15 mg/m^2 IV on day +1 followed by 10 mg/m^2 IV on days +3, 6, and 11 *or* 5 mg/m^2 IV on days +1, 3, 6, and 11	Monitor for toxicity: mucositis, LFTs for hepatic dysfunction, serum creatinine for renal impairment, fluid retention, and CBC for hematologic toxicity; methotrexate levels are not routinely monitored unless the patient develops renal dysfunction or third spacing; doses may be omitted if severe mucositis or hepatotoxicity develops
Mycophenolate[60]	15 mg/kg/dose IV twice daily beginning on day 0; change to PO when able to tolerate	Monitor for toxicity: CBC for neutropenia and severe GI symptoms
Pentostatin[64]	1.5 mg/m^2 IV weekly × 4 doses beginning day +8	Monitor for toxicity: BMP for renal impairment and CBC for thrombotic thrombocytopenic purpura
Cyclophosphamide[12]	50 mg/kg/day IV on days +3 and +4	Monitor for toxicity: BMP for renal impairment, LFTs for hepatic toxicity (including SOS), urinalysis for hemorrhagic cystitis, vital signs and possible cardiac workup for pericarditis (only for symptomatic patients)
Rabbit anti-thymocyte globulin (ATG)[67]	2.5-5 mg/kg/day IV beginning 3 days before transplant	Monitor for toxicity: frequent vital signs during infusion for fever, rash, cardiovascular and GI dysfunction, anaphylaxis and serum sickness
Alemtuzumab[65]	10-20 mg/day IV daily beginning 4-5 days before transplant	Monitor for toxicity: fever, chills, infection, and anaphylaxis
Treatment		
Methylprednisolone[a] *or* Prednisone[a,57]	1-2 mg/kg/day	Monitor for toxicity: glucose for hyperglycemia, blood pressure for hypertension, labile mood, bone osteopenia, avascular bone necrosis, impaired wound healing, and adrenal insufficiency
Mycophenolate[57]	1.5-2 g PO daily in divided doses	As above
Sirolimus[57]	1-2 mg/day; then adjust based on levels	As above
Denileukin diftitox[57]	9 mcg/kg on days 1, 3, 5, 15, 17, and 19	Monitor for toxicity: LFTs for hepatic toxicity
Infliximab[57]	10 mg/kg/wk for at least 4 doses	Monitor for toxicity: anaphylaxis (rare)
Etanercept[57]	0.4 mg/kg/dose (maximum dose, 25 mg) SC twice weekly for 8 weeks	Monitor for toxicity; generally well tolerated
Rabbit ATG[57]	0.5 mg/kg for first dose followed by 1-1.5 mg/kg for subsequent doses	As above
Pentostatin[57]	1.5 mg/m^2 IV on days 1-3 and 15-17	As above

BMP, basic metabolic panel; CBC, complete blood count; GI, gastrointestinal; LFT, liver function test; PO, orally; SC, subcutaneous; SOS, sinusoidal obstruction syndrome.
[a]Considered 1st line therapy.

Another strategy to reduce the risk of acute GVHD is to reduce the number of donor T cells in the stem cell donation. In vivo T-cell depletion may be incorporated into conditioning regimens with agents such as ATG or alemtuzumab.[65] Uncontrolled trials of ATG with MAC regimens suggested that ATG could prevent GVHD, but may increase the risk of relapse and graft failure. A Cochrane review of six trials reported that ATG given with MAC regimens did decrease the risk of grade II to IV acute GVHD, but did not significantly improve overall survival, disease relapse or nonrelapse mortality.[66] The role of ATG with RIC transplantation has not been evaluated in a randomized controlled trial. The CIBMTR has reported that ATG recipients were more likely to have disease relapse, shorter overall and disease-free survival.[67] However, another observational study of European patients receiving RIC regimens reported reduced incidences of acute and chronic GVHD with similar relapse risk, nonrelapse mortality and survival.[68] Results from that study also suggested a dose effect with ATG doses of less than 6 mg/kg associated with improved outcomes. Based on these conflicting data, the use of ATG in RIC transplants should be reserved for clinical trials.

The role of ex vivo T-cell depletion is controversial.[56] Earlier reports of this technique were associated with an increased risk of graft failure, delayed immune reconstitution, leukemic relapse, CMV reactivation, and Epstein-Barr virus–related lymphoproliferative disorders. Most of these studies occurred when bone marrow was the preferred stem cell source. In a comparative analysis of patients who received ex vivo T-cell depletion or the standard calcineurin inhibitor and MTX prophylaxis, T cell–depleted stem cells

had lower rates of chronic GVHD. No differences in rates of graft rejection, leukemia relapse, treatment-related mortality, or overall survival rates were reported.[69]

It is difficult to predict which patients will develop acute GVHD. Risk factors are unable to accurately identify patients who will go onto develop GVHD. Biomarkers that could predict the development of GVHD could direct treatment before the patient develops severe disease. An ideal biomarker would be predictive of both disease onset and prognosis, inexpensive, and readily available in order to facilitate real-time clinical decision making. Many biomarkers have been studied including IL-2 receptor alpha, IL-8, peptidase inhibitor-3, regenerating islet-derived 3α (REG 3α), hepatocyte growth factor, serum albumin and microRNAs.[70] Although several biomarkers appear promising, they should not be used outside of a clinical trial.

Treatment of Acute Graft-Versus-Host Disease 10 Patients with mild skin-only acute GVHD (grade I) can be treated with topical corticosteroid preparations and counseled on the appropriate use of sunscreen. If a patient develops grades II to IV GVHD, prophylactic agents are continued, and high-dose corticosteroids in the form of IV methylprednisolone or oral prednisone are given.[56] The usual dosage is 1 to 2 mg/kg/day given in two divided doses; higher dosages have not been shown to be more efficacious. About 25% to 40% of patients with established acute GVHD respond to high-dose corticosteroids. If the patient responds, the corticosteroid dose is tapered gradually over several weeks to months, depending on response. In patients who experience a flare in GVHD during the taper phase, therapy consists of increasing the corticosteroid dose and then tapering more slowly. Oral beclomethasone dipropionate, a topically active corticosteroid, has been shown to reduce the frequency of gastrointestinal GVHD relapses when continued after prednisone taper.[71] Administration of beclomethasone has been associated with a better survival at 200 days and 1 year after transplant. Budesonide, another nonabsorbable corticosteroid, has also been evaluated in uncontrolled studies and may also reduce the need for sustained use of high-dose systemic corticosteroid administration.[71]

GVHD-associated mortality is strongly correlated to response to initial treatment and ranges from about 25% in patients who had a complete response to about 80% in patients who had no response or progressive disease. Several randomized trials have evaluated other agents combined with methylprednisolone in an effort to improve response to initial therapy for acute GVHD.[56] In a randomized phase II trial, 180 patients were treated with methylprednisolone 2 mg/kg/day combined with etanercept, mycophenolate mofetil, denileukin diftitox, or pentostatin.[72] After 28 days of treatment, efficacy and toxicity data suggested that the use of mycophenolate mofetil plus corticosteroids was the most promising regimen to compare with corticosteroids alone in a definitive phase III trial. This trial was halted early when a futility rule was met at a planned interim analysis. GVHD-free survival 56 days after randomization was not different between the groups. Based on the current published data, the use of glucocorticoid treatment with an additional agent for initial therapy of acute GVHD should only be done within the confines of a clinical trial.[57]

The mortality rate of patients with steroid-refractory GVHD is high. Criteria and indications for initiating secondary therapy for steroid-refractory acute GVHD have not been well defined in the literature. Although different centers may have varying criteria, in general, if the manifestations of acute GVHD in any organ worsen over 3 days of corticosteroid treatment or symptoms do not improve by 5 days, the patient likely will not respond to corticosteroids, and secondary therapy should be considered.[57] There is no standard treatment of patients with steroid-refractory acute GVHD because very few prospective comparative studies have been conducted to assess the efficacy of individual agents. Second-line therapy has consisted of continuation of corticosteroids with the addition of one or more of the following: ATG, mycophenolate mofetil, sirolimus, infliximab, etanercept, denileukin diftitox, alemtuzumab, or pentostatin.[57,73] One approach that has shown benefit as corticosteroid-sparing therapy is extracorporeal photopheresis. During this procedure, the patient's blood is exposed extracorporeally to 8-methoxypsoralen followed by ultraviolet A radiation and then returned to the patient. This process is thought to result in suppression of T-cell reactivity and induction of regulatory T cells. Clinical results have been positive, especially in patients with skin GVHD.[74] The choice of a second-line regimen for acute GVHD should be based on the risk of potential toxicities, interactions with other agents, convenience, and cost.

Clinical **Controversy...**

Optimal treatment of steroid-refractory GVHD is unclear. Comparative trials are needed to determine a standard approach to this difficult clinical condition.

Chronic Graft-Versus-Host Disease

Chronic GVHD is the major determinant of late transplant-related morbidity and mortality. The pathophysiology of chronic GVHD is poorly understood and likely involves inflammation, cell mediated immunity as well as humoral immunity and fibrosis.[75] The presentation of chronic GVHD is diverse and resembles a variety of autoimmune disorders. The incidence of chronic GVHD is 30% to 70%, and while its clinical manifestations usually present during the first year, it can also develop many years after transplant. Both HLA mismatching and transplantation from unrelated donor transplants help explain the growing incidence of chronic GVHD. The diagnosis of chronic GVHD is often based on clinical presentation, but biopsies of affected organs can help differentiate acute from chronic GVHD. More recently, the use of biomarkers has been studied in order to facilitate diagnosis and predict treatment response.[75] The risk of chronic GVHD increases with a previous history of acute GVHD, increasing donor and recipient age, patients who receive transplants from HLA-nonidentical donors and in patients who receive PBSC transplants (especially with higher $CD34^+$ cell doses). Unlike acute GVHD, prophylactic immunosuppression does not appear to reduce the incidence or severity of chronic GVHD.

Chronic GVHD resembles autoimmune diseases and can affect any organ or tissue of the body. The most common sites involved are the skin, mouth, liver, and eye, but other sites include the gastrointestinal tract, joints, muscles, and lungs. The National Institutes of Health (NIH) Consensus Development Project developed standardized criteria for the diagnosis of chronic GVHD and proposed a clinical scoring system for the evaluation of patients with chronic GVHD based on the extent of organ damage and degree of functional impairment.[75] The Working Group recommends that the diagnosis of chronic GVHD be made with the presence of at least one diagnostic clinical sign of chronic GVHD (eg, poikiloderma or esophageal web) or a distinctive manifestation (eg, keratoconjunctivitis sicca) confirmed by biopsy or other test (eg, Schirmer test). For patients with overlap syndrome, the NIH Working Group now recommends documenting all specific manifestations (acute and chronic) when establishing a diagnosis.

The clinical scoring system categorizes chronic GVHD into mild, moderate, and severe.[75] Mild chronic GVHD involves only one or two organs or sites (except the lung) with no clinically significant functional impairment. Moderate chronic GVHD involves at least one organ or site with clinically significant but no major disability, three or more organs or sites with no clinically significant functional impairment, or mild lung involvement. Severe chronic GVHD indicates major disability caused by chronic GVHD or at least moderate lung involvement.

Patients with mild skin-only chronic GVHD can be treated with a variety of topical preparations, such as clobetasol, TAC, and

pimecrolimus.[76] Other organs such as mouth, eyes and genital tract may also be treated with aggressive local therapy. Initial treatment of patients with more severe or systemic involvement of chronic GVHD consists of prednisone 0.5 to 1 mg/kg/day followed by taper with or without a calcineurin inhibitor. Although calcineurin inhibitors do not conclusively improve outcomes, they are often used to reduce toxicities of prolonged steroid therapy, especially in patients who may be at high risk for prednisone-related complications.[77] Treatment is continued until signs and symptoms of the disease have resolved and then are tapered gradually over an extended period of time. Patients with chronic GVHD may require prolonged immunosuppressive treatment for an average of 2 to 3 years from the initial diagnosis.

In addition to treatment specifically for chronic GVHD, ancillary therapies and supportive care should be recommended to lessen the symptoms of chronic GVHD.[77] Patients should be educated on the use of sunscreens (and avoidance of sun exposure) to reduce skin injury and exacerbation of GVHD skin lesions. Nonsclerotic skin lesions without erosions or ulcerations may respond well to emollients in addition to topical corticosteroids. Patients should be advised to maintain good oral hygiene with routine dental care. Saliva substitutes can be given for dry mouth symptoms, and topical corticosteroid gels can be used for localized and symptomatic oral lesions. Artificial tears or, if necessary for more severe symptoms, CSA or corticosteroid eye drops are useful for patients with chronic GVHD manifesting as dry eyes or conjunctivitis. Physical therapy is recommended to reduce functional loss as a result of steroid myopathy, joint contractures, and deconditioning.

Patients who do not respond to initial therapy have a very poor prognosis. Indications for secondary treatment include worsening symptoms, involvement of new organs, no improvement of symptoms after 1 month of therapy, inability to decrease steroid dose or significant treatment-related toxicity. Uncontrolled trials have investigated several therapies with varying degrees of success. To date, no consensus has been reached regarding the optimal choice for salvage therapy. When choosing initial salvage therapy, clinicians should consider agents with documented activity and an adequate safety profile as well as agents that are steroid sparing. Agents with reported activity in refractory chronic GVHD include thalidomide, extracorporeal photophoresis, TAC, sirolimus, pentostatin, mycophenolate mofetil, hydroxychloroquine, rituximab, imatinib, and others.[77,78]

Monitoring for long-term drug toxicities and infectious complications is critical during long-term immunosuppression. Infection is the primary cause of death in patients with chronic GVHD, and antimicrobial prophylaxis is an important component of the care of patients being treated for chronic GVHD.[77,78] Patients should receive oral trimethoprim–sulfamethoxazole, penicillin, an antifungal azole agent, and acyclovir to prevent infections commonly seen in immunocompromised patients. Routine monitoring for CMV reactivation should be performed. Some HSCT centers also administer IV immunoglobulin to patients with low serum immunoglobulin G levels. Patients who remain on long-term steroids should be monitored for steroid-induced osteoporosis and diabetes mellitus. Other potential long-term complications of chronic GVHD therapies include hyperlipidemia, cataracts, myelosuppression, elevated blood pressure, and renal dysfunction.

Infection

Patients undergoing high-dose chemotherapy with autologous or allogeneic HSCT are severely immunocompromised and therefore are at high risk for bacterial, fungal, and viral infections.[29,32] Management of these infections is discussed in detail in Chapters 121 and 122.

Late Complications

With the success of HSCT, the number of long-term survivors has grown. Many survivors experience delayed complications of transplantation and treatments used to prevent or treat those complications, including restrictive and obstructive pulmonary disease, bone and joint disease (including osteoporosis and avascular necrosis), cataract formation, endocrine dysfunction (including sterility and thyroid dysfunction), impaired growth and development, infections, cardiovascular disease, chronic renal and hepatic dysfunction, and secondary malignancies.[29,32,79] These effects are more frequent after allogeneic compared with autologous HSCT and among allogeneic HSCT patients, those with chronic GVHD tend to have a higher prevalence of multiple health conditions than those without chronic GVHD.[29,79] Physical recovery tends to occur earlier than psychological or work recovery. Full recovery usually takes several years, and about two-thirds of patients are without major limitations by 5 years. Both allogeneic and autologous transplants are associated with a several-fold increase in risk of premature death; relative mortality decreased with time but remained significantly elevated even 10 years after transplant. The leading cause of death is relapse of primary disease in both allogeneic and autologous HSCT patients, but allogeneic HSCT patients also continue to die from complications of chronic GVHD, while autologous HSCT patients more frequently succumbed to secondary malignancies.[29,79] Long-term monitoring of HSCT patients is required, both by transplant clinicians and primary care providers who are knowledgeable in the care of these patients, to screen for, prevent and treat late complications when such interventions are available. In 2012, the CIBMTR (in partnership with leading transplant organizations) published posttransplant care recommendations for adult and pediatric autologous and allogeneic HSCT recipients (www.cibmtr.org/posttransplant).

Assessment of Nutrition Status and Nutrition Requirements

141

Katherine Hammond Chessman and Vanessa J. Kumpf

KEY CONCEPTS

1. Malnutrition encompasses both overnutrition (obesity) and undernutrition.
2. Nutrition screening is distinct from assessment; it should be designed to quickly and consistently identify those with preexisting malnutrition or those at risk for malnutrition.
3. A comprehensive nutrition assessment is required to formulate a nutrition care plan for an individual found to be nutritionally-at-risk for nutrition-related poor outcomes.
4. A nutrition-focused physical examination and medical, surgical, and dietary history are essential components of a comprehensive nutrition assessment.
5. Evaluation of anthropometric measurements (weight, height, and head circumference) should be based on published standards.
6. Laboratory assessment of visceral proteins and other nutrition-related parameters must be interpreted in the context of physical findings, medical and surgical history, including acute and chronic inflammation, and clinical status.
7. Micronutrient or macronutrient deficiencies or toxicities or risk factors for these deficiencies or toxicities can be identified by a comprehensive nutrition assessment.
8. Evidence-based patient-specific goals should be established considering the patient's clinical condition and the need for maintenance or repletion in adults or continued growth and development in children.
9. Validated predictive equations are most often used to determine energy requirements; however, if available, indirect calorimetry is the most accurate bedside method to determine energy requirements.
10. Drug–nutrient interactions can affect nutrition status and the response to and adverse effects seen with drug therapy.

Nutrition care is a vital component of quality patient care and nutrition screening and assessment are integral parts of the nutrition care process. No single clinical or laboratory parameter is an absolute indicator of nutrition status, so information from a number of them must be collected and analyzed. This chapter reviews the tools most commonly used for accurate, relevant, and cost-effective nutrition screening and assessment, including various methods used to determine patient-specific macro- and micronutrient requirements and potential drug–nutrient interactions.

CLASSIFICATION OF NUTRITION DISEASE

1 Malnutrition is a consequence of nutrient imbalance. In general, deficiency states can be categorized as those involving protein and calories or single nutrients such as individual vitamins or trace elements. Starvation-associated malnutrition, marasmus, results from prolonged inadequate intake, absorption, or utilization of protein and energy. It occurs in patients with an inadequate food supply, anorexia nervosa, major depression, and malabsorption syndromes (Fig. 141-1). Somatic protein (skeletal muscle) and adipose tissue (subcutaneous fat) wasting occurs, but visceral protein (albumin [ALB] and transferrin [TFN]) production is usually preserved. Weight loss may exceed 10% of usual body weight (UBW; typical weight). Patients with starvation-associated malnutrition commonly have a prototypical wasted appearance.[1,2] Kwashiorkor, a form of starvation-associated malnutrition develops as a consequence of inadequate protein intake and is usually seen in areas where there is famine or limited food supply. In the United States, kwashiorkor has been seen in children and elderly individuals who are abused or neglected. Patients with kwashiorkor may not appear malnourished because of relative adipose tissue sparing, especially with mild undernutrition, but visceral (and to some degree somatic) protein stores are depleted, resulting in severe hypoalbuminemia and edema in more advanced cases. In patients with starvation-related malnutrition, enhancing nutritional intake or bypassing impaired absorption with specialized nutrition support can reverse the condition.[1,2]

Malnutrition can also develop as the result of an acute or chronic disease, especially those associated with mild-to-severe inflammation (see Fig. 141-1).[3,4] Patients with severe acute disease or injury (major infections, burns, trauma, and traumatic brain injury) or with chronic inflammatory diseases, organ failure, or cancer can develop disease-related malnutrition because of increased metabolic demands despite seemingly adequate nutrition intake. Individuals with starvation-related malnutrition can develop marked malnutrition when a severe injury or inflammatory process occurs simultaneously. In patients with disease-related, acute or chronic, malnutrition, simply providing nutrients in usual or even increased amounts may not be sufficient to reverse the nutrient imbalance. Regardless of the cause, undernutrition can result in changes in subcellular, cellular, or organ function that increase the individual's risks of morbidity and mortality.

Nutrition assessment can also be used to identify overnutrition: overweight and obese individuals and those at risk of becoming overweight or obese. Obesity is a major global healthcare concern: during 2011 to 2014, approximately 69% of U.S. adults were overweight (defined as a body mass index [BMI] greater than or equal to 25 kg/m^2)[5], and about 36.5% (82 million) were obese

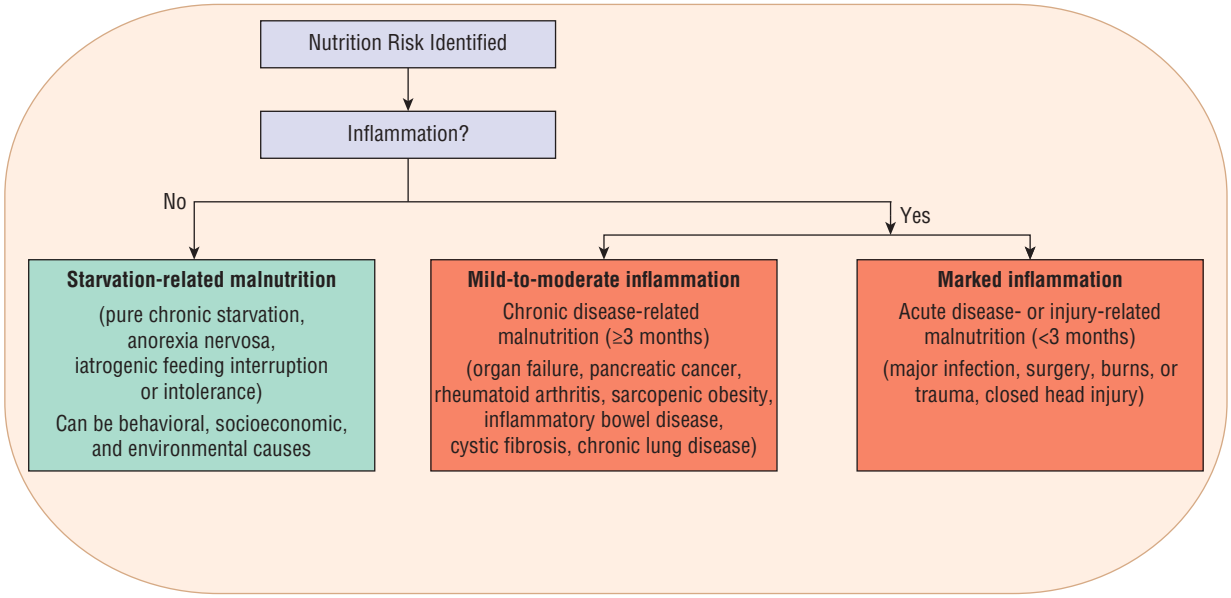

FIGURE 141-1 Etiologic basis for malnutrition diagnosis. (*Adapted from references 4 and 35.*)

(BMI greater than or equal to 30 kg/m^2).[6] Obesity prevalence in 2014 ranged from 21% in Colorado to about 36% in West Virginia, Arkansas, and Mississippi.[7] Additionally, 17% (12.7 million) of all U.S. children and adolescents (age 2-19 years) were obese (BMI greater than or equal to 95th percentile for age on the gender-appropriate BMI-for-age Centers for Disease Control and Prevention's [CDC] 2000 growth chart).[5,6,8] Many more children (approximately 32%) were overweight (BMI greater than or equal to 85th percentile for age).[5] Interestingly, there was no change in obesity prevalence among U.S. adults or children from 2011 to 2014 compared with 2003 to 2004.[6] After a steady increase in obesity prevalence since 1999, this leveling trend is encouraging. The consequences of obesity are numerous and include type 2 diabetes mellitus, cardiovascular disease, hypertension, and stroke (see Chapter 144).

Malnutrition is associated with higher morbidity and mortality rates in many settings. An effective nutrition screening program will consistently identify patients at nutrition-related risk alerting trained clinicians to perform a comprehensive nutrition assessment to accurately characterize baseline nutrition status, estimate nutrition needs, and develop a patient-specific nutrition care plan. Diligent monitoring of ongoing nutrition status can ensure that nutrition-related goals are being met and improve patient outcomes.

NUTRITION SCREENING

2 Nutrition screening is distinct from nutrition assessment.[9] It is not practical, cost-effective, or clinically warranted to conduct a comprehensive nutrition assessment on every individual; thus, nutrition screening provides a reliable, systematic method to identify persons for whom a detailed nutrition assessment is needed. A nutrition screen can be used to detect those who are overweight, obese, malnourished, or at risk for malnutrition; predict their health outcomes as a result of nutrition-related factors; and identify those who would benefit from nutritional intervention.

The ideal nutrition screening tool is quick, simple, and noninvasive and can be done by lay and healthcare providers in homes, long-term care facilities, ambulatory care clinics, and hospitals. Since 1995, the Joint Commission has included nutrition screening and assessment in its performance standards for accredited healthcare institutions.[10] Each entity must have a written nutrition screening process and criteria that determine when a more in-depth assessment will be performed. In hospitals, a nutrition screen must be completed within 24 hours of admission on all patients unless the institution's policy excludes certain patient populations. In hospitals, most screens are done by nurses.[11] For patients who are determined to be '*nutritionally-at-risk*' by the screening criteria, a comprehensive nutrition assessment must be completed within 48 to 72 hours. Periodic rescreening should occur at regular intervals determined by the institution and the patient population, usually every 3 to 7 days. Most nutrition assessments are completed by dietitians but may be completed by others including pharmacists with training in nutrition support.[11] For outpatients, nutrition screening should occur ideally at the first visit with a new provider and thereafter as warranted by the patient's condition.

Risk factor identification is the foundation of appropriate nutrition screening. Risk factors for undernutrition include recent unintended weight loss, presence and severity of acute and chronic disease states, drug and or other treatments, and socioeconomic factors that may result in a decreased nutrient intake or altered nutrient absorption, metabolism, or utilization. Risk factors for obesity include a family history of obesity, certain medical diagnoses (eg, polycystic ovary syndrome, Prader-Willi syndrome, and Cushing's syndrome), poor dietary habits, inadequate exercise, and some drug therapies. Various rating and classification systems have been proposed to screen for nutrition risk and guide subsequent interventions.[2,9,12–17] The Malnutrition Screening Tool (MST)[16] and the Subjective Global Assessment (SGA) are among the most frequently utilized.[17,18] In general, checklists of varying complexity are used to quantify a person's food and alcohol consumption habits; ability to buy, prepare, and eat food; weight history; diagnoses; medical and surgical procedures; drug therapies; and, history of specialized nutrition support (enteral or parenteral nutrition). Nutrition screening for children is based on the evaluation of growth parameters against the CDC or World Health Organization (WHO) growth charts[8,19] and the presence of medical conditions known to increase nutrition risk. Current estimates of the prevalence of in-hospital malnutrition for pediatric and adult patients, range from 13% to 88% depending on the patient population, disease severity, and the criteria used to identify its occurrence.[11] In any setting, patients determined to be nutritionally-at-risk should receive a timely comprehensive

nutrition assessment to verify nutrition-related risk and to formulate a nutrition care plan with monitoring parameters to ensure that desired outcomes are met.

ASSESSMENT OF NUTRITION STATUS

3 A comprehensive nutrition assessment is the first step in formulating a patient-specific nutrition care plan. Goals of nutrition assessment include identification of the risk factors associated with malnutrition, including disorders resulting from macro- or micronutrient deficiencies (undernutrition), obesity (overnutrition), or impaired nutrient absorption, metabolism or utilization; determination of the risk of nutrition-related complications; estimation of nutrition needs; and establishment of baseline nutrition parameters against which to measure nutrition therapy outcomes. Nutrition assessment should include a nutrition-focused medical, surgical, and dietary history; a nutrition-focused physical examination, including anthropometrics; and laboratory measurements.

Nutrition-Focused History and Physical Examination

4 The nutrition-focused medical, surgical, and dietary history serves to identify factors that predispose to malnutrition (eg, prematurity, chronic diseases, gastrointestinal [GI] dysfunction, alcohol abuse, and acute or chronic inflammation [cancer, surgery, and trauma]), and overnutrition (eg, poor dietary habits, limited exercise, chronic disease, and family history). The clinician should determine any history of weight gain or loss (intended or unintended), anorexia, vomiting, diarrhea, decreased or restrictive food intake, including enteral or parenteral nutrition (Table 141-1).

The nutrition-focused physical examination should assess each body system for physical findings associated with nutrition-related problems, such as muscle wasting, edema, or loss of subcutaneous fat.[20,21] The presence of findings commonly associated with malnutrition such as alopecia, dermatitis, glossitis, cheilosis, or jaundice should be noted (Table 141-2). Additionally, nonspecific indicators of ongoing inflammation or stress (eg, fever and tachycardia) should be documented (Table 141-3).

The SGA is a representative example of a relatively simple, reproducible, cost-effective, bedside approach to nutrition assessment.[17,18] This screening tool assesses five aspects of the medical and dietary history: weight change in the previous 6 months, dietary changes, GI symptoms, functional capacity of the patient, and disease states known to affect nutrition status. Weight loss of less than 5% of UBW is considered a "small" loss, 5% to 10% loss is "potentially significant," and more than a 10% loss is "definitely significant."

TABLE 141-1 Pertinent Data from a Nutrition-Focused Medical, Surgical, and Dietary History

Nutrition intake and dietary habits
Anorexia
Unusual or absent taste
Dietary intake, including vegetarianism
Specialized diets, including enteral or parenteral nutrition
Supplemental vitamin, mineral, or herbal intake
Food allergies or intolerance
Underlying pathology with nutritional effects
Chronic infections or inflammatory states
Neoplastic diseases
Endocrine disorders
Chronic illness, including pulmonary disease, liver cirrhosis, and kidney failure
Hypermetabolic states, such as trauma, burns, and sepsis
Digestive or absorptive disease, nausea, vomiting, diarrhea, and constipation
Hyperlipidemia
End-organ effects
Weight changes
Skin or hair changes
Exercise intolerance or fatigue
Gastrointestinal tract symptoms such as diarrhea, vomiting, and constipation
Gastrointestinal surgery
Bariatric surgery
Small bowel or colon resection or diversion
Gastrectomy
Miscellaneous
Catabolic medications or therapies, including corticosteroids, immunosuppressive agents, radiation, or chemotherapy
Other medications, including diuretics, laxatives, antipsychotics, or anabolic steroids
Genetic background, including body habitus of parents, siblings, and family
Alcohol or drug abuse

Data from references 1, 2, 9, 12, and 15-18.

TABLE 141-2 Physical Examination Findings Suggestive of Malnutrition

General
Edema (especially ankle and sacral)
Cachexia or obesity
Ascites
Signs and symptoms of dehydration, including poor skin turgor, sunken eyes, orthostasis, or dry mucous membranes
Muscle wasting or loss of subcutaneous fat
Fever
Tachycardia
Alopecia/dry brittle hair
Skin and mucous membranes
Thin, shiny, dry, or scaly skin
Decubitus ulcers
Ecchymoses or perifollicular petechiae
Poor healing of surgical or traumatic wounds
Pallor or redness of gums or fissures at mouth edge
Glossitis, stomatitis, or cheilosis
Musculoskeletal
Retarded growth or short stature
Bone pain or tenderness or epiphyseal swelling
Muscle mass less than expected for habitus, exercise level
Neurologic
Ataxia, positive Romberg test result,[a] or decreased vibratory or position sense
Nystagmus
Seizures or paralysis
Encephalopathy
Failure to meet age-appropriate developmental milestones
Hepatic
Jaundice
Hepatomegaly

[a]The Romberg test is a neurologic test used to detect problems with balance.

Data from references 2, 9, 12, 13, and 15-22.

TABLE 141-3 Assessment of Inflammation

Laboratory Assessment	Clinical Findings	Acute/Chronic Disease States
Decreased	Fever	Cancer
Albumin	Hypothermia	Celiac disease
Transferrin	Infection	Cystic fibrosis
Prealbumin	Urinary tract	Inflammatory bowel disease
Nitrogen balance	Pneumonia	Organ failure
Elevated	Bacteremia	Pancreatitis
CRP	Wound/incision	Rheumatologic disorders
Glucose	Abscess	Rheumatoid arthritis
% neutrophils	Trauma	Systemic lupus erythematosus
Decreased or increased	Burns	
WBC		
Platelets		

CRP, C-reactive protein; WBC, white blood cell count.

Data from reference 4.

Dietary intake is characterized as normal or abnormal, and the duration and degree of abnormal intake are noted. The presence of daily GI symptoms (anorexia, nausea, vomiting, and diarrhea) for longer than 2 weeks is significant. Functional capacity assesses the patient's energy level and whether the patient is active or bedridden. Finally, disease state impact on metabolic demands (no, low, moderate, or high stress) is documented. Four physical examination findings are rated as normal, mild, moderate, or severe: loss of subcutaneous fat (triceps and chest), muscle wasting (quadriceps and deltoids), edema (ankle and sacral), and ascites. The patient's nutrition status is then rated as adequately nourished, moderately malnourished or suspected of being malnourished, or severely malnourished. Critics of the SGA find it time-consuming and complex.[2] Another example of a simple screening tool, the Mini Nutritional Assessment, has been used extensively in geriatric patients and found to be useful in several care settings.[2,22]

Anthropometric Measurements

5 Anthropometric measurements, which are physical measurements of the size, weight, and proportions of the human body, are important parameters used to assess nutrition status. Common measurements are weight, stature (standing height or recumbent length), head circumference (for children younger than 3 years of age), and waist circumference. Measurements of limb size, such as skinfold thickness, midarm muscle circumference, and wrist circumference, may be useful in selected individuals. Bioelectrical impedance analysis (BIA) is also an anthropometric assessment tool. An individual's body measurements can be compared with normative population standards to identify clinical concerns and may be repeated at various intervals to monitor response to a nutrition care plan. In adults, nutrition-related changes in anthropometric measurements tend to occur slowly; several weeks or more may be required before detectable changes are noted. In infants and young children, changes occur more quickly. Significant acute changes in weight and skinfold thickness usually reflect changes in hydration, which must be considered when interpreting these parameters.

Weight, Stature, and Head Circumference

Body weight is a nonspecific measure of body cell mass, representing skeletal mass, body fat, and the energy-using component lean body mass (LBM). Fat-free mass includes skeletal muscle, bone, connective tissue, organs, and water while fat mass includes the subcutaneous fat beneath the skin and the visceral (internal) fat. Change in weight over time, particularly in the absence of edema, ascites, or voluntary losses, is an important indicator of altered LBM. Actual body weight (ABW) interpretation should include consideration of ideal weight-for-height, referred to as ideal body weight (IBW), UBW (typical weight), fluid status, and age (Table 141-4). Patients

TABLE 141-4 Evaluation of Body Weight and Waist Circumference

Parameter	Interpretation	NHLBI Obesity Classification	Waist Circumference	
ABW compared with IBW				
ABW <69% IBW	Severe malnutrition			
ABW 70%-79% IBW	Moderate malnutrition			
ABW 80%-89% IBW	Mild malnutrition			
ABW 90%-120% IBW	Normal			
ABW >120% IBW	Overweight			
ABW ≥150% IBW	Obese			
ABW ≥200% IBW	Morbidly obese			
ABW compared with UBW				
ABW 85%-95% UBW	Mild malnutrition			
ABW 75%-84% UBW	Moderate malnutrition			
ABW <75% UBW	Severe malnutrition			
BMI (kg/m²)				
Adults				
<16	Severe malnutrition			
16-16.9	Moderate malnutrition			
17-18.9	Mild malnutrition			
19-24.9	Healthy		Disease risk above BMI-related risk[a]—Waist Circumference	
Older Adults 22-30	Healthy		Women ≤89 cm (35 in) Men ≤102 cm (40 in)	Women >89 cm (35 in) Men >102 cm (40 in)
25-29.9	Overweight		Increased	High
30-40	Moderate obesity			
30-34.9		I	High	Very high
35-39.9		II	Very high	Very high
>40	Severe or morbid obesity	III	Extremely high	Extremely high
Children				
BMI for age <5th percentile	Underweight			
BMI for age 5th-84th percentile	Healthy			
BMI for age 85th-94th percentile	Overweight			
BMI for age ≥95th percentile	Obese			

[a]Increased risk for Type 2 diabetes mellitus, hypertension, and cardiovascular disease.

ABW, actual body weight; BMI, body mass index; IBW, ideal body weight; NHLBI, National Heart, Lung, and Blood Institute; UBW, usual body weight.

Data from references 8, 13, 36, and 38-41.

who are dehydrated will have a decreased ABW but not a loss of LBM. Once rehydrated, these patients must be reweighed to establish a baseline weight for nutrition evaluation. Edema and ascites increase total body water (TBW), thus increasing ABW but not LBM. Because the ABW of patients with severe edema and ascites should not be used for nutrition assessment; practitioners often use an estimated "*dry weight*" to account for this increase in TBW. Both acute and chronic changes in fluid status can affect the ABW; these changes often can be detected by monitoring the patient's daily fluid intake and output. Accurate weight measurement can be difficult in critically ill patients because of their clinical condition and stress-related water retention.

The IBW is a population reference standard against which the ABW can be compared. IBW-for-height reference tables are available, and IBW can be calculated using mathematical equations based on gender and height. Using the Hamwi method, IBW is calculated as (48 kg [106 lb] + 2.7 kg [6 lb] × [inches over 5 feet]) for adult men and for adult women as (45 kg [100 lb] + 2.3 [5 lb] × [inches over 5 feet]).[23] Using the Devine equations, IBW is calculated as 50 kg + (2.3 × inches over 60 feet) for adult men and 45.5 kg + (2.3 × inches over 6 feet) for adult women.[24] For both equations, a range of ± 4.5 kg for large or small frame size is used for interpretation purposes. For obese adults, use of an adjusted ABW has been recommended for nutrition-related calculations, where adjusted ABW = ([ABW – IBW] × 0.25-0.5) + IBW.[25-27] The use of this adjusted ABW is not evidence-based because most of the metabolic rate equations were formulated using ABW in a mix of obese and non-obese individuals.[25,27,28] The IBW of a child can be calculated as ([height in cm]^2 × 1.65)/1,000. Alternatively, IBW-for-height can be determined by identifying the body weight corresponding to the same growth channel as the child's measured stature on the appropriate CDC or WHO growth chart. Comparison with the 50th percentile weight-for-age has been suggested but can be misleading if the child's height is not also at the 50th percentile.

Change in weight over time can be calculated as a percentage of UBW (see Table 141-4). Use of UBW as a reference point may provide a more accurate reflection of clinically significant weight changes over time. However, unless documented in the medical record, determining UBW depends on patient or family recall, which may be inaccurate. The use of UBW avoids the inherent problems with normative tables and documents comparative changes in body weight. All weight changes should be interpreted relative to time. Unintentional weight loss, especially rapid weight loss (5% of UBW in 1 month or 10% of UBW in 6 months), increases the risk of nutrition-related poor clinical outcomes.[13,14]

Adult stature is determined by both genetics and nutrition. In infants, recumbent length is measured; in older children and adults, a standing height is preferred. If a standing height cannot be measured, the measurement of demispan can be used to estimate height. Demispan is determined in a seated patient by measuring the distance from the sternal notch to the web between the middle and ring fingers along a horizontally outstretched arm with the wrist in neutral rotation and zero extension or flexion. Demispan may more accurately assess stature in elderly adults, especially those with kyphosis or vertebral collapse. After the demispan is measured, height is estimated using the following equations: women: height (cm) = (1.35 × demispan [cm]) + 60.1; men: height (cm) = (1.4 × demispan [cm]) + 57.8.[29] Knee height may also be used to estimate stature and is especially helpful in patients with limb contractures, such as patients with cerebral palsy.[29-31] Knee height is measured from just under the heel to the anterior surface of the thigh just proximal to the patella. Using the average of two measurements rounded to the nearest 0.1 cm, height can be estimated using the following equations: women: height (cm) = 84.88 (0.24 × age [years]) + (1.83 × knee height [cm]); men: height (cm) = 64.19 (0.04 × age [years]) + (2.02 × knee height [cm]).[31]

Appropriate growth is the best indicator of adequate nutrition in a child. At each medical encounter, weight, stature, head circumference (until 3 years), and BMI (after 2 years) should be plotted on the WHO (younger than 2 years) or CDC gender- and age-specific growth curves.[8,19] The CDC charts were revised in 2000 from U.S. data only and indicate how U.S. children grow. The WHO charts developed in 2006 are preferred in those younger than 2 years because they include data from infants from six industrialized countries including the United States who were predominantly breastfed for the first 4 months of life and who were receiving some breast milk at 12 months, conditions felt to ensure optimal growth.[19] Specialized charts are also available for assessment of short- and long-term growth of premature infants.[32,33] For premature infants with corrected postnatal age of 40 weeks or more, the WHO growth charts can be used; however, weight-for-age, length-for-age, and head circumference-for-age should be plotted according to corrected postnatal age until 2 years, 3.5 years, and 3 years of age, respectively.

Recommended intervals between measurements in young children are weight, 7 days; length, 4 weeks; height, 8 weeks; and head circumference, 7 days in infants and 4 weeks in children until 3 years of age. Growth velocity can be used to assess growth at intervals too close to plot accurately on a growth chart (Table 141-5). In newborns, average weight gain is 10 to 20 g/kg/day (24-35 g/day in term infants; 10-25 g/day in preterm infants). The rate of weight gain declines considerably after 3 months of age; children 6 to 10 years of age gain about 2 to 3 kg/yr. The adolescent 'growth spurt' typically begins at 9 to 10 years in girls and 11 to 12 years in boys. During the 11 to 13 year-old-interval of maximum growth in height, girls will gain about 10 kg (22 lb) while boys gain 15.5 kg (33 lb). Length increases rapidly in infancy (see Table 141-5). In children 6 to 10 years of age, height increases by 2 to 3 in/yr (approximately 5-7.5 cm/yr) and continues until about 16 to 18 years of age in girls and 18 to 20 years of age in boys. Head growth (measured by head circumference), usually 0.5 cm/wk (0.2 in/wk) during the first year of life, can be compromised during periods of critical illness or malnutrition. Rapid head growth, especially at a rate faster than expected, suggests hydrocephalus and should be further evaluated.

Failure to thrive (growth failure) in children has commonly been defined as weight-for-age, length-for-age, BMI-for-age, or weight velocity below the 5th percentile or a weight deceleration crossing two or more major percentiles (major percentiles are defined as 97th, 95th, 90th, 75th, 50th, 25th, 10th, 5th, and 3rd).[34] In children, a significant weight loss is defined as: greater than 2% in 1 week; greater than 5% in 1 month; greater than 7.5% in 3 months; and, greater than 10% in 6 months. Malnutrition can be defined by using z-scores for weight-for-length, BMI-for-age, or length- or

TABLE 141-5 Expected Growth Velocities in Term Infants and Children

Age	Weight (g/day)	Height (cm/mo)[a]
0-3 mo	24-35	2.8-3.4
4-6 mo	15-21	1.7-2.4
7-12 mo	10-13	1.3-1.6
1-3 yr	5-9	0.6-1
4-6 yr	5-6	0.5-0.6
7-10 yr	7-11	0.4-0.5

Example of growth assessment
Age: 2 mo; weight: 3.2 kg; weight at 1 mo of age, 3.1 kg; time since last weight was obtained: 30 days.
Growth velocity = ([3.2 kg–3.1 kg] × 1,000 g/kg)/30 days = 3.3 g/day.
Interpretation: suboptimal growth; comprehensive nutrition assessment needed.

[a]Growth velocity of 1 cm/mo is equivalent to 0.4 in/mo.
Data from references 8 and 19.

height-for age: -1, mild malnutrition -2, moderate malnutrition; and, -3, severe malnutrition.[35] Weight-for-height evaluation is age independent and helps differentiate a stunted child (chronic malnutrition) from a wasted child (acute malnutrition). Short stature can be associated with chronic undernutrition, but short stature in the absence of poor weight gain suggests another etiology, such as growth hormone deficiency or constitutional growth delay.

Body Mass Index

Body mass index can be calculated as either body weight in kilograms divided by height in meters squared (kg/m^2) or body weight in pounds multiplied by 703 divided by height in inches squared (lb/in^2). The 2013 AHA/ACC/TOS joint guideline for management of obesity in adults endorses using BMI as the first step but not the sole criterion, to judge potential health risk.[36] A BMI of 25 kg/m^2 or higher is considered a risk factor for premature death and disability. Health risks increase as the BMI increases; however, individual variation, especially in very muscular persons, can lead to erroneous classification of nutrition status when BMI alone is used. Thus, BMI should be interpreted based on characteristics such as sex, frame size, race/ethnicity, and age. For example, at the same BMI, a woman tends to have more body fat than a man, and an older adult would have more body fat than a younger one. Also, Asians may have more body fat than whites, especially at lower BMIs, and thus health risks may be associated with lower BMIs in individuals of Asian descent.[37]

In general, a BMI between 18.5 and 24.9 kg/m^2 is indicative of a healthy weight, between 25 kg/m^2 and 29.9 kg/m^2 signifies being overweight, and 30 kg/m^2 or higher indicates obesity (see Table 141-4).[13,36,38] These BMI classifications may not be appropriate for those older than 60 years, where a BMI between 25 kg/m^2 and 30 kg/m^2 is not associated with the same increased nutrition-related risks seen in younger individuals.[39,40] BMI has also been used to assess undernutrition (less than 18.5 kg/m^2 indicates undernutrition), but this relationship is not as well established.[13,38] Children 2 years of age and older are considered overweight if their BMI is at or above the 85th percentile on the age- and gender-specific CDC BMI chart and obese if the BMI is at or above the 95th percentile.[8] Use of these charts at each medical encounter helps to heighten awareness of children whose BMI and family history put them at risk for adult obesity and its associated complications.

Waist Circumference

Waist circumference is a simple measurement used to assess abdominal (visceral) fat. Extra weight around the waist rather than peripheral (subcutaneous) fat confers a greater health risk than extra weight around the hips and thighs. The larger the waist, the greater the risk of obesity-related complications, especially diabetes mellitus, cardiovascular disease, and all-cause mortality.[36,41] Waist circumference is determined by measuring the distance around the smallest area below the rib cage and the top of the iliac crest. Men are at increased risk (beyond the BMI-related risk) if the waist circumference is greater than 40 inches (102 cm); women are at increased risk if the waist circumference is greater than 35 inches (89 cm) (see Table 141-4); and children are at risk if the waist circumference is at the 75th percentile or greater (16-17-year-old girls) or 90th percentile (all others) according to CDC age- and gender-specific standards.[42]

Waist-to-Hip and Waist-to-Height Ratios

The waist-to-hip ratio is determined by dividing the waist circumference by the hip circumference (maximal posterior extension of the buttocks). In adults, a waist-to-hip ratio of greater than 0.9 in men and 0.85 in women is considered an independent risk factor for adverse health consequences.[41] Waist-to-height ratio (both measured in centimeters) has been used to evaluate children at risk for the metabolic syndrome because, unlike waist circumference, it is independent of age and gender. A child with a waist-to-height ratio of more than 0.5 is considered at risk for developing the metabolic syndrome.[43]

Skinfold Thickness and Mid-Arm Muscle Circumference

More than 50% of the body's fat is subcutaneous; thus, changes in subcutaneous fat reflect changes in total body fat. Skinfold thickness measurement provides an estimate of subcutaneous fat, and mid-arm muscle circumference, which is calculated using the skinfold thickness and mid-arm circumference, estimates skeletal muscle mass. Although simple and noninvasive, these anthropometric measurements are used most commonly in population analysis and long-term monitoring of individuals. Triceps skinfold thickness is used most often, but reference standards also exist for subscapular and suprailiac measurements.[44] Consistent technique in the use of pressure-regulated calipers is essential for reproducibility and reliability in measuring triceps skinfold thickness.[45] Standards do not account for variation in bone size, muscle mass, hydration, or skin compressibility, and they do not consider obesity, ethnicity, illness, and increased age. Results should be interpreted cautiously as these parameters change slowly in adults, often requiring weeks before significant alterations from baseline can be detected. They will change more rapidly in young children.

Bioelectrical Impedance

Bioelectrical impedance is a simple, quick (less than 15 minutes), noninvasive, portable, and relatively inexpensive technique used to measure body composition.[46,47] When a weak, alternating electric current is applied to two appendages (wrist and ankle or both feet), impedance (resistance) to flow is measured as it passes through the body. Current is well conducted by water and electrolyte-rich tissues such as blood and muscle and poorly conducted by fat, bone, and air-filled spaces. Assessment of LBM, TBW, and water distribution can be determined with BIA. Increased TBW decreases impedance; thus, it is important to evaluate hydration along with BIA. Other potential limitations of BIA include variability with electrolyte imbalance and interference by large fat masses, environment, ethnicity, menstrual cycle phase, and underlying medical conditions.[47] Although BIA equations have high validity when used in the population in which they were developed (mostly young healthy adults), BIA calculations are subject to considerable errors if applied to other populations and if conditions are not identical (eg, electrode placement must be identical).[47] The lack of reference standards that reflect variations in individual body size and clinical condition also limits BIA use in clinical practice.[46]

OTHER NUTRITION ASSESSMENT TOOLS

Functional status assessment has been recommended as part of nutrition assessment, but the specific components of this assessment are not well defined. Muscle function is an end-organ response; thus diminished skeletal muscle function can be a useful indicator of malnutrition. Muscle function also recovers more rapidly in response to adequate nutrition support than anthropometric measurements. Simple assessments of functional status include ability to perform activities of daily living, participate in physical and occupational therapy, and wean from the ventilator. Hand-grip strength (forearm muscle dynamometry), respiratory muscle strength, and muscle response to electrical stimulation also have been used. Measuring hand-grip strength is a relatively simple, noninvasive, and inexpensive procedure that correlates well with patient outcome.[48,49] Normative standards supplied by the manufacturer of the dynamometer can be used. Hand grip strength is a proxy for LBM making it a good parameter for assessment of undernutrition. However, conditions that limit hand grip strength include rheumatoid arthritis, stroke, neuromuscular disease, dementia, and heavy sedation. Ulnar nerve

stimulation causes measurable muscle contraction and can be used in most intensive care units to monitor neuromuscular blockade. In malnourished patients, increased fatigue and a slowed muscle relaxation rate are noted; these indices return to normal with refeeding.

Other methods have been used to determine body composition in the research setting, including bioimpedance spectroscopy, dual energy x-ray absorptiometry (DXA), quantitative CT, air displacement plethysmography (BodPod®), three-dimensional photonic scanning, MRI, quantitative MRI, ultrasonography, and positron emission tomography.[47,50,51] These methods are complex and expensive to perform. DXA, best known for its use in measuring bone density, is a promising method for routine clinical practice because it can quantify mineral, fat, and LBM compartments and is available in most hospitals and many outpatient facilities. A central body DXA scanner requires a fair amount of space, and the cost depends on the scanner's complexity. Portable (or peripheral) DXA devices can be used to measure bone density in peripheral bones, such as the wrist, fingers, or heel, and have also been used to assess subcutaneous fat. Portable DXA scanners are much less expensive (about $10,000 compared to $80,000 for a central scanner) and can be used in community screenings. Further research is needed to determine how DXA can be used clinically in nutrition assessment. MRI and CT can measure subcutaneous, intra-abdominal, and regional fat distribution and thus also have the potential to be useful clinically.

Laboratory Assessment

6 Biochemically, LBM can be assessed by measuring the serum concentrations of the visceral proteins, ALB, TFN, and prealbumin (also known as transthyretin). C-reactive protein (CRP) can be useful as a marker of inflammation. Creatinine-height index has historically been calculated to assess LBM but is seldom used now because of the lack of evidence to support its value.

Visceral Proteins

Visceral proteins synthesized by the liver with the greatest relevance for nutrition assessments are serum ALB, TFN, and prealbumin. It is assumed that in undernutrition states, a low serum protein concentration reflects diminished hepatic protein synthetic mass and indirectly reflects the functional protein mass of other organs (heart, lung, kidney, and intestines). Many factors other than nutrition can affect serum concentrations of these proteins including age; abnormal kidney (nephrotic syndrome), GI tract (protein-losing enteropathy) or skin (burns) losses; hydration (dehydration results in hemoconcentration, overhydration in hemodilution); liver function (synthesis); and metabolic stress and inflammation (sepsis, trauma, surgery, and infection). Thus, visceral protein concentrations must be interpreted relative to the individual's overall clinical condition (Table 141-6). The significant influence of inflammation on visceral protein concentrations is now well established; thus these negative acute phase proteins may be considered to reflect the presence of inflammation more than the presence of malnutrition in many circumstances (see Table 141-3). Visceral protein concentrations for nutrition assessment are of greatest value in the presence of uncomplicated starvation and recovery. During severe acute stress (trauma, burns, and sepsis), these proteins are relatively poor markers of nutrition status because the resultant increased vascular permeability can lead to dramatic fluid shifts and the reprioritizing of liver protein synthesis increases the production of acute-phase reactants such as CRP, ferritin, fibrinogen, and haptoglobin.[52] CRP can be used in these cases to assess the degree of inflammation present: if CRP is elevated, then inflammation is a likely major contributing factor to decreased visceral protein concentrations. Assessing individual patient trends is most useful in these cases.

Albumin, the most abundant serum protein, is involved in maintenance of colloid oncotic pressure and binding and transport of numerous hormones, anions, drugs, and fatty acids. Although it has been widely used as a marker of chronic malnutrition, it is a relatively insensitive index of protein malnutrition because there is a large amount normally in the body (4-5 g/kg of body weight), it is extensively distributed in the extravascular compartment (60%), and it has a long half-life (18-20 days). However, chronic protein deficiency in the setting of adequate non-protein calorie intake leads to marked hypoalbuminemia because of a net ALB loss from the intravascular and extravascular compartments. Serum ALB concentrations also are affected by moderate-to-severe calorie deficiency and liver, kidney, and GI disease. ALB is a negative acute-phase reactant, and serum concentrations decrease with inflammation, infection, trauma, stress, and burns. Serum ALB concentrations less than 2.5 g/dL (25 g/L) can be expected to exacerbate ascites and peripheral, pulmonary, and GI mucosal edema as a result of decreased colloid oncotic pressure. Hypoalbuminemia also affects the interpretation of serum concentrations of calcium and highly protein bound drugs (eg, phenytoin and valproic acid).

Transferrin is a glycoprotein that binds and transports ferric iron to the liver and reticuloendothelial system for storage. Because it has a shorter half-life (8-9 days) and there is less of it in the body (less than 100 mg/kg of body weight), TFN will decrease in response to protein and energy depletion before the serum ALB concentration decreases. If a direct measure of serum TFN is not available, TFN concentration can be estimated indirectly from measurement of total iron-binding capacity, where TFN (in mg/dL) = (total iron-binding capacity [mcg/dL] × 0.8) – 43. Alternatively, TFN (mg/dL) = 0.7 × total iron-binding capacity (mcg/dL) and TFN (g/L) = 0.039 × total iron-binding capacity (μmol/L). TFN is also a negative acute-phase reactant, and its concentration is decreased in the presence of critical illness and inflammation. Iron stores also affect serum TFN concentrations: in iron deficiency, hepatic TFN synthesis is increased, resulting in increased serum TFN concentrations.

TABLE 141-6 Visceral Proteins Used for Assessment of Lean Body Mass

Serum Protein	Half-Life (Days)	Function	Factors Resulting in Increased Values	Factors Resulting in Decreased Values
Albumin	18-20	Maintains plasma oncotic pressure; transports small molecules	Dehydration, anabolic steroids, insulin, infection	Fluid overload; edema; kidney dysfunction; nephrotic syndrome; poor dietary intake; impaired digestion; burns; heart failure; cirrhosis; thyroid, adrenal, or pituitary hormones; trauma; sepsis
Transferrin	8-9	Binds Fe in plasma; transports Fe to bone	Fe deficiency, pregnancy, hypoxia, chronic blood loss, estrogens	Chronic infection, cirrhosis, burns, enteropathies, nephrotic syndrome, cortisone, testosterone
Prealbumin	2-3	Binds T_3 and, to a lesser extent, T_4; retinol-binding protein carrier	Kidney dysfunction	Cirrhosis, hepatitis, stress, surgery, inflammation, hyperthyroidism, cystic fibrosis, burns, zinc deficiency

T_3, triiodothyronine; T_4, thyroxine.

Prealbumin (transthyretin) is the transport protein for thyroxine and a carrier for retinol-binding protein. Prealbumin stores are low (10 mg/kg of body weight), and it has a very short half-life (2-3 days); thus, the serum prealbumin concentration may be reduced quickly after a significant reduction in calorie and protein intake (NPO status) or in patients with severe metabolic stress (trauma, burns). Prealbumin is most useful in monitoring the short-term, acute effects of nutrition support or deficits, as it responds very quickly in both situations. As with ALB and TFN, prealbumin synthesis is decreased in liver disease. Increased prealbumin concentrations may be seen in patients with kidney disease because of impaired excretion.

Clinical **Controversy...**

Serum visceral proteins (ALB, TFN, and prealbumin) have been used for many years as markers of nutrition status. With the growing recognition of the role that inflammation plays in the development of both acute and chronic malnutrition, the use of these visceral proteins as markers of malnutrition has been challenged. Assessing CRP concomitantly with these traditional visceral protein markers can assist the clinician in assessing their usefulness. However, the role of CRP in nutrition assessment requires further investigation.

Immune Function Tests

Nutrition status affects immune function either directly, via actions on the lymphoid system, or indirectly by altering cellular metabolism or organs that are involved with immune system regulation. Immune function tests most often used in nutrition assessment are the total lymphocyte count and delayed cutaneous hypersensitivity (DCH) reactions. Both tests are simple, readily available, and inexpensive. A lack of specificity, however, limits the usefulness of these tests as nutrition status markers.

Total lymphocyte count reflects the number of circulating T and B lymphocytes. Tissues that generate T cells are very sensitive to malnutrition, undergoing involution resulting in decreased T-cell production and eventually lymphocytopenia. A total lymphocyte count less than 1,500 cells/mm^3 (1.5 × 10^9 cells/L) has been associated with nutrition depletion.[2] Total lymphocyte count is reduced in the presence of infection (eg, human immunodeficiency virus [HIV], other viruses, and tuberculosis), immunosuppressive drugs (eg, corticosteroids, cyclosporine, tacrolimus, sirolimus, chemotherapy, and antilymphocyte globulin), leukemia, and lymphoma.

Delayed cutaneous hypersensitivity is commonly assessed using recall antigens to which the patient was likely previously sensitized, such as mumps and *Candida albicans*. Anergy is associated with severe malnutrition, and response is restored with nutrition repletion. Other immune function tests used in research include lymphocyte surface antigens (CD4, CD8, and the CD4:CD8 ratio), T-lymphocyte responsiveness, and various serum interleukin concentrations. A number of factors affect DCH, including fever, viral illness, recent live-virus vaccination, critical illness, irradiation, immunosuppressive drugs, diabetes mellitus, HIV, cancer, and surgery. Nutrients such as arginine, omega-3 fatty acids, and nucleic acids given in pharmacologic doses may improve immune function (see Chapter 143). Monitoring efficacy of a nutrition care plan that includes these potentially immune-modulating nutrients may include immune function assessment.

SPECIFIC NUTRIENT DEFICIENCIES AND TOXICITIES

7 A comprehensive nutrition assessment should include an evaluation for possible trace element, vitamin, and essential fatty acid deficiencies (EFAD) or toxicities. Because of their key role in metabolic processes (coenzymes and cofactors), a deficiency of any of these nutrients may result in altered metabolism and cell dysfunction. An accurate history to identify symptoms and risk factors for a specific nutrient deficiency or toxicity is critical. A nutrition-focused physical examination and biochemical assessment to confirm a suspected deficiency or toxicity should be done in all nutritionally-at-risk patients. Ideally, biochemical assessment would be based on the nutrient's function (eg, metalloenzyme activity) rather than simply measuring the serum concentration. Unfortunately, few practical methods to assess micronutrient function are available; thus, the nutrient's serum concentration is most often measured (**Table 141-7**).

Trace Elements

The trace elements that are essential in humans (at least one important role and a range of intakes within which homeostasis is maintained) are zinc, copper, manganese, selenium, chromium, iodine, molybdenum, and iron.[53-58] Each trace element is involved in a variety of biologic functions and is necessary for normal metabolism, serving as a coenzyme or playing a role in hormonal metabolism or erythropoiesis. Toxicities can occur with excess intake of some trace elements. With the current interest in complementary medicine, clinicians must ask patients about their use of all dietary supplements (see Table 141-7).

Iron is the most abundant trace element and is an important component of hemoglobin, myoglobin, and cytochrome enzymes; it is also involved in oxygen transport and cellular energy production. Patients with iron-deficiency anemia generally present with fatigue, weakness, and pallor, but they may have other symptoms (see Chapter 100). Inadequate iron intake, malabsorption, and blood loss are the principal causes of iron-deficiency anemia. Iron toxicity (overload) with possible organ damage can occur when chronic iron intake exceeds requirements, such as in patients receiving multiple blood transfusions over an extended period of time (1 unit of packed red blood cells provides 200 mg elemental iron). Iron deficiency or overload is confirmed by assessment of body iron stores, as reflected indirectly by measurement of hemoglobin, serum iron, total iron-binding capacity, and serum ferritin or directly by bone marrow staining or liver biopsy. Direct methods are the most accurate but are invasive and rarely necessary. Because indirect parameters may be altered by acute or chronic illness independent of iron stores, concomitant illness must be considered in their interpretation.[54,56]

Zinc, the second-most abundant trace element, is a cofactor in many enzymatic reactions involved in protein, fat, and carbohydrate metabolism and is involved in the regulation of gene expression, wound healing, and liver regeneration.[54,56,59] Most of the body's zinc (85%) is found in muscle and bone; less than 1% is found in the serum. Excess zinc intake is usually eliminated by the kidneys and GI tract; thus, zinc toxicity is uncommon except in overdoses. Patients at risk for zinc deficiency include those with anorexia, alcohol dependence, excessive bile, intestinal, or urine losses, increased metabolic demands (burns) or after bariatric surgery.[59] Zinc deficiency can develop in 14 days to 3 months with insufficient intake and is characterized by skin lesions (acrodermatitis enteropathica), a moist eczematous dermatitis that is most apparent in the nasolabial folds and around orifices, and other symptoms (see Table 141-7). Recovery is rapid with oral zinc supplementation; severe dermatitis can remit in as little as 4 to 5 days.[58] Zinc deficiency can be documented by the presence of low serum zinc concentrations.[53,59] However, serum zinc concentrations decrease during acute stress states (trauma, burns, and infection) and generally remain depressed until the stress resolves. Hair zinc analysis and urinary zinc excretion can also be used as biomarkers of zinc status.

Copper is a cofactor in oxidative enzymes vital to the function of hematopoietic, vascular, and skeletal tissue, as well as structure and function of the nervous system.[60-62] It is a component of ceruloplasmin and key metalloenzymes involved in iron metabolism

TABLE 141-7 Assessment of Trace Element Status

Trace Element	Signs of Deficiency	Signs of Toxicity	Factors Associated with Altered Plasma Concentrations	Monitoring
Chromium	Impaired glucose/protein utilization, peripheral neuropathy, low RQ, weight loss, increased LDL-C, increased free fatty acid concentrations	Industrial exposure: skin or nasal septum lesions, allergic dermatitis, increased incidence of lung cancer	**Decreased**: long-term inadequate intake **Increased**: kidney failure	Serum glucose, plasma chromium (unreliable)
Copper	Menkes' syndrome: progressive mental deterioration, vomiting, diarrhea, protein-losing enteropathy, hypopigmentation, bone and hair changes Deficiency: neutropenia, hypochromic anemia, pallor, dermatitis, neurological dysfunction, osteoporosis, myopathy, thrombocytopenia, decreased bone mineralization (children)	Wilson's disease: cirrhosis, Kayser-Fleischer rings,[a] kidney dysfunction, neurologic or psychiatric symptoms (tremors, slow speech, inappropriate behavior, personality changes) Mild chronic toxicity: fatigue, anemia, thrombocytopenia Acute toxicity: nausea, vomiting, diarrhea	**Decreased**: high zinc, iron, or vitamin C intake; corticosteroid use **Increased**: infection, rheumatoid arthritis, pregnancy, oral contraceptives, decreased biliary excretion	Serum copper and ceruloplasmin with CRP[b], CBC
Iodine	Hypothyroid goiter, neuromuscular impairment, deaf-mutism, increased embryonic and postnatal mortality, cognitive impairment, impaired fertility, congenital hypothyroidism (severe cases)	Thyrotoxicosis: nodular goiter, weight loss, tachycardia, muscle weakness, warm skin	**Decreased**: long-term inadequate intake	Serum T3,T4,TSH
Iron	Microcytic, hypochromic anemia (weakness, pallor, fatigue), glossitis, headache, dysphasia, nail changes, gastric atrophy, paresthesia, decreased cognitive function	Cirrhosis, cardiomyopathy, pancreatic damage, skin pigmentation changes	**Increased**: blood transfusion **Decreased**: blood loss; long-term iron-free PN	Serum ferritin[c], iron, percent iron saturation, iron binding capacity; CBC
Manganese	Nausea; vomiting; dermatitis; hair color changes; hypocholesterolemia; growth retardation; defective carbohydrate, lipid, and protein metabolism	Parkinsonian-like symptoms, hyperirritability, hallucinations, libido disturbances, ataxia, mental confusion, lack of attention, memory loss, weakness, seizures, facial nerve abnormalities, headache, dizziness, dystonia, peripheral neuropathy	**Increased**: decreased biliary excretion, high iron or vitamin C intake	Whole blood manganese, brain MRI
Molybdenum	Tachycardia, tachypnea, altered mental status, visual changes, headache, nausea, vomiting	Gout-like syndrome, increased urinary copper	**Decreased**: low birth weight, excessive GI losses	Urinary hypoxanthine, xanthine, and sulfite oxidase
Selenium	Muscle weakness or pain, cardiomyopathy, skin and hair pigmentation changes, macrocytosis, alopecia and growth retardation in infants	Nausea, vomiting, hair or nail loss, tooth decay, skin lesions, irritability, fatigue, peripheral neuropathy	**Decreased**: malignancy, liver failure, pregnancy, stress, infection **Increased**: reticuloendothelial-neoplasia	Plasma, serum, or whole blood selenium, RBC glutathione peroxidase; CBC
Zinc	Dermatitis (scaly, hyperpigmented skin lesions), stomatitis, glossitis, perioral and periungual ulceration, altered taste and smell, alopecia, diarrhea, apathy, depression, growth retardation, impaired wound healing, anorexia, confusion, immunosuppression, delayed sexual maturation, hypogonadism (decreased sperm count and function)	Acute: diarrhea, vomiting, nausea, dizziness, garlic-smelling breath; death with large IV doses Chronic: immunosuppression, decreased HDL-C, copper deficiency	**Decreased**: infection, burns, stress, hypoalbuminemia, corticosteroids, pregnancy, inflammation **Increased**: tissue injury, hemolysis, contaminated collection tube	Plasma or serum zinc with albumin and CRP, stool or ostomy output

CBC, complete blood count; CRP, C-reactive protein; GI, gastrointestinal; HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; MRI, magnetic resonance imaging; PN, parenteral nutrition; RBC, red blood cell; RQ, respiratory quotient; TSH, thyroid stimulating hormone.

[a]Kayser-Fleischer rings are dark rings that appear to encircle the iris of the eye.

[b]If CRP > 4 mg/dL (> 40 mg/L), serum copper concentration will be falsely elevated. Ceruloplasmin increased with inflammation, pregnancy, liver disease, malignancy, and myocardial infarction.

[c] If ferritin low, iron deficiency; if high, inflammation.

Data from references 13, 20, 53, 54, 56-58, and 61.

(ceruloplasmin), electron transport and energy metabolism (cytochrome oxidase), connective tissue and collagen cross-linking (lysyl oxidase, elastase, and monoamine oxidase), and free radical scavenging (superoxide dismutase), among other functions. Copper is absorbed in the duodenum and excreted through the bile bound to bile salts. Most copper (67%) is found in bone and muscle, and 60% to 95% of serum copper is bound to ceruloplasmin.[62] Signs and symptoms of copper deficiency are listed in Table 141-7 and include anemia,

neutropenia, and thrombocytopenia, and neurologic dysfunction. In severe cases, such as in Menkes' syndrome, copper deficiency is further manifested as hypothermia, hair and skin depigmentation, progressive mental deterioration, and growth retardation. Factors predisposing to copper deficiency include generalized malabsorption, protein-losing enteropathy, nephrotic syndrome, and copper-free parenteral nutrition.[60,62] Patients undergoing bariatric surgery are also at risk for developing copper deficiency as early as 2 months after surgery. Resolution typically occurs within 1 to 3 weeks after initiation of copper supplementation (1 mg/day). Copper deficiency is assessed using serum copper concentrations along with CRP and ceruloplasmin, which appear to reflect changes in copper status in both copper-depleted and copper-replete individuals.[61] While they are reliable indicators of severe copper deficiency, serum copper and ceruloplasmin concentrations may not detect marginal copper deficiency because serum concentrations may be altered by a variety of conditions including inflammation (see Table 141-7). Copper concentrations should be monitored routinely in patients receiving long-term parenteral nutrition. While long-term parenteral nutrition supplemented with copper increases the risk of copper toxicity, copper deficiency has been reported as a result of copper-free parenteral nutrition most often because of concern for accumulation with cholestasis and the resulting decrease in biliary elimination.[62] The chronic ingestion of excessive copper or inadequate elimination can result in cirrhosis as seen in Wilson's disease, an autosomal-recessive genetic disorder. Copper concentrations should be monitored every 2 to 6 months in patients receiving long-term parenteral nutrition.

Trivalent chromium is needed for insulin function and maintenance of normal blood glucose concentrations. A low-molecular-weight chromium binding substance, "*the glucose tolerance factor*", may enhance insulin receptor response to insulin.[63] Chromium is stored in the liver, spleen, soft tissues, and bones and excreted by the kidney. Chromium deficiency is characterized by glucose intolerance, increased insulin requirements, and impaired protein utilization. Patients with chromium deficiency also may have increased free fatty acid concentrations and a low respiratory quotient (RQ) (see Table 141-7). Chromium deficiency has only been identified in patients receiving long-term chromium-free parenteral nutrition. Serum chromium concentrations do not accurately reflect total body chromium status, presumably because the biologically active form of chromium is the low-molecular-weight chromium binding substance. Toxicity from trivalent chromium is not a common clinical concern; toxicity has been reported only with contaminated drinking water or industrial exposure. Chromium supplementation as an adjunct to aerobic exercise for weight loss has not been proven effective[64] (see Chapter 142).

Manganese is needed for the proper function of metalloenzymes, including arginase (amino acid metabolism via the urea cycle), pyruvate carboxylase and phosphoenolpyruvate carboxykinase (carbohydrate and cholesterol metabolism), superoxide dismutase (mitochondrial antioxidant), glycosyltransferases (bone formation via proteoglycans), and prolidase (wound healing).[54,56] Excess manganese is eliminated mainly in bile. Manganese deficiency has only been reported in association with the ingestion of chemically defined manganese-deficient oral diets. Table 141-7 lists common symptoms associated with manganese deficiency. Manganese toxicity is more concerning and has been described in industrial exposures via inhaled manganese and in patients receiving long-term manganese-supplemented parenteral nutrition in the setting of chronic cholestasis.[65-68] Manganese can accumulate in brain tissue and the newborn brain may be more susceptible to the effects of manganese toxicity.[66] Increased signal intensity on T1-weighted MRI of the globus pallidus has been found in patients with manganese toxicity. Whole-blood manganese concentrations are used to assess manganese status; serum concentrations do not correlate with either whole blood concentrations or MRI.[67] Clinical toxicity is evidenced primarily by extrapyramidal symptoms mimicking Parkinson's disease, such as headache, dizziness, tremors, ataxia, facial muscle spasms, and other symptoms.[54,65] These symptoms may be preceded by psychiatric symptoms, including irritability, aggressiveness, and hallucinations. In most reported cases, removing manganese from the parenteral nutrition solution resulted in resolution of neurologic symptoms within 6 months with partial or total normalization of the MRI after 1 to 2 years.

Selenium is incorporated into at least 25 enzymes known as selenoproteins, about half of which have a defined metabolic function. Important selenoproteins include selenoprotein P (antioxidant activity), glutathione peroxidase (antioxidant activity), iodothyronine deiodinase (thyroid hormone regulation), thioredoxin reductase (vitamin C), selenoprotein V (spermatogenesis), and selenoprotein S (inflammation and immune response).[54,56,69] Selenoprotein P is the major (60%) circulating form of selenium in serum. A key metabolic function of selenium is its role in the enzymatic cofactor selenocysteine, the 21st amino acid.[56] Prematurity, critical illness, chronic GI losses, and long-term selenium-free parenteral nutrition are associated with low serum selenium concentrations and decreased glutathione peroxidase activity.[54,56,69] The clinical significance of reduced serum selenium concentrations is unclear, but low selenium concentrations may increase susceptibility to physiologic stressors. Although critically ill patients require higher selenium intakes than normal, the optimal intake is unknown. Current recommendations range from 20 to 1,000 mcg/day.[70] Low serum selenium concentrations in critically ill patients correlate with low triiodothyronine (T_3) concentrations.[70] Serum selenium concentrations reflect acute distribution between tissues rather than selenium stores. Selenium deficiency is associated with muscle pain, wasting, and weakness (see Table 141-7), but severe biochemical deficiency is not always accompanied by these symptoms. Fatal cardiomyopathy has been reported in several cases.

Serum, erythrocyte, and whole-blood selenium, serum selenoprotein P, and serum, platelet, and whole-blood glutathione peroxidase activity respond to changes in selenium intake, but the response is heterogeneous.[69] Decreased serum selenium concentrations may indicate selenium deficiency, but reductions have also been observed in patients with malignancies, liver failure, pregnancy, alcoholism, and HIV; in patients receiving statins or corticosteroids; and in smokers. Selenium toxicity (selenosis) generally occurs only in those with long-term exposure to foods grown in selenium-rich soil (eg, U.S. Great Plains area) and may occur when intake exceeds 400 mcg/day for prolonged periods; although, the lowest reported adverse event intake is 850 mcg/day. Selenium toxicity results in hair and nail brittleness and loss, GI disturbance, skin rash, garlic breath odor, fatigue, irritability, and nervous system abnormalities.

Molybdenum is a cofactor for enzymes involved in catabolism of sulfur-containing amino acids, purines, and pyrimidines (xanthine, aldehyde, and sulfite oxidases).[54,56,71] Molybdenum deficiency is uncommon, but a rare genetic defect that prevents sulfite oxidase synthesis resulting in molybdenum deficiency has been identified. One case of molybdenum deficiency has been reported in a patient receiving long-term molybdenum-free parenteral nutrition who presented with symptoms that included tachycardia, tachypnea, headache, night blindness, nausea, vomiting, central scotomas, lethargy, disorientation, and ultimately coma (see Table 141-7). Symptoms were reversed when molybdenum was added to the parenteral nutrition solution.[72] Factors predisposing to molybdenum deficiency appear to be low birth weight,[73] excessive GI losses, and long-term inadequate intake. Biochemical abnormalities expected in molybdenum deficiency include very low serum and urine uric acid concentrations (low xanthine oxidase activity) and low urine inorganic sulfate concentrations with high urine inorganic sulfite concentrations (low sulfate oxidase activity).[71] Molybdenum toxicity has not been described.

Iodine is found primarily in the thyroid gland (70%-80%). Iodine deficiency may result in goiter formation (see Chapter 75). However, not everyone with an iodine-deficient diet will develop a goiter. Measurement of thyroxine (T_4), T_3, and TSH (thyroid stimulating hormone) can be used to assess iodine status (see Table 141-7). Intravenous iodine supplementation is not necessary except during long-term parenteral nutrition with minimal enteral intake. Iodine needs may be met by consumption of iodized salt or cutaneous iodine absorption from povidone–iodine, a topical antiseptic, used in catheter care. Use of povidone–iodine for this indication has virtually been eliminated with increased chlorhexidine use for catheter care, putting long-term parenteral nutrition patients at higher risk. Iodine excess is rarely a clinical concern when thyroid and kidney functions are normal except in overdoses.

Vitamins

Vitamins act as both catalysts (cofactors) and substrates in essential metabolic reactions. A comprehensive nutrition-focused history and physical examination is the most valuable means of assessing patients for vitamin deficiency or toxicity (**Table 141-8**). A thorough review of vitamins and their complex effects on nutrition and metabolism is beyond the scope of this chapter.[56,57,74,75] Generalized malnutrition is often associated with multiple vitamin deficiencies or increased needs; however, single vitamin deficiencies do occur. Thiamine (B_1) deficiency can result in early symptoms (dry or wet beriberi and GI symptoms) or advanced symptoms (lactic acidosis, Wernicke's encephalopathy, polyneuropathy, ataxia, and mental confusion) due to impaired oxidative and energy metabolism often leading to serious and potentially irreversible neurological damage or death.[56,76] Macrocytic anemia, peripheral neuropathy, and neuropsychiatric sequelae are also caused by vitamin B_{12} (cyanocobalamin) deficiency which can occur after gastric or ileal resection. Vitamin B_{12} deficiency has been reported with increasing frequency in adults, especially with prolonged gastric acid suppression.[77] There is a high prevalence of subclinical vitamin K deficiency in patients with chronic kidney disease, including those on hemodialysis or peritoneal dialysis. Vitamin K deficiency is a modifiable risk factor for cardiovascular disease and bone fracture in this patient population.[78]

The increasing prevalence of vitamin D deficiency is a worldwide concern, including all ages, genders, and racial/ethnic groups, especially children, elderly adults, individuals with dark skin, invalids and shut-ins, patients on long-term parenteral nutrition, and those living in temperate and higher latitudes.[79,80] Laboratory assessment can confirm the clinical suspicion of a deficiency state. Vitamins D2 (ergocalciferol) and D3 (cholecalciferol) are quickly converted to 25-OH-vitamin D via hydroxylation in the liver. The best marker for vitamin D deficiency is the serum concentration of 25-OH-vitamin D. Reference ranges for U.S. laboratories are typically 20 to 100 ng/mL (50-250 nmol/L) but the optimal range is likely above 30 ng/mL (75 nmol/L) based on the concentration associated with parathyroid hormone (PTH) stimulation and calcium absorption efficiency.[79] The first indication of a deficiency is usually a decrease in circulating serum concentrations of 25-OH-vitamin D. Subsequently, there is a decrease in urinary excretion of vitamin D, which is followed by diminished tissue concentrations. Because 1,25-$(OH)_2$-vitamin D is produced only when needed, not stored, and dependent on kidney function, intact PTH concentration, and calcium and phosphorus supply, it is not a useful marker of vitamin D deficiency (see Table 141-8; see Chapter 44)

Vitamin toxicity can occur, especially with fat-soluble vitamins (A, D, E, and K), which are stored in the body. Excessive dietary vitamin A intake (hypervitaminosis A) is linked to an increased risk of hip fractures in both men and women.[81,82] Vitamin D toxicity can cause significant hypercalcemia. With the exception of cyanocobalamin, which is stored in the liver, water-soluble vitamins are not stored in the body; consequently, the toxicity risk is minimal unless ingested in very high doses. Recent evidence, however, suggests that even water-soluble vitamins may be associated with adverse events when taken chronically in high doses. Although folic acid administration is definitively associated with a reduction in neural tube defects, its effect on some cardiac outcomes (as a result of its effect on homocysteine concentrations) is not established.[83] The administration of folic acid, vitamin B_6 (pyridoxine), and vitamin B_{12} after coronary artery stenting has been associated with an increased risk of stent restenosis.[84] With Americans' current use of nutrition supplements, clinicians should be alert for signs of hypervitaminosis (see Table 141-8) and inappropriate vitamin use and discuss rational supplement use with all patients.

Essential Fatty Acids

The human body can synthesize all fatty acids except the essential fatty acids, linoleic acid (an omega-6 fatty acid) and α-linolenic acid (an omega-3 fatty acid). Essential fatty acid deficiency (EFAD) can be prevented if approximately 5% of total calories are ingested as these fatty acids.[85,86] EFAD is rare in adults and children but can occur with prolonged use of lipid-free parenteral nutrition, severe fat malabsorption, very low-fat enteral feeding formulations or diets, high medium chain triglyceride-containing diets, and severe malnutrition, especially in stressed patients. Although the time course to develop EFAD is variable, overt EFAD has been shown to occur after 4 weeks of lipid-free parenteral nutrition, and biochemical evidence can occur within 1 week.[86] Because newborns, especially those born prematurely, have limited fat stores, they may develop EFAD more rapidly than adults. Biochemical evidence of EFAD has been noted within 72 hours after birth in preterm infants receiving fat-free intravenous solutions.[87] Symptoms of EFAD include dermatitis (dry, cracked, and scaly skin), alopecia, impaired wound healing, growth failure, thrombocytopenia, and anemia.

Linoleic acid is converted to arachidonic acid (20:4ω-6; a tetraene fatty acid). When linoleic acid is unavailable, oleic acid (18:1ω-9) is the preferred substrate, resulting in production of eicosatrienoic acid (20:3ω-9; a triene fatty acid). Thus, EFAD is associated with decreased tetraene and increased triene production. The usual ratio of trienes to tetraenes is less than 0.4; a ratio of greater than 0.2 indicates subclinical EFAD, but clinical symptoms of EFAD are generally only seen when the ratio is greater than 0.4.[88] EFAD diagnosis is generally made based on risk assessment and clinical findings with confirmation by measuring serum fatty acid concentrations.

Carnitine

Carnitine is a quaternary amine required for transport of long-chain fatty acids into the mitochondria for β-oxidation and energy production. Additionally, acyl compounds that are trapped within cells due to cell membrane impermeability to them can be esterified with carnitine and transported out of the cell, aiding in their elimination (detoxification), especially when the acyl compounds accumulate to inhibitory or toxic concentrations. Carnitine is available from a wide variety of dietary sources (especially meats) and can be synthesized by the liver and kidneys from lysine and methionine. Hepatic synthesis is decreased in premature infants, and low serum carnitine concentrations and overt carnitine deficiency have been documented in premature infants receiving carnitine-free parenteral nutrition or diets, as well as in those with inborn errors of carnitine metabolism.[89] Other predisposing factors for carnitine deficiency include chronic kidney[90] or liver disease,[89] chronic valproic acid[89] and zidovudine use,[91] and a vegetarian diet. The clinical presentation of carnitine deficiency includes generalized skeletal muscle weakness, hypotonia, failure-to-thrive, fasting hypoglycemia, encephalopathy, and coma.[89]

Although tissue concentrations, especially muscle, are higher than serum concentrations, in clinical practice, carnitine status is most often assessed by measurement of serum total and free

TABLE 141-8 Assessment of Vitamin Status

Vitamin	Signs of Deficiency	Laboratory Assay	Comments
Water-Soluble Vitamins			
Thiamine (B_1)	Early: anorexia, fatigue, depression, impaired memory or concentration Late: paresthesia, nystagmus, GI beriberi (nausea, vomiting, abdominal pain, lactic acidosis), beriberi (heart failure, edema), Wernicke's encephalopathy, Korsakoff's psychosis, peripheral neuropathy	Whole blood or erythrocyte transketolase activation test Blood thiamine pyrophosphate Erythrocyte glutathione reductase activity coefficient	Increased need with hemo- and peritoneal dialysis, alcoholism, malabsorption, hypermetabolism
Riboflavin (B_2)	Mucositis, dermatitis, cheilosis, glossitis, photophobia, corneal vascularization, lacrimation, decreased vision, impaired wound healing and growth, normocytic anemia	Urine riboflavin	
Pantothenic acid	Fatigue, malaise, headache, insomnia, vomiting, abdominal cramps	Serum pantothenic acid	
Niacin	Pellagra: dermatitis, dementia, glossitis, diarrhea, memory loss, headaches	Urine niacin and N_1-methylnicotinamide Erythrocyte NAD and NADP concentrations to determine "niacin number"	Flushing, nausea, and vomiting seen with hyperlipidemia treatment; increased need with hemo- and peritoneal dialysis
Pyridoxine (B_6)	Pellagra, dermatitis, glossitis, cheilosis, distal limb numbness or paresthesia, convulsions, microcytic anemia	Plasma pyridoxal 5-phosphate Urine 4-pyridoxic acid	Sensory neuropathy and seizures with very high doses (>2 g/day)
Folic acid	Macrocytic anemia, diarrhea, glossitis, cheilosis, angular stomatitis, fatigue, difficulty concentrating, irritability, headache, palpitations, shortness of breath, heart failure, tachycardia, postural hypotension, lactic acidosis, neural tube defects, impaired cellular immunity, paranoid behavior	Serum or plasma folate (acute) Red blood cell folate (chronic) Serum homocysteine	Decreased with increased cellular/tissue turnover (pregnancy, malignancy, hemolytic anemia); masks diagnosis of vitamin B_{12} deficiency; decreases risks of neural tube defects
Cyanocobalamin (B_{12})	Pernicious (megaloblastic) anemia, glossitis, spinal cord degeneration, peripheral neuropathy, paresthesias, pancytopenia, personality changes, dementia, depression, psychosis	Serum cobalamin Plasma homocysteine Urine or plasma methylmalonic acid[a] CBC	Decreased absorption in the elderly, distal ileal resection, loss of gastric intrinsic factor due to gastrectomy or long-term gastric acid suppression
Biotin	Dermatitis, depression, lassitude, somnolence	Urine biotin	
Ascorbic acid (C)	Enlargement or keratosis of hair follicles, impaired wound healing, anemia, lethargy, depression, bleeding, ecchymosis, scurvy	Plasma ascorbic acid Leukocyte ascorbate	GI disturbances, hyperoxaluria and kidney stones, excess iron absorption with excess intake; smokers need 35 mg/day more than nonsmokers; rebound scurvy with abrupt discontinuation after long-term high doses
Fat-Soluble Vitamins			
Vitamin A (includes retinol, retinal, retinoic acid, and retinyl esters)	Dermatitis, night blindness, xerophthalmia, Bitot spots,[b] pruritus, follicular hyperkeratosis, excessive deposition of periosteal bone, hair changes, poor growth and wound healing, impaired resistance to infection Irreversible: punctate keratopathy, keratomalacia, corneal perforation	Serum retinol Serum retinol-binding protein Serum retinyl esters (toxicity)	Teratogenic, liver toxicity with excessive intake; alcohol intake, liver disease, hyperlipidemia, and severe protein malnutrition increase susceptibility to adverse effects of high intake; β-carotene supplements recommended only for those at risk of deficiency (fat malabsorption); may reverse corticosteroid-induced poor wound healing
D	Rickets, osteomalacia, osteoporosis, muscle weakness, poor growth, hypocalcemia, immune dysfunction, cardiomyopathy	Serum 25-hydroxy-vitamin D	Elevated intake causes hypercalcemia, nephrocalcinosis, azotemia, poor growth; decreased in uremia, elderly (especially in winter), fat malabsorption
α-Tocopherol (E)	Hemolysis	Serum α-tocopherol Ratios of serum α-tocopherol to total lipids	Excess intake: hemorrhagic toxicity; increased risk of bleeding with anticoagulants; impaired leukocyte function
K	Bleeding (ecchymosis, petechiae, hematomas)	Prothrombin time INR	Anticoagulant therapy can be affected by supplements or diet

CBC, complete blood count; GI, gastrointestinal; INR, international normalized ratio; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate.

[a]Plasma methylmalonic acid concentrations increase with vitamin B_{12} deficiency.

[b]Bitot spots are spots which are oval, triangular, or irregular in shape and located superficially in the conjunctiva.

Data from references 13, 20, 21, 56, 57, and 75.

carnitine concentrations and acylcarnitine. Serum and urine carnitine concentrations are most helpful in primary carnitine deficiency (an inborn error of metabolism); acylcarnitine concentrations are more helpful in secondary causes of carnitine deficiency. When only total and free concentrations are available, the free is subtracted from the total to give the acylcarnitine concentration.[89]

NUTRIENT REQUIREMENTS

8 Individual nutrient requirements vary with age, gender, size, disease state, and clinical condition. Nutrition status, physical activity, and the need for continued maintenance of adequate nutrition or repletion in those with ongoing metabolic stress or malnutrition dictate the nutrient requirements for an individual. For obese patients, usual nutrition requirements may be altered because of desired weight loss or after bariatric surgery. In children, there is the added consideration of sustaining or reestablishing normal growth and development. Organ function (intestine, kidney, liver, and pancreas) may affect nutrient utilization. Nutrient requirements can be estimated using various methods interpreted in the context of patient-specific factors.

Recommended Dietary Allowances

The recommended daily allowances (RDAs) were first established in 1941, and in 1997, the Food and Nutrition Board introduced a new designation for nutrition reference values: the dietary reference intakes (DRIs).[92] The four DRI categories are estimated average requirements (EARs), RDAs, adequate intakes (AIs), and tolerable upper intake levels (ULs). The nutrient intake that meets the needs of half of the healthy persons in a group (EAR) can be used for planning nutrient intakes for groups. The RDA, the nutrient intake that meets the needs of almost all persons in a designated group, is approximately 2 standard deviations above the EAR for nutrients for which the requirement is well defined and 1.2 times the EAR for other nutrients. To evaluate an individual's daily intake, the RDA is the most appropriate comparator. AI, defined as the average intake for the designated group that appears to sustain a particular nutrition state, growth, or other functional indicator of health, is reserved for nutrients for which no EAR or RDA has been determined. Finally, the UL is the maximum nutrient intake unlikely to pose adverse effects in almost all persons in a designated group.[92]

Dietary reference intakes have been established for six nutrient groups: calcium, phosphorus, magnesium, vitamin D, and fluoride; folate and other B vitamins; antioxidants (eg, selenium and vitamins C and E); trace elements; macronutrients (eg, protein, fat, carbohydrates, and fiber); and electrolytes and water. Because of the increased prevalence of vitamin D deficiency, calcium and vitamin D recommendations were revised in 2010.[93] The U.S. Department of Agriculture's website includes an Interactive DRI for Healthcare Professionals, which calculates a generally healthy individual's DRI-based nutrition needs.[94]

According to the DRIs, adults and children older than 1 year of age should consume 45% to 65% of their total calories as carbohydrates. Recommended fat intakes vary by age: 1 to 3 years, 30% to 40%; 4 to 18 years, 25% to 35%; and, adults, 20% to 35% of total calories. Infants, especially premature infants, require a higher proportion of calories from fat (approximately 40%-50% of total calories) to ensure normal neurological development. Protein recommendations also vary by age: 1 to 3 years, 5% to 20%; 4 to 18 years, 10% to 30%; and, adults, 10% to 35% of total calories.[85]

Energy

9 Energy requirements of individuals can be estimated using published, validated equations or can be measured directly. The most appropriate method is determined by a variety of factors, including severity of illness and resource availability.

Estimating Energy Expenditure

Daily energy expenditure consists of the basal energy expenditure (BEE), diet-induced thermogenesis (10%), and energy used for physical activity. In sick or injured patients, the BEE is increased because of stress-related hypermetabolism, but the physical activity and the energy needed for metabolism are usually reduced. For example, continuous infusion enteral feeding, often used in critically ill patients, results in minimal diet-induced thermogenesis (5%) when overfeeding is not present.[28] Failure to account for these changes can result in overfeeding.

More than 200 methods for determining an individual's daily energy requirement have been published.[2,28,95-97] These methods use population estimates of calories per kilogram of body weight (kcal/kg), equations that estimate energy expenditure (kcal/day or kJ/day; 1 kcal is equivalent to 4.184 kJ), or indirect calorimetry. The simplest method to determine energy requirements is to use population estimates of calories required per kilogram of body weight. This method assumes standard values for health or the energy requirements associated with various disease states or clinical conditions, as well as the additional requirements for repletion of a malnourished individual. Most do not take into consideration age- or gender-related differences in energy needs. No stress or activity modifiers are used with these equations because the effect of the clinical condition (hypermetabolism) has been captured in the calculation. Daily adult requirements by this method can be estimated as shown below:[95-97]

1. Healthy, normal nutrition status, minimal illness severity: 20 to 25 kcal ABW/kg/day (84-105 kJ ABW/kg/day).
2. Illness, metabolic stress (BMI less than 30 kg/m^2): 25 to 30 kcal ABW/kg/day (105-126 kJ ABW/kg/day).
3. Illness, metabolic stress (BMI greater than or equal to 30 kg/m^2): 11 to 14 kcal ABW/kg/day (46-59 kJ ABW/kg/day) or 22 to 25 kcal IBW/kg/day (92-105 kJ ABW/kg/day).
4. Major burn injury (greater than or equal to 50% total body surface area) or repletion: greater than or equal to 30 kcal ABW/kg/day (greater than or equal to 126 kJ ABW/kg/day).[98]

When using the ranges in 3 above, as the BMI increases, the number derived using ABW compared to IBW becomes quite disparate. Accuracy is improved by using the ABW recommendation for patients with BMI 30-50 kg/m^2 and the IBW recommendation when the BMI is greater than 50 kg/m^2. When these recommendations are used for patients with a BMI of 30 kg/m^2 or more, the calories provided allow for permissive underfeeding (provision of approximately 80% of estimated or measured energy needs), which decreases infection rates and hospital length of stay.[28] **Table 141-9** shows suggested calorie intakes (kcal/kg) for maintenance and normal growth of healthy infants and children.[85] These maintenance energy requirements are approximately 150% of the basal metabolic rate, with the additional calories provided to support usual activity and growth. For all ages, energy requirements increase with fever, sepsis, major surgery, trauma, burns, and long-term growth failure and in the presence of chronic conditions such as bronchopulmonary dysplasia, congenital heart disease, and cystic fibrosis. Energy needs may decrease with obesity and neurologic disability (eg, cerebral palsy).

Numerous equations are available to estimate energy expenditure in adults and children (**Tables 141-10** and **141-11**, respectively).[2,28,95-97] The Harris-Benedict equations, derived in 1919 from a study of 239 individuals, are still used by some clinicians for assessing energy requirements in adults. They have the advantage of incorporating the patient's age, height, weight, gender, and clinical condition into the estimation. These equations were derived from oxygen consumption measurements made in normally nourished healthy individuals who were in a fasting and resting state. Although they are commonly referred to as the "BEE equations," they actually estimate resting energy expenditure (REE), the amount of energy

TABLE 141-9 Dietary Reference Intakes for Energy and Protein in Healthy Children

Age (Reference age/weight)	Estimated Energy Requirement (kcal/day)[a]		Protein RDA (g/kg/day)[b]
	Boys	Girls	
0-6 mo (3 mo/6 kg)	570	520	1.52[c]
7-12 months (9 mo/9 kg)	743	676	1.5
1-2 yr (24 mo/12 kg)	1,046	992	
1-3 yr (24 mo/12 kg)			1.1
3-8 yr (6 yr/20 kg)	1,742	1,642	
4-8 yr (6 yr/20 kg)			0.95
9-13 yr (11 yr/M: 36 kg; F: 37 kg)	2,279	2,071	0.95
14-18 yr (16 yr/M: 61 kg; F: 54 kg)	3,152	2,368	0.85

F, female; M, male; RDA, recommended dietary allowance.

[a]1 kcal is equal to approximately 4.18 kJ.

[b]Protein requirements in children with moderate to severe stress increase by 50% or more.

[c]Adequate intake.

Data from reference 85.

expended at rest by a fasting, awake individual in a temperature-controlled environment performing only basal functions such as breathing, circulation, and metabolic processes.

Because these equations approximate REE, the results have been historically modified by a factor that adjusts for the individual's clinical condition. For example, an individual who is confined to bed may require a calorie intake that is only 20% to 30% above the REE, while a person who has sustained a severe burn injury may require 150% to 200% of the calculated REE. Some clinicians multiply the calculated REE by both a stress factor and an activity factor.

TABLE 141-10 Estimates of Energy Expenditure in Adults[a]

Healthy Adults
Harris-Benedict[b] Equations (kcal/day)
Men: BEE = 66 + (13.75W + 5H [cm]) – (6.8A)
Women: BEE = 655 + (9.6W + 1.8H [cm]) – (4.7A)
DRI Equations (kcal/day)[c]
Men: EER = 662 – 9.53A + (PA × 15.91W) + 539.6H (m)
Women: EER = 354 – 6.91A + (PA × 9.36W) + 726H (m)
PA = 1 if sedentary; 1.12 if low active; 1.27 if active; and 1.45 if very active
Mifflin-St. Jeor Equations (kcal/day)
Men: 10W + 6.25H (cm) – 5A + 5
Women: 10W + 6.25H (cm) – 5A – 161
Critically Ill Adults
Penn State Equations (kcal/day)
Age ≥60 years with BMI ≥30 kg/m^2: Mifflin(0.71) + T_{max}(85) + Ve(64) – 3085
All others: Mifflin(0.96) + T_{max}(167) + Ve(31) – 6212

A, age in years; BEE, basal energy expenditure; BMI, body mass index; DRI, dietary reference intakes; EER, estimated energy requirement; H, height in centimeters or meters, as indicated; PA, physical activity factor; T_{max}, maximum body temperature in the previous 24 hours in degrees centigrade; Ve, minute ventilation in L/min; W, actual body weight in kilograms.

[a]No real consensus exists as to which formula is best in all situations. Many clinicians use more than one equation and calculate a range of acceptable intakes.

[b]The common practice of using an adjusted body weight for obesity in these calculations is not supported by the original data that used actual body weight in all cases up to a BMI of 56 kg/m^2 in men and 40 kg/m^2 in women.

[c]1 kcal is equal to approximately 4.18 kJ.

Data from references 2, 28, 95, and 96.

TABLE 141-11 Equations to Estimate Energy Expenditure in Children[a,b]

FAO/WHO/UNU 2001 (kcal/day)[b]
0-12 Months
Breastfed
TEE (kcal/day) = –152 + 92.8W
TEE (MJ[c]/day) = –0.635 + 0.388W
Formula fed
TEE (kcal/day) = –29 + 82.6W
TEE (MJ[c]/day) = –0.122 + 0.346W
Boys 1-17 Years
TEE (kcal/day) = 310.2 + 63.3W – 0.263W^2
TEE (MJ[c]/day) = 1,298 + 0.265W – 0.0011W^2
Girls 1-17 Years
TEE (kcal/day) = 263.4 + 65.3W – 0.454W^2

DRI Equations (kcal/day)
Birth through 2 years of age
EER = (89W – 100) + GF
GF = 175 kcal if 0-3 months; 56 kcal if 4-6 months; 22 kcal if 7-12 months; 20 kcal if 13-35 months
3-18 years of age
Boys: EER = 88.5 – (61.9A) + PA (26.7W + 903H) + GF
Girls: EER = 135.3 – (30.8A) + PA (10W + 934H) + GF
GF = 20 kcal if 3-8 years; 25 kcal if 9-18 years
PA = 1 if sedentary; 1.13-1.16 if low activity; 1.26-1.31 if normal activity; and 1.42-1.56 if very active

A, age in years; DRI, dietary reference intakes; EER, estimated energy requirement; FAO/WHO/UNU, Food and Agriculture Organization/World Health Organization/United Nations University; GF, growth factor; H, height in meters; PA, physical activity factor; TEE, total energy expenditure; W, actual body weight in kilograms.

[a]No real consensus exists as to which formula is best in all situations. Many clinicians use more than one equation and calculate a range of acceptable intakes.

[b]Additional daily calories are needed for growth; about 2 kcal/g of weight gain desired.

[c]1 kcal is equivalent to approximately 4.18 kJ; 1 MJ = 1,000 kJ.

Data from references 85, 101, and 102.

Because validation studies have shown that these equations overestimate REE by 6% to 15%, the calculated REE should be multiplied by either a stress factor or an activity factor to avoid further overestimation of the individual's energy needs.[2] It should also be noted that ABW (up to a BMI of 56 kg/m^2 in men and 40 kg/m^2 in women), not IBW or adjusted body weight, was used to generate the original data with these equations and thus should be used for these calculations.[96] Overestimation of energy needs with the Harris-Benedict equations is well documented.[28,96] When compared to indirect calorimetry, the accuracy has been shown to be about 34%.[99] The Mifflin-St. Jeor equations tend to be more accurate in healthy adults than the Harris-Benedict equations (see Table 141-10): the accuracy rate is 80% in patients who are not obese (BMI less than or equal to 30 kg/m^2) and 70% in obese patients (BMI greater than 30 kg/m^2).[28,99]

There is no individual method proven to accurately determine the energy needs of all critically ill patients.[95] The Penn State equations are the most accurate in critically ill adults receiving mechanical ventilation[28] (see Table 141-10), but the accuracy is only about 67% when compared to indirect calorimetry measurements.[99] The Penn State modified appears to be more accurate in older obese patients, with an accuracy of approximately 74% when compared to indirect calorimetry measurements in the same individuals.[99] There is no consensus as to the best equation for critically ill adults who are not mechanically ventilated. The metabolic response to stress in children appears to be different than in critically ill adults; thus, "stress factors" used in adults, shown in Table 141-12, are not appropriate for use in estimating energy use in children.[100-102]

TABLE 141-12 Stress Factors for Use in Adults

Condition	Factor
No Stress	
Confined to bed	1.2
Out of bed: normal activity	1.3
Catch-up growth	1.5
Mild Stress[a]	
Postoperative recovery: uncomplicated surgery	1-1.15
Trauma: mild (eg, long-bone fracture)	1.2
Moderate Stress[a]	
Sepsis (moderate)	1.2-1.4
Trauma: CNS (sedated)	1.3
Trauma: moderate to severe	Children: 1.5
	Adults: 1.3-1.4
Severe Stress[a]	
Sepsis (severe)	Children: 1.6
	Adults: 1.3
Trauma: CNS (severe)	Children: up to 2.0
	Adults: up to 1.3
Burns (proportionate to burned area)[b]	Up to 2.0

CNS, central nervous system.

[a]Assumes decreased activity during periods of stress.

[b]Formulas specifically for estimating energy needs in burned children and adults have been published and are likely to be more accurate. See reference 98.

Data from reference 2.

Clinical **Controversy...**

Many equations have been published for estimating energy requirements of patients in a variety of settings. Indirect calorimetry is becoming more widely available for use in many patient settings. Whether estimating energy needs using an appropriate validated equation is cost-effective and/or improves outcomes versus measuring the energy requirements using indirect calorimetry is not yet established.

Measuring Energy Expenditure

The most accurate method to determine energy expenditure in clinical practice is to measure it using indirect calorimetry (metabolic gas monitoring), but capital and operational costs limit its availability. Handheld calorimeters have been shown to produce similar results to metabolic carts and may be a viable alternative to the more expensive equipment in both the inpatient and outpatient setting.[103]

Indirect calorimetry methodology is based on pulmonary gas exchange: when a substrate (carbohydrate, fat, or protein) is oxidized, heat is produced, oxygen is consumed, and carbon dioxide is expired in a constant amount depending on the substrate being oxidized. More carbon dioxide is produced when a gram of glucose is metabolized than either a gram of protein or a gram of fat. Indirect calorimetry is a noninvasive procedure in which oxygen consumption (VO_2, mL/min) and carbon dioxide production (VCO_2, mL/min) are measured, and the measured resting energy expenditure (MREE; kcal/day) is calculated using the abbreviated Weir equation as MREE = ([3.94 VO_2 + 1.11 VCO_2] + [2.17 uN_2]) × 1.44.[99,104,105] The urinary nitrogen component (uN_2) is often omitted when calculating energy expenditure because it accounts for less than 4% of the energy expenditure in critically ill patients, and its omission results in only a 1% to 2% calculation error.[28,105] Excluding the nitrogen component obviates the need for a 24-hour urine collection, which can be difficult in many patients and delay the measurement in others.

The MREE represents the total energy expended during the time period over which the measurements were taken extrapolated to a 24-hour period to approximate daily energy requirements. MREE reflects changes in energy requirements resulting from diseases or clinical conditions, but it does not include energy required for repletion of a malnourished individual or growth in a child. The energy intake required for these functions is accounted for by multiplying MREE by a metabolic or activity factor: mechanically ventilated, critically ill, 1; critically ill, no mechanical ventilation, 1 to 1.1; adult acute, not critically ill, 1.1 to 1.4, depending on activity; adult needing repletion or a child, 1.3 to 2; adult outpatient, 1.1 to 2, depending on activity; and adult depletion (weight loss), less than 1.[104,105]

Indirect calorimetry also can be used to determine the patient's RQ, calculated as VCO_2/VO_2, which reflects substrate oxidation and characterizes substrate utilization. RQ values for nutrient substrates are fat, 0.7; carbohydrate, 1; protein, 0.8; and mixed substrate (fat, carbohydrate, and protein), 0.85. RQ values greater than 1 represent either lipogenesis or hyperventilation; less than 0.7 may indicate a ketogenic diet, fat gluconeogenesis, or ethanol oxidation. Values outside the physiologic range of 0.67 to 1.3 suggest an invalid test. Clinically, the RQ is used to determine if a patient is being overfed, which is likely if the RQ value is greater than 1.

Indirect calorimetry is a respiratory measurement that does not reflect metabolism in all clinical situations. Indirect calorimetry overestimates REE for patients with hyperventilation, metabolic acidosis, overfeeding, and if there are air leaks anywhere in the ventilator circuit. Underestimation of REE is likely with hypoventilation, metabolic alkalosis, underfeeding, and gluconeogenesis. Mechanically ventilated patients are technically easier to study because the indirect calorimeter can be integrated into the ventilator circuit. However, the patient must be at complete rest for 1 hour, must not receive bolus feedings either by feeding tube or orally for 4 hours, should have no changes in substrate delivery for 12 hours, and must be on a fraction of inspired O_2 of less than 0.6 with a positive end-expiratory pressure less than 5 cm H_2O (approximately 0.5 kPa) to ensure an accurate steady-state reading. Unfortunately, many of the patients in whom indirect calorimetry would be most useful will not meet these requirements. Indirect calorimetry should be considered in any patient in whom uncertainty in estimating energy requirements needs to be minimized, such as adults and children who are severely malnourished (BMI less than 18.5 kg/m^2) or obese (BMI greater than 30 kg/m^2), who have unexplained high partial arterial pressure of carbon dioxide ($PaCO_2$) concentrations or minute ventilation, spinal cord injuries, who experience weight loss despite apparently receiving adequate protein and energy intakes, critically ill surgery patients receiving parenteral nutrition, and patients unable to be weaned from the ventilator.[28,104,105]

Protein

Daily protein requirements are based on age, gender, nutrition status, disease state, and clinical condition. Table 141-9 lists the RDAs for protein for children; for individuals older than 18 years of age, the RDA is 0.8 g/kg/day, which is significantly less than most Americans typically consume.[85] In adults older than 60 years of age, protein needs are increased to 1.5 g/kg/day to reduce the loss of LBM that occurs with aging, and 1.5 to 2 g/kg/day or more may be needed in states of metabolic stress (infection, trauma, and surgery).[85,97,106] Protein requirements are also higher in pregnant and lactating women (1.1 g/kg/day or 6-10 g protein per day above the usual RDA).[85]

Protein metabolism depends on both kidney and liver function. Critical illness results in a hypercatabolic state in which there is both increased protein synthesis and degradation. The goal of protein administration is to minimize catabolism by maximizing protein synthesis. Consequently, protein requirements are increased to 1.2 to 2 g/kg/day in critically ill patients. For obese critically ill

patients, protein needs are 2 g/kg IBW or more if the BMI is between 30 and 40 kg/m^2 and 2.5 g/kg IBW or more if the BMI is greater than 40 kg/m^2.[95] Adults with significant total body surface area burns have protein requirements as high as 2.5 to 3 g/kg ABW/day. In children with significant burns, between 20% and 25% of their total calorie needs should be provided as protein.[98] Soft tissue defects and large stool or ileostomy losses also increase protein requirements. Liver failure typically results in the need for protein restriction (0.5 g/kg/day) unless a hypercatabolic state is also present, which will increase requirements to 1.5 g/kg/day. Protein needs in patients with kidney failure are variable and affected by the various renal replacement therapies available. The application of these protein intake guidelines requires both clinical judgment and frequent monitoring of kidney and liver function, serum chemistries, clinical condition, and nutrition outcomes.

Nitrogen is found only in protein and at a relatively constant ratio of 1 g nitrogen per 6.25 g of protein. This ratio may vary somewhat for enteral and parenteral feeding formulations, depending on the biologic value of the protein source. The adequacy of protein intake can be assessed clinically by a nitrogen balance study—measuring urinary nitrogen excretion and comparing it with nitrogen intake. Nitrogen balance indirectly reflects protein use or the protein catabolic rate, which increases with hypercatabolism. As the stress level increases, a concomitant increase in protein catabolism results in an increase in urinary nitrogen excretion. The amount of urine urea nitrogen (UUN) measured in a 24-hour urine collection in healthy individuals, accounts for 80% to 90% of the total urine nitrogen (TUN) excreted. Nitrogen output (g/day) can be approximated as 24-hour UUN + 4, where 4 is a factor representing usual skin, fecal, and respiratory nitrogen losses. At higher UUN values (30 g nitrogen or more), then the use of a factor of + 6 may yield a more accurate measure of nitrogen output.[107] Alternatively, if available, TUN can be measured and may be more accurate, especially in critically ill patients who excrete more nitrogen-containing substances such as 3-methylhistidine. If TUN is used, then the best estimate of nitrogen output is TUN + 1.05.[107] In patients with kidney failure, in which case neither UUN nor TUN accurately represents net protein degradation, nitrogen balance can be approximated only with equations based on urea nitrogen appearance.[108]

Fat

The daily AI for men and women for α-linolenic acid is 1.6 and 1.1 g, respectively; for linoleic acid, it is 14 to 17 g/day for men and 11 to 12 g/day for women.[85] Overall, for adults, fat should represent no more than 10% to 35% of total calories, with the recommendation that saturated fatty acids, *trans* fatty acids, and dietary cholesterol intake be kept as low as possible while a nutritionally adequate diet is consumed. Fat should constitute 30% to 40% of energy in children 1 to 3 years of age and 25% to 35% of energy in children 4 to 18 years of age.[85] Fat intake in children younger than 3 years of age is critical for proper central nervous system growth and development; generally, fat-restricted diets (skim milk) should not be imposed until after the age of 2 to 3 years except under medical supervision. A lower limit of 15% of total energy intake has been suggested as the minimum fat intake in children when fat restriction is warranted.[109]

Fiber

Reduced risk of coronary heart disease and maintenance of normal laxation have been attributed to dietary fiber intake.[110] Fiber intake may also have a role in colon cancer prevention and may promote weight control through its effect on satiety. Men and women 50 years of age and younger should ingest 38 g/day and 25 to 26 g/day, respectively, of total fiber. For men and women older than 50 years of age, the recommended intakes are 30 g/day and 21 g/day, respectively.[85] The AI for fiber has not been set for children younger than 1 year of age. Breast milk and infant formulas are essentially fiber-free. For older children, the recommended fiber intake is 19 g/day for children 1 to 3 years of age, 24 g/day for children 4 to 8 years of age, and 26 to 31 g/day for children 9 to 13 years of age.[85]

TABLE 141-13 Factors That Alter Fluid Requirements

Increased Requirements	Decreased Requirements
Fever	Fluid overload
Radiant warmers	Heart failure
Diuretics	Decreased urine output
Vomiting	Heat shields
Nasogastric suction	Relatively high humidity
Ostomy or fistula drainage	Humidified air via endotracheal tube
Diarrhea	Kidney failure
Glycosuria	Hypoalbuminemia with starvation
Phototherapy	Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Diabetes insipidus	
Increased ambient temperatures	
Hyperventilation	
Prematurity	
Excessive sweating	
Increased metabolism (eg, hyperthyroidism)	

Fluid

The daily fluid requirement for an adult depends on many factors but is generally estimated to be 30 to 35 mL/kg, 1 mL for each kcal (or 4.18 kJ) ingested, or 1,500 mL/m^2. Fluid requirements per kilogram of body weight are higher for children and even higher for preterm infants because of their higher percentage of TBW and basal energy needs. Additionally, premature neonates have increased fluid requirements because of greater insensible losses and the kidneys' inefficiency in concentrating urine. The Holliday-Segar method is a commonly used, quick, and simple method for estimating minimum daily fluid needs of children and adults. Children weighing less than 10 kg should receive at least 100 mL/kg/day. An additional 50 mL/kg/day should be provided for each kilogram of body weight between 11 kg and 20 kg and 20 mL/kg/day for each kilogram above 20 kg. Thus, the minimum fluid required for a child weighing 8 kg would be 800 mL/day, a 17-kg child would need 1,350 mL/day; and a 50-kg individual would need 2,000 mL/day.

Table 141-13 lists factors that alter fluid needs for both adults and children. All sources of fluid intake should be considered (eg, fluid vehicles for intravenous medications and intravenous or feeding tube flushes) when determining fluid requirements. Urine output and specific gravity as well as serum electrolytes and weight changes can be used to assess fluid status. A urine output of at least 1 mL/kg/h (in children) and approximately 40 to 50 mL/h (in adults) is considered adequate to ensure tissue perfusion. Urine output should be higher if large fluid volumes or high renal solute loads (eg, parenteral nutrition or concentrated enteral feeding formulations) are being administered. Urine specific gravity depends on the kidney's concentrating and diluting capabilities. Concomitant diuretic therapy, resulting in increased solute excretion, limits the usefulness of urine specific gravity as an assessment of fluid status.

Micronutrients

Requirements for micronutrients (electrolytes, minerals, trace elements, and vitamins) vary with age, gender, and the route by which the nutrient is ingested (Table 141-14; see Chapters 49 to 51).[53–58,74,92,111] Oral and parenteral requirements vary as a result of bioavailability considerations. Micronutrients poorly absorbed via the GI tract usually are required in greater amounts when given by the enteral than parenteral route. However, many water-soluble micronutrients are excreted more rapidly via the kidneys when administered intravenously. In these situations, the intravenous dose is

TABLE 141-14 Recommended Daily Electrolyte, Trace Element, and Vitamin Intake[a]

	Adult (≥19 yr of age)		Pediatric	
Nutrient	**Enteral**	**Parenteral**	**Enteral**	**Parenteral**
Electrolytes and Minerals

M, men; NE, niacin equivalents; RE, retinol equivalents; TE, tocopherol equivalent; W, women.

[a]Data represent either the recommended dietary allowance (RDA) or the adequate intake (AI) for each nutrient where established.

[b]Not established; as needed to maintain acid–base balance.

[c]Newborns and low-birth-weight or very-low-birth-weight infants or with concomitant disease (eg, necrotizing enterocolitis) may have higher requirements. Intake in nonhealthy children must be individualized.

[d]No RDA or AI has been established.

[e]An additional 20 mcg/day is recommended in patients with significant intestinal losses.

[f]May accumulate in cholestasis.

[g]Long-term parenteral nutrition only if no topical preparations containing iodide or iodized table salt are used.

[h]Higher doses may be required in patients with short bowel syndrome receiving long-term parenteral nutrition.

[i]Additional intake needed with small bowel losses, which can be 12 mg zinc/L or 17 mg zinc/kg of stool or ileostomy output; an additional 2 mg/day needed for acute catabolic stress.

Data from references 53-58, 74, 75, and 93.

greater than the oral dose. Other factors that affect micronutrient requirements include GI losses through diarrhea, vomiting, or high-output fistula or ostomies; wound healing; and hypermetabolism or hypercatabolism. Cutaneous micronutrient losses (eg, zinc, copper, and selenium) also may be significant after major burn injury. Sodium, potassium, magnesium, and phosphorus excretion are particularly dependent on kidney function, and in the settings of acute kidney injury or chronic kidney disease, intake will likely need to be restricted. Calcium needs, on the other hand, may be increased in these patients (see Chapters 44 and 45). Patients who are severely malnourished will have increased electrolyte requirements during early refeeding owing to preexisting deficiencies and rapid intracellular uptake with anabolism. Failure to provide adequate electrolyte replacement, especially phosphorus, and vitamin supplementation (thiamine) before delivery of full calories during refeeding has resulted in death from the refeeding syndrome.[112,113]

DRUG–NUTRIENT INTERACTIONS

10 Drug-induced nutrient deficiency, poor therapeutic response, enhanced drug toxicity, and failure to achieve desired nutrition outcomes can occur if either nutrition support or drug therapy is stopped as a consequence of adverse effects. Patient outcomes may be enhanced when an effective screening method to identify significant drug–nutrient interactions is coupled with a patient counseling program. An important part of the screening process is to recognize risk factors that influence drug–nutrient interactions. The potential for drug–nutrient interactions is greatest in pediatric and elderly individuals, those with poor nutrition status (obesity and marasmus), and those receiving multiple drug therapies or tube feedings.[114-120]

Mineral and electrolyte serum concentrations may change because of drug therapy. For example, with loop diuretics, urine sodium, potassium, calcium, and magnesium wasting may occur, causing a reduction in their respective serum concentrations. Alternatively, calcium excretion is reduced with thiazide diuretics (see Chapter 49). Serum electrolyte concentrations also may increase as a direct result of the drug's mechanism (potassium-sparing diuretics) or because of the drug's salt form (sodium piperacillin/tazobactam). Corticosteroids and cyclosporine are known to cause hyperglycemia; other drugs are prescribed to pharmacologically lower blood glucose concentrations (eg, insulin and oral hypoglycemics; see Chapter 74).

Vitamin and trace element status also may be affected by drugs (Table 141-15). For example, sulfasalazine therapy causes a decrease in folic acid, isoniazid therapy causes pyridoxine deficiency, and furosemide therapy may result in decreased thiamine concentrations. Drug therapy outcomes also may be affected by vitamin intake. For instance, the ingestion of high folic acid doses may decrease methotrexate's therapeutic effect, and changes in an individual's usual vitamin K or vitamin E intake may cause variability in warfarin's anticoagulant effects.

Drug-delivery vehicles also may contain nutrients. Most intravenous therapies (maintenance intravenous fluids, drugs, and electrolyte replacements) are delivered using solutions of either dextrose (dextrose 5% or 10% in water) or sodium (0.9% NaCl). Lipid emulsion (10%) is used as the vehicle for the anesthetic agent propofol and the intravenous calcium channel blocker clevidipine and contributes fat calories (1.1 kcal/mL or 4.6 kJ/mL) when continuous infusions are used. In these instances, nutrition support regimens must be adjusted to accommodate calories and other nutrients delivered through these therapies to avoid overfeeding and other complications.

TABLE 141-15 Drug and Nutrient Interactions

Drug	Effect
Antacids	Thiamine deficiency
Antibiotics	Vitamin K deficiency
Aspirin	Folic acid deficiency; increased vitamin C excretion
Cathartics	Increased requirements for vitamins D, C, and B_6
Cholestyramine	Vitamins A, D, E, and K and β-carotene malabsorption
Colestipol	Vitamins A, D, E, and K and β-carotene malabsorption
Corticosteroids	Decreased vitamins A, D, and C
Diuretics (loop)	Thiamine deficiency
Efavirenz	Vitamin D deficiency caused by increased metabolism of 25(OH)-vitamin D and 1,25-$(OH)_2$-vitamin D
Histamine$_2$ antagonists	Vitamin B_{12} malabsorption (reduced acid results in impaired release of B_{12} from food)
Isoniazid	Vitamin B_6 and niacin deficiency
Isotretinoin	Vitamin A increases toxicity
Mercaptopurine	Niacin deficiency
Methotrexate	Folic acid inhibits effect
Orlistat	Vitamins A, D, E, and K malabsorption caused by fat malabsorption
Pentamidine	Folic acid deficiency
Phenobarbital	Increased vitamin D metabolism
Phenytoin	Increased vitamin D metabolism, decreased folic acid concentrations
Primidone	Folic acid deficiency
Protease inhibitors	Vitamin D deficiency (impaired renal hydroxylation)
Proton pump inhibitors	Vitamin B_{12} malabsorption (reduced acid results in impaired release of B_{12} from food)
Sulfasalazine	Folic acid malabsorption
Trimethoprim	Folic acid depletion
Warfarin	Vitamin K inhibits effect; vitamins A, C, and E may affect prothrombin time
Valproic acid	Zinc
Zidovudine	Folic acid and B_{12} deficiencies increase myelosuppression

Data from references 114-120.

PRACTICAL GUIDELINES FOR NUTRITION ASSESSMENT

The value of any marker used for nutrition screening is only as good as its ability to accurately identify the patient with malnutrition and to correlate with nutrition-related complications. The response of the various nutrition status markers to nutrition therapy and the correlation between improvement in these markers and decreased morbidity and mortality support their validity. However, when applied to an individual, most of these markers lack specificity and sensitivity, which makes the development of a clinically useful, cost-effective approach to nutrition screening challenging.

The importance of the nutrition-focused history and physical examination in both nutrition screening and nutrition assessment cannot be overemphasized. The minimum amount of objective data that can further substantiate the clinical impression and provide a baseline for subsequent monitoring is weight and serum ALB concentration. The cost effectiveness of the addition of other biochemical parameters is unknown. The assessment of other anthropometric measures is most useful in the setting of anticipated long-term nutrition support in which these measurements will serve as a longitudinal marker of response to the nutrition care plan.

Initially, nutrition requirements are determined on the basis of assumptions made about the patient's clinical condition and the nutrition needs associated with repletion or growth, if needed. After a nutrition intervention has been initiated, periodic reassessment of nutrition status is critical to determine the accuracy of the initial estimate of nutrition requirements. Nutrition requirements are dynamic in the setting of acute or critical illness—as the patient's clinical status changes, so will protein and energy requirements, further emphasizing the need for continued reassessment.

Better markers of nutrition status and methods for determining patient-specific nutrition requirements are needed to allow further refinement of estimates of an individual's nutrition needs.

Functional tests and simple, noninvasive tests for body composition analysis hold promise for the future. However, until better methods of assessment become available clinically and are demonstrated to be cost effective, the currently available battery of tests will continue to be the mainstay of nutrition assessment.

ABBREVIATIONS

ABW	actual body weight
AI	adequate intake
ALB	albumin
BEE	basal energy expenditure
BIA	bioelectrical impedance analysis
BMI	body mass index
CDC	Centers for Disease Control and Prevention
CRP	C-reactive protein
DCH	delayed cutaneous hypersensitivity
DRI	dietary reference intake
DXA	dual-energy x-ray absorptiometry
EAR	estimated average requirement
EFAD	essential fatty acid deficiency
GI	gastrointestinal
HIV	human immunodeficiency virus
IBW	ideal body weight
LBM	lean body mass
MREE	measured resting energy expenditure
MRI	magnetic resonance imaging
MST	Malnutrition Screening Tool
RDA	recommended dietary allowance
REE	resting energy expenditure
RQ	respiratory quotient
SGA	Subjective Global Assessment
TBW	total body water
TFN	transferrin
TUN	total urine nitrogen
UBW	usual body weight
UL	tolerable upper intake level
UUN	urine urea nitrogen
VCO_2	carbon dioxide production
VO_2	oxygen consumption
WHO	World Health Organization

Parenteral Nutrition

Todd W. Mattox and Catherine M. Crill

KEY CONCEPTS

1. Development and implementation of an appropriate, individualized nutrition care plan requires definition of nutrition goals, determination of nutrition requirements and appropriate route of nutrient delivery, and design of a monitoring plan to evaluate suitability of the nutrition regimen as a patient's clinical condition changes.
2. The appropriate route of nutrition support depends on the functional condition of the patient's gastrointestinal (GI) tract, risk of aspiration, expected duration of nutrition therapy, and clinical condition.
3. Suitable candidates for parenteral nutrition (PN) therapy can be identified on the basis of their age, nutrition status, expected duration of GI dysfunction, and potential risks of PN therapy.
4. PN formulations include injectable amino acids, dextrose, fat, water, electrolytes, vitamins, trace elements, and other additives.
5. PN solutions may be appropriately formulated for administration by peripheral or central venous access.
6. PN formulations are available as standardized commercial premixed products or they may be compounded with an automated compounding device (ACD).
7. PN solutions may be infused continuously or intermittently.
8. Biochemical and clinical measurements for effective monitoring of patients receiving PN include serum chemistries, vital signs, body weight, total daily fluid intake and losses, and nutritional intake.
9. Non–catheter-related complications of PN therapy can be minimized by using age-appropriate nutrient dosing guidelines, frequent monitoring, and implementing rational adjustments to the PN regimen when metabolic abnormalities occur.
10. Individualized PN therapy should be based on nutrition therapy goals determined from a patient-specific nutrition assessment, type of available IV access, and macronutrient and micronutrient requirements.
11. A patient's nutrient requirements are affected by age, degree of metabolic demand, organ function, drug therapy, exogenous losses, acid–base status, and enteral intake in patients with recovering GI function.

INTRODUCTION

Maintenance of adequate nutrition status during illness has been recognized for more than 50 years as an integral part of the treatment plan for patients who are unable to attain and sustain oral nourishment. Successful techniques for providing IV nutrition support were introduced to clinical practice in adults and subsequently, infants in the late 1960s.[1] Use of central venous access was investigated to reduce risk of metabolic complications associated with IV fluid overload and electrolyte imbalances. The use of large central vessels permitted infusion of concentrated formulas, which decreased the fluid volume required and avoided the phlebitis that commonly occurred when hypertonic infusions were given peripherally.

Clinical experience and research fostered development of protocols that promoted better patient care and resulted in a decline in complications and costs associated with parenteral nutrition (PN) therapy.[2] The scope of practice for nutrition support clinicians has broadened as a result of increasing knowledge regarding the metabolic consequences associated with acute injury and chronic disease states. The pharmacist's role in providing safe and effective nutrition-support care requires knowledge of the principles of patient selection, initial therapy design, outcome monitoring, and strategies for providing therapy during PN product shortages.[3,4] In addition, the pharmacist is uniquely prepared to take on the responsibility for PN order verification as well as compounding and dispensing of the PN admixture. The PN order must be verified by a pharmacist to ensure the order is clear, complete, and correctly transcribed. A clinical review should be performed to confirm appropriate indication, nutrient dosing, and non-nutrient medication dosing. A pharmaceutical review should be performed to confirm compatibility of ordered nutrients and any non-nutrient medications in addition to the expected stability of the formulation.[4,5] Other responsibilities of the nutrition support pharmacist may include development of policy and procedures as well as quality improvement activities for patient care and operational processes associated with providing parenteral and enteral nutrition.[4-7] The clinical role of other healthcare professionals may be similar because of the evolving interprofessional approach to nutritional support.[8-10] This chapter reviews indications for PN, components of PN formulations, routes of IV administration, practical aspects of regimen design, solution admixture, outcome monitoring, and management of complications for both adult and pediatric (neonates, infants, and children) patients.

DESIRED OUTCOMES

1 The primary objective of nutrition support therapy is to promote positive clinical outcomes of an illness and improve a patient's quality of life. Four fundamental steps are key to providing optimal care for patients who require nutrition support. They are establishing patient-specific nutrition goals, determining nutrient requirements to achieve the nutrition goals, assuring delivery of the required nutrients, and subsequently assessing the nutrition regimen.[5-7]

A patient's nutrition goals can be established after a thorough nutritional assessment (see Chapter 141). Nutrient requirements and an appropriate route for delivery of the required nutrients can then be determined. Nutrition support goals include correction of the patient's caloric and nitrogen imbalances and any fluid, electrolyte, vitamin, or trace element abnormalities. An additional goal is to lessen the metabolic response to injury by minimizing oxidant stress

and favorably modulating immune response. These interventions should not cause or worsen other metabolic complications.

2 The gastrointestinal (GI) tract is the optimal route for providing nutrients unless obstruction or other GI complications are present (see Chapter 143).[11,12] Two other considerations that may impact selection of the optimal route for delivery of nutrition support include expected duration of nutrition therapy and risk of aspiration. Patients who have nonfunctional GI tracts or are otherwise not candidates for enteral nutrition may benefit from PN.

INDICATIONS FOR PARENTERAL NUTRITION SUPPORT

The association between malnutrition and development of complications and mortality is well documented for adult and pediatric patients.[12,13] Although improvement in various clinical nutrition markers has been reported for patients who received PN, the impact on clinical outcome has been difficult to demonstrate in many adult populations. Several investigations have reported a positive effect of PN on complications and mortality, but others have failed to confirm these findings.[11,14,15] Early studies have been criticized for defective study design, such as small sample sizes, inappropriate randomization, and inconsistent baseline nutrition status among the study and control groups, which hindered demonstration of the effectiveness of PN therapy. The impact of PN on clinical outcome has been more consistently demonstrated for critically ill infants and children, particularly those with acquired or congenital GI tract anomalies.[16] Consensus guidelines for PN use for adults (Table 142-1) and pediatric (Table 142-2) patients are based on clinical experience and investigations in specific patient populations.[11,12,14,16-20] Unfortunately, conflicting data have resulted in a lack of consistency in published guidelines from different sources, which complicates identification of the patient who is most likely to benefit from PN. However, these published reports may serve as resources for development of institution-specific standards.

3 The decision to initiate PN is based on the findings of an assessment performed after a patient demonstrates an inability to meet nutritional needs enterally for an extended time period. This assessment must include an evaluation of the patient's nutrition status, clinical status, age, and potential risks of initiating therapy (eg, infection and other metabolic abnormalities). The appropriate length of time to wait before starting PN therapy depends on patient age and clinical status.[11,12,14,16-20] Adult PN therapy is not an emergent intervention and should not be initiated until the patient is hemodynamically stable.[11] In general, previously well-nourished, clinically stable adults who are not candidates for enteral nutrition, should be considered candidates for PN after 7 to 14 days of suboptimal nutritional intake.[11,14,20] PN should be initiated as soon as possible in severely malnourished critically ill patients in whom EN is not feasible. Supplemental PN should be considered after 7-10 days in critically ill patients in whom greater than 60% of energy and protein requirements cannot be met by the enteral route alone.[11] The most appropriate time to initiate therapy for infants and children varies with age and nutritional status. Because early PN results in enhanced protein accretion and improved growth in extremely low-birth-weight infants, initiation of PN within the first 24 hours of life in preterm neonates has been recommended.[18,21,22] Withholding PN for 2 to 3 days after birth, coupled with slow advancement of nutrient substrate, only appears to deplete limited energy reserves and contribute to growth failure for many neonates.[21] PN should be initiated within 5 to 7 days for other pediatric patients who are unable to meet their nutrient requirements with via the enteral route.[16] Earlier intervention should be considered for term infants (within 2-3 days), critically ill pediatric patients (within 3-5 days), and those with preexisting malnutrition.

TABLE 142-1 Indications for Adult PN

1. Inability to absorb nutrients via the GI tract because of one or more of the following:
   a. Massive small bowel resection: Usually patients with less than 100 cm of small bowel distal to the ligament of Treitz without a colon or less than 50 cm of small bowel with an intact colon
   b. Intractable vomiting when adequate EN is not expected for 7–14 days.
   c. Severe diarrhea
   d. Bowel obstruction
   e. GI fistulae: PN is indicated in patients with prolonged inadequate nutritional intake longer than 5–7 days who are not candidates for EN
2. Cancer: Antineoplastic therapy, radiation therapy, or HSCT
   a. PN may be used in moderately to severely malnourished patients receiving active anticancer treatment who are not candidates for EN.
   b. PN is not routinely indicated for well-nourished or mildly malnourished patients undergoing surgery, chemotherapy, or radiation therapy.
   c. PN is unlikely to benefit patients with advanced cancer whose malignancy is unresponsive to treatment. However, use may be appropriate for carefully selected patients who have failed trials of less invasive medical therapies and have good performance status, an estimated life expectancy of longer than 40–60 days, and strong social and financial support.
   d. PN is appropriate in patients undergoing HSCT who are malnourished and who are anticipated to be unable to ingest or absorb adequate nutrients for 7–14 days. PN should be discontinued as soon as toxicities have resolved after stem cell engraftment.
3. Pancreatitis: PN may be used in patients with severe pancreatitis with prolonged inadequate nutritional intake longer than 5–7 days who are not candidates for EN. PN should be used when EN exacerbates abdominal pain, ascites, or fistula output.
4. Critical care
   a. PN should be used in malnourished patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements as soon as possible after ICU admission and adequate resuscitation.
   b. PN should be reserved and initiated only after the first 7 days of hospitalization for previously well-nourished patients.
   c. Organ failure (liver, renal, or respiratory): PN should be used in patients with moderate to severe catabolism when EN is contraindicated.
   d. Burns: PN should be used in those patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 4–5 days.
5. Perioperative PN
   a. Preoperative: For 5–7 days for patients with moderate to severe malnutrition who are undergoing major GI surgery if the operation can be safely postponed
   b. Postoperative: PN should be used in patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 7–14 days after surgery.
6. Hyperemesis gravidarum: when EN is not tolerated
7. Eating disorders: PN should be considered for patients with anorexia nervosa and severe malnutrition who are unable or unwilling to ingest adequate nutrition.

EN, enteral nutrition; GI, gastrointestinal; HSCT, hematopoietic stem cell transplantation; ICU, intensive care unit; PN, parenteral nutrition; SBS, short-bowel syndrome.

Data from references 11, 14, 15, 19, and 20.

Clinical **Controversy...**

Early enteral nutrition (within 24-48 hours of admission to an intensive care unit) is recommended as the preferred route for nutrition support in critically ill patients. Many clinicians maintain PN should be withheld unless enteral nutrition cannot be achieved within 7 days because of data that associate early PN with negative clinical outcomes. Conversely other clinicians may recommend early supplemental PN to prevent the protein–energy deficit that has been associated with worsening clinical outcomes in some studies.

TABLE 142-2 Indications for Pediatric PN

1. When enteral nutrition is unlikely to provide adequate nutritional requirements
   a. Premature infant within 24–48 hours
   b. Other pediatric patients within 5–7 days
2. When the GI tract is not functional or cannot be assessed
   a. Massive small bowel resection resulting in short-bowel syndrome
   b. Neonatal necrotizing enterocolitis
   c. Congenital anomalies of the GI tract
   d. Severe inflammatory bowel disease
   e. Intractable diarrhea or vomiting
   f. Graft vs host disease
   g. After chemotherapy
3. Infants and children requiring extracorporeal membrane oxygenation
4. Organ failure (liver, renal, pulmonary, pancreas) or congenital heart disease when enteral nutrition is contraindicated and the child is catabolic

GI, gastrointestinal; PN, parenteral nutrition.

COMPONENTS OF PARENTERAL NUTRITION

4 PN formulations include IV sources of protein, dextrose, fat, water, electrolytes, vitamins, trace elements, and other additives. PN solutions should provide the optimal combination of macro- and micronutrients to provide a patient's specific nutritional requirements. Macronutrients include water, protein, dextrose, and fat (Table 142-3). Micronutrients include vitamins, trace elements, and electrolytes. Both macronutrients and micronutrients are necessary for maintenance of normal metabolism. In general, macronutrients are used for energy (dextrose and fat) and as structural substrates (protein and fat). Micronutrients on the other hand support a variety of metabolic activities necessary for cellular homeostasis such as enzymatic reactions, fluid balance, and regulation of electrophysiologic processes.

Over the past 5 to 7 years, shortages of all PN components have been reported.[3,23] The unavailability of these products has resulted in delays in PN therapy initiation, restricted or limited nutrient dosing, and negative effects on all steps of the PN process that have compromised patient health and safety. Providing safe therapy during PN product shortages can be challenging for PN patients and practitioners.[5] Conservation recommendations and alternative therapy measures may need to be employed to optimize quality of care and avoid patient harm.[3]

Amino Acids

Protein in PN solutions is provided in the form of crystalline amino acids (CAAs), which when oxidized for energy yield 4 cal or approximately 17 J per gram of protein. However, including the caloric contribution from protein when calculating calories provided by the PN regimen is controversial.[24] While sufficient energy substrate should be provided to allow utilization of amino acids for protein synthesis rather than an energy source, oxidation of amino acids for energy has been demonstrated in critically ill patients and is thought to occur because of metabolic derangements seen during severe metabolic stress. Hence, some practice settings may differ in expressing calories provided by a PN regimen as total calories (protein, carbohydrate, and fat calories) or non-protein calories (carbohydrate and fat calories).

Commercially available CAA solutions may be categorized as standard amino acid solutions or modified amino acid solutions. Standard CAA solutions are designed for patients with "normal" organ function and nutritional requirements (see Table 142-3). Although standard CAA solutions differ in the proportion of specific amino acids, they contain a balanced profile of essential, semi-essential, and nonessential L-amino acids. Despite these differences, similar effects on markers of protein use have been reported.[25] The protein concentration, total nitrogen, and electrolyte content may also differ among products. Because the nitrogen concentration of dietary protein is approximately 16%, 6.25 (100 g protein/16 g nitrogen) is commonly accepted as the conversion figure for calculating the nitrogen amount provided by CAA protein. Differences in nitrogen content per gram of amino acids among CAA products may affect calculation of nitrogen amounts infused when determining nitrogen balance.[25,26] The clinical significance of these differences in determining nitrogen balance for routine clinical use is unknown.[26]

Electrolyte composition of standard CAA solutions varies from small, obligatory amounts to the provision of maintenance requirements of most electrolytes for an adult. Electrolytes provided by CAA solutions must be considered when determining a patient's individual requirements. CAAs are available in several different concentrations, which facilitates compounding of patient-specific PN regimens. Use of highly concentrated products (15%-20% amino acids)

TABLE 142-3 Macronutrient Components of PN Solutions

Nutritional Substrate	IV Source	Description
Fluid	Sterile water for injection USP	
Nitrogen	Crystalline amino acids Standard solutions	Contain a balanced profile of essential, semi-essential, and nonessential L-amino acids
	Disease-specific solutions	
	Hepatic encephalopathy	Amino acid profile includes higher BCAA concentrations and lower AAA and methionine concentrations
	Renal failure	Amino acid profile includes higher EAA and histidine concentrations
	Metabolic stress or trauma	Amino acid profile provides standard essential, semi-essential, and nonessential amino acids with higher BCAA concentrations
	Pediatrics	Amino acid profile includes standard essential, semi-essential, and nonessential amino acids with lower methionine, phenylalanine, and glycine concentrations; these solutions also contain taurine, glutamate, and aspartate
Energy		
Carbohydrate	Dextrose	
	Glycerol	Used in ProcalAmine (B. Braun Medical, Inc.)
Fat	IV fat emulsion LCT emulsions Mixed fat emulsions	Fatty acid source Soybean Soybean-Olive Oil SMOF (soybean oil, MCT, olive, and fish oils)
	Alternative fat emulsions (investigational)	Olive oil Fish oil Mixed fat emulsions: MCT-LCT MSF (MCT, soybean, and fish oils)

AAA, aromatic amino acids (includes phenylalanine and tyrosine); BCAA, branched-chain amino acids (leucine, isoleucine, and valine); EAA, essential amino acids (leucine, isoleucine, valine, phenylalanine, tryptophan, methionine, threonine, and lysine); LCT, long-chain triglycerides; MCT, medium-chain triglycerides; MSF, MCT, soybean, and fish oils; PN, parenteral nutrition; SMOF, soybean oil, MCT, olive, and fish oils; USP, United States Pharmacopeia.

is attractive for critically ill patients who typically require fluid restriction but have large protein needs. Modified amino acid solutions are designed for patients who have altered protein requirements, such as those with hepatic encephalopathy, renal failure, and metabolic stress or trauma, as well as for neonates and pediatric patients (see Table 142-3). These solutions tend to be more expensive than standard CAA solutions. The rationale for and clinical efficacy of modified amino acids in disease-specific PN regimens is also controversial because of inconsistency in clinical outcomes reported in multiple clinical trials.[11,15,19,27]

Several commercially available CAA solutions are designed to provide conditionally essential amino acids, which are considered nonessential during health because they are produced from other amino acids. However, under certain physiologic conditions, such as prematurity or sepsis, these amino acids cannot be synthesized in sufficient quantities.[25] CAA solutions specifically designed for neonates and pediatric patients contain increased amounts of taurine, aspartic acid, and glutamic acid. Other conditionally essential amino acids, such as cysteine, carnitine, and glutamine, are not available in commercial CAA solutions in pharmacologic amounts because they are relatively unstable or poorly soluble.[25]

Clinical **Controversy...**

Exclusive use of standardized, commercially prepared premixed IV products has been advocated to improve medication safety. However, the American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) has reported that patient safety data do not support the general use of standardized PN formulations across healthcare organizations.

Consequently, PN solutions may need to be modified to provide the desired amount of supplemental conditionally essential amino acids. For example, cysteine is a conditionally essential amino acid for preterm and term infants because of their enzymatic immaturity of the trans-sulfuration pathway. Cysteine may be added to PN solutions at the time of compounding as a supplement to CAA solutions and to enhance calcium and phosphate solubility by decreasing solution pH.[28] Carnitine is a quaternary amine required for long-chain fatty acid transport into the mitochondria for β-oxidation and energy production. Newborns are at risk for carnitine deficiency because of their immature biosynthetic capacity. Decreased plasma carnitine concentrations have been reported in infants and children receiving PN without carnitine.[18] Supplemental carnitine may be added to the PN solution at the time of compounding. Although the benefit of carnitine supplementation in PN has not been clearly identified, positive effects on nutritional markers, including improved fatty acid oxidation, weight gain, and nitrogen balance, have been documented. In general, carnitine supplementation is reserved for neonates expected to receive PN support for 7 days or longer.[18]

Glutamine is the most abundant free amino acid in the body and is an important intermediate for many metabolic processes. Glutamine is reported to have an important role in maintaining intestinal integrity, immune function, and protein synthesis during conditions of metabolic stress.[29] Investigations in humans and animals have reported positive effects on nutritional markers such as nitrogen balance, but others have reported significant improvement in other outcome markers, such as decreased length of hospitalization, incidence of infections, and GI toxicities associated with chemotherapy or radiation.[29] Unfortunately, the best candidate for response to glutamine therapy has not been clearly identified.[29] Use of both intravenous and enteral glutamine in combination with a variety of antioxidant supplements in critically ill adult patients has been associated with increased mortality.[30] Although an association between increased brain volume and head circumference has been reported in school-aged children, who were premature at birth and received glutamine during the first year of life,[31] the clinical usefulness of glutamine in neonates and infants is not clear.[29,32,33] Plasma glutamine concentrations increase with supplementation, but no beneficial effect on sepsis incidence or outcome, enteral feeding tolerance, necrotizing enterocolitis, growth, or mortality has been reported.[29,32,33] The clinical use of glutamine is further complicated because there is no parenteral glutamine formulation commercially available in the United States. Currently available CAA solutions do not contain glutamine because of poor solubility and instability. Use of parenteral glutamine requires special manufacturing techniques not readily available in many institutional pharmacies.[29] However, parenteral glutamine has been made available from several licensed pharmacies that extemporaneously compound glutamine crystalline powder under sterile conditions either as a separate parenteral solution or as a part of a CAA solution. Recent Food and Drug Administration (FDA) mandated changes in conditions under which a human drug product that has no applicable United States Pharmacopeia (USP) or National Formulary (NF) monograph or is not a component of an FDA-approved drug can be used to compound a prescription medication may create further obstacles to obtaining extemporaneously compounded glutamine-containing PN formulations. The FDA's Pharmacy Compounding Advisory Committee, which provides advice on scientific, technical, and medical issues concerning drug compounding, has recommended to not allow the use of alanyl-L-glutamine in compounding due to insufficient information to fully assess safety related to impurities of the product.[34,35]

Dextrose

The primary energy source in PN solutions is carbohydrate, usually in the form of dextrose monohydrate, hereafter referred to as dextrose which is available in concentrations ranging from 5% to 70%. When oxidized, each gram of dextrose provides 3.4 kcal (14.2 kJ). The appropriate IV dextrose dose depends on the patient's age, estimated caloric requirements, and clinical condition. For example, minimum dextrose requirements for neonates are estimated to be approximately 6 to 8 mg/kg/min and infusion rates should not exceed 14 to 18 mg/kg/min for infants or 4 to 7 mg/kg/min for adults.[18,21,36] The recommended dextrose dose for routine clinical care rarely exceeds 5 mg/kg/min for adolescents and adults.[18,36] Maintaining an age-appropriate dextrose infusion rate is necessary to minimize risk of adverse effects. If the dextrose infusion rate exceeds the glucose oxidation rate, metabolically expensive pathways, such as glycogen repletion and lipid synthesis, are favored, resulting in increased energy expenditure, increased oxygen consumption, and increased carbon dioxide production. Excessive dextrose infusion rates also may contribute to the development of hyperglycemia and an increase in the concentration of biochemical markers indicative of fatty infiltration of the liver.[36,37]

Carbohydrate sources that are not insulin-dependent have been investigated as an alternative to dextrose to improve glycemic control for patients with impaired insulin secretion or activity who require PN. Glycerol, a sugar alcohol, that provides 4.3 kcal/g (18 kJ/g), is the only dextrose alternative commercially available. It is available as an isotonic, 3% solution in combination with 3% amino acids and supplemental electrolytes (ProcalAmine, B. Braun Medical, Irvine, CA). Although the solution may be peripherally infused, a major disadvantage of this product is the dilute amino acid and carbohydrate concentrations. Most adult patients require up to 3 to 4 L/day of ProcalAmine solution together with IVFE as a caloric source to meet minimum energy requirements.[38] IV glycerol use for catabolic adults is safe and effective, but similar data are not available for infants and children.[39]

Intravenous Fat Emulsion

Intravenous fate emulsion (IVFE) is used as a concentrated source of calories and essential fatty acids. Although commercially available IVFE products have traditionally contained soybean oil (SO) or a combination of SO and safflower oil, IVFE products containing safflower oil are no longer commercially available. However, a new IVFE product containing a mixture of SO and olive oil (OO) was recently approved for use in adults.[40] SO-based IVFE products have been marketed in 10%, 20%, and 30% concentrations while the SO-OO product is only marketed as a 20% emulsion. The 10% SO IVFE products are currently unavailable because of discontinued production or a prolonged manufacturer's stock shortage.[18] Both types of IVFE contain egg phospholipids as an emulsifying agent and glycerol to make the emulsion isotonic. Although the caloric contribution of fat is 9 kcal/g (38 kJ/g), the caloric content of 10% IVFE is 1.1 kcal/mL (4.6 kJ/mL), 2 kcal/mL (8.4 kJ/mL) for the 20% emulsion, and 3 kcal/mL (12.6 kJ/mL) for the 30% emulsion because of the caloric contribution of the egg phospholipid and glycerol.[18] The fatty acid composition of SO IVFEs varies between approximately 44% to 62% linoleic acid and 4% to 11% linolenic acid.[41] While the fatty acid composition of the SO-OO product is approximately 14% to 22% linoleic acid, 0.5% to 4% linolenic acid, 44% to 80% oleic acid, 8% to 19% palmitic acid, and 0.7% to 5% stearic acid.[40] Linolenic acid, an omega-3 fatty acid, and linoleic acid, an omega-6 fatty acid, are both polyunsaturated long-chain triglycerides (LCTs).[41] Palmitic and stearic acids are saturated LCTs while oleic acid is an unsaturated LCT.[41] The concentrated SO IVFEs (20% and 30%) have a lower phospholipid-to-triglyceride ratio compared with 10% SO IVFE.[18,42] Because higher amounts of circulating phospholipids are associated with impaired triglyceride clearance in neonates and infants, 20% SO IVFE is the preferred product for this population. The more concentrated 30% IVFE would be an attractive alternative as well but its use is approved only for the preparation of total nutrient admixture (TNA) formulations which are not recommended for use in neonates and infants.[5,18,42]

SO–based IVFE is effective for treatment or prevention of essential fatty acid deficiency (EFAD) in both adult and pediatric patients. EFAD is the result of a biochemical deficiency of linoleic acid and arachidonic acid, which are considered essential for humans.[43] Linoleic and linolenic acids are important for a variety of functions such as cellular integrity, platelet function, postnatal brain development, and wound healing.[43] Normally, linoleic acid is converted to the tetraene arachidonic acid. When linoleic acid is not present in sufficient amounts, oleic acid is converted to the triene 5,8,11-eicosatrienoic acid, a fatty acid of lesser physiologic integrity, and as a result EFAD develops. EFAD may be prevented by providing 2% to 4% of total calories as linoleic acid and 0.25% to 0.5% of total calories as linolenic acid.[44] This may be achieved for most adult patients by giving approximately 100 g SO IVFE weekly.[36,44] Neonates and infants require a minimum of 0.5 to 1 g/kg daily.[18,45] The SO-OO product is currently not approved for use in pediatric patients because of its lower linoleic and linolenic acid content and lack of clinical data demonstrating provision of adequate essential fatty acids to prevent or treat EFAD when used in recommended doses.[40]

Plasma IVFE clearance is directly related to gestational age of infants and appears to be influenced by the infusion rate and the patient's clinical status.[18,42,45] The risk of developing hypertriglyceridemia decreases with longer infusion times.[42,44,45] Rapid IVFE infusions are reported to contribute to decreased oxygenation for neonates.[45,46] Adverse pulmonary effects are thought to be caused by polyunsaturated fatty acid (PUFA)–driven prostaglandin production, which results in altered vascular tone. Although the association between IVFE and pulmonary dysfunction is not clear, a boxed warning appears in the FDA product labeling for both SO and SO-OO IVFE that acknowledges deaths in preterm infants associated with pulmonary fat accumulation thought to be related to IVFE infusions.[18,40,47] In addition, data for animals and humans also suggest that rapid infusion of long-chain fatty acid formulations may have a negative impact on immunocompetence by saturating the reticuloendothelial system.[36,48]

As a caloric source, IVFE use may facilitate provision of adequate calories and minimize complications of nutrition therapy such as hyperglycemia, hepatotoxicity, or increased carbon dioxide production.[36] Although the frequency of acute adverse effects is reported to be less than 1% with current formulations, patients receiving their first IVFE dose should be monitored for dyspnea, chest tightness, palpitations, and chills. Headache, nausea, and fever also have been reported and might be associated with a rapid infusion rate. In general, IVFE use is contraindicated for patients with an impaired ability to clear fat emulsion, such as patients with pathologic hyperlipidemia, lipoid nephrosis, and hypertriglyceridemia associated with pancreatitis.[47] Finally patients with an egg allergy should be evaluated carefully for the nature and severity of the reaction before deciding to initiate a fat-based PN regimen.

Commercially available 10% and 20% IVFE products may be administered by either the central or the peripheral route. They may be added directly to the PN solution as a TNA, also referred to as a three-in-one system (lipids, protein, glucose, and additives), or they may be co-infused with the CAA-dextrose solution, commonly referred to as a two-in-one admixture.[44,47] The more concentrated 30% IVFE is only approved for use in the preparation of TNA and is not intended for direct IV administration.

IVFEs with SO as the lipid source have negative effects on immune function as the result of omega-6 PUFA influence on proinflammatory eicosanoid production. These negative effects on immune function have stimulated a search for alternative IVFE sources that provide adequate essential fatty acids but lower amounts of omega-6 FA such as the SO-OO emulsion.[41,48] The SO-OO IVFEs provide essential fatty acids, are a rich source of vitamin E, and appear to have a neutral effect on immune function because of the decreased amount of omega-6 PUFA linoleic acid.[41] Medium-chain triglycerides (MCTs) may offer several advantages, especially for critically ill patients. MCTs are hydrolyzed and cleared more rapidly than LCTs, and they do not accumulate in the liver. In addition, MCTs do not require carnitine for entrance into mitochondria for oxidation. However, MCTs are not a source of essential fatty acids. Subsequent studies of IV MCT-LCT mixtures in a number of patients demonstrate safety and efficacy comparable with standard LCT emulsions.[41,48]

Several alternative IVFE products are not currently available in the United States. However, one mixed IVFE product available in Europe that includes soybean oil, MCT, olive oil and fish oil was recently FDA-approved for use in adults. Other IVFE that are available outside the United States include a fish oil-based emulsion, and a soybean, MCT, and fish oil combination (Table 142-3).[41,48] (see Table 142-3). Fish oil–based IVFE contain predominantly omega-3 PUFAs, which are metabolized to cytokine mediators that may be less inflammatory and immunosuppressive than those derived from omega-6 PUFAs. The clinical effect of IVFE administration on immune function, as well as on patient morbidity and mortality, is not clear.[41,48] However, investigations of enteral solutions with a higher concentration of omega-3 PUFAs have reported decreased infections and improvement of in vitro immunologic indices in critically ill patients.[43,49] Recent evidence suggests that SO–based IVFE, which contains phytosterols and predominantly omega-6 PUFAs, may play a greater role in the development of PN-associated liver disease (PNALD).[50] Investigations of fish oil–based IVFE have reported improvement in or reversal of PNALD.[41,50] The SO-OO emulsion contains phytosterols as well, but the effect on development of PNALD is not known.

Clinical **Controversy...**

The association between SO IVFE and PNALD has stimulated modifications to standard clinical practice, including SO IVFE dose restriction and / or the replacement of SO IVFE with fish oil–based IVFE. The risk for developing EFAD as a result of decreased LCT when reducing or eliminating SO IVFE from the parenteral diet is controversial.

Although IVFE products remain the most common source of parenteral fat, a number of drugs have been introduced that contain lipid either as a vehicle for delivery or as a portion of the drug formulation. Propofol, an IV anesthetic, is delivered in a SO-in-water emulsion that has essentially the same composition and caloric concentration as 10% IVFE. This agent is used commonly for continuous sedation of mechanically ventilated patients and should be considered a potentially significant source of calories that may require adjustment of a patient's nutrition regimen.[51] Clevidipine is an injectable calcium channel blocker that contains 20% IVFE as a vehicle that may be a potentially clinically significant source of IV fat when used as a continuous infusion for multiple days of therapy.[52] The antifungal amphotericin B is available in several lipid-containing combinations such as liposomal and lipid complex formulations. The caloric contribution from these products when used in standard doses generally is small and is not clinically relevant.

Vitamins

The Nutrition Advisory Group of the American Medical Association (NAG-AMA) recommended in 1975 the daily parenteral supplementation of 13 essential (four fat-soluble and nine water-soluble) vitamins for pediatric and adult patients based on requirements for healthy people.[53]

Since these original recommendations, the NAG-AMA has revised the guidelines for children to primarily reflect changes for preterm infants requiring PN.[53] The FDA also mandated in 2000 changes in adult parenteral vitamin formulations (inclusion of vitamin K and higher doses of vitamins B_1, B_6, and C).[53]

The amount of vitamin K supplementation in parenteral multivitamin formulations has been debated. The NAG-AMA recommendation for vitamin K for adults is 2 to 4 mg weekly, while other practitioners recommend larger doses of 0.5 to 1 mg/day or 5 to 10 mg weekly.[44] Vitamin K was not included in early multivitamin formulations due to the potential for drug-nutrient interactions in patients receiving anticoagulants, and the amount mandated to be included in 2000 (150 mcg/day) was considerably lower than other recommended requirements. However, an investigation of patients receiving long-term IVFE-containing PN with vitamin K–free parenteral multivitamins at home suggested that supplemental vitamin K may not be necessary to maintain normal prothrombin times and plasma vitamin K concentrations.[54] SO used in IVFEs is a natural source of phylloquinone (vitamin K_1). However, the vitamin K concentration is dependent on the SO concentration in the IVFE.[54-56] Mean concentrations of 30.9 and 67.5 mcg/100 mL were reported for 10% and 20% Intralipid (Baxter Healthcare Corporation, Deerfield, IL), a SO–based IVFE. The bioavailability of vitamin K from IVFEs is unknown. Although hospitalized patients who received no additional vitamin K supplementation during short-term PN that included a low vitamin K-containing IVFE experienced minimal effects on international normalized ratio, supplemental vitamin K may be given intramuscularly or subcutaneously or added to the PN solution if needed.[55] Current recommendations suggest supplemental vitamin K is unnecessary when a vitamin K-containing multiple-vitamin product is used.[44]

The 2012 A.S.P.E.N. recommendations advocate for the continued availability of multivitamin products with and without vitamin K so that clinicians have the ability to withhold vitamin K supplementation in patients receiving warfarin therapy. Most adult parenteral multiple-vitamin products which are available commercially contain vitamin K. MVI-12, multivitamin infusion without vitamin K is available from Hospira, Inc. Lake Forest, IL. Two parenteral multiple-vitamin products are commercially available for use for pediatric patients. MVI-Pediatric (Hospira Inc.) and Infuvite Pediatric (Baxter Healthcare Corporation) are formulated to meet the revised NAG-AMA guidelines for infants weighing less than 1 kg (2.2 lb) and children up to 11 years. However, there are no commercially available injectable multivitamin products designed to specifically meet the unique requirements of premature infants, including higher vitamin A and lower doses of vitamins B_1, B_2, B_6, and B_{12}.

Vitamin requirements may be altered in malnutrition and other specific disease states or with certain drug therapies. Individual and combination products are available to provide additional or tailored supplementation, which may be necessary to prevent development of vitamin toxicities or deficiencies caused by altered metabolism or drug therapy.

The 2012 A.S.P.E.N. recommendations question whether the vitamin D content of parenteral multivitamins is adequate to meet current Recommended Dietary Allowances (RDA) and advocate for the addition of a parenteral vitamin D product for PN-dependent patients who are unresponsive to additional enteral vitamin D supplementation.[53] In addition, the recommendations support the continued production of adult injectable multivitamin products with and without vitamin K and for the supplementation of carnitine (2-5 mg/kg/day) in neonatal PN and choline in all patients receiving PN.[53]

Trace Elements

Many trace elements are an important part of metalloenzymes and function as cofactors in a variety of regulatory metabolic pathways.[57] Although 17 trace elements have demonstrated biologic importance, clear deficiency syndromes in humans have been described only for cobalt (as vitamin B_{12}), copper, iodine, iron, and zinc.[57-59] In 1979, the NAG-AMA recommended chromium, copper, manganese, and zinc supplementation for patients receiving PN.[53,57] Recommendations followed in 1984 to also supplement with selenium.[53,57] Although a clear deficiency syndrome for manganese has not been reported in humans, the NAG-AMA considered manganese essential based on case reports of patients receiving PN with metabolic complications that corrected after manganese supplementation. Reports of deficiency syndromes associated with selenium and molybdenum suggest that they also may be essential.[57,58] Although iodine deficiency has not been reported for patients receiving short-term PN, it has been observed in patients receiving long-term PN and may be related to the use of chlorhexidine for central-line care instead of povidone–iodine.[60]

Injectable trace elements are available as single-trace element solutions and as multiple-trace element combinations. The use of single-entity injectable products allows for individualization of trace mineral supplementation of chromium, copper, iodine, manganese, selenium, and zinc. Recent shortages have threatened the supply of both the combination and single-entity products.[3] Most combination products for adults provide the daily requirements for the trace elements considered essential by the NAG-AMA (ie, chromium, copper, manganese, selenium, and zinc).[18] While combination products approved for use in the United States for neonates and pediatric patients have contained only chromium, copper, manganese, and zinc, additional options are now available.[18] (Table 142-4) In response to widespread injectable trace element product shortages, the FDA implemented in 2013 a temporary enforcement discretion to allow the importation of alternative injectable trace element products.[61] A combination product for adults provides fluoride, iodine, molybdenum, and iron, in addition to the standard five trace elements included in US adult products

TABLE 142-4 Imported Sterile Injectable Parenteral Nutrition Products[61-63]

Imported Product (Manufacturer)	Content
Sodium Glycerophosphate Injection Glycophos™ (Fresenius Kabi, USA LLC)	- Contains 1 mmol phosphate and 2 mEq Na per mL compared to US products which contain 3 mmol phosphate and 4 mEq Na per mL.
Adult Trace Elements Addamel™ N (Fresenius Kabi, USA LLC)	- Copper contains 9 trace elements: zinc chloride chloride, manganese chloride, chromic chloride, sodium selenite, ferric chloride, sodium molybdate, potassium iodide, and sodium fluoride.
Pediatric Trace Elements Peditrace™ (Fresenius Kabi, USA LLC)	- Contains 6 trace elements: zinc chloride, copper chloride, manganese chloride, sodium selenite, potassium iodide, and sodium fluoride.
Zinc Injectable Zinc gluconate trihydrate (Aguettant)	- Active substance is equivalent to 1 mg of elemental zinc per mL.

(chromium, copper, manganese, selenium, zinc).[61] The pediatric combination product content differs from the US products in that it lacks chromium and includes selenium, fluoride, and iodine.[61] A single-entity injectable zinc product has also recently been made available.[62] Clinicians should be cautious when transitioning between products to ensure correct doses are being ordered, compounded, and administered to patients because the United States and imported products vary not only by trace element content but also by salt form and trace element doses per unit.[61] In addition, potential interactions resulting in stability or compatibility problems should be considered because frequently information for use of imported injectable products with US products is limited.

Requirements for trace elements also vary on the basis of the patient's clinical condition. For example, higher doses of supplemental zinc likely are necessary for patients with high-output ostomies or diarrhea because the GI tract is the predominant excretion route for zinc. Whereas manganese and copper are excreted through the biliary tract, chromium, molybdenum, and selenium are excreted renally. Hence, these trace elements should be restricted or withheld from PN solutions for patients with cholestatic liver disease and renal failure, respectively.

A.S.P.E.N. recommended formulation changes to the available injectable multiple-trace element preparations for PN patients.[53] The recommendations support overall decreased contamination of trace elements in large- and small-volume PN products.[53] The recommendations advocate for decreased copper and manganese, no (or decreased) chromium, and inclusion and increased dose of selenium in all injectable adult multiple-trace products.[53] The recommendations also support products with no chromium, decreased manganese, and the inclusion of selenium in all injectable pediatric multiple-trace products.[53]

Electrolytes

Electrolytes such as sodium, potassium, calcium, magnesium, phosphorus, chloride, and acetate are necessary PN components for the maintenance of many cellular functions. Electrolytes may be given to maintain normal serum concentrations or to correct deficits. Patients who have "normal" organ function and relatively normal serum concentrations of any electrolyte should receive "normal" maintenance electrolyte doses when PN is initiated and daily thereafter. Specific electrolyte requirements vary according to the patient's age, disease state, organ function, previous and current drug therapy, nutrition status, and extrarenal losses. Electrolytes are available commercially as single- and multiple-nutrient solutions. Multiple-electrolyte solutions are useful for stable patients with normal organ function who are receiving PN. Concentrated multiple-electrolyte solutions designed for addition to PN solutions generally contain only sodium, potassium, calcium, and magnesium. Phosphorus must be added as a separate additive. In response to a severe injectable phosphorus shortage, the FDA implemented a temporary enforcement discretion to allow importation of sodium glycerophosphate injection.[63] (see Table 142-4) This injectable organic phosphorus product has been reported to be more soluble with calcium chloride and calcium gluconate in PN solutions. However, widely used published calcium-phosphorus solubility data is only available for inorganic sodium phosphate with PN products available in the United States which makes use difficult with ACDs and compounding software. Further information regarding metabolism and requirements of vitamins, trace elements, and electrolytes is given elsewhere.[44,64]

DESIGNING A PARENTERAL NUTRITION REGIMEN

5 Several factors, including the patient's venous access, fluid status, and macronutrient and micronutrient requirements, are important considerations when designing the PN regimen. A patient's venous access and fluid status determines the maximum PN osmolar concentration which will impact the nutrient amount that may be provided. PN solutions may be administered by central or peripheral venous access. The patient's clinical condition determines which route is most appropriate.

Parenteral nutrition formulations may be provided as a two-in-one admixture that contains dextrose, CAA, and other necessary micronutrients or as a three-in-one admixture or TNA that contains dextrose, CAA, and IVFE, as well as other necessary micronutrients. Use of TNA solutions offers several potential advantages, including reduced inventory (infusion pumps, tubing, and other related supplies), decreased time for compounding and administration, a potential decrease in manipulations of the infusion line (which should correspond with a decreased risk of catheter contamination), and ease of delivery and storage for patients receiving home PN.[65] Potential disadvantages include increased risk of infections and stability and compatibility concerns. For example, the stability of TNA admixtures is less predictable than that of two-in-one admixtures, which makes their use less desirable in some patient populations such as neonates and infants.[44,66]

Routes of Parenteral Nutrition Administration

Peripheral Route

Peripheral parenteral nutrition (PPN) is an option for mild to moderately stressed patients for whom central access is unavailable or undesirable and function of their GI tract is expected to return within 10 to 14 days.[20,67] Potential PPN candidates should not be fluid-restricted or require large nutrient amounts. Lower concentrations of amino acids (3%-5% final concentration), dextrose (5%-10% final concentration), and micronutrients compared with central parenteral nutrition (CPN) must be used for peripheral administration. Because PPN solutions are relatively dilute, larger volumes are usually necessary to provide nutrient requirements. Additionally, many patients who receive PPN likely will require IVFE to achieve the desired caloric intake at levels consistent with CPN regimens. The primary advantages of PPN include a lower risk of infectious, metabolic, and technical complications.[67] Patients who have poor venous access as the result of multiple courses of chemotherapy, malnutrition, and illness of long duration which has required multiple venous accesses for fluid and medication administration as well as premature infants and the elderly are likely to be poor candidates for PPN.

TABLE 142-5 Osmolarities of Selected Parenteral Nutrients

Nutrient	Osmolarity
Amino acid	100 mOsm/%
Dextrose	50 mOsm/%
Lipid emulsion (20%)	1.3–1.5 mOsm/g
Sodium (acetate, chloride)	2 mOsm/mEq
Sodium phosphate	3 mOsm/mEq sodium
Potassium (acetate, chloride)	2 mOsm/mEq
Potassium phosphate	1.7–2.7 mOsm/mEq potassium
Magnesium sulfate	1 mOsm/mEq
Calcium gluconate	1.4 mOsm/mEq

PPN use is also limited by relatively poor peripheral vein tolerance to hypertonic solutions. Thrombophlebitis is a commonly reported complication for patients receiving PPN.[66] Although the risk of phlebitis is greater with solution osmolarities greater than 600 to 900 mOsm/L, peripherally administered TNA with much higher osmolarities to adults has been associated with low infusion-site complications in some centers.[66,67] Efforts to minimize development of phlebitis or infiltration sequelae for patients receiving PPN include addition of IVFE as a possible venous lumen protectant, subtherapeutic heparin doses (0.5-1 unit/mL) to prevent thrombus formation, or small doses of hydrocortisone (5 mg/L) to minimize access site inflammation.[66,67] However, the coinfusion of IVFE with PPN (ie, not provided as a TNA) has not been shown to reduce phlebitis. In addition, heparin has not been shown to reduce catheter-related thrombosis and is not compatible for use in TNAs.[66] Midline catheter use may offer some advantage and has been associated with a reduced risk of thrombophlebitis.[68] Although these catheters are not central venous access devices, they are longer and infuse into larger venous vessels that may dilute the PPN solution to a more tolerable osmolarity. The osmolarity of a PN solution may be estimated by using the guidelines for osmolarities of selected PN components in Table 142-5.

Central Route

CPN is the preferred route for PN delivery and is used predominantly for patients who require PN for periods of more than 7 to 14 days during hospitalization or indefinitely at home.[20,44,69] These patients may have large nutrient requirements; poor peripheral venous access; or fluctuating fluid requirements, such as metabolically stressed patients with extensive surgery, trauma, sepsis, multiple-organ failure, or malignancy. CPN solutions are highly concentrated hypertonic solutions that must be administered through a large central vein. Unlike peripheral veins, central veins have a higher blood flow, which quickly dilutes the hypertonic solutions. Disadvantages of CPN include risks associated with catheter insertion, routine catheter use, and care of the access site. Relative to peripheral venous access, central venous catheter (CVC) access is associated with a greater potential for infection. In addition, the risk of more serious catheter-induced trauma and related sequelae and other serious technical or mechanical problems is are greater than that with peripheral access.

The choice of central venous access site depends on a number of factors, including the patient's age and anatomy. CVCs vary in composition, lumen size, number of injection ports, and other features that affect ease or convenience of care and maintenance. CVCs for short-term use for adults are commonly inserted percutaneously into the subclavian vein and advanced so that the tip is at the superior vena cava.[68] If this approach is not possible, the internal jugular vein can be used. Frequently, short-term central venous access is obtained for critically ill neonates via a catheter placed in the umbilical vein. Other sites for central venous access in infants and older children are similar to those in adults. When therapy is expected to last longer than 4 weeks, the catheter usually is tunneled subcutaneously before entering the central vessel, secured initially with retaining sutures, and anchored in place with a felt cuff that promotes subcutaneous fibrotic tissue growth around the catheter. The injection port may remain external or may be concealed entirely beneath the skin. Implanted CVCs have a larger port or reservoir that is surgically placed beneath the skin surface and anchored in the chest wall muscle. Peripherally inserted central catheters (PICCs) are venous access devices that are inserted into a peripheral vein (basilic, cephalic, or brachial) and advanced so that the tip is at the superior vena cava.[65] PICCs are increasingly used for both short- and long-term central venous access in acute or home care settings because of ease and economy of bedside placement.[44,69]

Constructing a Parenteral Nutrition Regimen

After the route of delivery is chosen, the components of the PN regimen are determined based on the patient's nutritional assessment. Although not recommended due to increased potential for errors, some healthcare systems may require the entire PN order to be written in individual components and additives on traditional paper order forms without the use of a standard order form. Standardized electronic PN orders suitable for computerized prescriber order entry (CPOE) have been recommended for all patients to minimize risk of errors associated with the ordering process.[5,44] Standardized order forms or clinical decision support within electronic PN ordering systems promote education of practitioners by providing brief guidelines for initiating PN and foster cost-efficient nutrition support by minimizing errors in ordering, compounding, and administration.[5,44,66] Standardized order forms also may include options for ordering certain related procedures, laboratory tests, protocols for patient management, or consultations with other medical services related to the patient's nutrition support.

Adult Parenteral Nutrition Solutions

6 In general, there are two methods for ordering adult PN. The "standard formula approach" offers a variety of admixtures with a fixed nonprotein-calorie-to-nitrogen ratio. This method usually includes different formulas for mild to moderately stressed patients, and those who have kidney or liver failure or are fluid-restricted. Because the nonprotein-calorie-to-nitrogen ratio is fixed, the daily amount of nutrient delivered depends solely on the volume infused. Standard institutional PN formulations may be compounded; however, standardized commercial PN products or "premixed" solutions are available from several manufacturers.[70] A standard institutional formula may promote clinician prescribing of a complete, balanced formulation and promote consistent provision of stable and compatible admixtures. However, efficiencies associated with use of the standard formula approach may be hindered if there is a frequent need to modify the PN formulation. Finally, standard PN formulations may be difficult to use in complicated patients, such as neonatal or pediatric patients, and those with severe malnutrition, organ failure, glucose intolerance, large GI losses, or critical illness.[70]

The "individualized formula approach" permits compounding of patient-specific admixtures. Compounding of the PN admixture is limited only by the concentrations of stock solutions and stability of the additives. The nutrient amount delivered depends on the daily volume of the PN solution infused and the nutrient amounts in the PN solution. The total daily amount of PN solution may be prepared in multiple bags or more cost-effectively in a single container.[44]

Traditionally, adult PN formulations have been ordered by expressing the final concentrations of each component in the solution. For example, CAA and dextrose are ordered commonly in final percentage, electrolytes in milliequivalents in milliequivalents (or millimoles) per liter, and per liter, and other additives in amount

(milliliters or units) per day. This inconsistency may promote confusion and misinterpretation of PN admixture contents that may result in harm, especially when patients are transferred between health system environments. To ensure that PN labels in all health system environments clearly and accurately reflect the PN admixture contents, guidelines for standardized adult PN labeling have been recommended.[5,44] In addition to including a variety of other information on the label such as dosing weight and administration route, the guidelines recommend expressing PN ingredients in amounts per daily volume, which minimizes the need for pharmaceutical calculations to determine the nutrient value of the admixture. Commercially available computer software for calculating PN formulations include the recommended A.S.P.E.N. labeling guidelines (Baxter Healthcare, Deerfield, Il.; B. Braun Medical Inc., Bethlehem, PA)[5,44] Pharmaceutical calculations of a an adult TNA PN regimen are briefly reviewed (Fig. 142-1).

Several guidelines are available to help simplify calculation of a PN regimen after a patient's nutritional requirements have been decided. For example, adult patients receiving only PN therapy may need larger volumes of fluid to provide maintenance requirements and replace extrarenal losses. However, patients requiring other IV drug therapy may receive adequate fluid from an additional IV maintenance solution (eg, 0.45% NaCl in 5% dextrose) or co-infused medications (or both). Depending on individual institutional

Calculation of an Adult PN Regimen

Patient case: A patient's daily nutritional requirements have been estimated to be 105 g protein and 2,200 total kcal. The patient has central venous access and reports no history of diabetes, hyperlipidemia, or egg allergy. The patient is not fluid-restricted. The PN formulation will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a TNA. Determine the total PN volume and administration rate by calculating the macronutrient solution volumes required to provide the desired daily nutrients. The PN products used for this regimen are 10% CAA, 70% dextrose, and 30% IVFE.

1. Determine the daily IVFE calories and volume.
   - 2,200 kcal/day × 30%–40% of total calories as fat = 660 – 880 kcal/day
   - Choose 660 kcal to minimize IVFE calories; calculate 30% IVFE volume

     660 kcal ÷ 3 cal/mL 30% IVFE = X mL X = 220 mL 30% IVFE

   - Calculate IVFE gram amount
     30 g/100 mL = X g/220 mL 30% IVFE X = 66 g IVFE

2. Determine the appropriate volume of 70% dextrose to deliver the desired dextrose calories
   - Dextrose calories = Total kcal – IVFE kcal – Protein kcal
     = 2,200 kcal – 660 kcal IVFE – (4 kcal × 105 g CAA) = 1,120 kcal
   - Calculate required dextrose (grams):

     1,120 kcal ÷ 3.4 kcal/g dextrose = 329 g dextrose

   - Determine 70% dextrose volume
     70 g/100 mL = 329 g/X mL 70% dextrose; X = 470 mL 70% dextrose

2. Determine the appropriate volume of 10% CAA
   10 g/100 mL = 105 g/X mL 10% CAA X = 1,050 mL 10% CAA

3. Determine the TNA PN volume and administration rate
   - Calculate CAA/dextrose/IVFE volume:
     470 mL 70% dextrose + 1,050 mL 10% CAA + 220 mL 30% IVFE = 1,740 mL
   - Add 100-200 mL for additives:
     Total TNA volume = approximately 1,840-1,940 mL/day
   - Calculate the administration rate:
     1,840 to 1,940 mL/day ÷ 24 h = 77 to 81 mL/h; round up to 80 to 85 mL/h

4. Choose final TNA regimen and determine final concentrations of CAA, dextrose, and IVFE
   - Final TNA regimen
     105 g CAA/329 g dextrose/66 g IVFE in 1,920 mL/d to infuse at 80 mL/h
   - Calculate final concentrations of CAA, dextrose, and IVFE
     - 105 g CAA/1,920 mL = X g/100 mL X = 5.5% CAA
     - 329 g dextrose/1,920 mL = X g/100 mL X = 17.1% dextrose
     - 66 g IVFE/1,920 mL = X g/100 mL X = 3.4% IVFE

FIGURE 142-1 Calculation of an adult PN regimen. To convert to energy units of kilojoules (kJ) multiply values with kilocalories as the numerator (kcal, kcal/mL, kcal/kg, kcal/g) by 4.18 to give the corresponding value in kilojoules (kJ, kJ/mL, kJ/kg, kJ/g). (CAA, crystalline amino acids; IVFE, intravenous fat emulsion; PN, parenteral nutrition; TNA, total nutrient admixture.)

practices, maximally concentrating the PN admixture and using an inexpensive maintenance fluid to manage hydration may provide a cost-effective regimen that requires fewer adjustments. Another guideline that may be helpful in designing a PN regimen is to allow a volume of approximately 100 to 150 mL/L of base solution (approximately 200-300 mL/day) for electrolytes and other additives. PN regimens for patients who require very small amounts of additives, such as patients with kidney failure, may need further concentration.

Pediatric Parenteral Nutrition Solutions

Pediatric PN admixtures are typically ordered using an individualized approach because current safe clinical practice guidelines recommend nutrient intakes based on the patient's weight.[5,44] To simplify pediatric PN ordering, many institutions use a pediatric-specific PN order form that expresses daily nutrient amount based on weight. For example, protein and fat are ordered as grams per kilogram per day, dextrose as milligrams per kilogram per minute, and electrolytes as milliequivalents per kilogram per day. However, some institutions may order macronutrients by expressing the final concentration of each component in the solution. Current safe practice guidelines recommend ordering all PN ingredients based on weight as "amount per kilogram per day."[5,44] The PN bag label should accurately reflect the weight-based order as well. Calculations for determining a pediatric PN admixture are reviewed to illustrate fundamental concepts for ordering pediatric PN formulations (Fig. 142-2). Additional features of the pediatric PN label include the dosing weight, administration date and time, expiration date, infusion rate, and duration of infusion. Because infants and children generally receive daily maintenance fluid from the PN regimen, supplemental IV solutions are rarely needed. Pediatric PN may be provided as a two-in-one admixture or TNA. However, the TNA system is not recommended for compounding neonatal and infant PN because of IVFE instability with the often needed higher calcium and phosphorus concentrations.[44,66] The IVFE labeling guidelines for pediatric PN are similar to adult IVFE labeling recommendations.

Administration Techniques

PN admixtures should be administered with an infusion pump. The IV administration line for CAA-dextrose solutions should include a 0.22-micron inline filter to remove particulate matter, air, and any microorganisms that may be present in the solution. IVFE's may be administered separately from the CAA-dextrose solution by co-infusion into the PN line. A port beyond the inline filter must be used because the average size of IVFE particles is approximately 0.5 microns.[5,44] However, co-infused IVFE should also be filtered with a 1.2 micron filter.[47] The FDA recommends use of a 1.2-micron filter with TNA solutions, which may be effective in preventing catheter occlusion caused by precipitates or lipid aggregates.[5,44] This filter size is also reported to remove *Candida albicans*.

INITIATING AND ADVANCING THE PARENTERAL NUTRITION INFUSION

Adult Parenteral Nutrition

The patient's nutrition status, current clinical status, history of glucose tolerance, and dextrose concentration in the formula will dictate the infusion rate at which the adult PN solution should be initiated. Stable patients with normal organ function and stable baseline serum glucose concentrations have demonstrated minimal effect on serum glucose concentrations when PN is abruptly initiated or discontinued.[5,71] However, another approach is to begin the PN infusion and increase the rate gradually over 12 to 24 hours to the desired rate. The infusion rate may likewise be reduced in a stepwise fashion, such as decreasing the rate by 50% for 1 hour before discontinuation.[5,71] This approach should prevent development of hyperglycemia and rebound hypoglycemia, respectively. Alternatively, the PN regimen may be initiated at the goal infusion rate but with a hypocaloric dextrose dose. The dextrose dose can be increased daily to the goal based on patient response. Tapered initiation and cessation should be considered for patients receiving intermittent subcutaneous regular insulin; patients with severe kidney or liver disease; and patients with other disease states that have an increased risk for development of hyperglycemia or hypoglycemia, such as severe diabetes or pancreatic malignancy.

Although the IVFE dose should not exceed 2.5 g/kg per day or 60% of total daily calories, lower doses of 1 g/kg per day not to exceed 30% of calories have been recommended to minimize negative effects associated with long-chain fatty acids.[44] Manufacturer's information recommends IVFE infusion over 4 to 8 hours for adults.[47] However, co-infusion over 12 hours as a separate infusion with 2-in-1 admixtures and infusion over no longer than 24 hours in a TNA formulation appears to be the best clinical strategy to promote IVFE clearance and minimize risk of negative effects on infection control and pulmonary and immune function.[5,44]

The manufacturer's guidelines recommend initiating IVFE for adults with a test dose of 0.5 to 1 mL/min for the first 15 to 30 minutes because of the potential for an immediate hypersensitivity reaction.[47] For most patients, this is probably not necessary because of the relatively low incidence and benign nature of acute adverse reactions. In addition, infusion over 12 to 24 hours eliminates the need for a test dose because the infusion rate is within the range of the recommended test dose rates. Appropriate electrolytes should be provided to patients with normal organ function based on standard nutrient ranges.[44] Adjustments may be necessary depending on the patient's clinical condition. Adults and children older than 11 years should receive daily amounts of trace elements and an adult vitamin formulation.

Pediatric Parenteral Nutrition

Pediatric PN solutions are typically initiated with a volume calculated to provide the patient's daily maintenance fluid requirements on the first day of therapy. Individual nutrient substrates are then advanced daily as tolerated with the goal PN regimen generally being achieved by day 3 of therapy. However, the PN formulation should be initiated with the goal of achieving the desired protein dose on day one. The initial dextrose dose for older infants and children is based on their previous glucose tolerance. Although practices may vary, one approach is to start with 10% dextrose and advance the concentration in 5% increments daily, as tolerated, to goals of 10 to 14 mg/kg/min in infants, 8 to 10 mg/kg/min in children, or 5 to 6 mg/kg/min in adolescents.[18] Initial dextrose doses for premature infants should approximate fetal nutrient delivery rates of 5 to 6 mg/kg/min. Frequently, this results in a final PN dextrose concentration of 5% to 10%. The dextrose concentration for the neonatal PN should be advanced daily by 1% to 2.5% or by 2 to 4 mg/kg/min increments to a goal of 10 to 14 mg/kg/min (maximum, 14-18 mg/kg/min).[18] IVFE is usually initiated at 0.5 g/kg/day for neonates and 0.5 to 1 g/kg/day for infants and children and increased daily by 0.5 to 1 g/kg/day. Incremental increases of IVFE dose allow daily serum triglyceride evaluation and early detection of those with impaired fat clearance. The IVFE dose should not exceed 60% of total daily calories for neonates and 30% of total calories for children, and the maximum IVFE dose should not exceed 3 g/kg/day (approximately 30 kcal/kg/day [126 kJ/kg/day]) for infants and 2.5 g/kg/day for children.[18] The best clinical strategy for minimizing the risk of adverse effects associated with IVFE administration and promoting IVFE clearance is to infuse IVFE over 20 to 24 hours or at a rate of no more than 0.15 g/kg/h.[18,45,66]

IV electrolytes, vitamins, and trace elements should be initiated on the first day of therapy and continued as a daily component of

Calculation of a Pediatric PN Regimen

The nutrition requirements for a 2-week-old preterm neonate (28 weeks gestation; weight 1.2 kg) have been estimated to be 3.5 g/kg/day protein, 3 g/kg/day IVFE, 100 nonprotein kcal/kg/day, and 150 mL/kg/day fluid. The neonate has central access and no prior history of hyperlipidemia or egg allergy. The PN regimen will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a 2-in-1 solution with 20% IVFE co-infused into the PN infusion line. Determine the macronutrient calculations to deliver this neonate's nutrition goals; 10% pediatric CAA and 70% dextrose stock solutions will be used to compound the solution.

1. Determine the goal daily IVFE amount, volume, and administration rate
   - 3 g/kg/day IVFE × 1.2 kg = 3.6 g
   - Calculate 20% IVFE volume
     - 20 g/100 mL = 3.6 g/X mL
     - X = 18 mL/day of 20% IVFE (15 mL/kg/day)
   - Calculate the IVFE administration rate:
     - 18 mL 20% IVFE ÷ 24 hours = 0.75 mL/h (rate may need to be rounded up to 0.8 mL/h or down to 0.7 mL/h depending on precision capability of infusion pump)
2. Determine the goal 2-in-1 PN volume and administration rate
   - Total volume based on maintenance fluid requirements
     - 150 mL/kg/day (estimated fluid goal) – 15 mL/kg/day (20% IVFE) = 135 mL/kg/day for PN volume
     - 135 mL/kg/day × 1.2 kg = 162 mL/day
   - PN infusion rate is 162 mL/day ÷ 24 hours = 6.75 mL/h (rate may need to be rounded up to 6.8 mL/h or down to 6.7 mL/h depending on precision capability of infusion pump)
3. Determine the daily protein amount and the corresponding 10% CAA volume
   - Calculate the goal protein amount
     - 3.5 g/kg/day × 1.2 kg = 4.2 g/day
   - Calculate the 10% pediatric CAA stock solution volume
     - 10 g/100 mL = 4.2 g/X mL 10% pediatric CAA
     - X = 42 mL 10% pediatric CAA
4. Determine the daily dextrose amount, corresponding 70% dextrose volume, and final dextrose concentration in the 2-in-1 PN solution
   - Goal is to provide approximately 14 mg/kg/min dextrose
     - 14 mg x 1.2 kg × 1,440 minutes/day ÷ 1,000 mg/g = 24.2 g dextrose
   - Calculate the 70% dextrose volume
     - 70 g/100 mL = 24.2 g/X mL 70% dextrose
     - X = 34.6 mL 70% dextrose
   - Calculate the final dextrose concentration of the PN solution
     - 24.2 g dextrose/162 mL = X g/100 mL
     - X = 14.9% dextrose (round up to 15% dextrose final concentration)
     - 162 mL × 15% dextrose = 162 × 15 g/100 mL = 24.3 g dextrose
5. Determine the available volume for additives
   - 162 mL – 42 mL (10% pediatric CAA) – 34.6 mL (70% dextrose) = 85.4 mL
   - Depending on volume needed for additives, sterile water may be necessary to add to formulation to make final total volume of 162 mL
6. Determine the final PN regimen and provided nutrient amounts
   - Final PN regimen
     - 3.5 g/kg/day pediatric CAA and 15% dextrose to infuse at 6.75 mL/h
     - 3 g/kg/day (or 18 mL) 20% IVFE to infuse at 0.75 mL/h
   - Macronutrient calories

Dextrose:	24.3 g × 3.4 kcal/g	=	82.6 kcal
Protein:	4.2 g × 4 kcal/g	=	16.8 kcal
20% IVFE	18 mL × 2 kcal/mL	=	36 kcal
Total kcal (kcal/kg):			135.4 kcal (113 kcal/kg)
Nonprotein kcal (kcal/kg):			118.6 kcal (99 kcal/kg)

FIGURE 142-2 Calculation of a pediatric PN regimen. To convert to energy units of kilojoules, multiply values with kilocalories as the numerator (kcal, kcal/mL, kcal/kg, kcal/g) by 4.18 to give the corresponding value in kilojoules (kJ, kJ/mL, kJ/kg, kJ/g). (CAA, crystalline amino acids; IVFE, intravenous fat emulsion.)

the PN solution.[44] Children younger than 11 years should receive a vitamin product formulated for pediatric patients. Two multivitamin dosing schemas have been suggested for infants and children.[44] One method recommends 2 mL/kg/day for infants weighing less than 2.5 kg (less than 5.5 lb) and 5 mL/day for infants and children weighing 2.5 kg (5.5 lb) or greater. The other suggests 30% of a vial (1.5 mL/day) for infants weighing less than 1 kg (less than 2.2 lb), 65% of a vial (3.25 mL/day) for infants weighing 1 to 3 kg (2.2-6.6 lb), and 100% of the vial (5 mL/day) for children weighing more than 3 kg (6.6 lb) (up to 11 years of age). Adult injectable vitamin products

should not be used for infants because of potential neurotoxicity from accumulation of polysorbate and propylene glycol preservatives. Weight-based dosage recommendations for pediatric multiple trace element products are 0.3 mL/kg for children weighing less than 3 kg (less than 6.6 lb) and 0.2 mL/kg for children weighing 3 kg (6.6 lb) or greater (maximum, 5 mL/day). Children weighing more than 25 kg (55 lb) should receive an adult trace element product. The weight-based dosage recommendation for the imported pediatric multiple trace element product is different than that for the US products (1 mL/kg up to a maximum of 15 mL per day).[61] Weight-based doses of the multiple trace element products do not provide the recommended daily intake for all trace elements, so additional supplementation or individual dosing with single-entity products may be necessary. Individualized dosing allows for dose adjustment based on serum trace element assessment, individual patient characteristics (eg, cholestasis, stool losses, wounds), and the need to minimize administration of trace elements that accumulate in patients receiving chronic PN such as chromium and manganese. Pediatric patients receiving PN commonly transition from PN support to enteral nutrition gradually, over a period of days to weeks, by decreasing the PN infusion rate while increasing the enteral intake. The PN infusion rate should be reduced for 1 to 2 hours before stopping the infusion for neonates and infants because of their immature counter-regulatory mechanisms that contribute to an increased risk for developing rebound hypoglycemia.[16] Blood glucose concentrations should be measured within 15 to 60 minutes after the PN infusion ends.

Continuous versus Cyclic Infusions

7 Continuous infusions are attractive for patients with unstable fluid balance or glucose homeostasis. The intermittent or cyclic infusion of PN over less than 24 hours, usually for 12 to 18 hours each day, is useful for hospitalized patients with limited venous access in whom administration of multiple other medications requires interruption of the PN infusion.[71] Cyclic PN also may minimize the incidence or reverse the liver injury associated with continuous PN therapy. In addition, this delivery mode allows patients receiving PN at home the ability to resume a relatively normal lifestyle.[69,71] Various protocols have been reported that suggest incremental increases to the maximum infusion rate for a desired period of time followed by a gradual taper to discontinue the solution have been sugested.[16,71] However, metabolically stable adults and children older than 2 years receiving IVFE–based PN regimens are likely candidates for abrupt initiation and discontinuation of their intermittent PN regimen.[5,16,71,72] Cyclic PN should be used with caution for those with severe glucose intolerance, diabetes, or unstable fluid balance.

EVALUATION OF THERAPEUTIC OUTCOMES

8 Thorough and consistent monitoring of patients who are receiving PN is necessary to ensure that the desired nutritional outcomes are achieved and to prevent the occurrence of adverse effects or complications. Routine evaluation should include the assessment of the patient's clinical condition with a focus on nutritional and metabolic effects of the PN regimen. Serial documentation of a patient's response to their PN regimen is a helpful guide for determining appropriate adjustments in fluid, electrolyte, and nutrient therapies.

Serum concentrations of electrolytes, hematologic indices, and biochemical markers for kidney and liver function, and nutrition status should be measured before PN initiation and periodically thereafter depending on the patient's age, nutrition status, and clinical condition. The frequency of blood laboratory measurements for neonates and infants tends to be more conservative because of their smaller blood volumes and, in some cases, lack of central vascular access. Other important clinical measurements include vital signs, weight, total fluid intake and output, and nutritional intakes. Weekly measurements of height, length, and head circumference are helpful for monitoring nutritional changes in neonates. Monitoring parameters considered important for patients receiving PN and the suggested frequency of measurement for each are outlined in Fig. 142-3. Appropriate assessment and evaluation of patient data can identify potential complications that may be avoided or treated early. Monitoring protocols should be developed and tailored for the patient population, medical practices, and resources of individual practice settings.

COMPOUNDING, STORAGE, AND INFECTION CONTROL

The USP Chapter 797 details the procedures and requirements for compounding sterile preparations, including PN admixtures.[73] These standards apply to all healthcare settings in which sterile preparations are compounded and are used by boards of pharmacy, the FDA, and accreditation organizations such as The Joint Commission. Compounded sterile preparations are defined by risk level (immediate use, low, low with 12-hour beyond-use date, medium, and high) based on the probability of microbial, chemical, or physical contamination. PN solutions are classified as a medium-risk compounded sterile preparation. In general, PN solutions should be prepared using aseptic technique in a device or room that meets International Organization for Standardization (ISO) class 5 standards that is located in an ISO class 7 buffer area with an ISO class 8 ante area.[73] Preparation of PN formulations should be supervised by a pharmacist experienced in compounding IV solutions and knowledgeable about the stability, compatibility, and storage of PN admixtures. Quality assurance procedures should be developed to maintain safe and accurate admixture preparation. A standardized process for PN ordering, labeling, determining nutrient requirements, screening of the PN order, PN administration, and monitoring has been recommended to minimize risk of potentially life-threatening compounding errors.[5,44,70] The potential risk of infectious complications associated with PN solution contamination can be decreased greatly when pharmacy-based admixture programs follow specific guidelines developed to ensure proper compounding of PN solutions.[5,73]

In general, the type of solution being prepared dictates the compounding, storage, and infusion methods. Currently, the two most commonly used types of PN solutions are two-in-one admixtures with or without IVFE co-infused into the PN line and TNAs. Methods for compounding PN admixtures vary based on a healthcare system's patient population and medical practices and the number of PN admixtures that need to be prepared. PN base admixtures may be prepared by using gravity-driven transfer of CAA stock solutions to partially filled bags of concentrated dextrose stock solutions.[44,74] Other practice settings may use standardized commercial PN products with CAA and dextrose, and more recently, IVFE separated within a single bag that must be mixed before use.[44,70] Advances in compounding technology have facilitated the use of ACDs for preparing PN solutions. These devices are computer-based systems that perform the calculations necessary to determine volumes of nutrient-stock solutions for PN admixtures. In addition, most ACD systems include software that communicates the determined calculations directly to a transfer pump device that delivers fluid from the source container to the final container by either a volumetric or gravimetric fluid pumping system.[74] Advantages of ACDs include reduced personnel time and compounding materials and improved compounding accuracy. Disadvantages include the potential for equipment failure. Because of their acidic pH and hypertonicity, two-in-one PN admixtures are poor media for microbial growth.[44] However, several characteristics of IVFE, such as isoosmotic tonicity, near neutral to alkaline pH, glycerol content, and preservative-free

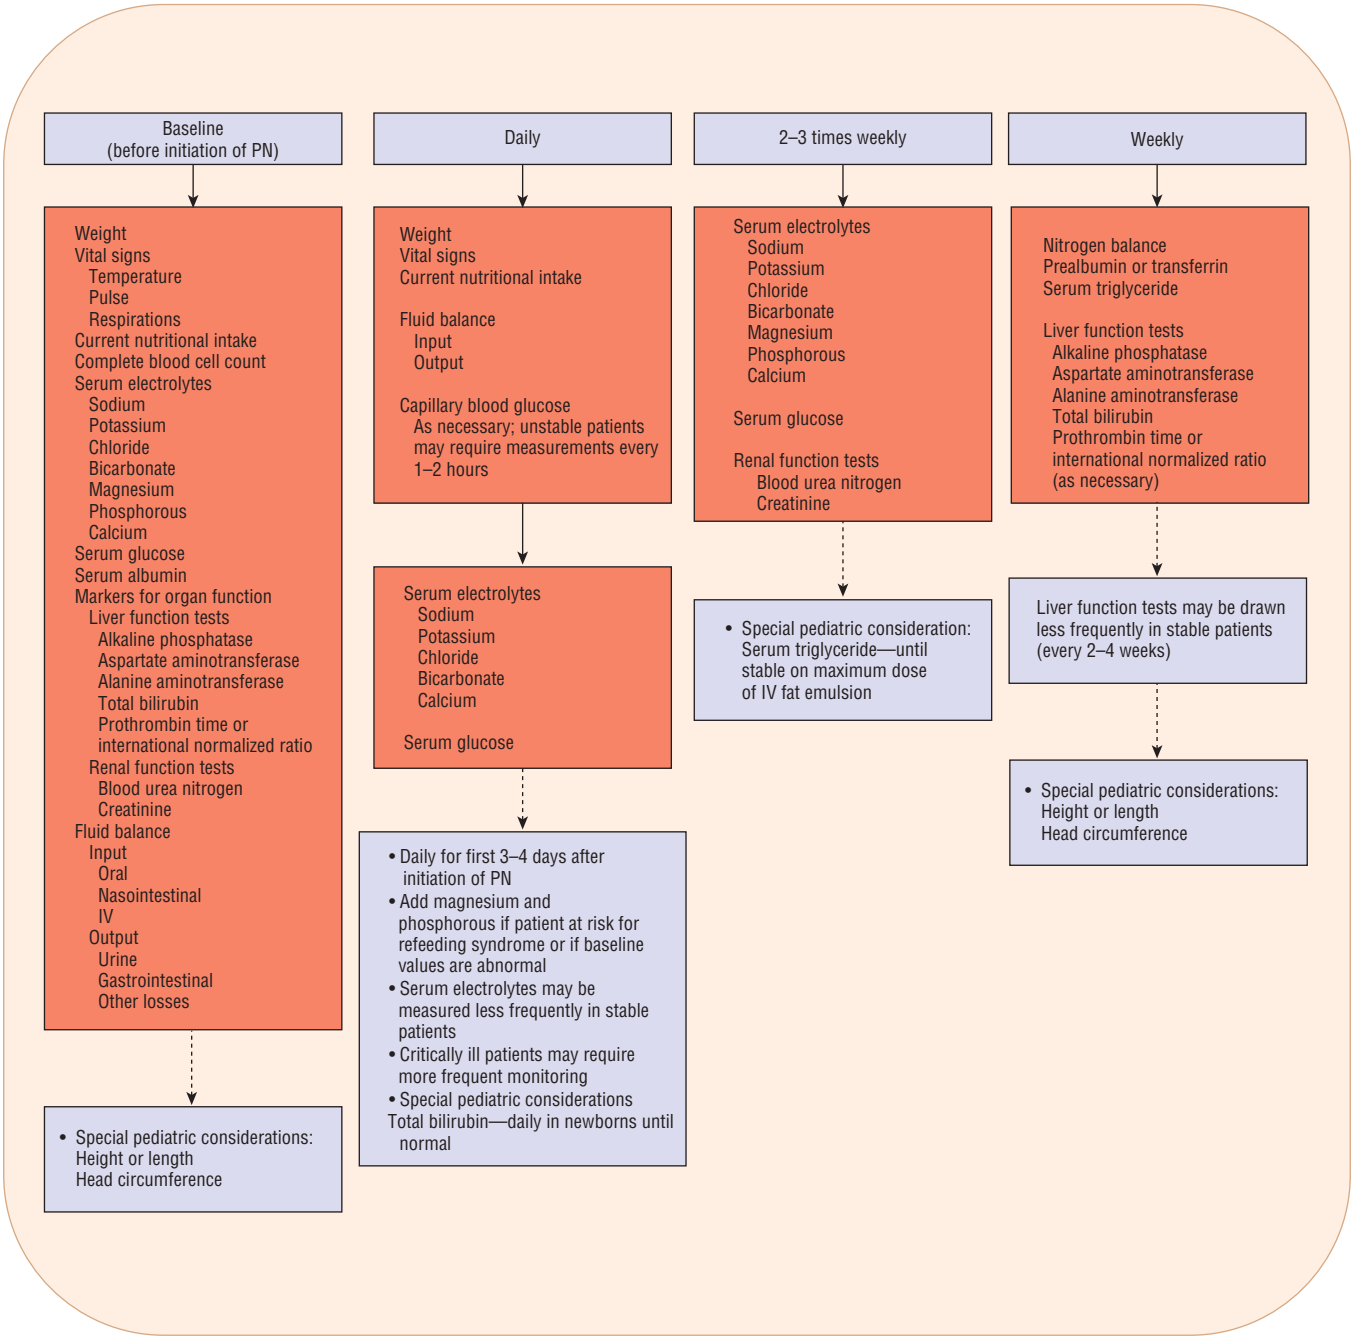

FIGURE 142-3 Monitoring strategy for patients receiving parenteral nutrition (PN).

formulations favor microbial growth, particularly at room temperature.[44] Other factors contributing to the potential for compromised IVFE stability or sterility include the container material, length of IVFE co-infusion with PN, length of time between administration set change, effect of infusion from the source container such as the original container, and infusion of IVFE transferred to a secondary container. When IVFEs are added to dextrose-CAA solutions to make TNAs, the growth potential is decreased, presumably because of the protective effects of the hypertonic dextrose-CAA solution and decreased pH.[66]

Because of the risk for microbial contamination, manufacturers recommend storage of PN solutions for as little time as possible after preparation. The USP 797 standards recommend storage times of not more than 30 hours at controlled room temperature (20°C to 25°C [68°F to 77°F]) and not more than 9 days at refrigerated temperatures (2°C to 8°C [36°F to 46°F]) for all medium-risk compounded sterile preparations, including PN admixtures.[73]

When co-infusing IVFE with PN (ie, not as a TNA), the appropriate IVFE dosage form (original packaging or re-packaged doses) and administration time to minimize risk of contamination is controversial. Unfortunately, The Centers for Disease Control and Prevention (CDC) guidelines offer no guidance for administration times.[68] Instead, the guidelines recommend administration tubing replacement every 24 hours for both IVFE infused separately or when given as part of a TNA. The guidelines also recommend administration tubing replacement no more frequently than at 96-hour intervals but at least every 7 days for tubing used continuously for infusion of IV solutions other than blood, blood products, or IVFE. More conservative recommendations have been presented.[5,44,66] The A.S.P.E.N. 2013 PN Safety Consensus suggests a 24-hour infusion time and administration tubing replacement every 24 hours for TNAs and 2-in-1 PN formulations and a 12-hour infusion time and administration tubing replacement every 12 hours for IVFE co-infused separately.[5]

Compliance with A.S.P.E.N. recommendations in pediatric patients is problematic. For example, an infant receiving 3 g/kg/day IVFE at an maximum infusion rate of 0.15 g/kg/h to promote lipid clearance and minimize metabolic complications, would require at least a 20-hour infusion.[18,45] To accommodate prolonged IVFE infusions, many institutions routinely infuse IVFE separately over 24 hours and change administration tubing for the IVFE and PN solution with each new bag because the use of TNA formulations is not recommended in neonates and infants. In addition, since commercially available IVFE products are not manufactured in unit volumes suitable for safe use in neonates and infants, institutions commonly transfer IVFE from the original container into another container to accommodate the smaller patient-specific volume to decrease risk of adverse events from infusion-related errors. A variety of methods have been utilized for repackaging IVFE. Syringe repackaging and aseptic transfer into sterile bags with the use of an ACD are not recommended because of higher contamination rates. Other methodologies, such as aseptic withdrawal of an appropriate IVFE volume resulting in a patient-specific dose in the original manufacturer's container (drawing-down) has been recommended as a potential option.[66] These multifactorial concerns with providing IVFE to pediatric patients have been addressed by the A.S.P.E.N. Safety Consensus Recommendations.[5] When prolonged IVFE infusions are required in neonates and infants, the daily dose should be divided in two separate 12-hour infusions. The IVFE container and administration tubing should be replaced every 12 hours.[5] When utilizing repackaged IVFE, the infusion time should not exceed 12 hours per unit and the administration tubing should be changed with each new infusion.[5,66]

Clinical **Controversy...**

The safety of repackaging IVFE before administration to neonates and infants has been heavily debated. Some clinicians maintain that the benefits of cost effectiveness and increased patient safety with administering smaller IVFE units outweigh the risks of microbial contamination, while others continue to advocate for the delivery of IVFE direct from the manufacturer's container to decrease infection risk.

Stability and Compatibility

Comprehensive current information regarding compatibility and stability of PN solutions can be found in several reference sources such as *Handbook on Injectable Drugs*[75] and *King Guide to Parenteral Admixtures*.[76] In many cases, the answer to a compatibility question may not be readily available, and a review of the primary literature may be necessary. When information is not available, clinical judgment and experience must be used to resolve the situation.

The stability of a PN formulation is determined by the rate or degree of component degradation and any resulting changes in chemical integrity or pharmacologic activity that may render the formulation unsuitable for safe administration. In general, the sterile combination of PN components accelerates the rate of physicochemical destabilization of all of the components in the formulation; certain amino acids, vitamins, and IVFE are the most susceptible nutrients.[44] When compounded and stored appropriately, the degree of degradation is usually not clinically relevant for most patients receiving short-term PN because many patients have sufficient stores of those susceptible nutrients to support any short-term periods of suboptimal intake. However, nutrient degradation that is more extensive may be problematic for patients with marginal nutrient stores who receive long-term PN. TNAs present additional stability challenges because of the presence of IVFE in the solution. IVFE stability in TNAs is affected by the amino acid and dextrose concentration, solution pH, order of mixing, electrolyte amounts, and final TNA volume as well as container material, storage conditions, and addition of nonnutrient drugs. Stability studies on the effect of specific electrolyte concentrations on TNA stability are limited. In general, IVFE stability is affected by the PN cation content. Divalent and trivalent cation additives such as calcium and magnesium have a greater destabilizing potential compared with monovalent cation additives such as sodium and potassium. However, when given in sufficiently high concentrations, monovalent cation additives may also increase instability. Cations act to reduce the surface potential of the emulsion droplet, thereby enhancing tendency to aggregate and ultimately, in some cases, destabilize the solution to coalescence or a "cracked" admixture.[5,28,44] When a cracked IVFE occurs, the oil phase separates from the water phase, resulting in the appearance of free oil fat globules. Early stages may appear as subtle changes in the uniformly white appearance of the TNA, which may progress to yellow oil streaks throughout the bag or development of an amber oil layer at the top of the admixture bag. TNA formulations with any visible free oil should be considered unsafe for parenteral administration because infusion of circulating fat globules may be of sufficient size to accumulate in the pulmonary vasculature and potentially compromise respiratory function. In general, the likelihood of preparing an unstable TNA formulation can be minimized by maintaining the final concentrations of CAA greater than 4%, dextrose greater than 10%, and IVFE greater than 2%.[5] Specific guidelines for compounding TNAs are reviewed elsewhere.[28,65]

Because of differences in pH among various CAA products and phospholipid content among IVFE products, the manufacturer of each product should be consulted for compatibility and stability information before routinely admixing components. One approach to compounding TNAs manually is to combine CAA, dextrose, and sterile water (if necessary) followed by the addition of electrolytes, vitamins, and trace elements. Then the solution should be visually inspected for precipitate or other particulates. Finally, IVFE may be added and the solution should then be visually inspected again to ensure a uniform emulsion exists.[28,44] Mixing components in this specific order may not be possible with the use of ACDs. Although CAA, dextrose, and IVFE may be simultaneously transferred to an admixture container, the ACDs manufacturer should be consulted for the optimal mixing sequence to ensure safe compounding of TNA formulations.

The precipitation of calcium and phosphorus is a common interaction that is potentially life-threatening.[18,28,44,77] The risk of precipitate formation is greater with increased solution temperature and pH, higher concentrations of calcium and phosphorus, lower concentrations of amino acids and dextrose, use of the chloride salt of calcium, improper mixing sequence when adding calcium and phosphorus salts, and the presence of other additives (including IVFEs).[18,28,44,77] In general, steps to minimize risk of calcium and phosphate precipitation in PN admixtures include the use of calcium gluconate instead of calcium chloride because it is less reactive, adding phosphate salts early in the mixing sequence, adding calcium last or nearly last, and agitating the mixture throughout the admixture process to achieve homogeneity. PN admixtures with a lower final pH should be used when clinically appropriate. Higher final concentrations of dextrose and CAA and lower final concentrations of IVFE favor a lower admixture pH. CAA product-specific solubility curves that are available from the manufacturer or primary literature should be consulted to project calcium and phosphorous solubility. The calculation of a sum or product of calcium and phosphate concentrations should not be used as the sole criterion for determining solubility because the product of calcium and phosphate concentrations vary inconsistently as calcium concentration decreases and phosphate concentration increases.[77]

Electrolyte stability in TNA solutions is difficult to assess because of poor visualization of a precipitate if one occurs.

PN solutions for neonates and infants tend to contain larger amounts of calcium and phosphorus, as well as other divalent cations, that limit the use of TNAs. Because of the limited amount of published stability information, the use of a two-in-one admixture with separate administration of IVFEs is recommended for neonates and infants.[44] In general, alternative methods of delivering electrolytes or medications should be pursued in any clinical situation in which TNA compatibility information is lacking. Because the addition of bicarbonate to acidic PN admixtures may result in the formation of carbon dioxide gas and insoluble calcium and magnesium carbonates, sodium bicarbonate use in PN admixtures is not recommended.[44] Use of a bicarbonate precursor salt such as acetate usually is preferred.

Vitamins may be affected adversely by changes in solution pH, presence of other additives, storage time, solution temperature, and exposure to light.[28] Because of variable stabilities of individual vitamins, IV vitamin solutions should be added to the PN solution as near to the time of administration as is clinically feasible and should not be in the PN solution longer than 24 hours.

Increased peroxide concentrations have been reported in IVFE and dextrose–amino acid solutions after addition of injectable multivitamins or exposure to air or light.[78] Multiple in vitro experiments have reported negative effects of peroxides and associated metabolites on organ and immune function. Peroxides are associated with neonatal hypoxic–ischemic encephalopathy, intraventricular hemorrhage, periventricular leukomalacia, chronic lung disease, retinopathy of prematurity, and necrotizing enterocolitis.[78] Neonates and infants are at increased risk for harmful effects of peroxides because they receive a higher daily peroxide load from PN solutions compared to adults and they have lower endogenous antioxidant levels. Protecting PN and IVFE solutions from light is therefore recommended to minimize peroxide formation.[78]

Many patients receiving PN also receive other IV medications. The compatibility of these medications with the PN solution is an important consideration for safe and effective drug delivery. Although some medications may be added directly to the PN solution and administered at the same rate as the PN infusion, most are administered as a separate admixture co-infused in the PN line. Several criteria should be considered before medications are added directly to the PN solution because of the potential for ineffective drug therapy or other complications associated with physiochemical incompatibility and stability of the PN solution.[44] First, the drug should be stable for at least 24 hours and should have pharmacokinetic properties appropriate for continuous infusion. Second, the chemical and physical compatibility of the medication with PN admixture components and other medications that may be co-infused concomitantly into the PN line should be verified. Advantages of using PN admixtures as drug vehicles include consolidation of dosage units, improved pharmacodynamics for certain drugs, conservation of fluid in volume-restricted patients, fewer venous catheter violations, and decreased compounding and administration times. However, a major disadvantage to the use of PN solutions as drug-delivery vehicles is the lack of compatibility and stability data. Medications frequently added to PN solutions include regular insulin and histamine-2 receptor antagonists.[41,75,76]

COMPLICATIONS OF PARENTERAL NUTRITION

Mechanical and Technical Complications

Mechanical and technical complications include malfunctions in the system used for IV delivery of the solution, such as infusion pump failure, problems with administration sets or tubing, or the CVC. Although problems associated with infusion pumps and administration sets can be decreased by appropriate equipment selection and routine care and monitoring, CVC-related complications are potentially life-threatening. Pneumothorax, catheter misdirection or migration into the wrong vein or improper positioning within the cardiac chambers, arterial puncture, bleeding, and hematoma formation may occur during surgical placement of the catheter. Many of these complications, in addition to venous thrombosis and air embolism, can occur after insertion. CVCs occasionally occlude or break during use and if these problems cannot be rectified easily, the catheter may need to be surgically replaced.

Infectious Complications

Infectious complications can be a major hazard for patients receiving CPN because of the increased risk associated with the presence of an indwelling CVC. The source of a CVC infection may be skin organisms from the catheter insertion site, contamination of the catheter hub, or hematogenous seeding of the catheter from a distant site. In addition, patients receiving PN therapy are often predisposed to infection because of compromised immunity or concomitant infection. Frequent use of broad-spectrum antibiotic therapy and malnutrition are also predisposing factors for development of infection. The risk of catheter infection is increased for those who require multiple manipulations of the line used for PN administration as well as those who experience failure of in-line bacterial filter, poor catheter placement technique, and poor CVC and insertion site care.[68]

Infection rarely develops secondary to solution contamination.[68,79] Strict adherence to protocols for preparation of PN admixtures should minimize this occurrence.[44,73] Catheter-related bloodstream infections (CRBSIs), defined as the presence of clinical manifestations of infection (eg, fever, chills, hypotension) associated with bacteremia or fungemia resulting from no apparent source other than the catheter, are common sources of systemic infection.[79] Before this diagnosis can be made, there should be evidence of more than one positive blood culture result obtained from the peripheral vein with growth of the same organism from a blood culture obtained from the catheter or catheter segment. When a CRBSI is suspected or confirmed, appropriate antimicrobial therapy should be initiated. Retention or removal of the central catheter depends on the patient's severity of illness, the suspected or identified pathogen, and the type of catheter involved. The catheter may be removed and replaced in the same site, the catheter may be removed and replaced at a different anatomic location, or it may not be replaced.[79] Filling the catheter with antimicrobials such as vancomycin or antiseptics such as 70% alcohol and allowing the solution to dwell for a period of time while the catheter is not in use is referred to as a catheter lock.[68] Antimicrobial catheter locks have been used to prevent and treat CRBSI in patients with long-term catheters such as those receiving home PN.[68,69] Specific guidelines for treatment of CRSBI have been recently reviewed.[79]

Clinical **Controversy...**

Ethanol catheter lock therapy has offered promise for the prevention and treatment of CRBSI. The best method for ethanol removal from the CVC after ethanol catheter lock is not known. If the ethanol is withdrawn from the CVC, blood is introduced into the CVC, which may increase the risk of biofilm formation. Alternatively, clearing the catheter by flushing the ethanol into the patient is concerning because there is no known safe amount of ethanol to routinely infuse into patients, particularly neonates and infants.

Metabolic and Nutritional Complications

9 Metabolic and nutritional complications associated with PN therapy are numerous; frequently multifactorial in origin; and if left untreated, potentially fatal. Metabolic abnormalities related

to substrate intolerance, fluid and electrolyte disorders, and acid–base disorders are summarized in multiple recent review articles and their management is briefly summarized in the following sections.[36,37,43,44,64,71]

Liver Disease

Parenteral nutrition–associated liver disease presents as elevations in total bilirubin, aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase. Both adult and pediatric patients who receive PN are at risk for developing PNALD; it is reported to occur in approximately 50% to 60% of children who receive long-term PN, with a higher incidence in premature infants.[37,80] No single etiology has been identified, although several risk factors have been reported, such as, degree of prematurity, sepsis, hypoxia, lack of enteral nutrition, small bowel bacterial overgrowth, GI conditions requiring surgical intervention, duration of PN therapy, and long-term administration of excessive calories.[37,80] PNALD in infants is characterized clinically by a serum direct bilirubin concentration greater than 2 mg/dL (more than 34.2 µmol/L).[37] Taurine deficiency has been proposed as an etiology of cholestasis for preterm infants and neonates.[37] Taurine is a conditionally essential amino acid that is not present in standard CAA solutions but is important for neonatal and infant bile metabolism. However, the preventative or therapeutic benefit of PN regimens with CAA solutions containing supplemental taurine is unclear. Recent studies have focused on the potential relationship between IVFE and the development of PNALD.[50] SO–based IVFEs contain large concentrations of plant sterols or phytosterols, which are inefficiently metabolized to bile acids by the liver. Experimental data suggest parenteral phytosterols may impair bile flow. Improvement or reversal of PNALD has been reported for patients who received a fish oil–based IVFE that is not currently commercially available in the United States.[50] Other PNALD treatments that have been investigated include providing reduced doses of SO–based IVFE and use of enteral fish oil in patients with limited oral intake.[50,81]

Risk factors for PNALD in adults include preexisting liver disease, sepsis, preexisting malnutrition, extensive bowel resection, prolonged duration of PN therapy, lack of enteral intake, nutrient deficiencies such as choline deficiency, and long-term administration of excessive calories.[37,80] PNALD in adults typically presents as steatosis and steatohepatitis on biopsy. Clinically, PNALD is characterized by mild elevations in serum liver enzymes, usually less than three times the upper limit of normal, with peak enzyme levels usually occurring between 1 and 4 weeks after initiating PN. In many cases, the liver abnormalities improve or resolve with manipulation of substrate intake or discontinuation of PN therapy. However, in severe cases, liver dysfunction may progress to overt failure and death despite use of traditional therapies such as using cyclic PN, ursodiol, and oral antibiotics for bacterial overgrowth; maximizing enteral feeding; and avoiding sepsis and parenteral overfeeding.[37,80] Intestinal transplant with or without liver transplantation has become a treatment option for PN-dependent patients who have progressive PNALD.

Hypertriglyceridemia

Hypertriglyceridemia, defined as serum triglyceride concentrations greater than 400 mg/dL (4.52 mmol/L) for adults and 150 mg/dL (1.70 mmol/L) to 200 mg/dL (2.26 mmol/L) for preterm infants, neonates, and older pediatric patients, may occur in patients receiving IVFE–based PN. Risk factors include preexisting liver or pancreatic dysfunction, sepsis, multiple-organ failure, degree of prematurity, IVFE infusion rate, and dose.[44,45]

IVFE–associated hypertriglyceridemia is generally thought to be caused by defective lipid clearance or an excessive rate of IVFE administration.[42,44] Premature infants and neonates have relatively slower lipid clearance than do adults because of immature metabolic pathways, including decreased lipoprotein lipase activity.[42,45] Reducing the IVFE infusion rate or dose or withholding IVFE therapy should be considered when patients present with hypertriglyceridemia or lipemic serum.[42,44] Use of low-dose heparin (1 unit/mL of two-in-one PN formulation) to stimulate lipoprotein lipase activity has been suggested as a potential therapeutic intervention to treat IVFE–associated hypertriglyceridemia in neonates.[16,42] However, others have suggested that the risk associated with heparin delivery via PN outweighs the clinical benefits because of the potential for compounding errors associated with confusion between heparin and insulin doses.[82] The role of carnitine for treatment of IVFE–associated hypertriglyceridemia is not clear.[16,42]

Hyperglycemia

Hyperglycemia is one of the most common complications of PN administration and is associated with a history of diabetes, metabolic stress, adverse effects of medications such as glucocorticoids, and excessive carbohydrate administration. In the pediatric population, additional risks for hyperglycemia include prematurity and surgery. The optimal blood glucose concentration for acutely ill hospitalized patients receiving PN is not known. However, a target range of 140 to 180 mg/dL (7.8-10 mmol/L) has been suggested for adults, and less than 150 mg/dL (8.3 mmol/L) has been suggested for neonates.[83,84] Clinical management of PN patients with hyperglycemia has not been well studied and is largely empiric. Blood glucose concentrations can be controlled with regular insulin, which may be given subcutaneously or added to the PN formulation. One approach for adult PN patients requiring insulin or oral hypoglycemic agents before starting PN therapy is to initiate PN with approximately 100 to 200 g of dextrose and add 0.05 to 0.1 units of regular insulin per gram of dextrose in the PN solution for those patients with mild hyperglycemia (130-150 mg/dL [7.2-8.3 mmol/L]). The insulin dose may be increased to 0.15 to 0.2 units per gram of dextrose for patients with moderate hyperglycemia (151-200 mg/dL [8.4-11.1 mmol/L]).[44,85] Blood glucose concentrations should be monitored every 4 to 6 hours. Blood glucose measurements above the goal range should be treated with regular insulin administered subcutaneously according to an appropriate sliding scale (see Chapter 74). The insulin dose is modified daily by adding 60% to 100% of the sliding-scale insulin given over the previous 24 hours to the PN formulation daily until blood glucose concentrations are stable and within the target range. When blood glucose measurements are stable, the dextrose dose may be advanced to achieve the therapeutic goal and the frequency of monitoring blood glucose concentrations may be decreased after blood glucose concentrations are stable within the target range at the goal dextrose dose. Use of a separate IV insulin infusion is most commonly used for pediatric patients, but it may also provide better and safer glycemic control for patients with very large insulin requirements or those with unstable marked fluctuations in their blood glucose concentrations.

Refeeding Syndrome

Severe and rapid declines in serum phosphate, potassium, and magnesium concentrations; fluid retention; and other micronutrient deficiencies are common features of the refeeding syndrome.[86,87] Individuals at greatest risk for refeeding syndrome are severely malnourished patients with significant weight loss who receive aggressive nutritional supplementation. In addition, those who are unfed for 7 to 10 days with evidence of stress or nutritional depletion; those with chronic diseases causing undernutrition such as cancer, cardiac cachexia, chronic obstructive pulmonary disease, or cirrhosis; and individuals who were previously morbidly obese and have experienced massive weight loss are at heightened risk for this syndrome.[87] Electrolyte abnormalities appear to be related to acute provision of macronutrient substrates that promote anabolism in an environment of depleted total body stores of phosphorus, potassium, and magnesium. Recommendations for

initiating PN in adults at risk for refeeding syndrome include providing 25% to 50% of the calculated nonprotein caloric requirements initially. The dextrose dose should be initiated at approximately 100 to 200 g/day. Calories should be advanced over 3 to 4 days to the desired goal. Because the metabolic abnormalities described with refeeding syndrome appear to be related primarily to acute provision of large amounts of dextrose, the goal protein dose may be provided with the initial PN infusion. Pediatric PN regimens are usually advanced over several days as a general practice for all pediatric patients. Additional recommendations for minimizing the risk of refeeding syndrome for pediatric patients include provision of additional phosphorus and potassium above standard nutrient requirements at the time PN is initiated.[88]

Complications Associated with Long-Term Parenteral Nutrition

Other nutritional complications of PN therapy may develop over a prolonged course of therapy (weeks to months) as a result of inappropriate intake of a particular nutrient. Certain conditions, such as metabolic stress in a previously malnourished patient, may elicit symptoms of deficiency much earlier if a nutrient is not appropriately provided. For example, lactic acidosis and other life-threatening complications associated with severe thiamine deficiency have been reported in patients who received PN solutions without multivitamin supplementation.[53] Maintenance doses of vitamins, trace elements, and essential fatty acids should be provided to all patients with normal age-related organ function receiving PN.

Essential Fatty Acid Deficiency

Patients receiving PN regimens without IVFEs for weeks to months are at risk for development of EFAD. Clinical signs of EFAD include hair loss, desquamative dermatitis, thrombocytopenia, malabsorption, and diarrhea resulting from changes in intestinal mucosa.[43,44] EFAD also may be diagnosed by evaluating plasma fatty acid profiles. Although this assessment is not routinely available, it can be provided by several larger regional laboratories. Historically, a triene-to-tetraene ratio more than 0.4 has been considered biochemical evidence for EFAD, however, individual laboratory reference ranges should be used when evaluating patients for EFAD.[18] Although the time in which EFAD may develop depends on the patient's nutrition status, disease state, and age, these manifestations may occur 2 to 4 weeks after initiation of fat-free PN in adults and within 48 hours in newborn infants.[43,45]

Metabolic Bone Disease

Metabolic bone disease has been reported for adults and children receiving long-term home PN.[37] This disorder in adults is characterized by osteomalacia with or without osteoporosis that may present without associated clinical, radiologic, or biochemical abnormalities. The diagnosis may not be made for premature infants until after the development of bone fractures or overt rickets. The etiology is poorly understood and likely multifactorial. Treatment options include pharmacologic intervention, calcium and vitamin D supplementation, and exercise. Because excessive vitamin D has also been implicated in the development of metabolic bone disease, others have recommended removal of vitamin D from the PN for patients with a normal 25-hydroxyvitamin D concentration and low serum parathyroid hormone and 1,25-hydroxyvitamin D concentrations.[16,37]

Trace Element and Vitamin Complications

Clinical symptoms of trace element deficiencies, although rare, have been reported for patients receiving long-term PN. More commonly, decreased serum trace element concentrations have been reported in a variety of patient populations. However, the clinical significance of abnormally low concentrations of many trace elements is not known because serum concentrations often do not correlate with total body stores.[53] Occasionally, patients may develop clinical toxicities from elevated vitamin or trace element concentrations as the result of increased intake or decreased metabolism. These abnormalities are frequently associated with an underlying disease state such as severe kidney or hepatic failure and may necessitate reduction in vitamin and trace element intake.

Many trace elements are present in PN components as contaminants.[53] Some investigations of patients with normal organ function who were receiving PN supplemented with commercially available parenteral multiple trace element solutions have reported concern with elevated serum concentrations of trace elements such as chromium and manganese.[53] Aluminum is a common contaminant of many sterile IV solutions, including those used for compounding PN. Calcium and phosphorus solutions are among those components with the highest levels of aluminum contamination.[89,90] Aluminum accumulation may occur during long-term PN therapy, especially for patients with reduced kidney function, and is associated with abnormal neurologic and hematologic function and metabolic bone disease in adults and premature infants.[37,89,90] Preterm infants are at higher risk of aluminum toxicities because they receive larger doses (micrograms per kilogram) from PN solutions than adults.[90] Preterm infants are also more likely to retain aluminum because of immature renal kidney function. Although the maximum safe level of IV aluminum intake is unknown, the FDA has reported that parenteral doses of 4 to 5 mcg/kg/day were associated with central nervous system and bone toxicity.[91] Even smaller amounts may result in tissue accumulation but no documented toxicity.

The FDA implemented a mandate in 2004 to restrict aluminum content in large-volume PN stock solutions (CAA, dextrose, sterile water for injection, IVFE) to a maximum of 25 mcg/L and for manufacturers to indicate the maximum aluminum concentration at expiration for both large- and small-volume parenteral products used for PN.[91] Investigations have determined actual aluminum concentrations in parenteral products to be lower than the amounts reported on the manufacturer's label, however, aluminum amounts in PN solutions still exceed FDA guidelines.[89,90] In addition, the aluminum content of parenteral products appears to vary considerably during the shelf life of the products and increases with time because of leaching from glass containers. The amount of aluminum contamination delivered to patients receiving long-term parenteral therapy such as chronic PN patients or dialysis patients, can be substantially reduced if newer stock solutions are used to prepare their PN.[89,90]

The amount of aluminum present in alternative imported trace element products is unknown because their initial approval was not based on FDA criteria.[61]

HOME PARENTERAL NUTRITION

Advances in technology for the delivery of IV solutions have allowed medically stable patients who require extended PN therapy to be maintained indefinitely on IV nutrition. An increasing concern for cost containment of healthcare services has fostered use of sophisticated infusion devices to provide PN at home. Numerous programs are now available outside the traditional healthcare setting to support patients who require long-term or permanent PN. Standards have been developed to promote safe and effective care.[69] Home PN services may be coordinated and administered through a hospital or by a commercial home care company.[69]

Many factors are considered in selecting candidates for home PN therapy. Significant benefit must be expected from the therapy. Examples of patients who have been maintained successfully with home PN include those with severe GI dysfunction secondary to Change from Crohn disease to Crohn's disease, ischemic bowel disease, severe GI motility disorders, extensive intestinal obstruction, and congenital bowel dysfunction.[69] The patient and the patient's caregiver must be willing to complete training and assume numerous

responsibilities for managing the new daily routine. Other logistics such as funding, procurement of solutions and supplies, and clinical management and follow-up must be individualized for each patient in order to achieve the desired outcomes.[69]

Patients commonly receive PN solutions from their home care provider. IV vitamins or other additives may be added daily by the patient or caregiver, depending on the arrangement with the home care provider. The solution generally is administered through the night by infusion pump over 8 to 20 hours.[69,71] A cycled regimen allows the patient time away from the pump during daylight hours and provides many patients with the freedom to have a reasonably normal daily routine. Clinical management and follow up are performed periodically according to the needs of the patient and the protocol of the home care provider or the managing healthcare team. A coordinated effort among several healthcare professionals, including physicians, pharmacists, nurses, dietitians, social workers, and the patient and the patient's caregiver, as well as the suppliers, is paramount to providing safe and effective management. Home PN affords some patients the potential for an ambulatory lifestyle while maintaining an IV feeding regimen that was previously only available in the hospital setting. For others, home PN may contribute to a better quality of life in the comfort of their homes.[69]

PHARMACOECONOMIC CONSIDERATIONS

Determining the true cost of PN support is difficult because numerous variables affect the provision of PN and the clinical response to therapy. PN therapy cost variables include the underlying indication for treatment, the administration setting (home or acute care), timing of PN initiation, therapy associated complications, and the type of PN formulation provided (compounded or standardized commercial PN product).[69,92-97] Expenses associated with PN therapy may be categorized as direct and indirect costs.[95] Direct costs may be further categorized as fixed or variable costs. Fixed costs do not depend on the volume of patients receiving therapy. For example, an ACD and the tubing sets required to transfer volumes of stock solutions to the administration bag would be considered fixed costs in many practice settings. These costs per patient tend to be highest in low-volume environments. Variable costs such as PN administration bags or standard commercial PN products depend directly on the number of patients receiving PN. Other direct costs include ancillary services required by patients receiving PN and costs related to the management of PN associated complications.

Clinical benefits and other clinical effects of PN (ie, reduction in hospital length of stay and frequency of complications) in specific patient populations have been evaluated but few investigations have reported a comprehensive economic assessment of PN therapy. Attempting to measure the cost or cost savings associated with reported benefits of PN therapy and other clinical effects based on results of controlled clinical trials is difficult.[93,94] Clinical outcome measurements and hence economic outcomes are influenced by multiple factors, including experimental design, sample size, and specific health system practices.[93,95,96,98,99] More recent cost analyses for PN therapy have focused on timing of initiating therapy in critically ill patients and choice of PN formulation (compounded or standard commercial PN product). In general, although individual investigations have reported cost savings with supplemental PN in critically ill patients unable to meet nutritional goals within 24 to 48 hours of intensive care unit (ICU) admission, others have reported no cost advantage with early PN intervention.[96] Similarly, while cost savings have been reported with use of standard commercial PN products compared to PNs compounded with an ACD, others have reported increased costs with other supportive care usually provided with compounded PN when standard commercial PN products were used.[98,100]

Although the results of economic analyses of PN remain controversial, similarities among several reports provide a basis for minimizing the costs of PN therapy:

1. Use PN only for the most appropriate patients as described by institution-specific criteria based on current consensus statements. Enteral nutrition should be used whenever feasible because the associated costs and complications are demonstrated to be less than those associated with PN.[97,101]
2. Reassess the need for routine laboratory monitoring measurements used for PN therapy. In general, the level of laboratory monitoring should decrease as a patient's clinical condition stabilizes.
3. Minimize the direct cost of PN by using efficient purchasing practices for PN solutions and compounding supplies through contract purchasing, streamlined compounding procedures, standardized administration times, single-bag PN solutions, and optimized monitoring plans. Some institutions may realize direct cost savings with use of standardized, commercial PN products depending on the usual daily PN census and patient population.[99] Others may reduce direct costs by outsourcing PN compounding to a third-party compounding pharmacy facility.

PERSONALIZED PHARMACOTHERAPY

10 11 Considerations for individualizing a patient's PN regimen include: goals determination based on a patient-specific nutrition assessment, selection of the optimal type of available vascular access, and macronutrient and micronutrient requirements. In general, both macronutrient and micronutrient doses are age and weights based but are also affected by the patient's degree of metabolic demand, organ function, other drug therapy, exogenous losses, and acid–base status. Nutrient amounts provided by the PN may also require adjustment based on enteral intake either orally or by feeding tube in patients with recovering GI tract function.

Patient-specific caloric goals include (a) adequate energy intake to promote normal growth and development in neonates, infants, and children; (b) energy equilibrium and preservation of fat calorie stores in well-nourished adults; and (c) positive energy balance in malnourished patients with depleted endogenous fat stores. Overweight patients with a body mass index above 30 kg/m^2 may require less caloric support than nonobese patients with the same clinical condition.[11] Critically ill adults may also benefit from a hypocaloric regimen.[11] Specific nitrogen goals are positive nitrogen balance or nitrogen equilibrium and improvement in the serum concentration of visceral protein markers such as transferrin or prealbumin in patients without systemic inflammation. Routine monitoring is necessary to ensure that the nutrition regimen is suitable for a given patient as the patient's clinical condition changes and to minimize or treat complications. The PN component doses usually require individualized adjustments as the patient's clinical condition affects further changes in metabolic stress, organ function, fluid and electrolyte balance, and acid–base status.

Appropriate patient selection, assessment, and monitoring are key to successful PN therapy and the prevention of unnecessary complications. Because pharmacists are actively involved in the provision of PN at many levels, including order verification, PN compounding and dispensing, direct patient care, education, and research, nutrition support is recognized as a pharmacy practice specialty.[102] In addition, as the interprofessional team based approach to specialized nutrition support has evolved, standards of practice have been defined for pharmacists as well as for other healthcare professionals.[4,8-10] Standardized order forms and monitoring protocols are useful tools to ensure safe administration and monitoring of PN therapy. The future of PN therapy and the role

of nutrition-support clinicians will be affected primarily by new insights from clinical research and economic challenges in the evolving healthcare environment.

Enteral Nutrition

Vanessa J. Kumpf and Katherine H. Chessman

143

KEY CONCEPTS

1. The gastrointestinal (GI) tract defends the host from toxins and antigens by both immunologic and nonimmunologic mechanisms, collectively referred to as the gut barrier function. Whenever possible, enteral nutrition (EN) is preferred over parenteral nutrition (PN) because it is associated with a lower risk of metabolic and infectious complications and is less expensive and invasive.
2. Candidates for EN are those with a sufficiently functioning GI tract to allow adequate nutrient absorption who cannot or will not eat and in whom enteral access can be safely obtained.
3. The most common route for both short- and long-term EN access is directly into the stomach. The method of delivery may be continuously via an infusion pump, intermittently via a pump or gravity drip, or bolus administration via gravity or syringe.
4. Patients unable to tolerate tube feeding into the stomach because of impaired gastric motility may benefit from feeding tube placement into the duodenum or jejunum. When feeding into the small bowel, the continuous method of delivery via an infusion pump is required to enhance tolerance.
5. Selection of the enteral feeding formulation depends on nutritional requirements, the patient's primary disease state and related complications, and nutrient digestibility and absorption. A standard polymeric formulation will be appropriate for the majority of adults and children.
6. Measurement of gastric residual volumes (GRVs) is often used to monitor GI tolerance in patients receiving gastric feeding. Although the practice has not been consistently reported to decrease aspiration risk, a high GRV may provide an early sign of GI dysfunction and alert the clinician to the need for intervention.
7. Management of diarrhea in patients receiving EN should focus on identification and correction of the most likely cause(s). Tube feeding-related causes include too rapid delivery or advancement, intolerance to the formula composition, and occasionally formula contamination.
8. Medication administration through a feeding tube requires selection of an appropriate dosage form and verification of appropriate enteral access. Medications that should not be crushed and administered through a tube include enteric-coated or sustained-release capsules or tablets and sublingual or buccal tablets.
9. The coadministration of medications with EN can result in alterations in bioavailability and/or changes in the desired pharmacologic effects. Medications known to interact with EN include phenytoin, warfarin, select antibiotics, antacids, and proton-pump inhibitors.

INTRODUCTION

Enteral nutrition (EN) is defined as the delivery of nutrients by tube or by mouth into the gastrointestinal (GI) tract. This chapter focuses on nutrient delivery through a feeding tube rather than oral food ingestion. The terms *enteral nutrition* and *tube feeding* are thus used interchangeably in this context. The goal of EN is to provide calories, macronutrients, and micronutrients to those patients who are unable to achieve these requirements from an oral diet. Increased recognition of malnutrition, along with improvements in enteral access techniques, feeding formulations, and methods to prevent and manage complications, have resulted in an increased use of EN across all healthcare settings. In this chapter, principles and practices related to the safe and successful use of EN therapy are described.

GASTROINTESTINAL TRACT PHYSIOLOGY

The GI tract plays a key role in the processing of ingested foods. Many of the processes involved in digestion, absorption, and utilization of nutrients are modifiable by the presence of acute and chronic illnesses.

Digestion and Absorption

Digestion and absorption are GI processes that generate the body's usable fuels.[1,2] Ingested nutrients are primarily large polymers that cannot be absorbed across the intestinal cell membrane unless they are transformed into an absorbable molecular form. Digestion consists of the stepwise conversion of a complex chemical and physical nutrient into a molecular form that is absorbable by the intestinal mucosa. Absorption from the GI tract is a multistep process that includes the transfer of a nutrient across the intestinal cell membrane. The nutrient ultimately reaches the systemic circulation through the portal venous or splanchnic lymphatic systems, provided that the GI or biliary tract does not excrete it. In addition, a coordinated interplay of GI motility and neurohormonal secretion is required to facilitate adequate digestion and absorption.

Nutrient digestion involves the complex coordination of multiple mechanical, enzymatic, and physiochemical processes.[1,2] Mechanical dissolution of food occurs by chewing, then mixing and grinding the stomach contents. Food stimulates secretion of numerous hormones and enzymes from the salivary glands, stomach, liver and biliary system, pancreas, and intestines (Table 143-1). As food traverses the gut lumen, these hormones modulate GI motility and the secretions from other organs of the digestive system. Nutrient absorption occurs within the gut lumen and is a specific function of the intestinal cell membrane, which is comprised of fingerlike projections called villi. Each individual villus is made up of epithelial cells called enterocytes. The enterocyte surface contains special luminal projections called microvilli, which provide an increased surface area that is referred to as the brush-border membrane.

TABLE 143-1 Gastrointestinal Enzymes and Hormones

Enzyme/Hormone	Site of Secretion	Main Actions
Amylase	Salivary glands, pancreas	Converts carbohydrates, starch, and glycogen to simple disaccharides
Cholecystokinin	Duodenum, jejunum	Stimulates pancreatic enzyme secretion and gallbladder contraction
Chymotrypsinogen	Pancreas	Breaks down proteins into peptides
Enteroglucagon	Duodenum, small intestine	Inhibits pancreatic enzyme secretion and bowel motility
Gastric inhibitory peptide	Small intestine	Decreases gastric motility and stimulates insulin secretion
Gastrin	Stomach, duodenum	Stimulates gastric acid secretion and mucosal growth
Glucagon	Pancreas	Stimulates hepatic glycogenolysis and inhibits motility
Lipase	Pancreas	Hydrolyzes dietary fat to release fatty acids
Pancreatic polypeptide	Pancreas	Inhibits gallbladder contraction and pancreatic and biliary secretion
Pepsinogen	Stomach	Converts large proteins into polypeptides
Secretin	Small intestine	Stimulates hepatic and pancreatic water and bicarbonate release
Trypsinogen	Pancreas	Breaks down proteins into peptides
Vasoactive inhibitory peptide	Small intestine, pancreas	Vasodilator; stimulates water and bicarbonate secretion, insulin and glucagon release, and small bowel secretions

The digestion and absorption of carbohydrate, fat, and protein within the small intestine are illustrated in Figure 143-1. Carbohydrates are presented to the small intestine in either a digestible or a nondigestible form. Polysaccharides (starches) and oligosaccharides (sucrose and lactose) undergo enzymatic digestion to simple sugars. The simple sugars are absorbed via active and passive transport mechanisms and are eventually released into the portal vein. Polysaccharides, such as cellulose complexes and other fiber components, pass undigested to the colon, where they are digested by bacteria and enzymes to short-chain fatty acids. Colonic absorption of short-chain fatty acids stimulates sodium and water reabsorption. The short-chain fatty acids serve as a systemic energy source and they provide nourishment for the colonic mucosa cells.

Fat is most often presented to the small intestine as long-chain triglycerides. Fat digestion requires pancreatic lipase release and formation of mixed bile salt micelles, which are then absorbed across the intestinal enterocyte. Within the enterocyte, triglycerides are reesterified and packaged into chylomicrons that are then transported into the lymphatic system. Medium-chain triglycerides (MCTs) can be absorbed intact by the mucosal membrane and are acted on by intracellular lipase within the enterocyte to release free fatty acids that pass directly into the portal vein.[3]

Protein is presented to the small intestine primarily as large polypeptides and to a lesser extent as free amino acids because of protein denaturation in the stomach. Polypeptide digestion generates oligopeptides, which are further hydrolyzed to dipeptides and tripeptides. Peptide absorption occurs via a peptide transport system while free amino acids are absorbed via specific amino acid transporters. These peptide carriers are very efficient, whereas free amino acid absorption appears to less efficient.[2]

Understanding the mechanisms involved in digestion and absorption can greatly enhance the rational use of EN in patients with normal or altered GI anatomy and/or function. Various circumstances may alter the efficacy of nutrient digestion and absorption. For example, the functional immaturity of the neonatal gut may lead to clinical problems associated with inadequate digestion and absorption of EN.

Gut Host Defense Mechanisms

1 Besides digesting and absorbing nutrients to maintain nutritional health, the GI tract is actively involved in defending the host

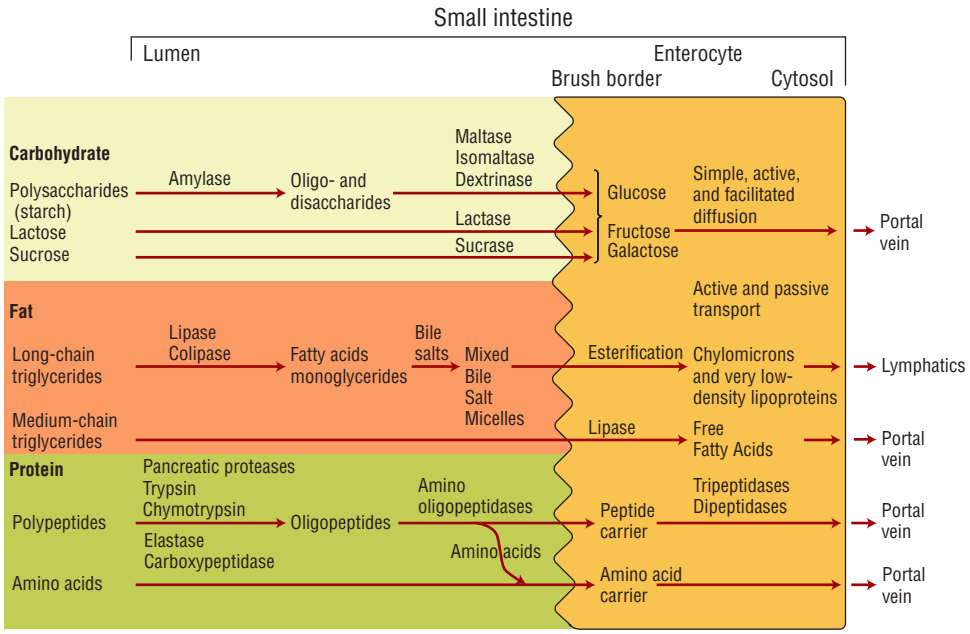

FIGURE 143-1 Schematic of carbohydrate, fat, and protein digestion.

from toxins and antigens by both immunologic and nonimmunologic mechanisms.[4] These gut host defense mechanisms are collectively referred to as the gut barrier function. The gut barrier acts to prevent the systemic spread of intraluminal bacteria and endotoxins to other organs and tissues. Hydrochloric acid secreted by the stomach kills most of the bacteria ingested with food. Under normal circumstances, a mucus layer coats the intestinal epithelium and thereby alters the adherence of bacteria to the cells of the GI tract but provides a favorable environment for anaerobic bacteria. Anaerobic bacteria, which normally colonize the mucus layer, aid in preventing tissue colonization by potential pathogens. Small bowel peristalsis further prevents bacterial stasis and overgrowth. The gut barrier function is also maintained by the intestinal immune system, known as the gut-associated lymphoid tissue (GALT). GALT regulates the local immune response to antigens within the GI tract. Specific immunoglobulins are secreted to kill the remaining organisms and neutralize any toxins they produce. The liver Kupffer cells help to maintain gut barrier function by clearing the portal blood of gut-derived bacteria and endotoxins. Gut barrier integrity may be affected negatively by numerous pathogenic insults, such as physiologic stress and ischemia, and a variety of drugs, including chemotherapeutic agents. The administration of certain probiotics can modify intestinal flora and may have beneficial effects in various disease states and patient populations by positively affecting the maintenance of gut barrier function and intestinal immune function.[5-7]

INDICATIONS FOR ENTERAL NUTRITION

2 The decision to initiate EN is based on a variety of factors. Suitable candidates are those who cannot or will not eat a sufficient amount to meet their nutritional requirements, those who exhibit a sufficient functioning GI tract to allow for nutrient absorption, and those in whom a method of enteral access can be safely initiated.[8-11] Thus, EN may be indicated in a variety of conditions or disease states (Table 143-2). For example, patients who have difficulty swallowing due to stroke, altered mental status, or obstruction in the head, neck, or esophagus due to cancer may benefit from EN. Extreme prematurity necessitates tube feeding because the suck–swallow-and-breath mechanism is not matured sufficiently to allow safe oral intake.[12]

TABLE 143-2 Potential Indications for Enteral Nutrition

Neoplastic disease	**Neurologic impairment**
Chemotherapy	Comatose state
Radiation therapy	Cerebrovascular accident
Upper GI tumors	Demyelinating disease
Cancer cachexia	Severe depression
Organ dysfunction	Cerebral palsy
Liver disease/failure	**Other indications**
Kidney insufficiency/failure	AIDS
Cardiac cachexia	Anorexia nervosa
ARDS/ALI	Complications during pregnancy
Bronchopulmonary dysplasia	Failure-to-thrive
Congenital heart disease	Geriatric patients with multiple chronic diseases
Organ transplantation	Extreme prematurity
Hypermetabolic states	Inborn errors of metabolism
Closed head injury	Cystic fibrosis
Burns	
Trauma	
Postoperative major surgery	
Sepsis	
GI disease	
Inflammatory bowel disease	
Short bowel syndrome	
Esophageal motility disorder	
Pancreatitis	
Fistulas	
Gastroesophageal reflux disease (severe)	
Esophageal or intestinal atresia	

AIDS, acquired immune deficiency syndrome; ALI, acute lung injury; ARDS, acute respiratory distress syndrome.

Critically ill patients who are endotracheally intubated represent a large percentage of hospitalized patients requiring EN. Traditionally, EN in the critically ill population was regarded as supportive care designed to provide nutrients during the period of time the patient was unable to maintain adequate oral dietary intake. Current evidence also supports the use of EN as a tool to modulate the stress response to critical illness and improve patient outcomes. Nutrition guidelines support the initiation of EN in critically ill adults[13-15] and children[16] who are unable to maintain volitional intake. Some of these patients may have reduced gastric emptying caused by sepsis, GI surgery, anesthetic agents, opioid analgesics, and underlying pathology, such as diabetic gastroparesis and burns. However, successful EN can often be achieved by advancing the tip of the feeding tube beyond the pylorus into the duodenum, or preferably into the jejunum. Small bowel feeding may also be appropriate for patients with gastric outlet obstruction, those with pancreatitis, those with moderate to severe gastroesophageal reflux, or those with high aspiration risk.

Contraindications to EN use and/or tube placement are distal mechanical intestinal obstruction, bowel ischemia, active peritonitis, uncorrectable coagulopathy, and necrotizing enterocolitis.[1,17,18] Conditions that my result in significant challenges to EN use include severe diarrhea, protracted vomiting, enteric fistulas, severe GI hemorrhage, hemodynamic instability, and intestinal dysmotility.

BENEFITS OF ENTERAL NUTRITION

The importance of maintaining nutrient delivery through the GI tract in patients without a contraindication to its use is well supported. The beneficial effects of EN, specifically in the critically ill patient, are further enhanced if EN is initiated within 24 to 48 hours of admission to an intensive care unit (ICU).[13-15]

Enteral Versus Parenteral Nutrition

Clinical studies comparing EN and parenteral nutrition (PN) in the critically ill adult patient demonstrate a decrease in infectious complications with the use of EN.[19-21] Infectious complications are thought to be less common with EN in part because EN supports functional gut integrity by stimulating bile flow and the release of endogenous trophic agents, such as cholecystokinin, gastrin, and bile salts. Provision of enteral nutrients appears to help maintain the intestinal mucosal villous height and support the mass of secretory immunoglobulin A (IgA)-producing immunocytes that comprise the GALT. In the setting of critical illness or severe injury, adverse changes in gut permeability and gut barrier function that result in increased risk for systemic infection and multiorgan dysfunction syndrome have been noted. By supporting gut integrity, the enteral feeding route is thought to lower infection risk and minimize organ failure.[13]

The incidence of infectious complications has been documented to be lower in EN patients with abdominal trauma, burns, severe head injury, major surgery, and acute pancreatitis. This reduction in infectious complications is primarily due to the lower incidence of pneumonia and catheter-related bloodstream infections and a decrease in abdominal abscess in trauma patients.[19-21] Unfortunately, interpretation of these studies is often complicated by small sample size and lack of standardization in timing of EN initiation and achievement of nutrition goals. Recently, the CALORIES trial randomized 2,400 adult critically ill patients who were expected to require nutritional support for at least 2 days to either EN or PN and initiated therapy within 36 hours of ICU admission.[22] No significant differences in infectious complications or mortality was noted and these findings challenge EN use as the preferred route for early nutritional support in critically ill patients.. There are no randomized, controlled trials that compare the use of EN and PN in children.[16]

Enteral nutrition is more physiologic than PN in terms of nutrient utilization and therefore is generally associated with fewer metabolic complications, such as glucose intolerance and elevated insulin requirements.[23] Enteral formulations contain both complex and simple carbohydrates, which results in slower carbohydrate absorption compared with the simple carbohydrate, dextrose, used in PN. In addition, enteral formulations that contain fiber and/or a high fat content will further slow carbohydrate absorption and reduce blood sugar elevations by delaying gastric emptying, accounting for better blood glucose control when carbohydrates are given via the enteral route. An additional physiologic benefit of enteral feeding is that it stimulates bile flow through the biliary tract and thus reduces the risk of developing cholestasis, gallbladder sludge, and gallstones, conditions that have been associated with long-term PN and bowel rest.[24] EN avoids the potential infectious and technical complications associated with the placement and use of a central venous access device required for PN. Finally, EN is less costly than PN when all factors associated with the therapy are considered.

Timing of Initiation

The timing of initiation of EN in the critically ill patient is of clinical significance. Initiating EN in the first 24 to 72 hours following admission appears to attenuate the stress response and may reduce disease severity and infectious complications when compared with the initiation of feedings after 72 hours.[13-15] Early EN has also been associated with a decrease in the release of inflammatory cytokines and fewer effects on gut permeability.[25] Clinical studies demonstrating reductions in infectious complications with EN compared with PN have been reported in the critically ill patient when feeding was initiated within 24 to 48 hours of hospital admission.[13-15,26] The benefit of fewer infectious complications was not apparent when the initiation of EN was delayed. A review of available studies comparing early versus delayed EN in critically ill patients revealed a trend toward a reduction in infectious complications with early EN.[13-15] In addition, a trend toward reduction in mortality associated with early EN has been noted.[13-15,26]

In critically ill patients who are hemodynamically unstable, early EN may result in gut ischemia because of poor gut blood flow and increased oxygen demand. Consequently, it is recommended that initiation of EN be delayed until the patient is fluid resuscitated and has an adequate perfusion pressure.[13] Once this goal is achieved, the initiation of EN at a low administration rate is considered appropriate, along with clinical monitoring to ensure GI tolerance and continued hemodynamic stability. Therefore, early EN (within 24-48 hours after hospital admission) is recommended in critically ill adult patients.[13-15] Although no randomized, controlled trials have assessed early EN in critically ill children, initiation of EN within 48 to 72 hours of admission is common.[16]

Early EN initiation is not warranted for previously well nourished, mild to moderately stressed adult patients. When oral intake is inadequate, it is reasonable to delay the initiation of EN for 5 to 7 days in these patients.[8] In the mild to moderately stressed adult patient who is moderately to severely malnourished, most clinicians would initiate EN sooner.

ENTERAL ACCESS

Advances in enteral access techniques have contributed to the expanded use of EN for conditions in which PN had previously been used. In particular, improved methods of achieving jejunal access for feeding have allowed the EN use during the early postoperative and post-injury period when gastric motility is typically impaired. As outlined in Table 143-3, various factors influence the selection of enteral access site and device, including anticipated duration of use and whether to feed into the stomach or small bowel. Figure 143-2 illustrates the predominant enteral access options.

Short-Term Access

3 Short-term enteral access is easier to initiate, less invasive, and less costly than the establishment of long-term access.[27] The most frequently used routes for short-term enteral access are established by inserting a tube through the nose or mouth and passing the tip into the stomach (nasogastric [NG]; orogastric [OG]), or jejunum (nasojejunal [NJ]; orojejunal [OJ]). In general, these tubes are used in the hospitalized patient when the anticipated tube feeding duration is less than 4 to 6 weeks. The orogastric route is generally

TABLE 143-3 Options and Considerations in the Selection of Enteral Access

Access	EN Duration/Patient Characteristics	Tube Placement Options	Advantages	Disadvantages
Nasogastric or orogastric	Short term Intact gag reflex Normal gastric emptying	Manually at bedside	Ease of placement Allows for all methods of administration Inexpensive Multiple commercially available tubes and sizes	Potential tube displacement Potential increased aspiration risk
Nasojejunal or orojejunal	Short term Impaired gastric motility or emptying High risk of GER or aspiration	Manually at bedside Fluoroscopically Endoscopically	Potential reduced aspiration risk Allows for early postinjury or postoperative feeding Multiple commercially available tubes and sizes	Manual transpyloric passage requires greater skill Potential tube displacement or clogging Bolus or intermittent feeding not tolerated
Gastrostomy	Long term Normal gastric emptying	Surgically Endoscopically Radiologically Laparoscopically	Allows for all methods of administration Low-profile buttons available Large-bore tubes less likely to clog Multiple commercially available tubes and sizes	Attendant risks associated with each type of procedure Potential increased aspiration risk Risk of stoma site complications
Jejunostomy	Long term Impaired gastric motility or gastric emptying High risk of GER or aspiration	Surgically Endoscopically Radiologically Laparoscopically	Allows for early postinjury or postoperative feeding Potential reduced aspiration risk Multiple commercially available tubes and sizes Low-profile buttons available	Attendant risks associated with each type of procedure Bolus or intermittent feeding not tolerated Risk of stoma site complications

EN, enteral nutrition; GER, gastroesophageal reflux.

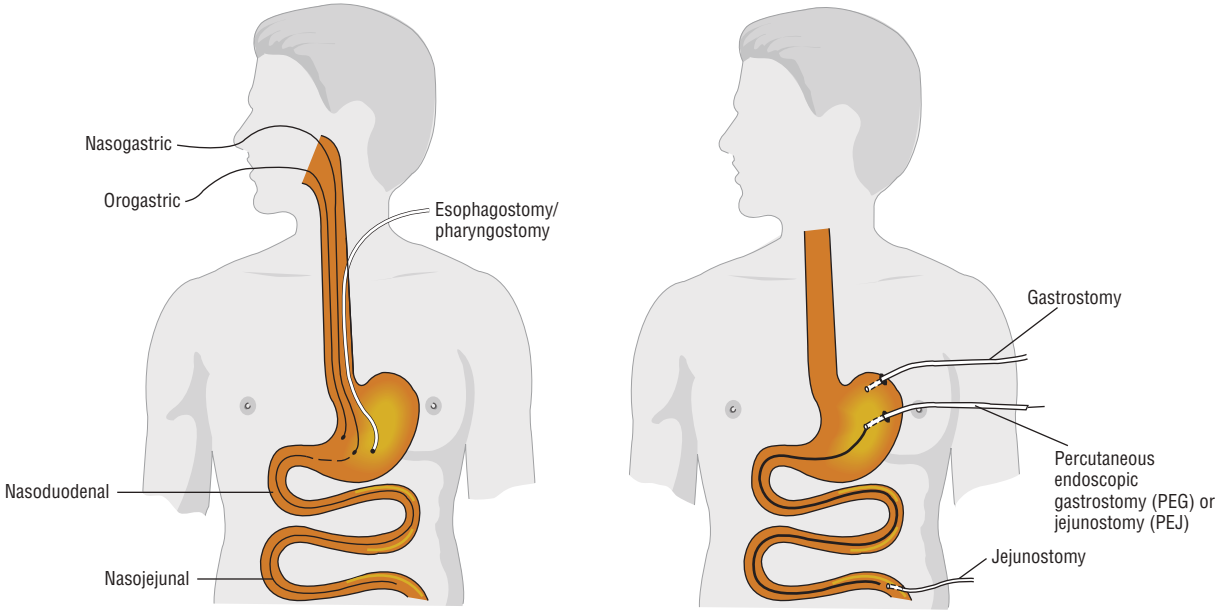

FIGURE 143-2 Access sites for tube feeding.

reserved for patients in whom the nasopharyngeal area is inaccessible or in young infants who are obligate nasal breathers. Because these routes do not require surgical intervention, they are the least invasive. The most common technique for placement is blind passage at the bedside by trained medical personnel. Several techniques have been described in the literature to help facilitate bedside placement and greater skill is required to advance the tip of the feeding tube beyond the pylorus.[17] Metoclopramide, a prokinetic agent, has been used with variable success to aid passage of the tube beyond the pylorus. A bedside electromagnetic tube placement device has also been used to guide tip position into the small bowel by attracting a metal tip on the end of the tube.[28,29] Alternatively, a variety of endoscopic and fluoroscopic techniques have been described to insert tubes into the small bowel.[17,27] Radiographic confirmation of appropriate tip placement should be obtained prior to use for all bedside placed feeding tubes.[9,17]

Nasogastric tubes vary in diameter and stiffness. Large-bore (greater than or equal to 14F) rigid NG tubes are used primarily to decompress the stomach but can also be used for feeding. There is a low incidence of clogging with these tubes, and they provide a reliable way to measure gastric residual volumes (GRVs). The major disadvantage associated with the use of these tubes is patient discomfort. Small-bore nasal tubes designed solely for feeding are available in varying lengths (12-60 inches [30-152 cm]) and diameters (3.5F-12F) to accommodate both pediatric (including neonates) and adult patients. The tip of the tube can be placed into the stomach or into the duodenum or jejunum (also referred to as transpyloric placement). These tubes consist of a lightweight, pliable silicone or polyurethane material that is designed for patient comfort. A disadvantage of small-bore tubes is that they more easily occlude, often as a result of improper medication administration or flushing technique. The feeding tube is frequently held in place only by a piece of tape on the nose or face; therefore, it can be inadvertently dislodged relatively easily. Nasal bridles have been used with variable results to secure the nasoenteric tube in place.[17] A bridle involves passing a piece of thin tubing or suture into one nostril, then around the bony portion of the nose, and out the other nostril, and finally tying the tubing around the feeding tube.

4 In general, gastric feeding is the least expensive and the least labor-intensive method for enteral feeding; however, feeding into the stomach is not always tolerated. Patients with impaired gastric motility may be predisposed to aspiration and pneumonia when fed into the stomach. Many critically ill, injured, and postoperative patients exhibit delayed gastric emptying, which limits their ability to tolerate gastric feeding. In addition, patients with diabetic gastroparesis or patients with severe gastroesophageal reflux disease or intractable vomiting are at a higher risk for aspiration of gastric contents, resulting in pneumonia. In these patients, placing the tip of the tube into the duodenum or jejunum has been suggested as a method to decrease aspiration risk.[17] Transpyloric feeding has been associated with a lower rate of vomiting and ventilator-associated pneumonia when compared to NG feeding.[30] However, the evidence to support the difference in aspiration and aspiration pneumonia risk associated with gastric and small bowel feeding is inconclusive. In general, small bowel feeding may be beneficial in patients who do not tolerate gastric feeding and offers an alternative to PN.[13-16]

Long-Term Access

Feeding tubes used for short-term enteral access are usually not optimal for long-term use because of patient discomfort, complications, and mechanical failures that develop over time. Long-term access should generally be considered when the need for EN is anticipated to be longer than 4 to 6 weeks. Many techniques can be used to establish long-term enteral access, including laparotomy, laparoscopy, endoscopic and image guidance (eg, fluoroscopy and ultrasound).[17] The ability to perform the various techniques will be somewhat dependent on the expertise and facilities available within each institution. Long-term enteral access options include gastrostomy and jejunostomy tubes.

A gastrostomy is the most common type of long-term enteral access. It eliminates the nasal irritation and discomfort associated with nasoenteric feeding tubes and inadvertent removal is uncommon. In addition, because feeding gastrostomies use large-bore tubes, clogging is less of a problem. The most commonly placed is the percutaneous endoscopic gastrostomy (PEG). The technique is minimally invasive and can be performed safely and cost-effectively in an endoscopy suite or at the bedside using conscious sedation and local anesthesia. Young children, however, will usually require general anesthesia for the procedure. Gastrostomy tubes are available in various sizes (12F-28F; 0.8-5 cm shaft lengths), material (eg, silicone and polyurethane), and have different retention mechanisms. Since smaller-diameter tubes are prone to more frequent occlusion

and dysfunction, the largest diameter size possible is preferred. For patient convenience, comfort, and cosmetic appearance, a low-profile skin-level gastrostomy device may be used. It is typically placed as an exchange tube for a preexisting gastrostomy or jejunostomy once the tract has matured but can also be used at the time of initial tube placement. This "gastric button" consists of a short, silicone, self-retaining conduit with either a mushroom tip or a balloon at the internal end and a one-way valve and small flange at the skin surface. Because this averts the external tube presence, it tends to be preferred in children or ambulatory adults who are receiving intermittent feedings. The exit site of all gastrostomies requires general stoma care to prevent inflammation and infection. Routine replacement of the gastrostomy tube at defined intervals (usually 3-6 months) is a standard of practice of many clinicians to prevent failure of the retention mechanism that can occur over time.[17]

In patients with a functional bowel but impaired gastric motility, pancreatitis, or who otherwise do not tolerate gastric feeding and require long-term enteral access, a jejunostomy may be an appropriate option.[27] Various endoscopic and fluoroscopic techniques are available for direct jejunostomy placement. A surgically placed jejunostomy may be an option if the patient requires a laparotomy or laparoscopy for other reasons. For patients who require small bowel feeding with simultaneous gastric decompression, a gastrojejunal tube may be placed utilizing various endoscopic, fluoroscopic, and surgical techniques.[15,30] Because jejunostomies use smaller-bore tubes, occlusion occurs more commonly than with gastrostomy tubes. Gastrojejunostomy tubes are often replaced every 3 to 6 months to prevent occlusion.

There are ethical implications regarding determination of appropriate candidates for long-term feeding tube placement.[17,31-35] Because a gastrostomy is relatively easy to place and many patients, families, and clinicians overestimate the benefits of EN, it is prone to inappropriate use. In certain patient populations, such as those with advanced dementia or other near end-of-life conditions, the placement of a gastrostomy is not recommended. Artificial nutrition and hydration (ANH) has not been shown to promote the healing of pressure ulcers, increase patient comfort or functional status, or prolong survival when compared to hand feeding in patients with advanced dementia.[31] From a clinical standpoint, ANH does not increase a patient's comfort or improve nutrition parameters of most terminally ill individuals and can result in medical complications.[32] Studies consistently demonstrate that survival rates are not improved in older patients with advanced dementia who receive tube feedings and it is associated with substantial burden, including agitation, greater use of physical and chemical restraints, recurrent aspiration, and tube-related complications.[33,34] Evaluation by a multidisciplinary team is warranted for all patients near the end of life to establish whether the benefit of EN outweighs the risks of feeding tube placement.[31,33-35]

ADMINISTRATION METHODS

Enteral nutrition may be administered by continuous, cyclic (continuous rate over a portion of the day), intermittent (infused over 20-60 minutes), or bolus (generally given in 5-10 minutes) methods and may be accomplished by syringe, gravity, or pump-controlled techniques. The deliver method depends on the location of the tip of the feeding tube, the patient's clinical condition and intestinal function, and the patient's tolerance to the tube feeding.

Continuous

Pump-assisted continuous administration of EN is generally the method of choice for most hospitalized patients, especially when initiating therapy. They may be candidates for transitioning to intermittent or bolus feeding for long-term use as their medical condition stabilizes, as described below. However, when EN is to be delivered into the small intestine, the continuous method is always preferred because it is associated with enhanced tolerance. The rapid delivery of feeding into the small intestine may contribute to abdominal distension, cramping, hyperperistalsis, and diarrhea (also referred to as *dumping syndrome*). Therefore, conversion to intermittent or bolus administration is not recommended for those with jejunostomies.

The delivery system for continuous administration generally includes a feeding set with attached reservoir bag or spike set that connects to a feeding container. The feeding set is attached to a pump and then connected to the patient's enteral access tube with an adaptor. Continuous administration may increase nursing time because routine checks are needed, but this disadvantage is usually offset by the improved tolerance. For adults, target EN administration rates generally range from 50 to 125 mL/h, although higher rates have been used without complications. In infants and children, goal administration rates vary with age and weight and should be sufficient to meet caloric needs while maintaining good GI tolerance. The primary disadvantage to this method of administration is the cost and inconvenience associated with the pump and administration sets. In the home care setting, battery-operated ambulatory enteral pumps that fit into a backpack with the feeding bag are available to allow the patient greater mobility.

Cyclic

A patient who is not eating well during the day because of complaints of fullness and lack of appetite or who is not able to consume enough calories during the day to meet increased needs (eg, trauma and burns) may benefit from cyclic EN, in which the enteral feeding is administered by pump only at night. In addition, nocturnal EN administration will free the patient from the pump during the day and allow for greater mobility. This increased mobility may be particularly useful for the home patient or patient requiring rehabilitation. This method may be used in patients with either gastric or small bowel access.

Bolus

The bolus administration of EN is commonly used for patients in the home or long-term care setting who have a gastrostomy. This administration technique involves the delivery of the enteral feeding formulation over 5 to 10 minutes. Essentially, the only equipment needed is a syringe to instill the feeding volume into the tube. Depending on the patient's nutritional requirements, a feeding volume of 240 to 500 mL is generally used and repeated four to six times daily. From a convenience standpoint, it is generally preferable to adjust the bolus volume in increments of the feeding formulation container size (usually 240-250 mL). Bolus volumes given to infants and children vary with age and weight (usually 30-240 mL) and should be sufficient to meet the patient's calorie needs. In neonates and young infants, the bolus regimen is usually begun with an every 3-hour schedule; in older infants and children, feedings may be given at a frequency needed to deliver four to five feedings daily.[18] In patients with duodenal or jejunal access, bolus delivery may result in cramping, nausea, vomiting, aspiration, and diarrhea. Bolus administration also should be avoided in patients with delayed gastric emptying and in patients who are at high risk of aspiration.

Intermittent

If a patient is experiencing intolerance to bolus administration over 5 to 10 minutes, it may be helpful to administer the prescribed volume over a longer time period, generally 20 to 60 minutes. For this method, the desired volume of feeding formulation is emptied into a reservoir bag or container with attached tubing and administered by an enteral pump or via gravity drip using a roller clamp. The bolus method of administration is more consistent physiologically with normal eating patterns than the continuous method.

One study in infants demonstrated that normal gallbladder emptying did not occur with continuous feedings but was present in those infants receiving bolus feedings.[36] Thus, those patients who need long-term EN and PN, especially children, may benefit when this approach is used because it may minimize the development of cholestatic liver disease.

INITIATION AND ADVANCEMENT PROTOCOL

Guidelines for the initiation and advancement of enteral feeding formulations vary greatly and are primarily tailored to patient tolerance. The typical recommendation for continuous EN administration for adults is to start at 20 to 50 mL/h and advance by 10 to 25 mL/h every 4 to 8 hours until the desired goal is achieved. For intermittent administration, the typical recommendation is to start with 120 mL every 4 hours and advance by 30 to 60 mL every 8 to 12 hours.[8,9] In children, continuous administration is often initiated at a rate of 1 to 2 mL/kg per hour (no more than 25-30 mL/h) or 2 to 4 mL/kg per bolus (no more than 30-90 mL) with advancement by similar amounts every 4 to 24 hours. In premature infants, feedings may be initiated at lower rates usually 10 to 20 mL/kg per day and advanced by similar rates daily.[11,18] Schedules for progression of tube feeding from initial to target rates are important and may influence tolerance. If the protocol is too conservative, it may take an excessively long period of time to reach nutrient goals. The practice of diluting enteral feeding formulations is not recommended unless necessary to increase fluid intake.[9] The development of an EN protocol within an institution that outlines initiation and advancement criteria is recommended to optimize achievement of nutrient goals.[13,14] Due to frequent interruptions of EN, some institutions have implemented volume-based feeding protocols to improve success in meeting targeted goals. Such a protocol shifts the focus from an hourly rate target goal to a 24-hour volume goal and provides guidance on how to adjust the rate of administration when EN is interrupted for reasons unrelated to GI tolerance.[37,38]

ENTERAL FEEDING FORMULATION SELECTION

Historically, enteral formulas were designed primarily to provide essential nutrients. Over the years, enhancements have been made to meet specific patient needs and improve tolerance. For example, nutrient composition has been enhanced by changing the content of the amino acids (eg, glutamine and arginine), increasing the omega-3 polyunsaturated fatty acid content, and adding RNA to enhance immune function and improve therapeutic outcomes. These specific nutrients have been called nutraceuticals or pharmaconutrients because of the intent to use them to modify disease processes and improve clinical outcomes. Currently, enteral feeding formulations are categorized by the FDA as medical foods.[9] They are considered components of supportive care and are simply regulated to ensure sanitary manufacture. Unfortunately, they are not subject to rules governing health claims, and promotion of medical foods for therapeutic intent is currently not regulated by the FDA.[39]

The macronutrient content of enteral formulas (namely, protein, carbohydrate, and fat) varies in nutrient complexity (Table 143-4). Nutrient complexity refers to the amount of hydrolysis and digestion a substrate requires prior to intestinal absorption. Polymeric or intact substrates are of similar molecular form as the foods we eat. Enteral formulas that contain partially hydrolyzed or elemental substrates are characterized as elemental or defined-formula diets. The caloric contribution of each of the macronutrients is as follows: carbohydrates, 4 kcal/g (17 kJ/g); protein, 4 kcal/g (17 kJ/g); and fat, 9 kcal/g (38 kJ/g).

TABLE 143-4 Enteral Formula Nutrient Complexity

Nutrient	Polymeric or Intact	Partially Hydrolyzed or Elemental
Carbohydrate	Starches Fruit, vegetable, cereal solids Glucose polymers Corn syrup solids Polysaccharides	Oligosaccharides Maltodextrins Disaccharides Maltose, sucrose, lactose Monosaccharides Glucose Galactose
Fat	Long-chain triglycerides Polyunsaturated fatty acids Corn oil Safflower oil Soybean oil Canola oil Marine oils	Medium-chain triglycerides Coconut oil Palm kernel oil Free fatty acids Linoleic
Protein	Whole Egg, milk, wheat, whey Isolates Caseinate salts Lactalbumin	Oligopeptides Dipeptides Tripeptides L-amino acids

Protein Composition

The essential amino acid content of the protein source determines the quality of the protein, and most commercially available enteral feeding formulations contain proteins of high quality. The form of the protein source in enteral formulas will determine the amount of digestion that is required for absorption. Polymeric or intact protein sources require digestion to smaller peptides and free amino acids before absorption. Protein sources, such as meat, milk, eggs, and caseinates, require digestion by hydrochloric acid, specific protein enzymes, and pancreatic proteases. Enteral formulations may also contain protein sources that are partially hydrolyzed to peptides or L-amino acids. As the molecular form of protein is reduced in size, the osmotic load of the enteral formulation is increased. Many commercially available enteral feeding formulations contain combinations of intact and partially hydrolyzed protein sources. Most enteral formulations are gluten-free.

Conditionally Essential Amino Acids

Glutamine and arginine are generally considered nonessential amino acids. However, during periods of high physiologic stress, the need for these nutrients may be increased beyond the body's synthetic ability; consequently, these amino acids are characterized as conditionally essential. Because they are usually present in low amounts in most enteral feeding formulations, formulations targeted for the critically ill may be supplemented with glutamine and/or arginine.

Glutamine serves as a key fuel for rapidly dividing cells, including enterocytes, endothelial cells, lymphocytes, and fibroblasts. The primary site of glutamine production is skeletal muscle. During critical illness, skeletal muscle catabolism provides an increased glutamine supply, but this may not be enough to meet the high rate of glutamine use by cells of the immune system and other cells involved in recovery and repair. Glutamine depletion may develop, particularly during prolonged periods of metabolic stress. Favorable outcomes have been documented in critically ill patients when enteral formulations have been supplemented with glutamine.[13,40] Its use has specifically been recommended in burn and trauma patients.[15] However, high dose glutamine supplementation in critically ill patients with shock and multiorgan failure should be used with caution.[14] This concern is based on a study in over 1,200 critically ill adults that showed no benefit and a trend toward increased mortality when high-dose glutamine was given as a combined parenteral and enteral supplement for 28 days.[41]

Arginine has been added to some immune-modulating enteral formulations in concentrations that range from 4.5 to 14 g/L. However, arginine supplementation remains controversial, especially in patients with sepsis.[40,42] Many of arginine's physiologic effects are mediated by its conversion to nitric oxide, which, in turn, modulates immune function, inflammation, and vasodilation. Some of these effects may be potentially harmful in the patient with sepsis, especially when higher arginine intakes are used.[13]

Carbohydrate Composition

The carbohydrate component of enteral feeding formulations usually provides the major source of calories. Polymeric or intact enteral formulations contain starches and numerous types of glucose polymers, which require digestion to monosaccharides prior to intestinal absorption (see Fig. 143-1). As the extent of hydrolysis of carbohydrates increases within an enteral formulation, the osmolality of the formulation increases. Simple sugars, such as glucose and galactose, contribute significantly to the osmolality of enteral formulations. Consequently, polymeric entities, rather than elemental sugars, are preferred. Glucose polymers provide a useful carbohydrate source that is tolerated by most individuals (see Table 143-4). The polymers are large chains that provide minimal osmotic load, yet are absorbed easily in the intestine. The one shortcoming of glucose polymers and oligosaccharides is that they are not as sweet as simple glucose and thus may decrease the palatability of orally consumed products. Finally, almost all commercially available enteral feeding formulations used in adults and older children are lactose-free because disaccharidase production within the gut lumen is reduced during illness and periods of prolonged bowel rest. Additionally, there is a high incidence of lactose intolerance in those of certain ethnic decent. Infant formulas are available with or without lactose.

Fat and Fatty Acid Composition

Fat is an important constituent in the diet because it provides a concentrated calorie source and serves as a carrier for fat-soluble vitamins. Sufficient linoleic acid is required to prevent essential fatty acid deficiency and should approximate at least 1% to 3% of total daily calories. The most common fat sources in enteral feeding formulations are vegetable oils (soy or corn) that are rich in polyunsaturated fatty acids. The fat concentration varies between less than 2% and 45% of total calories. High dietary fat content is associated with delayed gastric emptying. Enteral feeding formulations can also contain fat in the form of MCTs derived from palm kernel or coconut oils. Because MCTs do not contain linoleic acid, enteral formulations that contain MCTs will also have a source of long-chain triglycerides to provide essential fatty acids. Potential advantages of MCTs compared to long-chain triglycerides are that they are more water soluble, undergo rapid hydrolysis, require no pancreatic lipase or bile salts for absorption, and do not require carnitine for transport into the mitochondria, where they are converted to energy. They also do not require chylomicron formation for small bowel enterocyte absorption and are not transported via the lymphatic system.

The source of long-chain fat within some enteral formulations has been modified from omega-6 to omega-3 fatty acids in an effort to modulate the inflammatory response in patients with acute respiratory distress syndrome (ARDS), acute lung injury (ALI), and sepsis.[43] The omega-6 fatty acids are high in linoleic acid and are derived from vegetable oil, whereas the omega-3 fatty acids, derived from cold-water fish oils, are high in linolenic acid. Omega-6 fatty acids serve as precursors to certain arachidonic acid-derived cytokines that are potent inflammatory mediators and also decrease cell-mediated immune response; whereas omega-3 fatty acids are precursors for eicosapentanoic acid-derived cytokines which are less inflammatory. It has been proposed that if the dietary proportion of omega-3 fatty acids is increased and omega-6 fatty acids is decreased, less inflammation and immunosuppression may occur during metabolic stress.

Docosahexaenoic acid (DHA) and arachidonic acid (ARA) are two fatty acids abundant in human milk, but until recently, they were not contained in commercial infant formulas. Although the role of ARA supplementation is unclear, DHA is important in brain and eye development. In some studies, DHA and ARA supplementation provided benefits to a child's visual function and/or cognitive and behavioral development.[44] The FDA has classified plant-based fatty acid blends of DHA and ARA as generally recognized as safe (GRAS), and most infant formulas, as well as some products for pregnant and lactating women, are supplemented with these fatty acids.

Fiber Content

Fiber, in both soluble and insoluble forms, is added to several adult and pediatric enteral feeding formulations in amounts ranging from 5.9 to 24 g/L. Infant formulas generally do not contain fiber; however, at least one formula intended for use in infants with diarrhea contains soy fiber. Fiber supplementation is common in clinical practice, primarily because fiber-free enteral formulations are implicated as a contributing factor to both diarrhea and constipation. Soluble fiber undergoes bacterial degradation within the colon to produce short-chain fatty acids. Potential benefits of soluble fiber are its trophic effects on the colonic mucosa and promotion of sodium and water absorption within the colon. Insoluble fiber is undigested and may help decrease GI transit time by increasing fecal weight. Fiber supplementation may help to regulate bowel function in both normal individuals and those with altered colonic motility. In addition, the resulting short-chain fatty acids are an excellent energy source. Although beneficial effects of fiber supplementation have not been clearly proven in clinical studies, there is experimental evidence that fiber may play an integral role in normal nutrition, and risk is generally minimal, particularly in non-critically ill patients.[45] Fiber supplementation may be beneficial when long-term EN is required or in patients who experience diarrhea or constipation while receiving a fiber-free enteral formulation. Soluble fiber may also be beneficial in the critically ill patient who is hemodynamically stable and develops diarrhea while receiving EN.[13] Insoluble fiber should be avoided in all critically ill patients due to case reports of bowel obstruction.[13]

Osmolality and Renal Solute Load

The unit of measure of osmolality is milliosmoles per kilogram (mOsm/kg) or millimoles per kilogram (mmol/kg); iso-osmolar is considered to be approximately 300 mOsm/kg (mmol/kg). Osmolality and renal solute load can affect tolerance to enteral feeding formulations. The osmolality of a given enteral formulation is a function of the size and quantity of ionic and molecular particles, primarily related to the protein, carbohydrate, electrolyte, and mineral content within a given volume. Enteral formulations with greater amounts of partially hydrolyzed or elemental substrates have a higher osmolality than formulations containing polymeric or intact substrates. Therefore, formulations that contain sucrose or glucose, dipeptides and tripeptides, and amino acids are generally hyperosmolar. Increased caloric density also increases the osmolality of an enteral formulation. In general, the osmolality of commercially available enteral feeding formulations ranges from 300 to 900 mOsm/kg (mmol/kg). American Academy of Pediatrics guidelines recommend that enteral formulations for use in infants have an osmolality of 450 mOsm/kg (mmol/kg) or less which equates to an osmolality of 400 mOsm/L.[46]

Symptoms of gastric retention, diarrhea, abdominal distension, nausea, and vomiting have been attributed to enteral formulations with a high osmolality based on the assumption that higher osmolality draws water into the gut lumen. However, clinical evidence

to support this relationship between osmolality and GI tolerance is lacking. The practice of diluting hyperosmolar formulations has not been shown to enhance tolerance and should be discouraged unless dilution is done to increase fluid intake.[9] Factors, such as concurrent antibiotic therapy, method of enteral feeding administration, and the formulation's composition, are likely to play a greater role in GI tolerance than the osmolality.

The renal solute load is determined by the protein, sodium, potassium, and chloride content of the enteral formulation. Formulations that contain a greater solute load increase the obligatory water loss via the kidney. It is estimated that 40 to 60 mL of water is the minimal amount necessary to excrete 1 g of nitrogen. Those receiving high-protein enteral formulations unable to ingest or tolerate supplemental water may be at risk for developing dehydration.

CLASSIFICATION OF ENTERAL FEEDING FORMULATIONS

5 Most patients' nutritional needs can be met using a standard enteral feeding formulation; however, certain disease states or clinical conditions may warrant the use of a specialty feeding formulation. Development of an evidence-based, enteral formulary should focus on clinically significant characteristics of available formulations and avoid duplication. Categorizing enteral feeding formulations according to therapeutic class is necessary in developing a formulary system for adults (Table 143-5) and children (Table 143-6).

Standard Polymeric

A large number of commercially available enteral feeding formulations fall into the standard polymeric formulation category. These formulations are approximately isotonic (300 mOsm/L [300 mmol/L]), provide 1 to 1.2 kcal/mL (4.2-5 kJ/mL), and are composed of intact nutrients in a nutritionally balanced mix of carbohydrate, fat, and protein. They may contain dietary fiber. The nonprotein calorie-to-nitrogen ratio of these products is approximately 125:1 to 150:1. This ratio is a useful parameter for assessing protein density in relation to calories provided (see Chapter 141). Certain feeding formulations in this category may be promoted as high nitrogen but actually fall within standard protein amounts. To maintain isotonicity, many products within this category are not sweetened, making them unpalatable and generally suited only for tube feeding; however, flavored products are available for oral supplementation. The nutrient requirements of the majority of adults and children older than 1 year receiving EN can generally be met using feeding formulations in this category. Many term and preterm infant formulas will also fall into this category and available in formulations that provide 19 to 24 kcal/oz (2.7-3.5 kJ/mL) or 22 to 30 kcal/oz (3.1-4.2 kJ/mL), respectivly.[46]

High Protein

Enteral feeding formulations with a nonprotein calorie-to-nitrogen ratio less than 125:1 can be categorized as high protein. The lower the ratio, the higher the protein density in relation to calories provided. In patients with high protein requirements, it is generally unacceptable to use a feeding formulation with standard protein amounts because the volume necessary to meet protein requirements will result in excessive calorie intake. Patients who may be candidates for a high-protein feeding formulation are critically ill patients and those with pressure sores, surgical wounds, and high output enterocutaneous fistulas. In general, adult patients with estimated protein requirements exceeding 1.5 g/kg per day may benefit from a high-protein formulation. High-protein formulations may also be beneficial in mechanically ventilated patients who are receiving propofol for sedation. The vehicle for propofol is a soybean fat emulsion that contains 1.1 kcal/mL (4.6 kJ/mL). At therapeutic dosages, propofol intake can significantly contribute to caloric intake, and a high protein formulation may be beneficial in allowing for the provision of protein requirements while minimizing overfeeding.

TABLE 143-5 Adult Enteral Feeding Formulation Classification System

Category	Features	Indications
Standard polymeric	Isotonic 1-1.2 kcal/mL (4.2-5 kJ/mL) NPC:N 125:1-150:1 May contain fiber	Designed to meet the needs of the majority of patients Patients with functional GI tract Not suitable for oral use
High protein	NPC:N <125:1 May contain fiber	Patients with protein requirements >1.5 g/kg/day, such as trauma patients and those with burns, pressure sores, or wounds Patients receiving propofol
High caloric density	1.5-2 kcal/mL (6.3-8.4 kJ/mL) Lower electrolyte content per calorie Hypertonic	Patients requiring fluid and/or electrolyte restriction, such as kidney insufficiency
Elemental	High proportion of free amino acids Low in fat	Patients who require low fat Use has generally been replaced by peptide-based formulations
Peptide-based	Contains dipeptides and tripeptides Contains MCTs	Indications/benefits not clearly established Trial may be warranted in patients who do not tolerate intact protein due to malabsorption
Disease-specific		
Kidney	Caloric dense Protein content varies Low electrolyte content	Alternative to high caloric density formulations, but generally more expensive
Liver	Increased branched-chain and decreased aromatic amino acids	Patients with hepatic encephalopathy
Lung	High fat, low carbohydrate Antiinflammatory lipid profile and antioxidants	Patients with ARDS and severe ALI
Diabetes mellitus	High fat, low carbohydrate	Alternative to standard, fiber-containing formulation in patients with uncontrolled hyperglycemia
Immune-modulating	Supplemented with glutamine, arginine, nucleotides, and/or omega-3 fatty acids	Patients undergoing major elective GI surgery, trauma, burns, head and neck cancer, and critically ill patients on mechanical ventilation Use with caution in patients with sepsis Select nutrients may be beneficial or harmful in subgroups of critically ill patients
Oral supplement	Sweetened for taste Hypertonic	Patients who require supplementation to an oral diet

ALI, acute lung injury; ARDS, acute respiratory distress syndrome; MCT, medium-chain triglyceride; NPC:N, nonprotein calorie-to-nitrogen ratio.

TABLE 143-6 Pediatric Enteral Feeding Formulation Classification System

Formula Type	Features	Indications
Infants		
Cow's milk-based	Standard energy density for feeding: 20-24 kcal/oz (2.8-3.3 kJ/mL); also available in concentrate (40 kcal/oz [5.6 kJ/mL]) and powder forms Standard formulation contains lactose, but also available as lactose-free	Normal, healthy infant
Soy protein-based	Standard energy density for feeding: 20 kcal/oz (2.8 kJ/mL); also available in concentrate (40 kcal/oz [5.6 kJ/mL]) and powder forms Lactose free May contain added soy fiber	Lactase deficiency or lactose intolerance, galactosemia, diarrhea (fiber added)
Prematurity	Standard energy density for feeding: 24 kcal/oz (3.3 kJ/mL); also available in 20 (2.8 kJ/mL) and 30 kcal/oz (4.2 kJ/mL) forms	Preterm infants weighing <2-3 kg (<4.4-6.6 lb)
Transition	Standard energy density for feeding: 22 kcal/oz (3.1 kJ/mL) Provide higher calcium and phosphorus content compared with term infant formulas	Preterm infants weighing <3 kg (<6.6 lb) and ready for discharge
Semi-elemental/ elemental	Standard energy density for feeding: 20 kcal/oz (2.8 kJ/mL) Hydrolyzed protein and free amino acids May contain ARA and DHA Lactose free Typically contain MCTs ranging from 5% to 86% of fat content	Malabsorption, cow's milk protein allergy, chylothorax, cystic fibrosis, biliary atresia, short bowel syndrome, food allergies
Special diets	Low electrolyte/mineral content	Kidney disease
Children Ages 1-10 Years		
Standard	Standard energy density for feeding: 30 or 45 kcal/oz (1 or 1.5 kcal/mL [4.2 or 6.3 kJ/mL]) Intact protein; 30-38 g/L May contain added fiber	Functioning GI tract requiring tube feedings
Semi-elemental/ elemental	Standard energy density for feeding: 20-30 kcal/oz (2.8-4.2 kJ/mL) Hydrolyzed protein and free amino acids Lactose-free MCTs range from 33% to 87% of fat content	Malabsorption, cow's milk protein allergy, chylothorax, cystic fibrosis, biliary atresia, short bowel syndrome, food allergies

ARA, arachidonic acid; DHA, docosahexaenoic acid; MCT, medium-chain triglyceride.

High Caloric Density

High caloric density formulations are concentrated to provide less fluid and electrolyte intake in comparison to a standard polymeric formulation. They provide approximately 2 kcal/mL (8.4 kJ/mL) and similar calorie and protein intake can be achieved as a standard polymeric formulation, using half the volume. High caloric density formulations are often necessary for patients who require fluid and/or electrolyte restriction, such as those with kidney or heart failure. Although specialty enteral formulations targeted for acute kidney injury and chronic kidney disease are available, many patients with kidney failure can be managed using a product in this category.

Elemental/Peptide-Based

Formulations in this category contain protein and/or fat components that are hydrolyzed into smaller, predigested forms. Traditionally, enteral formulations in this category were referred to as elemental and contained a high proportion of protein in the form of free amino acids and a low amount of fat. Many of these formulations have been reformulated to provide a portion of the protein in the form of dipeptides and tripeptides and fewer free amino acids because dipeptides and tripeptides are more readily absorbed than an equivalent intake of free amino acids.[48] These peptide-based formulations may be beneficial in patients with impaired digestion or absorption. Peptide-based formulations are generally higher in fat than the more elemental formulations and use MCTs in varying proportions as the fat source.

Evidence to support the use of elemental or peptide-based formulations is limited, and their routine use is generally not recommended. Patients who do not tolerate standard, intact nutrient formulations as a result of malabsorption or short bowel syndrome might be candidates for a trial of a peptide-based formulation. In addition, elemental or peptide-based products that have higher percentages of MCTs and small amounts of long-chain triglycerides may be beneficial for patients with severe pancreatic insufficiency, such as chronic pancreatitis and cystic fibrosis; severe abnormalities of the intestinal mucosa, such as untreated celiac disease; biliary tract disease, such as biliary atresia or severe cholestasis; or chylothorax or chylous ascites.

Disease Specific

Enteral feeding formulations also have been designed to meet unique nutrient requirements and manage metabolic abnormalities associated with specific disease states. Specialized enteral feeding formulations are marketed for use in adult patients with kidney and liver failure; lung disease, including ARDS; diabetes mellitus; wound healing; and metabolic stress. There are no disease-specific enteral products currently marketed for use in infants or children younger than 10 years of age. Thus, modular supplements may be necessary in these patients (see discussion in Modular Products section).

Specialized enteral formulations designed to modulate the inflammatory response in adult patients with severe metabolic stress have been referred to as immune-modulating formulations or immunonutrition. These formulations are supplemented with nutrients such as glutamine, arginine, antioxidants, nucleotides, and omega-3 polyunsaturated fatty acids, because of their potential role in regulating immune function. There is lack of consensus between the professional nutrition societies guidelines regarding the use of immune-modulating enteral formulations in critically ill patients.[13-15] Positive results have been reported in patients undergoing major elective GI surgery and cancer surgery of the head and neck, those with severe trauma or burns, and critically ill patients on mechanical

ventilation. The use of immune-modulating enteral formulations in these select patient populations has resulted in significant reductions in infectious complications, hospital length of stay, and duration of mechanical ventilation.[43,49] In contrast, two recent multicenter trials revealed no improvement in infectious complications or other clinical end points and possible harm with immune-modulating formulations[50] or when enteral immunonutrition was a provided as a twice daily supplement.[51] The heterogeneity of studies and lack of consistency between the various immunonutrition supplementation regimens makes it impossible to recommend their use in critically ill adult patients at this time. Immune-modulating formulations are not currently recommended for use in children because of the lack of evidence to support their use.[16]

Clinical **Controversy...**

The value of adding probiotics to EN in the ICU setting is controversial. The use of probiotics has reduced ventilator-associated pneumonia, antibiotic-associated diarrhea, and overall infections in critically ill patients. However, increased risk of mortality has been shown when probiotics are used concomitant with fiber and jejunal feeding in patients with severe acute pancreatitis. The benefits of probiotics appear to be variable and likely product-specific and dose dependent. Recommendations regarding their use are difficult to provide at this time.

Oral Supplements

In general, oral supplements are not intended for tube feeding but to enhance an oral diet. They are sweetened to improve taste and therefore are hypertonic (approximately 450-700 mOsm/kg [mmol/kg]), but osmolality is rarely a problem in the patient with a functioning GI tract. However, in the tube-fed patient, a sweetened product is unnecessary and may contribute to GI intolerance, particularly diarrhea. Powder supplements that are mixed with milk should be avoided in lactose-intolerant patients. In addition to liquid supplements, puddings, gelatins, bars, and milkshake-like supplements are available.

Modular Products

A module is a powder or liquid form of a nutrient (eg, protein, carbohydrate, fat, and dietary fiber) that is used to supplement nutrition intake when the diet or commercially available enteral formulation does not fully meet a patient's needs.[47] Alternatively, formulations available in powder or concentrate can be mixed with less water than needed for the standard dilution to deliver more nutrients in less volume. Infant formulas can be prepared to provide increased caloric density beyond the standard 19 to 20 kcal/oz (2.7-2.8 kJ/mL); concentrations of 22 to 30 kcal/oz (3.1-4.2 kJ/mL) are routinely used. The mixing process required for modular components increases the potential for bacterial contamination and incorrect preparation. Contamination is a particular concern with the use of blenders and reconstitution of powders.[9,52] A number of methods are used to fortify human milk so that it meets the needs of a premature infant fortify for added calories, protein, and minerals. They have been shown to improve nutritional outcomes in human milk-fed premature infants.[53,54]

Rehydration

Oral rehydration formulations are useful in maintaining hydration or treating dehydration in adult and pediatric patients with high GI output. Such formulations are available commercially in powder or liquid form or can be extemporaneously compounded. They can be administered orally or given via a feeding tube. The glucose content of oral rehydration solutions is important because it stimulates active transport systems, which, in turn, stimulate passive glucose-coupled sodium and water uptake. Therefore, oral or enteral administration of rehydration solutions may decrease fecal water loss and generate a positive fluid and electrolyte balance.[55,56]

FORMULARY AND DELIVERY SYSTEM CONSIDERATIONS

For an institution's enteral formulary, generally no more than one product per category is necessary, and it may be possible to omit certain categories based on the specific patient population cared for within a given institution. Additional selection criteria include container size and type, liquid or powder form, shelf life, ease of use, and cost.

Most enteral products are available as ready-to-use, prepackaged liquids, but a few are available in the powdered state and require reconstitution prior to use. Advantages of ready-to-use liquid formulations are convenience and reduced susceptibility to microbiologic contamination. One disadvantage is that more storage space may be required. The ease or convenience of a ready-to-use liquid is especially important for self-care patients, the disabled, and those who have difficulty reading or following printed instructions. Ready-to-use liquid enteral formulations are generally available in ready-to-hang rigid plastic containers or bags (*closed system*), cans, or bottles. Bolus administration of EN is usually achieved using formulas available in cans or bottles. However, when formula from a can/bottle is used for continuous or cyclic administration, it must first be poured into a feeding bag and attached to an administration set to allow for administration via a pump. This "open system" has a higher risk of microbial contamination than the ready-to-hang containers. The use of a powder formula is also considered an open delivery system.

Contamination of enteral feeding formulations is a potential cause of diarrhea.[8,9] Contamination is caused by a lack of attention to proper handling techniques, inadequate cleaning and disinfection of preparation equipment, and the use of nonsterile or contaminated tube-feeding additives. Unlike liquid formulations, powdered products are not guaranteed by the manufacturer to be sterile because it is not possible to sterilize the powder without destruction of some of its components. Contamination of milk powder and consequently powdered infant formulas with *Enterobacter sakazakii* (*Cronobacter* species) has been reported.[52] Contamination of one infant formula at the manufacturing site with *E. sakazakii* was implicated in the death of an infant in a neonatal ICU, prompting FDA warnings regarding the use of powdered formulations in premature neonates and other immunocompromised infants.[57] Closed-system containers supply a ready-to-hang, prefilled, sterile supply of formula in volumes of 1 to 1.5 L. Most but not all enteral formulations intended for use in adults and some pediatric formulations are available in the closed-administration system. The closed-administration system also offers the advantage of not requiring refrigeration and allowing hang times up to 48 hours, whereas the conventional open-delivery system necessitates hang times of generally 4 to 8 hours.

New enteral connectors are currently being integrated into the EN marketplace to prevent enteral misconnections and improve patient safety. An enteral misconnection occurs when a component of the enteral feeding system is inadvertently connected to a non-enteral site, such as a tracheostomy tube, peritoneal dialysis catheter, or other medical device or IV tubing. Misconnections are commonly attributed to the use of universal connectors that allow for misconnections between incompatible systems.[58] Due to several reports of serious patient harm, including death, an international standard (ISO 80369) has been developed to guide the redesign of all small-bore connectors and the new enteral connectors, referred to as the ENFit™ system.[59] The ENFit™ connector provides a unique connection that is not compatible with any other device and has been

specifically designed for all nutrition sources, enteral administration sets, enteral syringes, and all feeding tubes.[59] Filling and administration instructions for syringes used to deliver medications via feeding tubes will differ from oral syringes. Information about these processes and other resources is available at the Global Enteral Device Supplier Association (GEDSA) web site (www.stayconnected.org).[60]

COMPLICATIONS AND MONITORING

The majority of complications associated with EN are metabolic, GI, or mechanical. The early detection and management of potential complications is necessary to allow for the safe and successful use of EN. In addition, measures to avoid complications should be incorporated into the management of all patients receiving EN (Table 143-7).

Metabolic Complications

Metabolic complications associated with EN are similar to those associated with PN, but the incidence tends to be lower.[23] Critically ill patients, especially those with underlying organ dysfunction, are at risk of developing complications related to hydration and electrolyte imbalance and altered glucose control. Patients who present with a history of minimal dietary intake for an extended period of time and have experienced significant weight loss are at risk of developing refeeding syndrome which can be evidenced by hypophosphatemia, hypokalemia, hypomagnesemia, thiamine deficiency, and sodium retention.[61] The frequency of clinical and laboratory assessment to monitor hydration, electrolytes, organ function, and glucose adequately for a patient who is critically ill or at risk of developing refeeding syndrome is greater than for a stable hospitalized patient or patients residing in rehabilitation units or at home (see Table 143-7). Patients receiving long-term EN at home may require laboratory monitoring only every 2 to 3 months, depending on their clinical status. Besides macronutrient content, it is important to evaluate the actual water and micronutrient content provided by the enteral formulation, especially in critically ill patients. Supplemental fluid, electrolytes, and minerals may be required in some patients. Conversely, for patients who have fluid retention or elevated serum electrolytes, the enteral formulation may need to be changed to one that is more concentrated or provides less of a particular nutrient, if available.

TABLE 143-7 Suggested Monitoring for Patients on Enteral Nutrition

Parameter	During Initiation of EN Therapy	During Stable EN Therapy
Vital signs	Every 4-6 hours	As needed with suspected change (ie, fever)
Clinical assessment		
Weight	Daily	Weekly
Length/height (children)	Weekly-monthly	Monthly
Head circumference (<3 years of age)	Weekly-monthly	Monthly
Total intake/output	Daily	As needed with suspected change in intake/output
Tube-feeding intake	Daily	Daily
Enterostomy tube site assessment	Daily	Daily
GI tolerance		
Stool frequency/volume	Daily	Daily
Abdomen assessment	Daily	Daily
Nausea or vomiting	Daily	Daily
Gastric residual volumes	Every 4-8 hours (varies)	As needed when delayed gastric emptying suspected
Tube placement	Prior to starting, then ongoing	Ongoing
Laboratory		
Electrolytes, blood urea nitrogen/serum creatinine, glucose	Daily until stable, then 2-3 times/week	Every 1-3 months
Calcium, magnesium, phosphorus	Daily until stable, then 2-3 times/week	Every 1-3 months
Liver function tests	Weekly	Every 1-3 months
Trace elements, vitamins	If deficiency/toxicity suspected	If deficiency/toxicity suspected

EN, enteral nutrition.

Gastrointestinal Complications

6 The GI complications associated with tube feeding include nausea, vomiting, abdominal distension, cramping, aspiration, diarrhea, and constipation. GRV refers to the volume of contents in the stomach and is measured by using a syringe and aspirating from a large-bore NG or gastrostomy tube. Although it has been recommended as a method to identify patients at risk of vomiting, aspiration and/or ventilator-associated pneumonia, this has not been validated in clinical studies.[8,62-64] However, it remains a widely used tool to help clinicians assess GI tolerance in patients receiving gastric tube feeding via continuous administration. The frequency of measuring GRV generally varies between every 4 and 8 hours, and most institutions follow a protocol that directs the frequency of monitoring and at what volume and for how long to hold feedings.[64] In critically ill patients receiving gastric feeding, GRVs should be measured every 4 hours.[13] Measurement of GRV is not recommended in patients receiving bolus or intermittent feedings.

If high GRVs occur, the response is often to stop or decrease the rate of continuous feedings. However, other signs and symptoms of intolerance should also be considered before stopping feeding because frequent interruptions in EN delivery can adversely affect the attainment of nutrition outcome goals. A trend toward increased GRV is generally more important than one isolated high measurement. Generally, in the absence of other signs of intolerance, EN should not be held when the GRV is less than 500 mL.[13,65] If symptoms are present, and GRVs are elevated, a decrease in the tube feeding rate or discontinuation may be warranted. Measures to reduce aspiration risk should be implemented when GRVs are consistently elevated, including elevating the head of the patient's bed to a 30° to 45° angle and changing to postpyloric continuous feeding. In addition, it may be beneficial to initiate a prokinetic agent such as metoclopramide or erythromycin to improve gastric emptying rate.[13,66] Other potential interventions include minimizing the use of narcotics, sedatives, or other agents that may slow gastric emptying and correcting underlying fluid and electrolyte imbalances that can impair GI motility.[67] Unless GRVs are excessive (greater than 500 mL in adults), they should generally be reinstilled (refed) through the tube to minimize nutrient, fluid, and electrolyte losses.[9,68]

Aspiration pneumonia is considered the most serious complication associated with tube feeding. Although aspiration is a fairly common event for critically ill patients receiving tube feeding, progression to aspiration pneumonia is difficult to predict. Risk factors for aspiration include a previous aspiration episode, decreased consciousness, neuromuscular disease, structural airway or GI tract abnormalities, endotracheal intubation, vomiting, persistently high GRVs, and prolonged supine positioning.[62] Identification of these risk factors, along with close GRV monitoring, is recommended for all critically ill patients receiving tube feeding. Historically, blue food coloring had been added to enteral formulations in an attempt to detect aspiration. However, because of its low sensitivity for detection and association with several serious adverse events, including

death, the addition of blue food dye to enteral formulations is not advised.[13,69] There are currently no reliable methods available to detect aspiration in enterally fed patients.[13,70]

Clinical **Controversy...**

The optimal dose of EN in critically ill adult patients is a subject of debate. The intentional use of "permissive" underfeeding or trophic EN (10-20 mL/h) in critically ill adult patients requiring short ICU lengths of stay may result in improved GI tolerance and similar short-term outcomes when compared to full feeding. However, the strategy of intentional underfeeding may not be appropriate for patients at high nutrition risk as defined by disease severity, preexisting malnutrition, and anticipated prolonged ICU length of stay.

Diarrhea is the most common GI complication in patients receiving EN, but the actual incidence is unclear due to the lack of a standard definition and the large number of contributing factors.[8,23] When monitoring for diarrhea, stool frequency, consistency, and volume should be evaluated, and previous bowel habits should be considered. Diarrhea has been defined as more than three liquid stools daily or a stool volume of more than 250 to 500 mL/day (20-25 mL/kg per day in children) for at least two consecutive days.[23] Therefore, the intermittent occurrence of one or two loose stools does not constitute diarrhea or require intervention.

7 Diarrhea in patients receiving tube feeding may be caused by a number of factors, and management should be directed at identifying and correcting the most likely cause(s).[71] Tube feeding-related factors that may contribute to diarrhea include too rapid delivery or advancement of formula, intolerance to the formula composition, administration of large volumes of feeding into the small bowel, and formula contamination. Thus, measures to prevent or manage diarrhea related directly to the tube feeding should address these potential causes.[23,67,72] If diarrhea occurs when using a fiber-free formulation, a fiber-containing formulation may be considered. If using a high-fat formulation, it may be beneficial to switch to a formulation lower in fat or having a higher proportion of the fat supplied as MCTs; although, a high MCT concentration has also been associated with diarrhea. Finally, it is important to assess the risk of bacterial contamination of the formula and take steps to minimize any potential risk factors. If infectious etiologies have been excluded, severe diarrhea may require pharmacologic treatment with loperamide, diphenoxylate/atropine, or opioids (see chapter 36).

Drug therapy, particularly the use of broad-spectrum antibiotics, is a common cause of diarrhea that is unrelated to tube feeding. Sorbitol, used as a sweetening agent in many liquid formulations to enhance palatability, is an osmotic laxative that can cause diarrhea. In addition, many drugs available in a liquid form are hyperosmolar, which may contribute to diarrhea, especially when these medications are not diluted properly before administration. Because many patients receiving tube feeding also receive medications in a liquid form, all medications should be evaluated for their potential contribution. Infectious causes, such as antibiotic-induced bacterial overgrowth by *Clostridium difficile* or other intestinal flora, need to be considered when diarrhea develops. Malabsorption, secondary to the underlying disease state or condition, may also cause diarrhea.

Mechanical Complications

Mechanical complications of EN are those associated with the feeding tube, including tube occlusion or malposition, and inadvertent nasopulmonary intubation. Feeding tube occlusion usually results from improper medication administration and/or flushing. Kinking of the tube also may cause occlusion. Adult feeding tubes should be flushed with at least 15 to 30 mL of water before and after administering any medication. If more than one medication is scheduled for a given time, each should be administered separately, and the tube should be flushed with 5 to 15 mL of water between drugs.[9,73] Flush volume will be less for children but should be adequate to ensure complete flushing of the medication through the tube.[74] The frequency of flushing should be at least every 8 hours during continuous feeding and before and after each intermittent feeding. If tube occlusion occurs, the tube should be irrigated with warm water. Other fluids such as colas and cranberry juice have been used to irrigate occluded tubes but have not been shown to be any more effective than warm water. Some success in reestablishing patency has been shown with the use of pancreatic enzymes mixed with sodium bicarbonate.[73] Declogging devices that are specifically designed to unclog feeding tubes are available. They have been designed to either mechanically break through or remove the occlusion or provide an applicator and syringe prefilled with pancreatic enzymes and various powders targeted to restore patency.[8,73]

Inadvertent nasoenteric tube removal or displacement has been reported in approximately 40% of patients receiving EN.[75] An agitated or confused patient may pull at the feeding tube and cause its removal or malposition. Measures to decrease agitation and confusion should be attempted. Securing the tube with tape may be helpful, as well as marking the tube with permanent ink at the exit site to assess for position change. A nasal bridle that uses a magnetic retrieval system has proven to be a simple and effective method for securing nasoenteric feeding tubes and preventing accidental removal.[70]

When a feeding tube is inserted nasally or orally, there is a risk that the tube may inadvertently enter the tracheobronchial tree. The risk may be higher in patients who have an impaired cough or gag reflex and when a stylet is used for tube insertion. Proper positioning of the tube should always be confirmed by radiography prior to feeding initiation and routinely reassessed to avoid inadvertent administration of enteral formula into the lung.

Other Complications

Infectious complications of feeding tube placement include sinusitis (with nasoenteric placement), exit site-related infections (eg, cellulitis, subcutaneous abscess, and necrotizing fasciitis), and intraabdominal infections (eg, peritonitis and abscess). Leaking and bleeding around the exit site can also occur.[17] Formation of excessive granulation tissue around the exit site is often the cause of leaking and bleeding and can be managed by applying silver nitrate and topical corticosteroids.

A unique complication of tube feeding use in children, especially in the first year of life, is the development of oral hypersensitivity, poor oral/motor skills, and food aversion when oral feeding is held. In these children, transitioning from tube to oral nutrition can be difficult and protracted. The involvement of an occupational or speech therapist, behavioral psychologist, or other trained individual, as well as perseverance by the family, often is necessary to improve oral intake. Avoidance of a strict nothing by mouth (NPO) status, if possible, and oral stimulation programs for those children who must remain NPO are recommended to avoid this complication.[76]

NUTRITION CARE PLAN

A nutrition care plan that incorporates nutrition assessment and therapy goals should be developed for all EN patients (see Chapter 141). Desired outcomes of EN are to promote an adequate nutritional state in adults and to promote growth and development of infants and children. The EN goals are individualized and based on

meeting estimated fluid, calorie, protein, and micronutrient requirements. The desired end point should be included in the care plan. The end point may be resolution of a disease or condition that impairs ability to eat, such as in a critically ill trauma patient who is expected to transition back to an oral diet. EN may be considered a lifelong therapy for those with a permanent impairment that restricts or limits eating, such as gastroparesis.

Assessing the outcome of EN requires monitoring objective measures of body composition, protein and energy balance, and muscle function and wound healing. In addition to optimizing nutrition, the goal of EN is to reduce disease-related morbidity and mortality. Measures of disease-related morbidity include length of hospital stay, infectious complications, and the patient's functional status and sense of well-being. A target weight should be established for each patient and energy content from the EN regimen adjusted as needed to safely achieve or maintain the target weight. In general, in adults, no more than 1 to 2 pound [approximately 0.45-0.9 kg] per week should be gained or lost. Children should be followed using standard growth velocity expectations. EN may be used to supplement an oral diet when oral intake is inadequate and should be modified as needed based on changes in tolerance.

DRUG DELIVERY VIA FEEDING TUBE

Using enteral feeding tubes to deliver drugs is a common practice and offers an alternative for patients unable to take drugs by the oral route. However, in addition to tube occlusion, effects on drug bioavailability and other potential interactions need to be considered when using this route. Medications have been given as a concomitant bolus administration via the feeding tube or admixed with the enteral feeding formulation.

Concomitant Drug Administration

8 Concomitant administration of medications with enteral feedings can be extremely complicated and potentially deleterious. Delivering medications directly into the stomach allows for the normal process of drug dissolution. Medication delivery directly into the small bowel however may result in alterations in drug dissolution because the stomach is bypassed. In addition, therapeutic effects designed to occur within the stomach, such as with antacids and sucralfate, may not be achieved. Because many drugs are best absorbed in the fasting state, they should be administered on an empty stomach whenever possible. Patients on bolus gastric feeding must receive these medications appropriately spaced between feedings, and patients on continuous feeding will require feeding interruptions for drug administration.

Selecting the proper medication dosage form for coadministration with the tube feeding is another important consideration. Medications in sublingual form, sustained-release capsules or tablets, and enteric-coated tablets should not be crushed and therefore should not be administered via enteral feeding tubes.[9,73] Solid dosage forms that are appropriate to crush should be prepared as a very fine powder and mixed with 15 to 30 mL of water or other appropriate solvent before administering through the tube. In addition, many capsules may be opened and the contents administered in the same manner. Pellets contained inside microencapsulated dosage forms should generally not be crushed. It may be acceptable to administer intact pellets through larger bore feeding tubes, provided that the pellets are small enough and drug absorption is not compromised.[77,78] To avoid the need to crush a solid dosage form, liquid dosage forms are commonly preferred for administration through feeding tubes. However, the risk of GI intolerance should be considered because of the hyperosmolality of many liquid formulations and possible sorbitol content.[73,79] Although the use of a liquid dosage preparation may be more convenient than a solid dosage form, it may not be the best choice if GI intolerance is an issue.

Clinical **Controversy...**

The source of water used to flush the feeding tube and maintain patient hydration via the feeding tube is controversial. Tap water is adequate for the otherwise healthy, immunocompetent patient. However, the acute or chronically ill patient receiving EN may be at higher risk from exposure to nonsterile tap water and may benefit from the use of purified water. Nosocomial infections from contaminated tap water sources have been reported in critically ill patients. The use of purified water for tube-feeding flushes in at-risk patients has been recommended by some clinicians.

Admixture of Drugs with Enteral Feeding

Mixing liquid medications with certain enteral feeding formulations is associated with several types of physical incompatibilities, including granulation, gel formation, separation, and precipitation.[73,77] Not only can these physical incompatibilities inhibit drug absorption, but gel formation may clog small-bore feeding tubes. Physical incompatibility with medications is more common in formulations that contain intact protein than in those with hydrolyzed protein. Also, medication and enteral formula incompatibilities are more common with the use of acidic pharmaceutical syrups. The most prudent recommendation is to avoid the routine admixture whenever possible, especially for nonaqueous preparations and syrups. In the clinical setting, exceptions do exist, such as adding sodium or magnesium to enteral formulas to assist in maintaining or repleting electrolytes.

Drug–Nutrient Interactions

9 The most significant drug–nutrient interactions that can occur during continuous enteral feeding are those in which the drug's bioavailability is reduced, and the desired pharmacologic effect is not achieved (Table 143-8).[80] Unfortunately, limited clinical studies are available to document the extent of this problem with enteral feeding. Most of the observations are anecdotal case reports involving few patients. One of the well-documented interactions is between phenytoin and enteral feeding. Phenytoin serum concentrations may decrease by 50% to 75% when phenytoin is given concomitantly with EN, possibly as a result of the binding of phenytoin to calcium caseinates or protein hydrolysates in the enteral formulation. Patients typically require higher than normal phenytoin doses while receiving EN.[73,77] The patient's clinical response and phenytoin serum concentrations should be monitored to assure that the desired therapeutic effects are achieved.

Decreased bioavailability of certain antibiotics, particularly quinolones, has been documented when coadministered with enteral feeding due to complexation with multivalent cations such as calcium, magnesium, and iron contained in the feeding.[73,77] Although the practice of holding tube feeding for 30 minutes before and 30 minutes after quinolone administration has been recommended, it has not been shown to improve drug absorption. Another option is to increase the quinolone dose when given concurrently with EN. There is evidence to suggest that ciprofloxacin absorption is significantly decreased when given via a jejunostomy tube, so this practice should be avoided, if possible.[73]

Warfarin resistance has been documented during enteral feeding, possibly as a consequence of decreased absorption or the antagonist effects of vitamin K in the feeding formulation. Before 1980, it was thought that the content of vitamin K (up to 1,330 mcg/1,000 kcal [or 317 mcg/1,000 kJ] of enteral feeding formula) was contributing to the pharmacologic interaction with warfarin. Subsequently, the vitamin K content within formulas intended for use in adults was

TABLE 143-8 Medications with Special Considerations for Enteral Feeding Tube Administration

Drug	Interaction	Comments
Phenytoin	Reduced bioavailability in the presence of tube feedings Possible phenytoin binding to calcium caseinates or protein hydrolysates in enteral feeding	To minimize interaction, holding tube feedings 1-2 hours before and after phenytoin has been suggested; this has no proven benefit Adjust tube-feeding rate to account for time held for phenytoin administration Monitor phenytoin serum concentration and clinical response closely Consider switching to IV phenytoin if unable to reach therapeutic serum concentration
Fluoroquinolones Tetracyclines	Potential for reduced bioavailability because of complexation of drug with divalent and trivalent cations found in enteral feeding	Consider holding tube feeding 1 hour before and after administration Avoid jejunal administration of ciprofloxacin Monitor clinical response
Warfarin	Decreased absorption of warfarin because of enteral feeding; therapeutic effect antagonized by vitamin K in enteral formulations	Adjust warfarin dose based on INR Anticipate need to increase warfarin dose when enteral feedings are started and decrease dose when enteral feedings are stopped Consider holding tube feeding 1 hour before and after administration
Omeprazole Lansoprazole	Administration via feeding tube complicated by acid-labile medication within delayed-release, base-labile granules	Granules become sticky when moistened with water and may occlude small-bore tubes Granules should be mixed with acidic liquid when given via a gastric feeding tube An oral liquid suspension can be extemporaneously prepared for administration via a feeding tube

INR, International normalized ratio.

reduced to less than 200 mcg/1,000 kcal (or 48 mcg/1,000 kJ). However, warfarin resistance continues to be reported, and a warfarin dosage increase may be required in patients receiving EN.[73,81] The International Normalized Ratio should be closely monitored in patients receiving both warfarin and enteral feedings. Conversely, when EN is discontinued, a reduction in warfarin dosage may be required.

CLINICAL BOTTOM LINE

Identifying appropriate candidates for EN and designing a personalized EN regimen and monitoring plan is a complex process that is often under-appreciated. The successful use of EN can minimize the need for PN in patients unable to meet nutrient requirements with an oral diet. Ultimately, no disease process can improve with prolonged starvation and malnutrition. A.S.P.E.N. has identified safety issues related to the administration and management of EN and created practice recommendations based on evidence-based research and expert opinion.[9] These guidelines address the provision and assessment of nutrition support therapy, including EN, for adult and pediatric critically ill patients.[13,16] A multidisciplinary team approach, either as a formal nutrition support service or as a team of caregivers within the practice setting, is recommended to optimize patient outcomes.

ABBREVIATIONS

ALI	acute lung injury
ANH	artificial nutrition and hydration
ARA	arachidonic acid
ARDS	acute respiratory distress syndrome
DHA	docosahexaenoic acid
EN	enteral nutrition
GALT	gut-associated lymphoid tissue
GI	gastrointestinal
GRV	gastric residual volume
ICU	intensive care unit
IgA	immunoglobulin A
MCT	medium-chain triglyceride
NG	nasogastric
NJ	nasojejunal
NPO	nothing by mouth
OG	orogastric
OJ	orojejunal
PEG	percutaneous endoscopic gastrostomy
PN	parenteral nutrition

Obesity

Amy Heck Sheehan, Judy T. Chen, Jack A. Yanovski, and Karim Anton Calis

KEY CONCEPTS

1. Two clinical measures of excess body fat, regardless of sex, are the body mass index (BMI) and the waist circumference (WC). BMI and WC provide a better assessment of total body fat than weight alone and are independent predictors of obesity-related disease risk.
2. Excessive central adiposity increases risk for development of type 2 diabetes, hypertension, and dyslipidemia.
3. Weight loss of as little as 5% of total body weight can significantly improve blood pressure, lipid levels, and glucose tolerance in overweight and obese patients. Sustained, large weight losses (eg, after bariatric surgery) are associated with a lower risk of cardiovascular events and death and with long-term improvements in many of the complications associated with obesity.
4. Clinicians should consider the weight-altering effects of medications used to treat comorbid conditions (eg, antidepressants, antipsychotics, antiepileptics, and antidiabetics) and select medications that promote weight loss or are weight-neutral.
5. Bariatric surgery is reserved for patients with extreme obesity having a BMI more than or equal 40 kg/m^2 or BMI more than or equal to 35 kg/m^2 with significant comorbidities.
6. Pharmacotherapy may be considered an adjunctive treatment in patients with a BMI more than or equal to 30 kg/m^2 or BMI of 27 to 30 kg/m^2 with a comorbidity if comprehensive lifestyle modifications (ie, diet, exercise, and behavioral modification) fail to achieve or sustain weight loss.
7. Weight regain occurs with a high probability when pharmacotherapy for obesity is discontinued.
8. Pharmacotherapy should be discontinued if weight loss of at least 5% is not achieved after 12 weeks of maximum-dose therapy with lorcaserin, phentermine-topiramate, or bupropion-naltrexone because significant weight loss is unlikely to be achieved despite continued therapy. Liraglutide should be discontinued if weight loss of at least 4% is not achieved after 16 weeks of therapy.
9. The Food and Drug Administration (FDA) does not regulate labeling of herbal and food supplement diet agents, and content is not guaranteed.

INTRODUCTION

Since 1980, the prevalence of obesity worldwide has more than doubled.[1] It is now estimated that at least two of every three women and three of every four men are overweight or obese in the United States, and the number of obese women outnumbers those who are overweight.[2] While the rise in childhood obesity appears to have reached a plateau, the prevalence remains historically high with one of every three adolescents currently considered overweight or obese.[3] The presence of obesity and overweight is associated with a significantly increased risk for the development of many diseases (Table 144-1),[4-19] poorer outcomes of comorbid disease states, and increased health-care costs. As of 2008, it was estimated that obesity accounted for 9.1% of total medical expenditures in the United States, and the cost of treating obesity-related illnesses in adults approached national health spending of $147 billion annually.[20] National and global initiatives to stem the obesity epidemic have been established through prevention strategies, consensus guidelines, and best practices.[5,21-24] This chapter reviews the epidemiology, pathophysiology, and therapeutic approaches for the management of obesity. Although nonpharmacologic treatment modalities are discussed, the pharmacotherapy of obesity is highlighted, and the role of pharmacotherapy relative to the other therapeutic options is critically reviewed.

EPIDEMIOLOGY

One of the global health targets set by the World Health Assembly is to halt the rise of diabetes and obesity.[23] Obesity in the United States has increased in prevalence since the 1960s. The National Health and Nutrition Examination Survey (NHANES) II data (1976-1980) estimated the prevalence of obesity among adults in the United States at 15%.[25] During NHANES 1999 to 2000, the prevalence increased two-fold to 30.9%, and by 2011 obesity affected 34.9% of the adult population.[2,3] While the trends in obesity appear to have leveled off in recent years, prevention of obesity remains a public health priority due to its high prevalence. Children who are overweight are likely to remain overweight as adults. Furthermore, overweight or obese children and adolescents have a higher risk of premature mortality and morbidity as adults.[26] Therefore, childhood and early adulthood are critical intervention periods for prevention of obesity in the future. The prevalence of obesity varies by sex among racial and ethnic minorities within the United States. The highest prevalence is observed among non-Hispanic black women (56.8% obese) compared with 39.2% for non-Hispanic black men.[2] Non-Hispanic blacks are more likely to have extreme obesity compared to other ethnic groups. This gender disparity is also associated with the level of parental education. Young black women from the lowest educated families are at greater risk of obesity compared with young black men.[27] Obesity is reported in approximately one-third of White men and women, and the prevalence is also high among Hispanic men and women, exceeding 35%.[2] Educational achievement, which is linked to socioeconomic status, is also correlated with the fraction of people who are overweight; the prevalence of overweight is greatest in those with less than a high school education.

ETIOLOGY

Obesity occurs when there is increased energy storage resulting from an imbalance between energy intake and energy expenditure over time. The specific etiology for this imbalance in the vast majority of

individuals is multifactorial, with genetic and environmental factors contributing to various degrees. In a small minority of individuals, excess weight may be attributed to an underlying medical condition or an unintended effect of a medication.

Genetic Influences

Observational studies in humans and experimental studies in animal models have demonstrated the strong role of genetics in determining both obesity and distribution of body fat. In some individuals, genetic factors are the primary determinants of obesity, whereas in others, obesity may be caused primarily by environmental factors. The genetic contribution to the actual variance in body mass index (BMI) and body fat distribution is estimated to be up between 40% and 70%.[28] A number of single-gene mutations producing extreme obesity have been identified, but such mutations are rare and account for a relatively small number of the total cases of obesity.[28] The total number and identity of contributing genes are still being determined, as is the means by which the many potential so-called "obesity" genes interact with each other and with the environment to produce the obese phenotype.

Environmental Factors

Many of the societal changes associated with economic development over the past 40 years have been implicated as potential causes for the increase in the prevalence of obesity.[29] These include an abundant and easily accessible food supply and the material comforts of modern life in Western civilizations, which have contributed to a reduction in physical activity. Advances in technology and automation have resulted in more sedentary lifestyles during both work and leisure time for most individuals. At the same time, there has been a significant increase in the availability and portion size of high-fat foods, which are aggressively marketed and are often more convenient and less expensive than healthier alternatives. This modern environment has been described by some as "obesogenic" because it is likely to result in a state of positive energy balance in many individuals (Fig. 144-1).[30] Obesity has also been reported more frequently among individuals within close social networks (eg, siblings, spouses, and friends), with a person's risk of becoming obese increasing significantly if a friend in his or her social network is obese.[31] Finally, it should be noted that cultural factors, socioeconomic status, and religious beliefs may influence eating habits and body weights.

Medical Conditions

Occasionally, patients present with obesity secondary to an identifiable medical condition. Conditions associated with weight gain include iatrogenic and idiopathic Cushing syndrome, growth hormone deficiency, insulinoma, leptin deficiency, and various psychiatric disorders, such as depression, binge-eating disorder, and schizophrenia. Hypothyroidism is often included in this list, but it mostly causes fluid retention (myxedema) and is generally not a cause of significant obesity. Genetic syndromes that have obesity as a major component are extremely rare and include Prader-Willi, Wilms' tumor, aniridia, genitourinary abnormalities or gonadoblastoma, and mental retardation (WAGR), Simpson-Golabi-Behmel, Cohen, Bardet-Biedl, Carpenter, Börjeson, and Wilson-Turner syndromes. The clinician evaluating a patient for obesity needs to be aware of these potential conditions. The physical examination of obese patients always should include an assessment for secondary causes of obesity, including genetic syndromes.

Medications

An increasing number of medications are associated with unintended weight gain.[32] These include several anticonvulsants (eg, carbamazepine, gabapentin, pregabalin, and valproic acid), antidepressants (eg, mirtazapine and tricyclic antidepressants), atypical antipsychotics (eg, clozapine, olanzapine, quetiapine, and risperidone), conventional antipsychotics (eg, haloperidol), and hormones (eg, corticosteroids, insulin, and medroxyprogesterone). Although the pharmacologic mechanism responsible for weight gain is usually drug-specific, in most cases the precise mechanism is unknown.

PATHOPHYSIOLOGY

The pathophysiology of obesity involves numerous factors that regulate appetite and energy balance.[33-35] Disturbance of these homeostatic functions results in an imbalance between energy intake and energy expenditure.

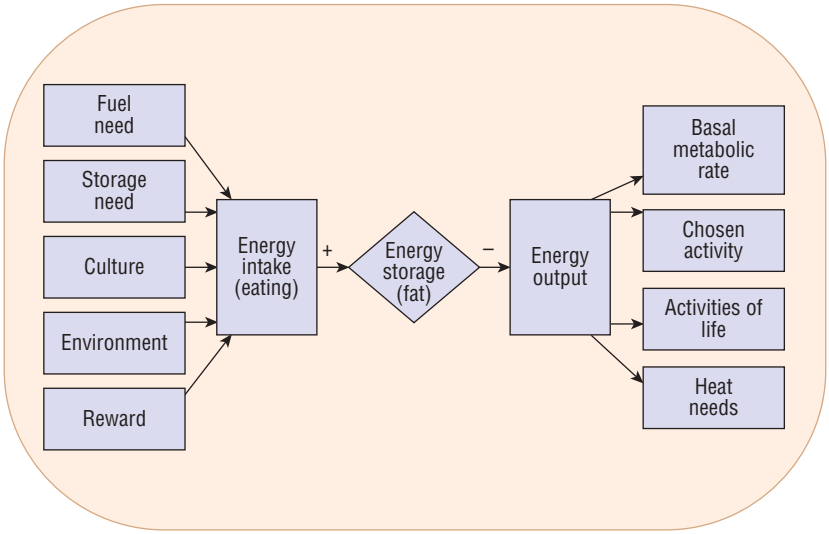

FIGURE 144-1 Net energy stores are determined by various inputs and outputs. Simply stated, obesity occurs when there is an imbalance between energy intake and expenditure.

Appetite

Human appetite is a complex process that is the net result of many inputs within a neural network involving principally the hypothalamus, limbic system, brainstem, hippocampus, and elements of the cortex.[33-35] Within this neural network, many neurotransmitters and neuropeptides have been identified that can stimulate or inhibit the brain's appetite network and thereby affect total caloric intake. The first receptor systems found to alter food intake in animals and humans were the biogenic amines. Serotonin, also known as 5-hydroxytryptamine (5-HT), and cells known to respond to 5-HT are found throughout the central nervous system (CNS) and the periphery. Currently, two major noradrenergic receptor subtypes are recognized (α and β), each with multiple subtypes. Histamine and dopamine also demonstrate multiple receptor subtypes, but their role in the regulation of human eating behaviors and food intake is less well documented. Table 144-2 summarizes the major effects of direct receptor stimulation, inhibition, and changes in synaptic cleft amine concentrations on food intake.

Many neuropeptides also influence appetite within the hypothalamus. Most research has focused on the neural projection between parts of the hypothalamus and the arcuate nucleus with signals to the paraventricular nucleus. The key peptides in this projection are thought to include neuropeptide Y and α-melanocyte–stimulating hormone. Neuropeptide Y is the most potent known stimulator of eating, and α-melanocyte–stimulating hormone action at the melanocortin 3 and 4 receptors is one of the crucial inhibitors of eating.[33] The lateral hypothalamus has been referred to as the "hunger" center within the brain. The most prominent of the lateral hypothalamic peptides, orexin, increases food intake stimuli within the lateral hypothalamus.[33] Another important neuropeptide stimulator of eating that principally originates in the lateral hypothalamus is melanocyte-concentrating hormone. Neurons in the lateral hypothalamus use orexin and melanocyte-concentrating hormone to communicate with other neurons throughout the brain and thereby affect a number of functions beyond appetite.[33] Table 144-2 summarizes the major effects of various neuropeptides on food intake. Although hunger and satiety functions are thought to be primarily regulated by the hypothalamus, humans eat in response to a broad set of stimuli, including reward, pleasure, learning, and memory.

Peripheral appetite signals also dramatically affect food intake.[33,34] Leptin, a hormone that is secreted by adipose cells, acts on the arcuate nucleus of the hypothalamus and elsewhere in the brain to decrease appetite and increase energy expenditure.[33,34] Studies conducted in leptin-deficient mice and humans revealed that exogenous leptin administration produced significant weight loss. However, recombinant leptin replacement therapy in obese humans who are not leptin deficient has not proved successful because obese humans appear to be leptin resistant.[33] Figure 144-2 shows the peripheral link that leptin appears to provide in signaling the CNS about the status of fat cell mass.

Other peripheral signals important to the brain's processing of appetite include several gut hormones, notably those released by the intestine in response to passage of digesting food such as glucagon-like peptide-1 (GLP-1), oxyntomodulin, and peptide YY.[34] Each of these

TABLE 144-2 Effects of Various Neurotransmitters, Receptors, and Peptides on Food Intake[33,34]

Anatomic Region	Increased Eating	Decreased Eating

AgRP, agouti-related protein; CART, cocaine-and-amphetamine-regulated transcript; CCK, cholecystokinin; CRH, corticotropin-releasing hormone; GLP-1, glucagon-like peptide-1; MCH, melanocyte concentration hormone; α-MSH, α-melanocyte-stimulating hormone; NPY, neuropeptide Y; PYY, peptide YY.

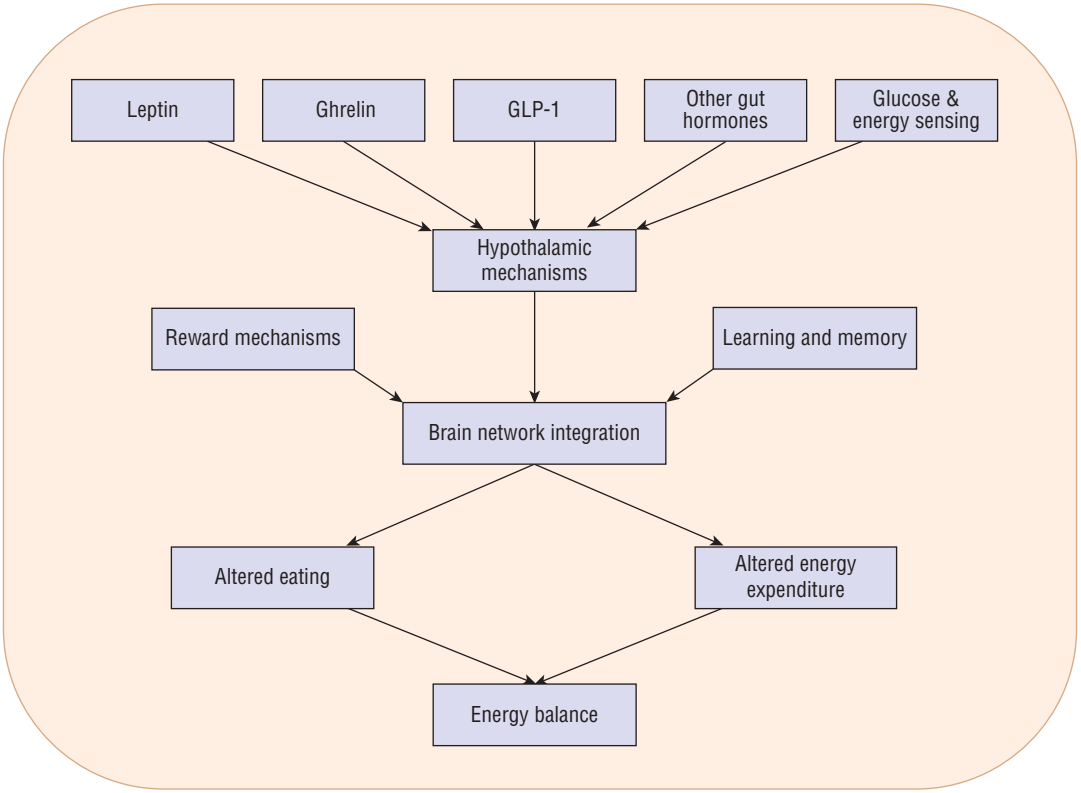

FIGURE 144-2 Intrinsic hypothalamic hunger and satiety mechanisms are modified by input from fat tissue via leptin, and from the gut via ghrelin, glucagon-like peptide-1 (GLP-1), and other hormones. Additional input is derived by direct sensing of prevailing glucose and other energy signals. The hypothalamus generates signals that are integrated within brain networks, which also receive additional signals. The brain network effects change in energy balance by modifying food intake and energy expenditure.

hormonal signals suppresses eating in animals and humans. GLP-1 has other effects, most importantly as an incretin, which facilitates release of insulin by pancreatic β cells in response to meal-related glucose. Ghrelin, another important gut hormone that is released from the distal stomach and duodenum, stimulates appetite. An understanding of the relationships among the brain, its many neurotransmitters and neuropeptides, environmental stimulation of brain activities, and other hormones is still evolving.

Energy Balance

The net balance of energy ingested relative to energy expended by an individual over time determines the degree of obesity (see Fig. 144-1). An individual's metabolic rate is the single largest determinant of energy expenditure. Resting energy expenditure (REE) is defined as the energy expended by a person at rest under conditions of thermal neutrality. Basal metabolic rate (BMR) is defined as the REE measured soon after awakening in the morning at least 12 hours after the last meal. Metabolic rate increases after eating based on the size and composition of the meal. It reaches a maximum approximately 1 hour after the meal is consumed and returns to basal levels 4 hours after the meal. This increase in metabolic rate is known as the *thermogenic effect of food*. The REE measures the energy costs of the wakeful state and may include the residual thermogenic effect of a previous meal. Physical activity is the other major factor that affects total energy expenditure and is the most variable component. With regard to energy storage, there are two major types of adipose tissue, white and brown. The primary function of white adipose tissue is lipid manufacture, storage, and release. Brown adipose tissue, once believed to be found only in infants, is now recognized to exist in most adults.[36] It is more commonly identified in lean than obese individuals, but its importance for human obesity remains unclear. Whereas lipid storage occurs in response to insulin, lipid release is seen during periods of calorie restriction. Brown adipose tissue is notable for its ability to dissipate energy via uncoupled mitochondrial respiration.[36] Both white and brown adipose tissues are highly innervated by the sympathetic nervous system, and adrenergic stimulation via β-adrenergic receptors (β_1, β_2, and β_3) is known to activate lipolysis in fat cells as well as increase energy expenditure in adipose tissue and skeletal muscle.

CLINICAL PRESENTATION

Although obesity is readily apparent, most obese patients seek healthcare only when obesity-associated comorbidities become problematic. The National Institutes of Health (NIH) has established a stratification of weight excess based on associated medical risks.[37] These levels of excess weight are defined on the basis of BMI, a measure of total body weight relative to height. Using metric units, BMI (kg/m^2) is defined as weight in kilograms divided by height in meters squared (kg/m^2). Using pounds and inches, BMI (kg/m^2) is estimated as (weight [lb]/height [inches^2]) $\times$ 703. Adults with a BMI of 25 to 29.9 are considered "*overweight*"; the terms *obese*, and *extreme obese* are reserved for those with a BMI of 30 to 39.9, and 40 and over, respectively. While the precise definition of childhood obesity is still lacking, the Endocrine Society clinical practice guideline currently classifies children and adolescents ages 2 to 18 years with a BMI at the 95th percentile or above as obese, and those with a BMI between the 85th and 94th percentiles as overweight.[38] Because BMI may overestimate the degree of excess body fat in some clinical situations (eg, edematous states, extreme muscularity, muscle wasting, and short stature), the assessment of body composition in such cases often requires clinical judgment.

1 BMI is an acceptable measure of obesity and is the practical method of defining obesity in the clinic and epidemiologic studies;

however, it does not always correspond to excess fat. There are well-established differences in the relationship between BMI and obesity-related risks among disparate racial, sex, and ethnic groups. For example, BMI underestimates risks among Asians;[39] whereas Caucasians tend to have higher level of visceral adipose tissue than African American adults at higher levels of BMI and waist circumference.[40] Central obesity reflects high levels of intra-abdominal or visceral fat, and this pattern of obesity is associated with an increased propensity for the development of hypertension, dyslipidemia, type 2 diabetes, and cardiovascular disease (sometimes referred to as the "metabolic syndrome"). Thus, in addition to the absolute excess fat mass, the distribution of this fat regionally in the body has important clinical effects. Intra-abdominal fat is best estimated by imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) but can be approximated through measurement of waist circumference (WC). Clinically, WC is the narrowest circumference measured in the area between the last rib and the top of the iliac crest. The current definition for high-risk WC is greater than 40 inches (102 cm) in men and greater than 35 inches (89 cm) in women.[6] Routine determination of WC should be implemented in those with BMIs between 25 and 34.9 kg/m^2 to assess additional metabolic risk. However, after a patient's BMI reaches 35 kg/m^2, it is not necessary to measure WC because it will likely be elevated and adds little in terms of risk prediction.[5]

2 Although BMI and WC are related, each measure independently predicts disease risk. Both measurements should be assessed and monitored during therapy for obesity.[5,6] The risks for development of type 2 diabetes, hypertension, or cardiovascular disease at various stages of obesity based on BMI or WC are outlined in Table 144-3. Note that increased WC confers increased risk even in normal-weight individuals.

Comorbidities

Obesity and overweight are associated with an increased risk of all-cause mortality. The greater the BMI, the greater the risk of cardiovascular diseases (CVD), type 2 diabetes, and all-cause mortality in both men and women.[5] Substantial reduction in life expectancy has been predicted in adults with BMIs greater than 35 kg/m^2.[41] Excessive body fat affects virtually all organ systems. A plethora of evidence continue to link obesity with numerous disease states and health conditions (see Table 144-1).[4-19] Therefore, it is important for clinicians to assess the presence of these chronic conditions in all overweight and obese individuals.[35] Because obese individuals are also at risk for developing many malignancies, adherence to routine age- and risk- appropriate cancer screening guidelines is recommended.[35] Furthermore, hypertension, hyperlipidemia, coronary heart disease, cerebrovascular accidents, insulin resistance, glucose intolerance, and diabetes are all known cardiac risk factors that tend to cluster in obese individuals. Aggressive management of these comorbid cardiovascular risk factors and other obesity-related medical conditions (eg, sleep apnea, major depression, osteoarthritis, nonalcoholic fatty liver disease) is warranted in an obese individual regardless of an individual's weight loss efforts.[6,35]

TREATMENT

Available treatment options for the chronic management of obesity include reduced caloric intake, comprehensive lifestyle intervention, pharmacotherapy, implantable medical devices, and bariatric surgery.

Desired Outcomes

Weight management is commonly considered successful when a predefined amount of weight has been lost such that a final goal is achieved. The ultimate goal of treatment must be defined clearly and may be absolute weight loss if obesity is present without other comorbid conditions. If improvement in blood glucose, blood cholesterol, and hypertension are primary goals, then these must be defined appropriately and may include setting target levels for low-density lipoprotein cholesterol, glycosylated hemoglobin, or blood pressure. In 2013, an updated evidence-based guideline on the management of overweight and obesity was published by the Obesity Society (TOS), American Heart Association (AHA), and American College of Cardiology (ACC),[5] which recommended the initial weight loss goal for adults to be approximately 5% to 10% of the baseline weight over a 6-month period. Success may also include end points of decreasing the rate of weight gain or maintaining a weight-neutral status. All too often patients expect to lose weight overnight, only to be disappointed. Thus, it is important to set a time course for the plan. A significant number of web-based resources for supporting both patient and practitioner weight-management activities are available.[6,22,42]

General Approach to Treatment

To achieve meaningful weight loss goals, successful obesity treatment plans require incorporation of comprehensive lifestyle interventions such as healthy diet, adequate physical activity, and behavioral modifications as the cornerstone of weight management.[5] Once the need for weight loss has been determined, the clinician needs to assess a patient's readiness to engage in weight loss efforts and identify any potential barriers to success. They need to initiate a dialogue with each patient who is overweight or obese to ensure they understand the potential health consequences of excess body weight and benefits of appropriate weight management. Specific weight goals should be established that are consistent with medical needs and the patient's personal desire. For most overweight and obese patients, a weight loss goal of 5% to 10% of initial weight is reasonable. Patients should not be allowed to attain an abnormally low body weight (ie, less than their estimated ideal body weight).

3 Patients seeking help for obesity do so for many reasons, including improvement in their quality of life, a reduction in associated morbidity, and increased life expectancy. Because weight stigma is prevalent in the western culture, numerous individuals seek therapy for obesity primarily for cosmetic purposes and often have unrealistic goals and expectations. Aggressive marketing of weight loss programs, therapies, and diets—parallel to the fashion industry's standards of desirable body profiles—has led many individuals to set impossible goals and expectations. In some cases, these individuals will go to extreme measures to achieve weight loss. Consequently, clinicians must be careful to fully discuss the risks of therapies and to clearly define the achievable benefits and magnitude of weight loss. Obese patients should be redirected away from trying to achieve an "ideal weight" to the more realistic goal of modest (eg, loss of 5%-10% of body weight) but sustained, medically relevant weight loss. In practice, goals should be set based on many factors, including initial body weight, patient motivation and desire, presence of comorbid conditions, and age. The Look Action for Health in Diabetes (AHEAD) study found that patients with diabetes who maintained weight loss of at least 7% with intensive lifestyle modifications for a period of almost 10 years did not experience a reduced incidence of cardiovascular events, but they did have a reduced need for diabetes medications and improvement in physical function and other health benefits.[43] Indeed, in overweight and obese patients with diabetes, lifestyle modification with sustained weight loss of greater than 5% have been shown to improve HbA1c level, ameliorate hyperglycemia, hyperlipidemia, and hypertension within a year.[44] For obese individuals with osteoarthritis, significantly more weight reduction may be required to improve symptoms. These data emphasize the importance of defining end points and measures of success in any weight-loss plan.

4 Weight-loss interventions must be founded on lifestyle changes, such as a modification in eating practices; complemented by drug therapy, if indicated; and in some cases, surgery (Fig. 144-3). Before recommending any therapy, the clinician must evaluate the patient for the presence of secondary causes of obesity. If a secondary cause is suspected, then a more complete diagnostic workup and the initiation of appropriate therapy may be warranted. The next step in patient evaluation is to determine the presence and severity of other medical conditions that are either directly associated with obesity (eg, diabetes, cardiovascular diseases, uncontrolled hypertension) or that have an impact on therapeutic decision making (eg, history of pancreatitis, cardiac arrhythmia, seizure disorders, concurrent medications).[35] The Endocrine Society Clinical Practice Guideline for the Pharmacological Management of Obesity emphasizes that clinicians should always consider the potential weight-altering effects of all medications a patient is receiving for the management of comorbid conditions and select medications that are weight-neutral or promote weight loss (strong recommendation with moderate quality evidence).[35] For example, in patients with type 2 diabetes, antidiabetic agents that promote weight loss (eg, metformin, glucagon-like pepetide-1 analogs or sodium-glucose-linked transporter-2

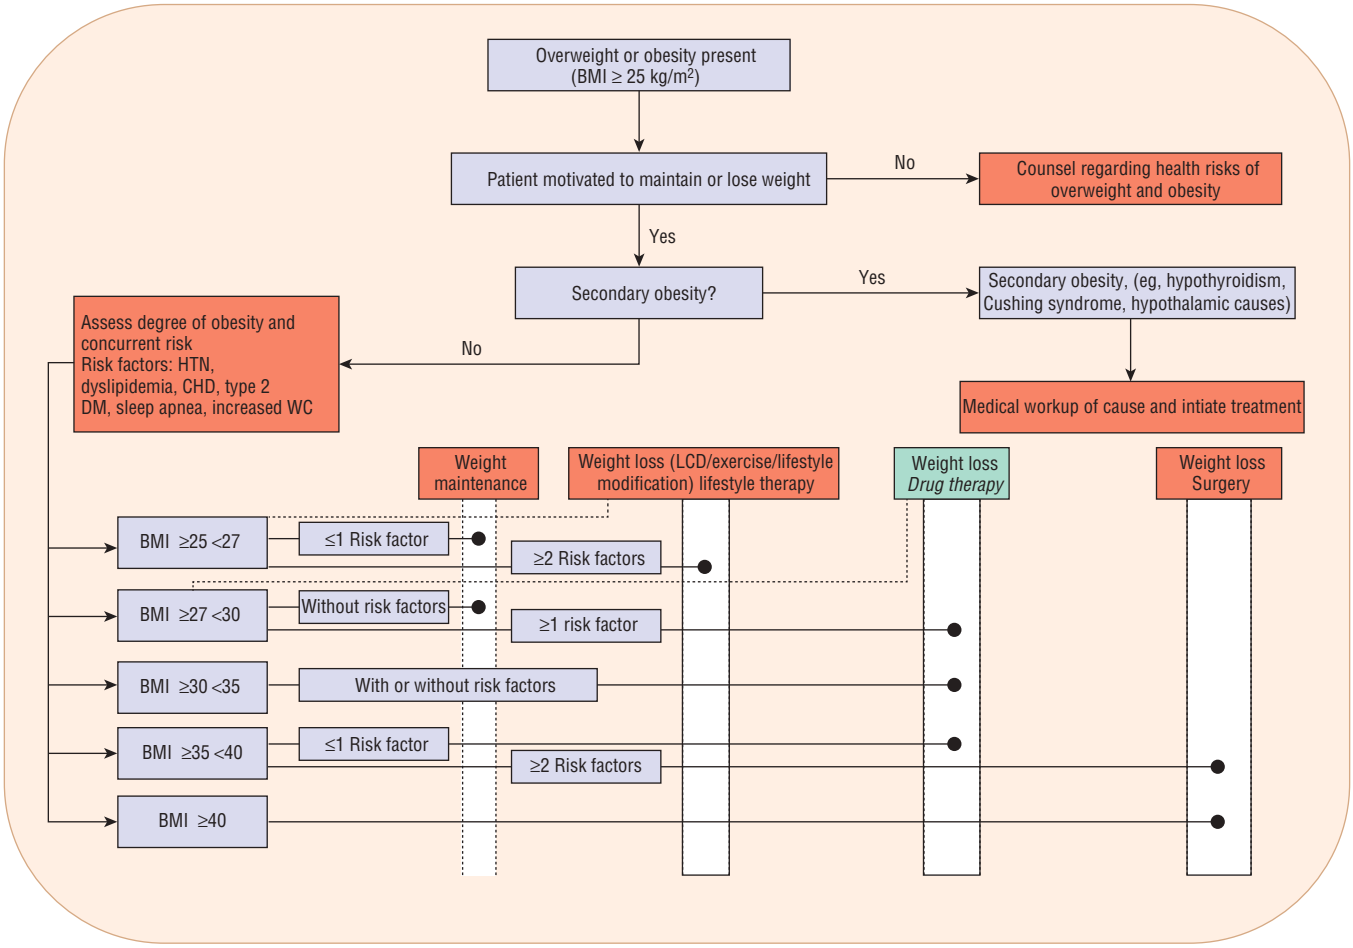

FIGURE 144-3 Treatment algorithm. Candidates for pharmacotherapy are selected on the basis of body mass index and waist circumference criteria along with consideration of concurrent risk factors. Medication therapy is always used as an adjunct to a comprehensive weight-loss program that includes diet, exercise, and behavioral modification.[5,35] CHD, coronary heart disease; DM, diabetes mellitus; HTN, hypertension; LCD, low-calorie diet; WC, waist circumference (more than or equal to 40 inches [more than or equal to 102 cm] for men and more than or equal to 35 inches [more than or equal to 89 cm] for women).

inhibitors) are preferred. Appropriate laboratory tests to exclude or quantify the degree of specific conditions such as diabetes, liver dysfunction, and nephropathy should be performed as indicated by the history and physical examination. Based on the outcome of this medical evaluation, the patient should be counseled on treatment options, benefits, and risks. Ultimately, lifelong therapeutic goals should consist of maintenance of reduced body weight and prevention of weight gain.

Nonpharmacologic Therapy

Nonpharmacologic therapy, including reduced caloric intake, increased physical activity, and behavioral modification is the mainstay of obesity management. This combination is recommended as first-line therapy for all patients with BMI more than or equal to 25 kg/m^2 by The Endocrine Society Clinical Practice Guidelines for the Pharmacological Management of Obesity (graded as strong recommendation with high quality evidence).[35] Although the difference is subtle, it should be noted that the AHA/ACC/TOS Guidelines for the Management of Overweight and Obesity in Adults do not recommend weight loss therapy for patients with BMI between 25 and 29.9, unless the patient has CVD risk factors.[5] Weight loss will require significant effort on the part of the patient to change their lifestyle and comply with the management plan. If the patient is not ready to meet these expectations, then early counseling will reduce the chance of frustration for the patient, clinician, and possibly other family members. Providing basic education can lead to a significant change in motivation and desire to lose weight and improved compliance.

Reduced Caloric Intake

Current adult guidelines recommend reduced caloric intake through adherence to a low-calorie diet (LCD).[5] The LCD should provide a daily caloric deficit of 500 to 750 kcal (2,092-3,138 kJ), which generally correlates to a total intake of 1,200 to 1,500 kcal/day (5,021-6,276 kJ/day) for women and 1,500 to 1,800 kcal/day (6,276-7,531 kJ/day) for men. Severely obese individuals will require more energy, at least at the start of dietary restriction. Adherence to the LCD has been shown to result in an average weight loss of 8% after 6 months.[6]

Numerous diet and nutrition plans are available to aid patients in their pursuit of weight loss, and current guidelines allow for choice among many potential evidence-based diet plans.[5,6] Popular diets include moderate energy-deficient plans (eg, Weight Watchers, LEARN [Lifestyle, Exercise, Attitude, Relationships, Nutrition], and Jenny Craig), vegetarian-based plans (eg, Ornish), and low carbohydrate plans (eg, Zone and Atkins). Short-term weight loss is significant for almost all diet plans. However, long-term weight loss and maintenance of weight loss are less promising, primarily because of difficulty with adherence. Therefore, the choice of diet plan should be determined based on patient-specific preferences, health status, and ability to consistently adhere to the specific recommendations of the diet.[5] A recent meta-analysis of 48 clinical trials assessing the efficacy of various diets concluded that differences in weight loss among popular named diets are not clinically significant,[45] highlighting the general consensus that macronutrient composition of the diet may not be as important as consistent adherence to reduced energy consumption.

Very-low-calorie diets, providing less than 800 kcal/day (3,349 kJ/day), are generally not recommended.[6] Although very-low-calorie diets can often result in early weight loss, long-term results have been disappointing because it is difficult for individuals to maintain compliance.[44] Additionally, very-low-calorie diets require intensive medical monitoring and should only be used in certain situations under the supervision of an experienced clinician. Regardless of the diet program, it is clear that energy consumption must be less than energy expenditure to achieve weight loss (see Fig. 144-1). The challenge is to develop a diet plan that leads to consistent adherence by the patient and sustained weight loss and maintenance.

Comprehensive Lifestyle Intervention

Comprehensive lifestyle intervention encompasses the combination of reduced caloric intake, increased physical activity, and behavioral modification. Increased physical activity is an important component in achieving the state of greater energy expenditure than energy intake that is necessary to lose weight and maintain weight loss. When increased physical activity is attempted as monotherapy, only modest weight loss has been reported.[46] However, when it is combined with reduced calorie intake and behavior modification, it can augment weight loss and improve obesity-related comorbidities and cardiovascular risk factors.[5,6] Moderate physical activity for at least 30 minutes per day, on most days of the week, is recommended. Greater levels (ie, 200-300 min/wk) may be required to augment weight loss and maintain lost weight. Patients should be advised to start slowly and gradually increase intensity. All obese patients should receive a medical examination before embarking on a physical activity program.

Current adult guidelines recommend initiation of a comprehensive lifestyle program to help overweight and obese patients adhere to the prescribed LDC and increase physical activity per week (NHLBI Grade A; strong recommendation).[5] On-site, individual or group, behavioral counseling sessions offered by a trained clinician on at least 14 occasions during a 6-month time period are preferred. However, electronic or commercial based programs may also be effective. For patients who have successfully lost weight during the first 6 months, long-term participation in a comprehensive lifestyle program is recommended. The primary aim is to help patients choose lifestyles that are conducive to safe and sustained weight loss. Most such programs use self-monitoring of diet and exercise to increase patient awareness of behavior and as a tool for the clinician to determine patient compliance as well as patient motivation. Clinical studies evaluating the efficacy of high-intensity comprehensive lifestyle interventions that include a reduced-calorie diet, increased exercise, and in-person behavioral counseling sessions have reported an average weight loss of 8 kg after 6 months.[5,6]

Implantable Medical Devices

Recently, the FDA approved two new implantable medical devices for weight reduction in obese patients. vBloc® neurometabolic therapy, is indicated for weight loss in adults with a BMI of 40 to 45 kg/m^2, or a BMI of 35 to 39.9 kg/m^2 with at least one comorbidity who have failed a supervised weight management program within the past 5 years.[47,48] The vBloc® neurometabolic therapy, delivered via a pace-maker like device called the Maestro® Rechargeable system, is implanted subcutaneously on the vagal trunk with the electrodes designed to intermittently block the communication with the vagus nerve. The vagus nerve is known to regulate digestion through autonomic communication between the brain and the stomach. Blockage of the vagal communication is believed to alter multiple physiological mechanisms related to food intake and energy metabolism, thus resulting in increased satiety and weight loss. The implanted neuroregulator is controlled by the clinician with an external programming device to deliver at least 12 hours of intermittent vagal nerve block. The ReCharge trial evaluated the effect of vagal nerve block in patients with morbid obesity, the percentage of excess weight loss (defined as weight loss above a BMI of 25 kg/m^2) was significant with 24% excess weight loss (9% of initial body weight) reported in the vagal nerve block treatment group compared to 16% excess weight loss (6% of initial body weight) reported in the sham control group.[47] In obese patients with type 2 diabetes, 25% excessive weight loss was reported along with 1% decrease in A1c for those who received the vBloc® device which was active for 12 to 15 hours daily.[48] Patients with cirrhosis, portal hypertension, esophageal varices, hiatal hernia, planned MRI or diathermy, and patients with a permanently implanted, electrical-powered medical device are contraindicated

for the vBloc® therapy. Common adverse events with vBloc® therapy include neuroregulator site pain, nausea, abdominal pain, heartburn or dyspepsia. Although safety and efficacy of this device has only been studied up to 1 year, long-term data continue to be collected from ongoing clinical trials.[47,48] Unfortunately, once the device is turned-off, patients will often regain the weight lost.

The ReShape Dual Balloon device is indicated for weight reduction in patients with BMI of 30 to 40 kg/m^2 with one or more obesity-related comorbidities who have failed previous weight loss attempts with diet and exercise alone.[49] The balloon device is implanted into the stomach through a minimally invasive endoscopic procedure. After placement, the balloon is then inflated with saline and blue dye (methylene blue) to trigger the feelings of fullness by occupying the space in the stomach which helps patients reduce hunger and improve appetite control. While the balloon device does not alter the stomach's nature anatomy like bariatric surgery, the placement is only intended to be temporarily and should be removed 6 month after insertion as the device itself will deflate over time. Patients who failed to have the device removed after 6 months experienced an increased risk of intestinal obstruction due to migration of the deflated balloon and may require surgical removal of the device. In clinical trials, the average weight loss reported with the ReShape Dual Balloon device was 14.3 lbs (6.5 kg; 6.8% of total body weight) compared with 7.2 lbs (3.3 kg; 3.3% of total body weight) reported in the control group.[49] Six months following the removal of the device, patients treated with the balloon device maintained an average reduction of 9.9 pounds (4.5 kg) of the 14.3 pounds (6.5 kg) that was initially lost. Potential adverse effects from this procedure are primarily related to endoscopic sedation. Once the device is placed in the stomach, patients may experience vomiting, nausea, abdominal pain, diarrhea, and feelings of indigestion. Therefore, this balloon device is not indicated in patients with previous gastrointestinal (GI) or bariatric surgery, inflammatory intestinal or bowel disease, large hiatal hernia, symptoms of delayed gastric emptying, severe liver damage, or active *Helicobacter pylori* infection. In addition, patients who are pregnant, breastfeeding or taking anticoagulants, anti-inflammatory, or other gastric irritates daily are not candidates for the device. Finally, patients currently taking selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and monoamine oxidase inhibitors (MAOIs) should use this device with caution due to the potential for balloon rupture and release of methylene blue which with these concurrent therapies can increase risk of developing serotonin syndrome.

Clinical **Controversy…**

Current practice guidelines state that bariatric surgery may be considered in patients with a BMI of 40 kg/m^2 or above or BMI of 35 kg/m^2 with significant comorbidities, as an increasing body of literature indicates improvements in comorbidities and prolongation of life after bariatric surgery. Most long-term data are for the Roux-en-Y gastric bypass procedure; the long-term outcomes of other approaches remain somewhat uncertain. Researchers are also beginning to study the effects of bariatric procedures among patients with BMIs below 35 kg/m^2 for remediation of comorbid conditions such as diabetes, but the long-term benefits, risks, and cost-effectiveness of this approach remain unclear.

Bariatric Surgery

5 Consistent with the growing obesity epidemic, the demand for bariatric surgery has increased drastically over the past 2 decades. Surgery currently remains the most effective and durable intervention for the treatment of obesity. Current clinical practice guidelines recommend that surgical intervention be reserved for patients with extreme obesity (BMI ≥ 40 kg/m^2) or BMI greater than 35 kg/m^2 with significant comorbidities such as hypertension, type 2 diabetes, or obstructive sleep apnea (NHLBI Grade A; strong recommendation).[5,50] Surgery may also be offered to patients with BMI between 30 kg/m^2 and 34.9 kg/m^2 with diabetes or metabolic syndrome but the long-term data have yet to demonstrate its overall benefits.[5,50]

Surgical weight loss options should only be considered in patients who have met the eligibility criteria and have failed other recommended methods for weight loss. It is critical for bariatric surgical candidates to fully understand the surgical risks and be able to adhere to the extensive postoperative care plan, follow-ups, and necessary lifelong dietary and lifestyle adjustments to ensure the long-term success of the procedure.

The four common surgical procedures are (1) adjustable gastric banding, (2) sleeve gastrectomy, (3) biliopancreatic diversion with duodenal switch, and (4) conventional Roux-en-Y gastric bypass. The adjustable gastric banding and sleeve gastrectomy are designed to reduce the volume of the stomach and thus restrict the rate of nutrient intake. The biliopancreatic diversion with duodenal switch is primarily malabsorptive in nature, and the length of the diversion determines the extent of nutrient malabsorption. The conventional roux-en-Y gastric bypass is the most common procedure currently performed in the United States and worldwide.[51] This hybrid procedure combines a restrictive approach with a degree of malabsorption induced by reducing the size of the stomach pouch and causing food to bypass parts of the small intestine. Techniques that involve redirection of the flow of nutrients so as to have humoral and malabsorptive effects, generally yield greater and longer lasting weight loss than the purely restrictive methods.[51] Ultimately, reductions in excess body weight of approximately 23.4% (range 14%-52%) can be achieved within the first 1 to 2 years, with a modulation to 16.1% after 10 years as patients often experience weight regain after surgical procedures.[51] The extent of weight loss and the potential for weight regain after bariatric surgery is multifactorial as metabolic, anatomic, and lifestyle changes can all impact the outcome of the procedure. Improvements in the peri- and postoperative care of gastric surgery patients have reduced morbidity and mortality associated with bariatric surgeries. The operative 30-day mortality rates reported range from 0.1% to 1.2%, depending on the type of procedure.[51] Some of the most common early surgical complications are gastric and anastomotic leaks, bleeding, wound infections, and pulmonary emboli. Due to the disruption of the normal gastric anatomy and physiology, postsurgical patients are often at risk for severe micronutrient deficiencies such as vitamin B_{12} and anemia.[52] Therefore, empiric supplementation with daily adult multivitamin plus minerals, elemental calcium, vitamin D, folic acid, thiamine, elemental iron, and vitamin B_{12} is essential to prevent nutritional deficiencies in bariatric patients.[50] All bariatric surgical patients should undergo routine and nutritional monitoring after the procedure. Weight losses resulting from bariatric surgery are often accompanied by dramatic improvements, and sometimes complete resolution, of many obesity-related complications.[51,53] Significant reduction in risks of stroke, myocardial infarction, cardiovascular deaths, as well as the incidence of type 2 diabetes and cancer (in women), have also been documented after bariatric surgery.[53-57] Furthermore, a significant 52% reduction in mortality for patients who underwent bariatric surgery compared with those who did not receive any surgical intervention has been noted.[54]

After experiencing weight loss, many gastric surgery patients are able to discontinue pharmacotherapy for glucose lowering, dyslipidemia, hypertension[50] and reduce medication costs.[55] However, the need for use of proton-pump inhibitors or H_2-receptor antagonists are often increased.[52] It is imperative for clinicians to recognize that bariatric interventions not only alter nutrient absorption but also may impede drug absorption and can cause potential serious consequences.[52,58]

Achlorhydria, reduced surface area for intestinal and gastric absorption, and alterations in drug metabolism via the intestinal metabolic pathways (eg, cytochrome P450 enzymes or efflux transporters) after bariatric surgery can lead to altered dissolution and/or absorption of many medications. Reduced bioavailability has been reported for some antimicrobials, immunosuppressives, anticonvulsants, highly lipophilic tricyclic antidepressants, SSRIs, and levothyroxine.[52] Furthermore, concurrent administration of proton-pump inhibitors may also alter bioavailability of weak basic drugs such as antifungals (eg, ketoconazole), certain antibiotics and some cardiovascular medications (eg, digoxin) as well as hinder the absorption of micronutrients.[52] Therefore, clinicians need to recognize that the standard dosage regimens recommended for presurgical patients may need to be adjusted. Close therapeutic monitoring of all orally administered medications after surgery, particularly those with narrow therapeutic ranges, is highly recommended because dosage form selection, dose conversion, or therapeutic interchange may be necessary to avoid or minimize absorption problems and ensure optimal patient outcomes.

Pharmacologic Therapy

6 and 7 The debate regarding the appropriateness of obesity pharmacotherapy remains heated, fueled by the recognized national need to treat a growing epidemic and the medical and litigious fallout from the adverse effects of medications which were ultimately withdrawn from the US market (ie, fenfluramine [Pondomin], dexfenfluramine [Redux], and sibutramine [Meridia]). Strategies for the pharmacologic management of obesity have historically focused on modulating central or peripheral sites that regulate energy balance. Long-term pharmacotherapy may have a place in the treatment of obesity for patients who have no obvious contraindications to approved drug therapy, as the likelihood of weight regain after treatment discontinuation is quite high.[59] According to current guidelines, pharmacotherapy is an adjunct to comprehensive lifestyle intervention in adults who are motivated to lose weight, have failed to achieve or sustain weight loss with lifestyle changes alone, and have a BMI more than or equal to 30 kg/m^2 or a BMI more than or equal to 27 kg/m^2 with at least one weigh-related comorbidity (Graded as a strong recommendation with high quality evidence).[35] Furthermore, patients who meet the BMI requirements and have a history of failed attempts to lose weight or maintain weight loss with comprehensive lifestyle intervention alone may also be candidates for pharmacotherapy.[35] A pharmacotherapy treatment algorithm based on these treatment guidelines is depicted in Fig. 144-3. Table 144-4 lists the status of the most common classes of agents currently available.

A multidisciplinary team approach to the management of obesity is necessary to ensure long-term success. It is common for patients to use a combination of nonprescription, prescription, and other complementary and alternative therapies to attain the desired weight loss goal. Therefore, clinicians should maintain a high degree of sensitivity toward the potential polypharmacy practices of patients with obesity. Finally, it is prudent to consider specific patient factors and characteristics along with the efficacy and safety profiles of individual therapies when determining if use of a pharmacologic intervention is warranted.

Agents Approved for Long-Term Use

8 There are currently five products approved in the United States for the chronic management of obesity. These include the lipase inhibitor orlistat (Xenical, Genentech USA, South San Francisco, CA; Alli, GlaxoSmithKline, Middlesex, UK), the serotonin 2C receptor agonist lorcaserin (Belviq, Arena Pharmaceuticals GmbH, Zofingen, Switzerland), the combination product phentermine–topiramate extended release (Qsymia, Vivus, Inc, Mountain View, CA), the combination product naltrexone-bupropion extended-release tablets (Contrave, Takeda Pharmaceuticals America Inc, Deerfield, IL), and the GLP-1 receptor agonist liraglutide (Saxenda, Novo Nordisk Inc, Plainsboro, NJ). Pharmacotherapy management guidelines recommend discontinuation of drug therapy in patients who fail to lose sufficient amounts of body weight after 3 months and in patients who experience significant adverse events, with consideration given to potential alternative weight loss agents (strong recommendation with high-quality evidence).[35] Table 144-6 lists clinical and economic considerations for use of the products approved for long-term use.[35,59]

Clinical Controversy...

Obesity is considered a chronic disease. None of the FDA-approved agents for obesity has been shown to have cardiovascular benefit, and the optimal treatment duration remains unknown. Because discontinuation of drug treatment tends to result in weight regain, continuation of an effective and well-tolerated drug regimen is common practice.

Lipase Inhibitor: Orlistat Excessive intake of dietary fat is one of the contributing factors in the development of obesity. GI (gastric, pancreatic, and carboxyl ester) lipases are essential in the absorption of the long-chain triglycerides. Additionally, lipase is known to play a role in facilitating gastric emptying and secretion of other pancreaticobiliary substances. Orlistat (Xenical) is a synthetic derivative of lipstatin, a natural lipase inhibitor produced by *Streptomyces toxytricini*. The drug is minimally absorbed and induces weight loss by persistent lowering of dietary fat absorption through selective inhibition of the GI lipase. Furthermore, lower luminal free fatty acid concentrations result in malabsorption of cholesterol. Up to 30% reduction in fat absorption occurred with daily doses of 120 mg three times daily with meals.[59] A nonprescription formulation of orlistat (Alli) is approved in the United States at a reduced daily dose of 60 mg three times daily.[59] The drug must be taken within 1 hour of consuming foods that contain fat in order to exert its effect. If a meal is skipped or contains no fat, the dose of orlistat can be omitted.

Clinical studies using orlistat as an adjunct to diet therapy demonstrate dose-dependent reductions in fat absorption. Overall, results from clinical trials demonstrate that orlistat modestly increases the amount of weight lost and decreases the amount of weight regained during medically supervised weight loss programs.[59,60] The longest trial that evaluated the safety and efficacy of orlistat is XENDOS (XENical in the prevention of Diabetes in Obese Subjects), a 4-year, double-blind, randomized, placebo-controlled prospective study.[61] Although weight regain was observed with continual therapy beyond the first year of orlistat therapy, results from this study show moderate weight loss sustained after 4 years of treatment compared with placebo, 12.8 lb (5.8 kg) and 6.6 lb (3.0 kg), respectively. Weight loss using orlistat also decreased the rate of development of type 2 diabetes by 37.3% in patients with impaired glucose tolerance. Improved glycemic control can be attained in patients with type 2 diabetes by inducing or increasing weight loss with orlistat in addition to diet management.[59,60] In some cases, dosages or the number of antidiabetic medications may be reduced or discontinued.[60] Significant improvements in lipid profile (reduction in total and low-density lipoprotein [LDL] cholesterol), glucose control, and other markers of metabolism are seen when using orlistat in addition to the diet.[59,60] Orlistat is approved for the chronic treatment of obesity in adults and adolescents between ages 12 abd 16 years. The recommended dose is 120 mg three times daily taken within 1 hour of consuming a fat-containing meal.

At least one GI complaint (soft stools, abdominal pain or colic, flatulence, fecal urgency, or incontinence) has been reported in up to

TABLE 144-4 FDA-Approved Pharmacotherapeutic Agents for Weight Loss

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comment
Gastrointestinal Lipase Inhibitor					
Orlistat	Xenical	120 mg three times daily with each main meal containing fat	120 mg three times daily with each main meal containing fat		Approved for long-term use Take during or up to 1 hour after the meal Omit dose if meal is occasionally missed or contains no fat
Orlistat	Alli[a]	60 mg three times daily with each main meal containing fat	60 mg three times daily with each main meal containing fat		Same as Xenical
Serotonin 2C Receptor Agonist					
Lorcaserin	Belviq	10 mg twice daily	10 mg twice daily	Use with caution in moderate renal impairment and severe hepatic impairment; not recommended in patients with end state renal disease	Approved for long-term use Controlled substance: C–IV
Phentermine–Topiramate Combination					
Phentermine and topiramate extended release	Qsymia	3.75 mg of phentermine and 23 mg of topiramate once daily for 14 days; then increase to 7.5 mg of phentermine and 46 mg of topiramate once daily	7.5 mg of phentermine and 46 mg of topiramate once daily to a maximum dose of phentermine 15 mg and topiramate 92 mg once daily	Maximum dose for patients with moderate or severe renal impairment or patients with moderate hepatic impairment is 7.5 mg of phentermine and 46 mg of topiramate	Approved for long-term use Take dose in the morning to avoid insomnia Controlled substance: C–IV
Naltrexone-Bupropion Combination					
Bupropion and naltrexone extended release	Contrave	8 mg naltrexone/90 mg bupropion (1 tablet) once daily in the morning for 1 week; then 8 mg naltrexone/90 mg bupropion twice daily (morning and evening) for 1 week; then 16 mg naltrexone/180 mg bupropion in the morning and 8 mg naltrexone/90 mg bupropion in the evening for 1 week; then 16 mg naltrexone/180 mg bupropion twice daily (morning and evening)	16 mg naltrexone and 180 mg bupropion (2 tablets) twice daily	Maximum dose for patients with moderate or severe renal impairment is 8 mg naltrexone/90 mg bupropion (1 tablet) twice daily Maximum dose for patients with hepatic impairment is 8 mg naltrexone/90 mg bupropion (1 tablet) once daily in the morning	Approved for long-term use Do not take dose with high-fat meal
Glucagon-Like Peptide-1 Antagonist					
Liraglutide	Saxenda	0.6 mg once daily for 1 week 1.2 mg once daily for 1 week 1.8 mg once daily for 1 week 2.4 mg once daily for 1 week 3.0 mg once daily for 1 week * administered by subcutaneous injection	3 mg once daily	Use with caution in mild, moderate, and severe renal and hepatic impairment	Approved for long-term use Inject subcutaneously in the abdomen, thigh, or upper arm Administer at any time of day without regard to the timing of meals
Noradrenergic Agents					
Phendimetrazine	Bontril PDM; Bontril Slow-Release	Conventional tablet: start at 17.5 mg two or three times daily, given 1 hour before meals Extended-release capsule: 105 mg once daily 30-60 minutes before morning meal	70-105 mg/day	Use caution in patients with renal impairment	Approved for short-term monotherapy Controlled substance: C–III Prescriptions should be written for the smallest quantity to minimize possibility of overdose
Phentermine	Adipex-P, Suprenza	Orally disintegrating tablet: 15 or 30 mg once every morning Phentermine hydrochloride: 15-37.5 mg/day given in one or two divided doses; administer before breakfast or 1-2 hours after breakfast	Orally disintegrating tablet: 15 or 30 mg once every morning Phentermine hydrochloride: 15-37.5 mg/day given in one or two divided doses; administer before breakfast or 1-2 hours after breakfast	Use with caution in patients with renal impairment	Approved for short-term monotherapy Controlled substance: C–IV Prescriptions should be written for the smallest quantity to minimize possibility of overdose Individualize to achieve adequate response with lowest effective dose

(*continued*)

TABLE 144-4 FDA-Approved Pharmacotherapeutic Agents for Weight Loss (*Continued*)

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comment
Diethylpropion	Tenuate, Tenuate Dospan	Immediate release: 25 mg three times daily administered 1 hour before meals Controlled release: 75 mg once daily administered at midmorning	75 mg/day	Use with caution in patients with renal impairment	Approved for short-term monotherapy Dose should not be administered in the evening or at bedtime Controlled substance: C–IV

[a]Available without a prescription.

80% of individuals using prescription-strength orlistat. These complaints are most common in the first 1 to 2 months of therapy, are mild to moderate in severity, and tend to improve with continued orlistat use. Limiting dietary fat before initiation of orlistat therapy may be beneficial in decreasing initial GI complaints. Severe diarrhea secondary to orlistat use can affect the absorption of orally administered drugs, such as oral contraceptives, fat-soluble vitamins (A, D, E, and K), and β-carotene.[60] Therefore, supplementation with a multivitamin should be considered during therapy. In the presence of severe diarrhea, women receiving oral contraceptives should be advised of the need to use alternative backup methods because absorption of oral contraceptive may be reduced.[60] Although orlistat does not appear to alter the pharmacokinetic profiles of other agents, including digoxin, glyburide, metformin, phenytoin, fluoxetine, amitriptyline, phentermine, losartan, nifedipine, captopril, atenolol, furosemide, alcohol, or atorvastatin, reduced fat absorption can potentially affect the absorption of lipophilic drugs, such as lamotrigine, valproic acid, gabapentin, and amiodarone.[62,63] Decreased vitamin K absorption has also been noted and can alter the patient's warfarin dosage needs. Clinicians should also be aware that orlistat may directly interfere with the absorption of other narrow therapeutic range drugs, such as cyclosporine and levothyroxine.[33] In patients requiring concomitant therapies with orlistat, close monitoring is warranted to ensure an adequate therapeutic response. Separation of the administration times of the medications may minimize these potential drug interactions. Finally, there have been rare postmarketing reports of liver damage with the use of orlistat.[63] Although causality has not been definitively linked to orlistat, patients are advised to notify their healthcare providers if they notice signs and symptoms of liver injury, such as development of itching, yellow eyes or skin, dark urine, loss of appetite, or light-colored stools.

Serotonin Receptor Agonist Lorcaserin (Belviq) is a selective serotonin (5-HT_{2C}) receptor agonist, approved for chronic weight management in patients who are obese (BMI of greater than or equal to 30 kg/m^2) or overweight (BMI of greater than 27 kg/m^2) with at least one weight-related comorbidity.[64] At the recommended dose of 10 mg twice daily, lorcaserin selectively activates central 5-HT_{2C} receptors on hypothalamic anorexigenic pro-opiomelanocortin neurons. Activation of central 5-HT_{2C} receptors results in appetite suppression, leading to reduced energy intake and enhanced satiety.

Clinical trials evaluating the efficacy of loracaserin, used in combination with a LCD and exercise counseling, have reported a modest but significantly greater weight loss compared with placebo.[65,66] The Behavioral Modification and Lorcaserin for Overweight and Obesity Management (BLOOM) trial was a 2-year, randomized, placebo-controlled, double-blind, prospective trial that enrolled more than 3,000 obese and overweight patients.[65] Mean weight loss at 1 year was 5.8 kg (12.8 lb) in the lorcaserin group compared with 2.2 kg (4.8 lb) in the placebo group. Patients in the lorcaserin-treated group also experienced significant improvements in fasting glucose, insulin, total cholesterol, LDL cholesterol, and triglyceride concentrations at the end of the first year. Although weight regain was observed during the second year of the trial, 68% of the

TABLE 144-5 Clinical and Economic Considerations for Long-Term Pharmacotherapy Options

Drug	Brand Name	Weight Loss Above Diet and Exercise Alone (1 year)[35,59,73]	Cost for 30 days of Therapy[a]	Comments[35]
Orlistat	Xenical	2.9-3.4 kg (6.5-7.5 lb)	$512.11	—Use may be limited by GI intolerance —Suggested for patients with cardiovascular disease (The Endocrine Society; weak recommendation with low quality evidence)
Lorcaserin	Belviq	3.6 kg (7.9 lb)	$199.50	—Increased risk of serotonin syndrome if used in combination with other serotonergic and dopaminergic drugs —Suggested for use in patients with cardiovascular disease (The Endocrine Society; weak recommendation with low quality evidence)
Phentermine and topiramate extended release	Qsymia	6.6-8.6 kg (14.5-18.9 lb)	$186.00- 7.5 mg-46 mg $199.50- 15 mg-92 mg	—Limited distribution under FDA Risk Evaluation Mitigation Strategy (REMS)
Bupropion and naltrexone extended release	Contrave	4.9 kg (10.8 lb)	$199.50	—Lowers seizure threshold (bupropion) —Rare reports of hepatotoxicity (naltrexone) —Drug interactions with opioids, CYP2B6 inducers and CYP2D6 substrates
Liraglutide	Saxenda	5.8 kg (12.8 lb)	$1,068.00	—Injectable —Reduces HbA1c and fasting glucose —Risk of medullary thyroid carcinoma and Multiple Endocrine Neoplasia syndrome type 2 —Rare reports of pancreatitis, gall bladder disease, and suicidal ideation

[a]Cost of therapy based on maintenance dose using wholesaler acquisition cost (WAC) as of August 24, 2015.

TABLE 144-6 Drug Monitoring

Drug	Brand Name	Adverse Reactions	Monitoring Parameters	Comments
Gastrointestinal Lipase Inhibitor				
Orlistat	Xenical, Alli[a]	Soft stools, diarrhea, abdominal pain or colic, flatulence, fecal urgency, incontinence, liver damage (rare)	BMI; calorie and fat intake; serum glucose in patients with diabetes; thyroid function in patients with thyroid disease; liver function tests in patients exhibiting symptoms of hepatic dysfunction	Supplement with a multivitamin during therapy to prevent vitamin deficiency
Serotonin 2C Receptor Agonist				
Lorcaserin	Belviq	Headache, dizziness, fatigue, nausea, dry mouth, constipation, hypoglycemia in patients with diabetes, psychiatric disorders, priapism, elevated serum prolactin level	BMI; calorie and fat intake; serum glucose in patients with diabetes; complete blood count, depression or suicidal thoughts; signs or symptoms of serotonin syndrome; signs or symptoms of valvular heart disease	Discontinue if 5% weight loss not achieved by week 12
Phentermine–Topiramate Combination				
Phentermine and topiramate extended release	Qsymia	Constipation, dry mouth, paraesthesia, dysgeusia, insomnia, hypoglycemia in patients with diabetes	BMI; calorie and fat intake; serum glucose in patients with diabetes; pregnancy; depression or suicidal thoughts; mood or sleep disorders; heart rate; serum electrolytes and creatinine at baseline and during treatment	Discontinue or escalate dose if 3% weight loss not achieved by week 12 on phentermine 7.5 mg and topiramate 46 mg Discontinue if 5% weight loss not achieved by week 12 on phentermine 15 mg and topiramate 92 mg Gradually discontinue phentermine 15 mg and topiramate 92 mg to prevent possible seizure
Bupropion-Naltrexone Combination				
Bupropion and naltrexone extended release	Contrave	Nausea, constipation, headache, vomiting, dizziness, insomnia, dry mouth and diarrhea	BMI; calorie and fat intake; serum glucose in patients with diabetes; heart rate and blood pressure; signs and symptoms of hepatotoxicity, neuropsychiatric reactions, and suicidal thoughts or behavior	Discontinue if 5% weight loss not achieved by week 12
Glucagon-Like Peptide-1 Antagonist				
Liraglutide	Saxenda	Nausea, diarrhea, constipation, vomiting, dyspepsia, hypoglycemia, and abdominal pain	BMI; calorie and fat intake; serum glucose in patients with diabetes; signs and symptoms of pancreatitis; heart rate; signs and symptoms of gallbladder disease and suicidal ideation	Discontinue if 4% weight loss not achieved by week 16
Noradrenergic Agents				
Phendimetrazine Phentermine Diethylpropion	Bontril PDM; Bontril Slow-Release Adipex-P, Suprenza Tenuate, Tenuate Dospan	Increased blood pressure, ischemic events, palpitations, tachycardia, valvular disease, urticaria, agitation, dizziness, headache, insomnia, overstimulation, psychosis, restlessness, dry mouth, constipation, thirst, diarrhea	Baseline cardiac evaluation (for preexisting valvular heart disease, pulmonary hypertension); echocardiogram during therapy; weight, waist circumference; blood pressure	Approved as monotherapies only for short-term use (a few weeks). Discontinue if satisfactory weight loss has not occurred within the first 4 weeks of treatment or if tolerance develops Abrupt discontinuation after prolonged high doses may be associated with extreme fatigue and depression

BMI, body mass index.

[a]Available without a prescription.

patients who had previously achieved 5% weight loss during the first year were able to maintain this level of weight loss by the end of the second year. The efficacy of lorcaserin has also been shown in patients with type 2 diabetes, with an average weight loss of 4.5% and significant improvements in HbA_{1c} and fasting glucose after 1 year of treatment.[67] Based on data from clinical trials, the approved label states that lorcaserin therapy should be discontinued if 5% weight loss not is not achieved by week 12 because it is unlikely that a benefit will be seen.[64]

The most common adverse effects associated with the use of lorcaserin in clinical trials were headache, dizziness, constipation, fatigue, and dry mouth.[65] Previous serotonergic agents (eg, dexfenfluramine) used for weight loss have been associated with cardiac valvulopathy.[62,68] The mechanism for this toxicity is thought to be related to stimulation of $5HT_{2B}$ receptors on cardiac cells. At therapeutic doses, lorcaserin is selective for central $5HT_{2C}$ receptors. During clinical trials, the incidence of cardiac valvulopathy was not significantly different between patients who received lorcaserin (2.4%) and those who received placebo (2%).[64] However, patients should be counseled to contact their healthcare providers if they experience signs or symptoms of cardiac valve disease such as dyspnea or edema. Lorcaserin should not be used in combination with other serotonergic and dopaminergic drugs because of the increased risk of serotonin syndrome or neuroleptic malignant syndrome–like reactions. Lorcaserin should be used cautiously in patients with congestive heart failure because these patients may be at an increased

risk for cardiac valvulopathy. Additional rare adverse effects that clinicians should be aware of include psychiatric disorders, priapism, and elevated serum prolactin concentrations. Lorcaserin is classified as a controlled substance in class IV due to potential for abuse.

Phentermine–Topiramate Extended Release A combination product containing phentermine and topiramate extended release (Qsymia) is approved for chronic weight management in patients who are obese (BMI of greater than or equal to 30 kg/m^2) or overweight (BMI of greater than 27 kg/m^2) with at least one weight-related comorbidity.[69] Phentermine is structurally similar to amphetamine, but it has less severe CNS stimulation and a lower abuse potential. Its mechanism of action centers on its ability to enhance norepinephrine (NE) and dopamine neurotransmission, resulting in appetite suppressing effects. Topiramate is an antiepileptic drug. Although the exact mechanism for its efficacy in weight management is not known, it may decrease appetite and increase satiety through multiple pathways, including effects on γ-aminobutyrate, voltage-gated ion channels, excitatory glutamate receptors, or carbonic anhydrase.[69] The doses of phentermine (3.75-15 mg) and topiramate (23-92 mg) in this combination are significantly lower than the therapeutic doses of each separate product when used as monotherapy for obesity (37.5 mg) and epilepsy (400 mg), respectively. The recommended dosing strategy for phentermine–topiramate extended release involves gradual titration, staring with 3.75 mg of phentermine and 23 mg of topiramate once daily for 14 days and then increasing the dose to 7.5 mg of phentermine and 46 mg of topiramate once daily.[69] After 12 weeks of therapy, the dose may be increased again to 11.25 mg of phentermine and 69 mg of topiramate for 14 days and then to a maximum dose of 15 mg of phentermine and 92 mg of topiramate daily. Likewise, when discontinuing therapy, the dose should be gradually decreased by taking a dose every other day for at least 1 week to prevent the possible precipitation of seizures.

Clinical trials evaluating the efficacy of phentermine–topiramate, when used as an adjunct to a reduced-calorie diet and lifestyle changes, have reported dose-dependent weight loss and significant reductions in blood pressure, total cholesterol, LDL cholesterol, triglycerides, fasting glucose, and HbA_{1c}.[70,71] The CONQUER trial was a randomized, placebo-controlled, double-blind, prospective trial of 2,487 overweight or obese patients with two or more obesity-related comorbidities.[70] After a 4-week dose titration phase, subjects were randomized to receive (a) placebo, (b) 7.5 mg of phentermine with 46 mg of topiramate, or (c) 15 mg of phentermine with 92 mg of topiramate daily. Weight loss at 1 year was significantly greater than placebo in both of the treatment groups, with a mean weight loss of 8.1 kg (17.8 lb) in the 7.5-mg phentermine and 46-mg topiramate group and a mean weight loss of 10.2 kg (22.4 lb) in the 15-mg phentermine and 92-mg topiramate group. The efficacy of phentermine–topiramate has also been documented in patients with class II and class III obesity (mean BMI, 42 kg/m^2), with a reported mean weight loss of 10.9% after 1 year of treatment.[71]

The most common adverse effects associated with the use of phentermine–topiramate in clinical trials were constipation, dry mouth, paraesthesia, dysgeusia, and insomnia.[70,71] Because topiramate is a known teratogen, this drug is contraindicated in pregnancy because fetal exposure in the first trimester increases the risk of cleft lip or cleft palate. To manage the potential risk of teratogenicity, the drug is only available through a limited distribution process under a risk evaluation and mitigation strategy (REMS).[69] All women of childbearing age must have a documented negative pregnancy test result before beginning treatment and then monthly to continue therapy. Topiramate has been associated with acute myopia associated with secondary angle-closure glaucoma, and phentermine can cause mydriasis from adrenergic stimulation. Therefore, this product is also contraindicated in patients with glaucoma. The potential for hypertensive crisis with coadministration of phentermine and MAOIs exists; therefore, patients should have stopped an MAOI for at least 14 days before use of any adrenergic agent. Phentermine–topiramate is also contraindicated in patients with untreated hyperthyroidism.

Monitoring parameters and drug interactions that clinicians should be aware of include known issues related to both components of the formulation. Of note, increases in heart rate greater than 10 beats/min were observed in approximately 50% of patients receiving phentermine–topiramate during clinical trials.[69] In patients receiving the highest dose, 19% experienced increases in heart rate that were greater than 20 beats/min. Therefore, heart rate should be monitored in all patients, particularly those with preexisting CVD. Decreases in serum bicarbonate were also noted in clinical trials, which were generally mild with peak decreases observed after 4 weeks of therapy. Decreases in serum potassium and increases in serum creatinine were also reported. Therefore, monitoring of serum electrolytes and creatinine is recommended at baseline and during therapy. Clinicians should be aware that concomitant use of non–potassium-sparing diuretics may potentiate the risk for hypokalemia. Although pregnancy risk is not expected, use of phentermine–topiramate concomitantly with oral contraceptives may result in breakthrough bleeding because of increased exposure to progestin and decreases exposure to estrogen. Phentermine–topiramate is classified as a controlled substance in schedule IV because of the abuse potential of phentermine. Similarly to lorcaserin, therapy should be discontinued if 5% weight loss is not achieved after 12 weeks.[69]

Naltrexone–Bupropion Extended Release A combination product containing naltrexone and bupropion extended release (Contrave) was approved in 2014 for chronic weight management in patients who are obese (BMI of more than or equal to 30 kg/m^2) or overweight (of more than or equal to 27 kg/m^2) with at least one weight-related comorbidity.[72] Naltrexone and bupropion are both approved separately for treatment of alcohol and opioid dependence, and depression and smoking cessation, respectively.[73] Bupropion is a dopamine and norepinephrine reuptake inhibitor, and naltrexone is an opioid antagonist. Although the exact weight-loss mechanism of action is not known for this drug combination, stimulation of release of α-MSH in hypothalamus by bupropion and inhibition of endogenous opioids by naltrexone are thought to contribute to a decrease in appetite.[73] The recommended dosing strategy for naltrexone-bupropion extended-release involves gradual titration, starting with one tablet (8-mg naltrexone/90-mg bupropion) per day and slowly increasing the dose over a period of 4 weeks to a maintenance dose of two tablets twice daily. Doses greater than 32 mg of naltrexone and 360 mg of bupropion (ie, 4 tablets) per day are not recommended. Patients should be advised to not take their dose with a high-fat meal as this would result in increased systemic exposure to both naltrexone and bupropion.

Four randomized, placebo-controlled, clinical trials evaluating the efficacy of naltrexone/bupropion, when used in combination with a reduced-calorie diet and lifestyle changes, have reported significantly more weight loss with naltrexone/bupropion compared to placebo, as well as improvements in high-density lipoprotein (HDL) cholesterol, triglycerides, glucose, and insulin.[74-77] The average total weight loss reported among the four studies was 7.3 kg (95% CI, 7.0-7.6 kg) following 1 year of treatment,[73] with the greatest amount of weight loss (9.7 kg) reported in nondiabetic subjects who were also receiving intensive behavior modification therapy.[76]

The most common adverse effects associated with the use of naltrexone/bupropion in clinical trials were nausea, constipation, headache, vomiting, dizziness, insomnia, dry mouth, and diarrhea.[72] Approximately 24% of patients who received naltrexone-bupropion in clinical trials discontinued treatment due to adverse events, with nausea being the most frequently cited reason.[72] Statistically significant

increases in heart rate (2.1 beats/min) and blood pressure (1.8-2.3 mm Hg systolic and 1.7-2.1 mm Hg diastolic) were observed in patients receiving naltrexone-bupropion compared with those who received placebo during the first 3 months of therapy. Although the clinical significance of these increases is unknown, blood pressure and pulse should be monitored at baseline and at regular intervals following initiation of therapy. Naltrexone-bupropion should not be used in patients with uncontrolled hypertension.[72] Naltrexone monotherapy has been associated with rare reports of hepatotoxicity, and patients receiving naltrexone-bupropion should be advised of the signs and symptoms of acute hepatitis. Bupropion lowers the seizure threshold in a dose-dependent manner, and has been associated with serious neuropsychiatric reactions and an increased risk of suicidal thoughts and behavior when used for smoking cessation and treatment of depression. Bupropion has also been reported to cause activation of mania, serious allergic reaction, and angle-closure glaucoma.

Clinicians should also be aware of potential drug interactions with naltrexone-bupropion. Because of the opioid antagonist effects of naltrexone, naltrexone-bupropion is contraindicated in patients receiving chronic opioid or opiate agonist therapy, and also in patients undergoing abrupt withdrawal of chronic alcohol, benzodiazepine, barbiturate or antiepileptics. Bupropion is metabolized by cytochrome P450 2B6 (CYP2B6) and inhibits cytochrome P450 2D6 (CYP2D6). Therefore, any medication that induces CYP2B6 (ie, rifampin, carbamazepine, etc) could potentially reduce the effects of bupropion, and bupropion could increase the effects of medications that are CYP2D6 substrates (ie, SSRIs, tricyclic antidepressants, antipsychotics, etc). Bupropion is also contraindicated with concomitant use of MAOIs As with other long-term pharmacologic treatments for obesity, weight loss may increase the risk of hypoglycemia in patients with type 2 diabetes receiving antidiabetic medications. Finally, treatment with naltrexone-bupropion should be discontinued if 5% weight loss is not achieved after 12 weeks.

Glucagon-Like Peptide-1 Receptor Agonist Liraglutide Liraglutide (Saxenda), an analog of GLP-1, is the latest medication approved in the United States for chronic weight management in patients who are obese (BMI of more than or equal to 30 kg/m^2) or overweight (BMI of more than 27 kg/m^2) with at least one weight-related comorbidity.[78] Endogenous GLP-1 is released in response to food digestion and stimulates GLP-1 receptors in the brain to reduce appetite. GLP-1 also stimulates insulin secretion and reduces glucagon secretion. For that reason, several GLP-1 receptor agonists, including liraglutide, are currently approved for the treatment of type 2 diabetes at recommended doses of 1.2 mg or 1.8 mg daily far less than the maintenance dose for weight loss of 3 mg daily.[78] Liraglutide is administered subcutaneously and is available in prefilled, multidose pens. When used for weight loss, a 5-week dose escalation schedule is recommended to improve tolerability of GI adverse events. It should be initiated at a dose of 0.6 mg daily, and increased weekly by 0.6-mg increments to a final maintenance dose of 3 mg daily. If the patient cannot tolerate the GI adverse events at any point during the dose escalation phase, a dose increase may be delayed by a week. Patients should be instructed on the proper technique for subcutaneous injection into the abdomen, thigh, or upper arm.

The efficacy of liraglutide for the management of overweight and obesity has been studied in patients with and without diabetes.[78-80] The Satiety and Clinical Adiposity-Liraglutide Evidence in Nondiabetic and Diabetic Individuals (SCALE) Obesity and Prediabetes study was a 56-week, randomized, placebo-controlled, double-blind, prospective trial of approximately 3,700 obese and overweight patients without diabetes.[79] Mean weight loss after 1 year of treatment was 8.4 kg (18.5 lb) in the liraglutide group compared with 2.8 kg (6.1 lb) in the placebo group. As expected, patients in the liraglutide-treated group also experienced significant improvements in HbA_{1c}, fasting glucose and insulin, and had a lower prevalence of prediabetes at the end of the trial. In the SCALE Diabetes trial, 840 overweight or obese subjects with type 2 diabetes were randomized to liraglutide 3 mg daily, liraglutide 1.8 mg daily, or placebo in combination with a LCD and exercise program for 56 weeks.[80] The average weight loss after 1 year of treatment was 6.4 kg (14 lbs) for the liraglutide 3-mg group, 5 kg (11 lbs) for the liraglutide 1.8-mg group, and 2.2 kg (4.8 lbs) in the placebo group. Significant improvements in fasting glucose and the number of subjects achieving HbA_{1c} targets of less than or equal to 7% (≤ 0.07; ≤ 53 mmol/mol Hb) (69.2% vs 27.2%) and less than or equal to 6.5% (≤ 0.065; ≤48 mmol/mol Hb) (56.5% vs 15%) in the liraglutide 3-mg group compared to the placebo group.

The most common adverse effects associated with the use of liraglutide in clinical trials were nausea, diarrhea, constipation, vomiting, dyspepsia, hypoglycemia, and abdominal pain.[78-80] GI complaints are the most common reason for premature discontinuation of therapy, underscoring the importance of the slow dose-escalation schedule with initiation of therapy. Rare cases of acute pancreatitis (0.3%), potentially leading to fatal hemorrhagic or necrotizing pancreatitis, have been reported with the use of liraglutide.[78] Small increases in resting heart rate averaging 2 to 3 beats/min have been reported in clinical trials. However, in some cases increases were as high as 20 beats/min. Although the clinical significance of these increases is unknown, heart rate should be regularly monitored in all patients receiving liraglutide. Cholelithiasis (1.5%), cholecystitis (0.6%), and suicidal ideation (0.2%) have also been observed during clinical trials.[78] Liraglutide carries a boxed-warning about the risk of thyroid C-cell tumors, including medullary thyroid carcinoma (MTC), and is contraindicated in patients with a personal or family history of MTC or multiple endocrine neoplasia syndrome type 2 (MEN2). Hypoglycemia may occur when liraglutide is used in combination with other antidiabetic agents (particularly sulfonylureas and insulin) in patients with type 2 diabetes. Therefore, dose adjustments of antidiabetic medications may be necessary. Because liraglutide increases gastric emptying time, clinicians also should be aware that absorption of concomitantly administered oral medications may be altered. Liraglutide should be discontinued if weight loss of at least 4% is not achieved after 16 weeks of therapy.

Agents Approved for Short-Term Use Several noradrenergic agents are currently approved by the FDA for short-term weight loss. Because short-term therapy is not consistent with current national guidelines for the chronic management of obesity, these agents have limited clinical utility in practice.

Phentermine Phentermine is available in both immediate-release and sustained-release formulations. However, the value of sustained-release formulations is questionable based on the reported phentermine plasma half-life of 12 to 24 hours.[81] Phentermine is an effective adjunct to diet, exercise, and behavior modification for producing weight loss in excess of that seen with placebo.[81,82] Intermittent phentermine therapy appears to elicit comparable weight loss as that seen with continuous use. However, most individuals experience weight regains during therapy and generally always after discontinuing use.[81] A single dose of 30 mg once daily in the morning provides effective appetite suppression throughout the day. Divided doses of 8 mg immediately before meals, however, are common. Doses greater than 30 mg daily do not improve effectiveness.[82] Evening or nighttime dosing should be avoided because of insomnia. Significant increases in blood pressure, palpitations, and arrhythmias can occur with phentermine administration. Use is not advisable in hypertensive patients. Pharmacotherapy management guidelines recommend against the use of sympathomimetic agents in patients with uncontrolled hypertension or a history of CVD (strong recommendation with high-quality evidence).[35]

The potential for hypertensive crisis with coadministration of phentermine and MAOIs is noted in the product labeling of each

agent; therefore, patients should be off an MAOI for at least 14 days before use of any adrenergic agent to avoid excessive adrenergic stimulation syndromes.[83] Phentermine use is contraindicated in patients with hyperthyroidism or agitated states and in those who are abusers of substances such as cocaine, phencyclidine, and methamphetamine, again because of the potential for excessive adrenergic stimulation syndromes and abuse potential. Mydriasis from adrenergic stimulation can worsen glaucoma, and patients diagnosed with glaucoma should not receive phentermine. Patients with diabetes may experience altered insulin or oral hypoglycemic dosage requirements soon after beginning therapy and before any substantial weight loss. Phentermine remains the most widely prescribed weight management medication by obesity specialists despite product labeling that indicates short-term (a few weeks), monotherapy use only.[81] This usage pattern deviates from the current national recommendations that promote only long-term drug intervention when obesity pharmacotherapy is appropriate.[35]

Clinical **Controversy…**

Although phentermine is only approved for short-term use, it continues to be the most widely prescribed weight loss drug in the United States. Some clinicians consider use of long-term phentermine to be reasonable in select patients given the low cost and a lack of serious long-term adverse events reported in the literature over the past 20 years. Select patients include those without evidence of CVD, psychiatric disease, or substance abuse; without clinically significant increases in blood pressure or heart rate while receiving phentermine; and documentation of significant weight loss while receiving phentermine.

Diethylpropion Diethylpropion stimulates NE release from presynaptic storage granules. Increased adrenergic neurotransmitter concentrations activate hypothalamic centers, which result in decreased appetite and food intake. This drug undergoes extensive first-pass hepatic metabolism. Active metabolites are eliminated renally and account for about 70% of the administered dose. The elimination half-life of these metabolites is about 8 hours.[82] Less than 10% of the parent compound is recovered in urine. No specific dosing recommendations exist for use in patients with renal or hepatic insufficiency. Diethylpropion can be taken in divided daily doses, generally 25 mg three times daily before meals. An extended-release formulation is also used by some clinicians, usually as 75 mg taken once daily in the morning or midmorning. Both dosing regimens are effective in achieving short-term weight loss in excess of placebo.[84] Complaints of insomnia increase if late afternoon dosing is used. Diethylpropion causes less stimulation of the CNS than mazindol and generally causes less insomnia than phentermine. Patients with severe hypertension or significant CVD should not receive diethylpropion. Patients with diabetes may experience decreased insulin or oral hypoglycemic dosage requirements soon after beginning therapy and before any substantial weight loss. More frequent blood glucose self-monitoring and medical follow-up are warranted when treating diabetic patients with diethylpropion.

Amphetamines Appetite suppressant effects of the amphetamines were well recognized in the 1930s. Amphetamines activate central noradrenergic receptor systems as well as dopaminergic pathways at higher doses by stimulating neurotransmitter release. Increases in blood pressure and mild bronchodilation are attributed to peripheral α- and β-receptor activation. Amphetamines are no longer widely used for the treatment of obesity because of their powerful stimulant effects and addictive potential.

Off-Label Use of Serotonergic Agents Serotonin is an important neurotransmitter involved in many human physiologic systems such as sleep–wake cycles, sensitivity to pain, blood pressure, mood, and eating behaviors. Increasing central serotonin levels disrupts the body's natural development of satiety by decreasing the amount of food consumed and prolongs the time between food intake.[85] Some serotonergic agents increase central serotonin concentrations via stimulating release of presynaptic stores or inhibition of reuptake into storage granules. Additionally, either the parent compound or metabolites of these agents may stimulate postsynaptic 5-HT receptors directly. Peripheral serotonin effects that have an impact on appetite, such as slowing gastric motility, have been described. A major distinction between serotonergic and noradrenergic anorexiants is that serotonergic agents lack the central stimulant effects and thus the abuse potential seen with the noradrenergic compounds.[84] Conversely, decreased wakefulness, altered sleep patterns, and changes in affect can be seen. Some of the serotonergic agents were first studied as antidepressants and when weight loss was noted in some patients, they began to be used as weight management agents. These drugs are not approved by the FDA as weight management agents and are currently not recommended for the treatment of obesity. Nonetheless, some practitioners have prescribed these agents for the treatment of obesity "off label" either alone or in combination with phentermine.

Fluoxetine is a serotonergic agent that has been prescribed as an appetite-suppressing agent. Higher doses of fluoxetine (60 mg) were generally used for weight loss as opposed to the lower doses (20 mg) frequently used for the treatment of depression. A meta-analysis of five fluoxetine trials in patients with diabetes resulted in weight loss of 4.3 kg (9.4 lb) compared with placebo over periods of up to 1 year.[86] Evidence also demonstrates sustained benefits in fasting blood glucose, HbA_{1c}, and triglycerides in patients with poor glycemic control. However, weight regain was noted to occur with discontinuation of medication.

The safety and efficacy of phentermine–serotonin reuptake inhibitor combinations is limited. A case report of adverse experiences (eg, impaired mentation, tremor, hyperreflexia, and GI symptoms) with unintentional concurrent use of phentermine and fluoxetine reinforces the need for caution by prescribers of this unapproved combination therapy.[87] Although cases of pulmonary hypertension have been reported in patients exposed to fluoxetine,[88] serious adverse effects such as cardiac valve abnormalities in excess of baseline prevalence have not been reported in relation to SSRI use for obesity therapy.[89]

Noradrenergic–Serotonergic Agents Until 2010, sibutramine was available as Meridia in the United States for long-term use for weight loss. This agent induced weight loss by decreasing appetite and maintaining or increasing thermogenesis via increasing the synaptic concentration of serotonin, NE, and dopamine through reuptake inhibition. The Sibutramine Cardiovascular OUTcomes (SCOUT) study—the first prospective trial that evaluated the potential benefits of sibutramine on cardiovascular outcomes in obese or overweight individuals with preexisting CVD, type 2 diabetes mellitus, or both, failed to provide any reassurance regarding sibutramine's safety.[90] Although individuals taking sibutramine had modest weight loss, improvement in cardiovascular outcomes was not seen. Conversely, subjects with preexisting CVD actually had an increased risk of nonfatal myocardial infarction and nonfatal stroke. Because of concerns that the effectiveness of sibutramine on weight loss is counterbalanced by increased rather than decreased cardiovascular risk, the drug was voluntarily withdrawn from the US market.

Complementary and Alternative Therapies 9 Many complementary and alternative therapy products are currently promoted for weight loss. A nationwide survey of US consumers reported that about 34% of adults reported that they had used "dietary supplements" specifically for the purposes of weight loss.[91] It is important for clinicians to be aware that the regulation of dietary supplements is less rigorous

than that of prescription and over-the-counter drug products. As such, a manufacturer of a dietary supplement does not have to prove the safety or effectiveness of the product before it is marketed. Of concern, some herbal and food supplement diet agents contain pharmacologically active substances that should be used with caution or avoided in obese patients with conditions such as diabetes, hypertension, and significant CVD. In addition, many marketed products have been reported to lack consistency in labeling versus actual product content, and a number of dietary supplements have been found to contain undeclared prescription drugs.[92] Common herbal and natural products that have been used for weight loss include hoodia, green tea, citrus aurantium, fenugreek, caffeine, ephedrine, capsaicin, yohimbine, chitosan, guar gum, hydroxycitric acid, and garcina cambogia.[93,94]

PERSONALIZED PHARMACOTHERAPY

Genetic influences are estimated to contribute between 40% and 70% of the actual variance in body weight and fat distribution.[28] As such, identifying specific genes involved in the development of obesity is an area of extensive research. Several gene variants associated with the development of obesity have been identified through the use of genome-wide association studies (GWAS).[95] However, the use of personalized pharmacotherapy to treat obesity has only been documented in patients with congenital leptin deficiency.[96] This is an extremely rare condition in which administration of recombinant human leptin results in significant improvement in body weight and other associated abnormalities of leptin deficiency. Recommendations regarding how currently available medications can be individualized to maximize patient benefit are not yet available.

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation and management of a patient with obesity requires careful clinical; biochemical; and, if necessary, psychological evaluation. This evaluation should include an assessment of the patient's current medical condition and medication regimen. A multidisciplinary team including, but not limited to, a physician, nutritionist, psychologist, behavioral expert, and pharmacist should be involved in the care of obese individuals.

Monitoring the Pharmaceutical Care Plan

Assessment of patient progress should be documented frequently.[5] Each encounter should document weight, WC, BMI, blood pressure, medical history, and patient assessment of obesity medication tolerability.[5] Chronic use of obesity medications should be consistent with the approved product labeling. According to current pharmacologic management guidelines, efficacy and tolerability of the medication should be assessed monthly for the first 3 months, followed by visits every 3 months thereafter (weak recommendation with low quality evidence).[35] If the patient has failed to demonstrate weight loss or maintenance of prior weight, medication therapy should be discontinued after 3 months (strong recommendation with high quality evidence).[35] To achieve optimal weight loss, patients should be instructed about the importance of adherence to prescribed medication and lifestyle changes. The Short Form 36 (SF-36) has been used as a quality-of-life evaluation tool for obese patients undergoing programmatic weight loss. Quarterly assessments of well-being and quality of life using validated assessment tools can be helpful in objectively quantifying the effectiveness of therapy.

Patients with diabetes receiving weight loss medication require more intense medical monitoring and self-monitoring of blood glucose. Insulin therapy may need to be adjusted with the start of obesity medication therapy. Some patients with diabetes may require daily telephone contact with a healthcare provider to assist in adjusting their hypoglycemic therapy. Weekly patient visits to a healthcare setting may be necessary for 1 to 2 months until the effects of diet, exercise, and weight loss medication become more predictable. As frequent as quarterly assessment of HbA_{1c} may be appropriate in patients with type 2 diabetes who lose weight to aid in adjustment of hypoglycemic therapy. Lipid profiles can normalize or improve with weight loss. Lipid status should be assessed semiannually or annually in patients with hyperlipidemia to determine the need for continued hyperlipidemia therapies. Weight loss also can result in normalization of blood pressure in hypertensive obese patients. Assessment of appropriateness of antihypertensive therapy should occur with each follow-up visit.

CONCLUSION

Obesity is a chronic disease with a prevalence that has increased dramatically over the past 30 years. Increased body weight is a consequence of increased energy storage resulting from an imbalance between energy intake and energy expenditure over time, which is influenced by many factors, including genetics and the environment. Nonpharmacologic therapy, including reduced caloric intake, increased physical activity, and behavioral modification, is currently the mainstay of obesity management. Drug therapy may be considered as an adjunct for patients who fail to achieve adequate weight loss with comprehensive lifestyle modifications. Currently, five products—orlistat, lorcaserin, phentermine–topiramate extended release, naltrexone-bupropion extended release, and liraglutide—are approved by the FDA for the long-term treatment of overweight and obesity. Bariatric procedures have evidence for long-term efficacy for weight reduction, but they also introduce surgical comorbidities and, for the most efficacious procedures, may cause significant nutritional deficiencies. Treatment of obesity should be individualized, considering factors such as patient desires, age, degree and duration of obesity, and the presence or absence of medical conditions both directly related to obesity and those that may have an impact on the therapeutic decisions. Regardless of the chosen treatment plan, the management of obesity is a lifelong process requiring patient support and careful monitoring for safety and efficacy.

nephrotoxicity of, 664–665
Angiotensin II (ATII), 84–85, 612
Angiotensin II receptor blockers/neprilysin inhibitor, 107
Angiotensin receptor blockers (ARBs), 188*t*, 536*b*, 617–618, 767
for acute coronary syndromes, 166
allergic reactions to, e323
for chronic hearth failure, 106–107
for focal segmental glomerulosclerosis, 685
for glomerulonephritis, 680
for hypertension, 57–59, 57*t*–58*t*
for immunoglobulin A nephropathy, 691
myocardial infarction and, 186–187
nephrotoxicity of, 664–665
for stable ischemic heart disease, 148
Angiotensin receptor/neprilysin inhibitor, 101–102
Angiotensin-converting enzyme inhibitors (ACEIs), 105–106, 147–148, 188*t*, 536*b*, 617–618, 767
for acute coronary syndromes, 166, 175*t*
cough from, e207–e208
for focal segmental glomerulosclerosis, 685
for glomerulonephritis, 680
glycemic control, 1161*t*
for immunoglobulin A nephropathy, 691
myocardial infarction and, 186–187
Anidulafungin
for febrile neutropenia, 1956
for oropharyngeal candidiasis, 1896
Animal bites, 1732*t*, 1753–1755
epidemiology of, 1753
etiology of, 1753, 1754*t*
pathophysiology of, 1753
treatment of, 1754–1755
evidence-based, 1736*t*
nonpharmacologic, 1754–1755
outcomes of
desired, 1754
therapeutic, evaluation of, 1755
pharmacologic, 1737*t*, 1754–1755
Anionic transporters, e240, e242*t*
Ankle-branchial index (ABI), e162, e187, e188*t*. *See also* Peripheral arterial disease (PAD)
Ankylosis, 1439
Anopheles mosquito, e379
Anorexia nervosa. *See also* Eating disorders
diagnostic criteria and clinical presentation of, 960–961, 961*b*, 961*f*
epidemiology of, 959
prognosis of, 963–964
treatment of
nonpharmacologic, 964–965
pharmacologic
antidepressants, 965
antipsychotics, 965
therapeutic outcomes of, evaluation of, 968
Anosognosia, e271
Anovulatory bleeding, 1265*t*
Antacids, 444, 445*t*, 469
Antería, e26
Anthonisen criteria, 1688
Anthralin, 1564–1565
Anthrax, e88, e142–e145
as a bioweapon, e142
clinical presentation of, e143, e143*t*
epidemiology of, e142
etiology of, e142
historical perspective on, e142
pathophysiology of, e142–e143
treatment of, e143–e145
postexposure prophylaxis in, e143–e144
preexposure prophylaxis in, e143
for suspected or confirmed cases, e144–e145, e144*t*
Antiandrogens, 2167, 2171–2174, 2172*t*–2173*t*, 2175*t*
Antiarrhythmics, 197–200, 210–212, 211*t*, 221–222. *See also* Arrhythmias
classification of, 197–199, 198t
class Ia, 197, 221
class Ib, 197–198
class Ic, 198
class II, 198–199
class III, 199, 221
doses, 202*t*
electrophysiologic actions, 197
pharmacokinetics of, 201*t*
side effects of, 200*t*
for ventricular fibrillation, 30*t*, 32
Antibacterial agents
for acne vulgaris, 1546–1549
adverse effects and monitoring of, 1552*t*–1553*t*
azelaic acid, 1548
bacterial resistance to, 1548
benzoyl peroxide, 1546
dapsone, 1548
oral, 1547–1548
steroids, intralesional, 1548–1549
topical, 1547
dosing by age group, 1670*t*
Antibiotic-associated diarrhea (AAD), 516
Antibiotics. *See also specific agents and infections*
for acute bacterial rhinosinusitis, 1711–1712, 1712*t*
for acute otitis media, 1708–1709, 1709*t*

Drug Abuse Warning Network (DAWN), 977
Drug allergy, e313–e328
classification of, e315–e316, e315*t*
DRESS, e316
drug hypersensitivity reactions, e316
SCARs, e316
TEN, e316
type I (immediate) reaction, e315
type II (delayed) reaction, e315
type III (delayed) reaction, e315–e316
clinical manifestations of, e316–e318
anaphylaxis, e316–e317
drug fever, e317
drug rash with eosinophilia and systemic symptoms, e317
drug-induced autoimmunity, e317–e318
hematologic reactions, e318
respiratory reactions, e318
serious cutaneous adverse reactions, e318
serum sickness, e317
serum sickness-like disease, e317
vasculitis, e318
definition of, e313
drugs causing
ACE inhibitors, e323
angiotensin receptor blockers, e323
anticonvulsants, e323
aspirin, e321–e322
biologics, e324
betaβ-lactam antimicrobials, e319–e320, e320*f*
cancer chemotherapy agents, e323
chlorhexidine, e323–e324
insulin, e321
NSAIDs, e321–e322
pharmaceutical excipients and additives, e322
radiocontrast media, e320–e321
sulfonamides, e322
effectors of, e314–e315
cellular elements of, e314
mediators in, e314–e315
mechanisms of, e313–314
p-i concept in, e314
prohapten/hapten concept in, e314
risk or severity of, e318–e319
treatment of, e324–e328
for anaphylaxis, e324–e325, e325*t*
for delayed allergic reactions, e325
drug tolerance and desensitization in, e326–e327, e327*t*
graded challenge in, e327–e328
skin testing in, e325–e326, e326*t*
Drug fever, e317
Drug hypersensitivity reactions (DHRs), e313, e316, e336
Drug reaction with eosinophilia and systemic symptoms (DRESS), e316, e317, 1029
Drug-induced autoimmunity, e317–e318
Drug-induced disorders
acne vulgaris, 1537
autoimmune disease, e317–e318
dermatologic, e336–e339
acneiform, e338
acute generalized exanthematous pustulosis, e338
allergic, e336
angioedema, e336–e337, e337*t*
drug hypersensitivity reactions, e336
fixed drug eruptions, e337
hyperpigmentation, e337*f*, e338
irritant, e336
maculopapular, e336
photosensitivity, e338
serum sickness-like reactions, e337
Stevens-Johnson syndrome, e337–e338
toxic epidermal necrolysis, e337–e338
urticaria, e336–e337
fever, 1650
glaucoma, 1508, 1509t
hematologic disorders
agranulocytosis, e348–e349
hemolytic anemia, e349–e351
megaloblastic anemia, e351–e352
thrombocytopenia, e352–e355
hyperprolactinemia, e289, e289*t*
hypokalemia, 760–761, 760*t*
kidney disease, 657–671 (*See also* Kidney disease, drug-induced)
liver disease, e229–e235 (*See also* Drug-induced liver disease (DILD))
pulmonary diseases, e203–e214
ACE inhibitor–induced cough, e207–e208
adverse drug reactions, e203
apnea, e203–e204, e204*t*
bronchospasm, aspirin induced, e204–e206
incidence of, e203
natural rubber latex allergy, e207
from oxygen toxicity, e210, e210*f*
pulmonary edema, e208–e209, e208*t*
narcotic-induced, e208–e209
other drugs, e209
pulmonary eosinophilia, e209–e210, e209*t*
pulmonary fibrosis, e210–e213, e211, e211*t*
Drug-induced liver disease (DILD), e229–e235
assessment of
histologic changes, e231–e234
centrolobular necrosis, e231–e233, e232*f*
hepatocellular necrosis, generalized, e232*f*, e233
liver vascular disorders, e233
nonalcoholic steatohepatitis, e233
phospholipidosis, e233
toxic cirrhosis or fibrosis, e233
liver enzyme changes, e230–e234
cholestatic injury, e230–e231
hepatocellular injury, e230
mixed hepatocellular and cholestatic injury, e231
medication related problem, e234–e235, e234*f*, e235*t*
severity of medication related problem, e235, e235*t*
epidemiology of, e229–e230
mechanisms of
apoptosis stimulation, e230
autoimmunity simulation, e229
calcium homeostasis disruption and cell membrane injury, e230
cytochrome P450 enzyme metabolic activation, e230
idiosyncratic reactions, e229–e230
liver neoplastic disease, e230
mitochondrial injury, e230
Drug-nutrient interactions, 2339, 2339*t*
Ductal carcinoma in situ (DCIS), 2086
Dulaglutide, 1169*t*
Duloxetine, 1058*t*, 1366, 1424–1426, 1430–1431
Dutasteride, 1341*t*
Dysbetalipoproteinemia, 277
Dyshidrotic eczema, definition of, 1578*t*
Dyskinesia Identification System: Condensed User Scale (DISCUS), e274*t*
Dyskinesias, 904
Dyslipidemia. *See also specific types*
clinical presentation of, 277*b*
from combined hormonal contraceptives, 1249–1250
definition of, 272
epidemiology of, 271–272
lipoprotein metabolism and transport in, 273–277, 273*t*, 274f
patient evaluation in, 277–279, 278*t*, 279*t*
Dyslipidemia treatment, 280–293
in children, 288
in concurrent diseases, 288–289
for diabetic dyslipidemia, 287
in elderly, 287–288
evidence-based recommendations, 1148*t*
general approach to, 280–281
for hypertriglyceridemia, 286–287
for low HDL cholesterol, 287
nonpharmacologic, 281–282, 281*t*
partial ileal bypass in, 289
portacaval shunts in, 289
outcomes of
desired, 280, 281*t*
therapeutic, evaluation of, 292–293
pharmacoeconomic considerations in, 289
pharmacologic, 282–286, 283*t*, 284*t*
in women, 288
Dysmenorrhea, 1272–1273
in adolescent females, 1273
clinical presentation of, 1272*b*
definition of, 1272
epidemiology of, 1272
etiology of, 1272
primary, 1272
secondary, 1272
treatment of, 1272–1273
algorithm for, 1273*f*
evaluation of, therapeutic, evaluation of, 1273
general approach to, 1272
nonpharmacologic, 1273
outcomes of, desired, 1272
pharmacologic, 1265*t*, 1273
drug class in, 1273
NSAIDs, 1273
progesterones, 1273
Dysphagia, in Parkinson disease, 899*t*
Dyspnea. *See also specific types and disorders*
in COPD, 380–381
treatment of, e110–e111
Dysthymia, 1064*t*
Dystonia, 904, 1026

E

Early goal-directed therapy (EGDT), 335
East Asians, beliefs and values, e27*t*
Eating disorders, 959–968
definition of, 959
diagnostic criteria and clinical presentation of, 960–962
anorexia nervosa, 960–961, 961*b*, 961*f*
binge-eating disorder, 962, 963*f*
bulimia nervosa, 961–962, 962*b*, 962*f*
epidemiology of, 959–960
etiology of, 960
medical complications of, 962–963
pathophysiology of, 960

Eating disorders treatment, 963–968
  general approach to, 964, 964*t*
  nonpharmacologic
    for anorexia nervosa, 964–965
    for binge eating disorder, 966
    for bulimia nervosa, 965
  outcomes of
    desired, 963
    therapeutic, evaluation of, 968
  pharmacologic
    for anorexia nervosa
      antidepressants, 965
      antipsychotics, 965
    for binge eating disorder, 966–968
    for bulimia nervosa
      antidepressants, 965–966
      selective serotonin reuptake inhibitors, 966
  prognosis of, 963–964
Ebola, e146–e149, e396
  biologic agents in, measles, e149–e151
  clinical presentation of, e146–e147, e154*b*
  epidemiology of, e146
  etiology of, e146
  pathophysiology of, e146
  treatment of, e147–e149, e147*f*
    postexposure prophylaxis in, e149
    preexposure prophylaxis in, e148–e149, e148*t*

types of, 1308*t*
Erectile dysfunction treatment, 1312–1330
general approach to, 1313*t*–1315*t*, 1316*f*
outcomes of
desired, 1312
therapeutic, evaluation of, 1329–1330
personalized pharmacotherapy in, 1329
phosphodiesterase inhibitors, 1316–1323
testosterone replacement regimens, 1323–1325
unapproved agents, 1328–1329
papaverine, 1328–1329
penile prostheses, 1329, 1329*f*
phentolamine, 1329
yohimbine, 1328
vacuum erection device in, 1312, 1316, 1317*f*
Ergocalciferol, 629–631, 630*t*
Ergotamine tartrate, 935
for cluster headache, 940
for migraine, acute, 932*t*
Eribulin, 2040*t*
Erlotinib, 2043*t*, 2056–2057
Ertapenem, 1833*t*
Erwinia asparaginase, 2228
Erysipelas, 1734
clinical presentation of, 1734*b*
definition of, 1734
etiology of, 1732*t*
treatment of, 1734
evidence-based, 1735*t*
outcomes of
desired, 1734
therapeutic, evaluation of, 1734
pharmacologic, 1734
Erythritol tetranitrate, 150*t*
Erythrocyte sedimentation rate (ESR), 1441
Erythromycin
for acne vulgaris, 1547, 1553*t*
for chlamydial infections, 1852, 1852*t*
for gonorrhea, 1846, 1847*t*
Erythropoiesis, stimulation of, 1592–1593, 1593*f*
Erythropoiesis stimulating agents, 623–625, 624*t*, 626*f*
adverse effects of, 624–625
dosing and administration, 625
drug-drug interactions, 624–625
efficacy of, 624
pharmacodynamics of, 624
pharmacokinetics of, 624
pharmacology and mechanism of action, 624
Erythropoietin, e407–e408
Escherichia coli, 1798, 1808*t*
Escitalopram, 1053*t*. *See also* Selective serotonin reuptake inhibitors (SSRIs)
E-selectin (ELAM-1), 275
Eslicarbazepine
advantages and disadvantages of, 856
adverse effects of, 852*t*, 856
dosing and administration of, 856
drug interactions, 856
for exacerbations, 855–856
mechanism of action, 855
monitoring of, 852*t*
pharmacokinetics of, 855–856
Esmolol, 317–318
Esmolol hydrochloride, 74*t*
Esomeprazole, 444, 445–446, 463t, 466–468, 472*t*

Esophageal candidiasis
clinical presentation of, 1895*t*
treatment of
in HIV patients, 1898
in non-HIV patients, 1898
Esophageal manometry, in gastrointestinal tract evaluation, e227
Esophagogastroduodenoscopy (EGD), e224–e225, e225*f*
Essential fatty acid deficiency (EFAD), 2331, 2359
Essential hypertension, 46
Esters, 922*t*
Estrogens, 1249, 1335, 2104*t*
for Alzheimer disease, 806
in menopause and perimenopausal/postmenopausal hormone therapy, 1292–1294
adverse effects of, 1292
dosage and administration of, 1292, 1293*t*
oral, 1292
other routes of administration in, 1294
for osteoporosis, 1473
Eszopiclone, 1114
Etanercept, 1448–1449, 1567–1568, 2315*t*
Ethambutol
adverse effects and monitoring of, 1794*t*
for CNS infection, 1677
dosing by age group, 1670*t*, 1788*t*
for tuberculosis, 1786*t*, 1790, 1790*t*
Ethanol, e88
Ethinyl estradiol, 2104*t*
Ethinyl estradiol transdermal patch, 1266*t*, 1281*t*
for endometriosis, 1281*t*
Ethionamide, 1788*t*, 1790*t*, 1792
Ethosuximide
advantages and disadvantages of, 856
adverse effects of, 852*t*, 856
dosing and administration of, 856
drug interactions, 856
for epilepsy, 856
mechanism of action, 856
monitoring of, 852*t*
pharmacokinetics of, 856
therapeutic range of, e44*t*
Ethyl chloride, e91t
Ethylenediamine tetraacetic acid (EDTA), e207
Etodolac, 1425*t*, 1489*t*
Etomidate, 1211*t*, 1212, 1212*t*
Etonogestrel, for endometriosis, 1281*t*
Etoposide, 2040*t*, 2308*t*
Etravirine, 2011*t*, 2013*t*, 2014
Euglobulin clot lysis time (ECLT), 1612*t*
Euthyroid sick syndrome, 318
Event monitors, e171
Everolimus, 157, e427*t*, e430*t*, e431, 679, 1405–1406, 2045*t*, 2058, 2104*t*
Exemestane, 2104*t*
Exenatide, 1169*t*
Exercise stress testing, e172–e173, e173*t*
contraindications to, e173*t*
treadmill testing, e172
Exercise testing, e200–202, e201*t*
Exercise-induced bronchospasm, 350–351, 350f. *See also* Asthma
Exfoliants (peeling agents), 1544–1545
adverse effects and monitoring of, 1552*t*
resorcinol, 1544
retinoids, topical, 1545
salicylic acid, 1544
sulfur, 1544–1545
Exogenous thyroid hormone, 1187
Expectorants, 395
Expiratory reserve volume (ERV), e196
Extended-spectrum β-lactamases (ESBL), 1818
Extracorporeal membrane oxygenation (ECMO), 28, 131
Extrapulmonary tuberculosis, 1780. *See also* Tuberculosis
Extravasation, 2069
Extreme obese, 2386
Eye
anatomy of, 1504*f*
optic disk, 1505, 1505*f*, 1505*t*
visual field, 1505, 1505*f*, 1505*t*, 1506*f*
Ezogabine
advantages and disadvantages of, 856
adverse effects of, 852*t*, 856
dosing and administration of, 856
drug interactions, 856
for epilepsy, 856
mechanism of action, 856
monitoring of, 852*t*
pharmacokinetics of, 856

F

Fab fragments, e303
Factor V Leiden, e76
Factor VIII, 529
Factor VIII concentrate replacement, 1615–1616, 1615*t*
False hyperkalemia, 760
False hypokalemia, 760
Famciclovir, 1855
Famotidine, 444, 446, 463t, 465, 471, 472*t*
Fas ligand pathway, e301
Fasciolopsis buski, e375
Fat
daily requirements, 2336
in enteral nutrition, 2372
intravenous fat emulsion, 2347–2348
Fatigue
in multiple sclerosis, 830
in Parkinson disease, 899*t*
Fatty acids, in enteral nutrition, 2372
Favipiravir, e148*t*, e149
Fc fragments, e303
Febrile neutropenia, in cancer patients, 1943–1960
clinical presentation of, 1945, 1945*b*
etiology of, 1943–1945
Febrile neutropenia treatment, in cancer patients
antibiotic therapy in, after initiation of empirical therapy, 1951, 1952*t*–1955*t*
antifungal therapy in, 1956
antimicrobials therapy in, duration of, 1957–1958
antiviral therapy in, 1956, 1957*t*
approach to, 1945–1949, 1946*f*, 1947*f*, 1947*t*–1948*t*, 1949*t*
colony-stimulating factors in, 1958, 1958*t*
empirical regimes in
β-lactam, 1949–1950
plus aminoglycosides, 1950
fluoroquinolones in, 1950
oral, 1951
vancomycin in, 1950–1951
evidence-based, 1947*t*–1948*t*
outcomes of
desired, 1945
outcome evaluation for, therapeutic, 1960
prophylaxis in, 1958, 1959*t*
for bacterial infections, 1958–1959
for fungal infections, 1959–1960
for other infections, 1960
Febuxostat, 1490*t*, 1491*t*
Fecal occult blood tests, 2140–2141, 2141*t*
Felbamate
advantages and disadvantages of, 857
adverse effects of, 852*t*, 857
dosing and administration of, 857
drug interactions, 857
for epilepsy, 856
mechanism of action, 856
monitoring of, 852*t*
pharmacokinetics of, 857
Felty syndrome, 1441
Fenamates, 914*t*
Fenoldopam mesylate, 74*t*
Fenoprofen, 1425*t*, 1489*t*
Fentanyl
dosing and administration of, 917*t*
for substance-related disorders, 977
Ferric carboxymaltose, 622*t*
Ferric citrate, 629
Ferritin, serum, 1596
Ferumoxytol, 622*t*
Fesoterodine, 1341*t*
Fesoterodine fumarate, 1362
Fetal hemoglobin, 1629
Fever. *See also specific disorders*
definition of, 1649
drug-induced, 1650
false-positives, 1650
infection and, 1649–1650
Feverfew, 938
Fexofenadine, 1526*t*
Fiber, 2336, 2372
Fibrillation. *See specific types*
Fibrinolytic therapy, 175*t*, 177, 184, 188*t*
Fibroblasts, 347
Fibrosis, e233–234
Fick principle, e182
Filgrastim, e407
Finasteride, 1341*t*
Fingolimod, 823*t*, 824*t*, 826–827
Fish oil, 646, 691
Fixed drug eruptions, e337
Fixed-schedule therapy, 996
Flakka, 981
Flecainide, 198, 200*t*, 202*t*, 210
Flexible sigmoidoscopy, 2140
FLG gene, 1578–1579
Flight of ideas, e271
Flow-volume loop, e196, e197*f*
Fluconazole
for CNS infection, 1675
for coccidioidomycosis, 1919
dosing by age group, 1670*t*
for histoplasmosis, 1916
for HSCT infections, 1963
for invasive fungal infections, 1934
for onychomycosis, 1905
for oropharyngeal candidiasis, 1896, 1897
for vulvovaginal candidiasis, 1891–1892, 1891*t*
Flucytosine
for CNS infection, 1675
dosing by age group, 1670*t*
for invasive fungal infections, 1933
Fludarabine, 2038*t*, 2050, 2197
Fludrocortisone, 1219
Fluid, 2336, 2336*t*
Flumazenil, 984
Flunisolide, 1526*t*
Fluoracil, 2146–2148, 2151–2154
Fluoropyrimidines, e79*t*, 2050
Fluoroquinolones, e88*b*, 1161*t*, 1833*t*
for acne vulgaris, 1547
adverse effects and monitoring of, 1656*t*
hepatotoxicity of, e229
for HSCT infections, 1962
for prostatitis, 1840
Fluorouracil, e78*t*, e79*t*, 2038*t*
Fluoxetine, e78*t*, 966, 1053*t*, 1105. *See also* Selective serotonin reuptake inhibitors (SSRIs)

Fluoxymesterone, 1314*t*, 1322*t*, 2104*t*
Fluphenazine. *See also* Antipsychotics
  pharmacokinetics of, 1023
  for schizophrenia, 1018*t*, 1020
Flurbiprofen, 808, 1425*t*
Flutamide, 2172t, 2174
Fluticasone, 1526*t*
Fluvastatin, 148
Fluvoxamine, 966, 1053*t*, 1105. *See also* Selective serotonin reuptake inhibitors (SSRIs)
Focal onset seizures, 839, 841
Focal segmental glomerulosclerosis, 668, 684–685
  clinical presentation of, 684
  epidemiology of, 684
  etiology of, 684
  pathophysiology of, 684
  prognosis of, 685
  steroid-resistant, 685
  treatment of, 684–685
    angiotensin receptor blockers, 685
    angiotensin-converting enzyme inhibitors, 685
    calcineurin inhibitors, 685
    cytotoxic agents, 685
    mycophenolate mofetil, 685
    rapamycin inhibitors, 685
    steroids, 684–685
Focal seizures, 839. *See also* Epilepsy
Folate, 1054, 2135
Folate antagonists, 2050–2051
  methotrexate, 2050–2051
  pemetrexed, 2051
  pralatrexate, 2051
Folic acid, 1596, 2332*t*
Folic acid deficiency anemia, 1602–1603
  epidemiology of, 1602
  etiology of, 1602
  laboratory evaluation of, 1602
  pathophysiology of, 1602
  treatment of, 1602–1603, 1603*t*
Follicle-stimulating hormone (FSH), e280, e281*t*, 2166
Follicular phase, in menstrual cycle, 1245
Folliculitis, 1537, 1733–1734
  clinical presentation of, 1733b
  definition of, 1733
  etiology of, 1733
  treatment of, 1733–1734
    evidence-based, 1735*t*
    outcomes of
      desired, 1733
      therapeutic, evaluation of, 1734
    pharmacologic, 1734, 1737*t*
Fondaparinux, 253–254
  for acute coronary syndromes, 174*t*, 182, 188*t*
  adverse effects of, 253
  dosing and administration of, 254
  drug-drug interactions, 253
  efficacy of, 253
  pharmacokinetics of, 253
  pharmacology and mechanism of action, 253
  for thrombocytopenia, drug-induced, e355
  for venous thromboembolism, 245
Food, thermogenic effect of, 2386
Food poisoning, 1807–1809
  botulinum toxin in, 1808–1809
  epidemiology of, 1807–1809
  etiology of, 1808
  pathogens in, 1808*t*
  treatment of, 1808–1809
Foot ulcers, 1175
Forced expiratory volume (FEV), e196
Forced vital capacity (FVC), e196
Formoterol, 389
Fosamprenavir, 2014, 2014*t*
Fosaprepitant, 501*t*, 502–503
Foscarnet
  dosing by age group, 1670*t*
  drug interactions, 1653*t*
Fosfomycin trometamol, 1833*t*
Fosphenytoin
  allergic reactions to, e323
  for status epilepticus, 874
  therapeutic range of, e44*t*
Fournier gangrene, 1745
Frameshift mutation, e69
Fresolimumab, 687
Frontloading therapy, 996
Frovatriptan, 932*t*, 933*t*
Fructose, 523
Fulvestrant, 2104*t*, 2105
Functional incontinence, 1353. *See also* Urinary incontinence
Functional residual capacity (FRC), e196
  etiology of airflow limitation in, 379
Fungal infections, invasive, 1909–1936. *See also specific infections*
  aspergillosis, 1928–1932
  blastomycosis, 1916–1917
  Candida infections, 1923–1928
    candidemia, 1923–1928
    candiduria, 1928
  coccidioidomycosis, 1917–1920
  cryptococcosis, 1920–1923
  diagnosis of, 1913
  histoplasmosis, 1913–1916
  mycology of, 1909–1911, 1910*f*
    antifungal agent resistance in, 1910–1911, 1912*f*
    antifungal agent susceptibility in, 1910, 1911*t*–1912*t*
    clinical *vs.* microbial resistance, 1910
  pathogenesis and epidemiology of, 1912–1913
  risk factors for, 1913
  treatment of, 1913
    antifungal therapy in, 1932–1936, 1933*f*
      amphotericin B, 1932–1933
      azoles, 1934
      drug interactions, 1935
      drug monitoring in, 1935–1936, 1936*t*
      echinocandins, 1933–1934
      fluconazole, 1934
      flucytosine, 1933
      isavuconazole, 1935
      itraconazole, 1934
      posaconazole, 1935
      voriconazole, 1934–1935
    for emerging pathogens, 1932
      Fusarium, 1932
      mucor infections, 1932
      Scedosporium, 1932
Fungal infections, superficial, 1889, 1889–1905. *See also specific infections*
  oropharyngeal candidiasis, 1892–1900
  prevalence of, 1889
  skin, hair, and nail mycotic infections, 1900–1905
  vulvovaginal candidiasis, 1889–1892
Furamide, e387*t*
Furazolidone, e387*t*
Furosemide, 125*t*, 540*t*, 766
