1 Sickle cell syndromes, which can be divided into sickle cell trait (SCT) and sickle cell disease (SCD), are a group of hereditary conditions characterized by the presence of sickle cell hemoglobin (HbS) in red blood cells. SCT is the heterozygous inheritance of one normal β-globin gene producing HbA and one sickle gene, producing HbS (HbAS). Individuals with SCT are asymptomatic. SCD can be of homozygous or compounded heterozygous inheritance. Homozygous HbS (HbSS) has historically been referred to as sickle cell anemia (SCA) which now also includes HbSβ^0-thal due to similarities in clinical severity. The heterozygous inheritance of HbS with another qualitative or quantitative β-globin mutation results in sickle cell hemoglobin C (HbSC), sickle cell β-thalassemia (HbSβ^+-thal and HbSβ^0-thal), and some other rare phenotypes.[1,2]

Over the years, progress has been made in understanding the relationship between clinical severity and genotype, as well as the natural history of common morbidities associated with SCD. Ongoing research focuses on pharmacotherapies to treat SCD and prevent organ damage. Recent advances in the care of SCD patients have increased life expectancy. Therefore, the transition from pediatric to adult medical care has become a focus to further improve survival and quality of life.[1-7]

SCD is a chronic illness with significant psychosocial consequences for patients, caregivers and society. Frequent hospitalizations can interrupt schooling and result in employment difficulties.[8-10] Acute complications of the disease can be unpredictable, rapidly progressive, and life threatening. Later in life, chronic organ damage and cognitive or emotional impairment can develop.[1,2,7] Because of the complexity and gravity of the illness, it is essential that comprehensive care is available to all patients and that all providers involved have a good understanding of the disease and its management.[1,2,8,11]

EPIDEMIOLOGY

2 SCD affects millions of people worldwide and is most common in people with African heritage.[1,12] The most common SCD genotype is HbSS (~60%-65%), followed by HbSC (~25%-30%), HbSβ^+-thal and HbSβ^0-thal (~5%-10%). Other variants account for less than 1% of patients.[1,2] The disease is common among those with ancestors from sub-Saharan Africa, India, Saudi Arabia, and Mediterranean countries.[2,13] In the United States, about 100,000 Americans have SCD with a prevalence of 1 in 2,500 newborns, 1 in 365 African Americans and 1 in 36,000 Hispanic births.[1,14,15] About 2 million Americans have SCT with a prevalence rate of 1 in 13 African Americans and 1 in 100 Hispanics.[15,16]

About 275,000 babies are born with SCD every year with 85% of births in Africa.[2,12] The prevalence of SCD in the region is determined by the frequencies of SCT. The distribution of SCT reflects the survival advantage in regions where malaria is endemic as the gene mutation offers partial protection against serious malarial infection. Red blood cells (RBCs) carrying the abnormal sickle hemoglobin prevent the normal growth and development of *Plasmodium falciparum* within RBCs. Individuals with SCT are more likely to survive acute malarial illness whereas individuals with SCD-HbSS often present with more severe disease. The incidence of the sickle gene in a population correlates with the historical incidence of malaria and SCT results in partial resistance to the disease.[1,2,12,17]

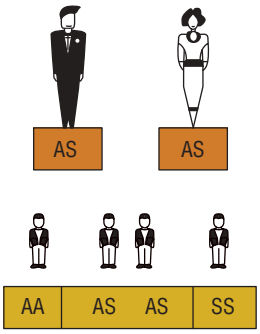

FIGURE 102-1 Sickle cell gene inheritance scheme for both parents with sickle cell trait (SCT). Possibilities with each pregnancy: 25% normal (AA); 50% SCT (AS); 25% sickle cell anemia (SS). (A, normal hemoglobin; S, sickle cell hemoglobin)

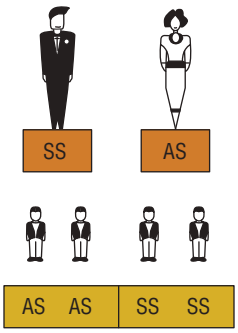

FIGURE 102-3 Sickle cell gene inheritance scheme for one parent with sickle cell trait (SCT) and one parent with sickle cell anemia (SCA). Possibilities with each pregnancy: 50% SCA (SS); 50% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin)

The prevalence of SCD is highest in sub-Saharan Africa. Other areas where the sickle mutation can be found include the Arabian Peninsula, the Indian subcontinent, and the Mediterranean region. Genetic analysis shows that the mutation found in Arabic patients is different from the mutation in those of African descent. SCD gene variants associated with different geographic locations may be responsible for variations in clinical manifestations.[3,5,13]

ETIOLOGY

Normal hemoglobin (hemoglobin A [HbA]) is composed of two α chains and two β chains ($\alpha_2\ \beta_2$). The biochemical defect that leads to the development of HbS involves the substitution of valine for glutamic acid as the sixth amino acid in the β-polypeptide chain. Another abnormal hemoglobin, hemoglobin C (HbC), is produced by the substitution of lysine for glutamic acid as the sixth amino acid in the β-chain. Structurally, the α chains of HbS, HbA, and HbC are identical. Therefore, it is the chemical differences in the β-chain that account for sickling and its related sequelae.[1-3,7]

Homozygous HbSS is the most common form of SCD and occurs when an individual inherits both maternal and paternal β-globin alleles that code for HbS. Figures 102-1 to 102-4 show the probability of inheritance with each pregnancy for the offspring of parents with HbA, SCT, and HbSS. If both parents are carriers, the offspring will have a 25% risk of inheriting SCD and a 50% risk of SCT (see Fig. 102-1). β-Thalassemia is a quantitative hemoglobinopathy resulting from a genetic defect in β-globin production. β-Thalassemia can be co-inherited with HbS and may vary from no β-globin production (β^0) to some β-globin production (β^+). Individuals with HbSS and HbSβ^0-thal have a more severe course than those with HbSC and HbSβ^+-thal and are now both referred to as SCA.[2,7,13]

Several haplotypes characterize the sickle gene, resulting in different clinical and hematologic courses. The three most common haplotypes in the United States are the Bantu haplotype, characterized by severe disease; the Senegal haplotype, characterized by mild disease; and the Benin haplotype, characterized by a course intermediate to that of the other two haplotypes. Although there are a number of other haplotypes seen around the world, the major types outside of the United States include Saudi Arabian and Cameroon, both with milder courses of illness.[2,3,5,7]

PATHOPHYSIOLOGY

Normal adult RBCs contain predominantly HbA (96%-98%). Other forms of hemoglobin are HbA_2 (2%-3%) and fetal hemoglobin (<1%). Normal RBCs are biconcave shape and able to deform to squeeze through capillaries.[1-3,18] Fetal hemoglobin (HbF) is present predominantly in fetal RBCs and is a tetramer of two α-globin chains and two γ-globin chains ($\alpha_2\gamma_2$). Prior to birth, HbF is the predominant hemoglobin type. At around 32 weeks gestation, a switch from the production of γ chains to β chains occurs and consequently, an increase in HbA production is seen. Increased HbF production is seen under severe erythroid stress, such as anemia, post-hematopoietic stem cell transplantation, or chemotherapy or in the hereditary condition, hereditary persistence of fetal hemoglobin (HPFH) where a mutation in the β-globin gene cluster results in continued HbF production after birth. HPFH is a benign, asymptomatic condition.[3,5,19]

In the pathogenesis of SCD, the following are responsible for the various clinical manifestations: impaired circulation, destruction of RBCs, stasis of blood flow and ongoing inflammatory responses. These changes result directly from two major disturbances involving

RBCs: abnormal hemoglobin polymerization and membrane damage (Fig. 102-5).

The solubilities of HbS and HbA are the same under conditions of normal oxygenation. Because of increased hydrophobicity as a result of the valine substitution, solubility of deoxygenated HbS is reduced. Saturation of deoxy-HbS leads to intermolecular binding and formation of thin bundles of fibers, which initially are unstable. However, the increased binding of deoxy-HbS eventually results in cross-linked fibers and stable polymers. This process is influenced by mean corpuscular hemoglobin concentration (MCHC), temperature, intracellular pH, and the circulating amount of HbS. Polymerization allows deoxygenated hemoglobin molecules to exist as a semisolid gel that protrudes into the cell membrane, leading to distortion of RBCs (sickle shaped) and loss of deformability. The presence of sickled RBCs increases blood viscosity and encourages sludging in the capillaries and postcapillary venules. Such obstructive events lead to local tissue hypoxia, which tends to accentuate the pathologic process.[1,2,6]

When reoxygenated, polymers within the RBCs are lost and the RBCs eventually return to normal shape. This process contributes to the vasoocclusive manifestation in that HbS-containing RBCs are able to enter the microvasculature when oxygenated, but sickle when deoxygenated. The cycle of sickling and unsickling results in damage to the cell membrane, loss of membrane flexibility, and rearrangement of surface phospholipids. Membrane damage also alters ion transport, resulting in potassium and water loss, which can lead to a dehydrated state enhancing the formation of sickled forms. After continual repetitions of the process, the RBC membrane develops into rigid irreversibly sickled cells (ISC). Unlike the reversible sickled cells (RSC), which have normal morphology when oxygenated, ISCs are elongated cells and remain sickled when oxygenated. More rigid membranes of HbS-containing RBCs retard flow, particularly through the microcirculation. In addition, sickled RBCs tend to adhere to vascular endothelial cells, which further increase polymerization and obstruction.[1,2,6]

Intermolecular binding and polymer formation are reduced by HbF and to a lesser degree by HbA_2. RBCs that contain HbF sickle less readily than cells without. ISCs, not surprisingly, have a low HbF level. Increased levels of HbF, as in the case of the Saudi Arabian genotype, result in a more benign form of SCD. The amount of HbF and HbA_2 in relation to HbS influences the clinical manifestations and accounts for some of the variability in severity among SCD genotypes.[2,3,5]

Intravascular destruction of sickle cells can occur at an accelerated rate. The stresses of circulation and repetitive sickle–unsickle cycles lead to cell fragmentation. Damage to the cell membrane promotes cell recognition by macrophages. Rigid ISCs are easily trapped, resulting in short circulatory survival and chronic hemolysis. The typical sickled cell survives for about 10 to 20 days, while the life span of a normal RBC is 120 days.[7] Anemia triggers the release of immature RBCs (reticulocytes) from the bone marrow prematurely. Surface adhesion proteins that maintain the reticulocytes inside the marrow adhere to the endothelium in postcapillary venules further blocking the mature HbS-containing RBCs leading to complete occlusion of microvessels.[6,7]

In addition to sickling, other factors contribute to the clinical manifestations associated with SCD. Sickled cells also interact with leukocytes, endothelial cells, and platelets to form an occlusive clot. Hemolysis releases free hemoglobin resulting in generation of reactive oxygen species, nitric oxide (NO) depletion, and vascular inflammation. Chronic NO depletion contributes to vasoconstriction, activation of platelet, and adhesion molecules such as vascular cell adhesion molecule 1 (VCAM-1) and production of potent vasoconstrictor and endothelin 1 (ET-1).[2,20]

Obstruction of blood flow to the spleen by sickle cells can result in functional asplenia, defined as the loss of splenic function with an intact spleen. These patients can also have deficient opsonization. Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly pneumococcal bacteria. Coagulation abnormalities in SCD can be the result of continuous activation of the hemostatic system or disorganization of the membrane layer.[2,6,7,20]

CLINICAL PRESENTATION

3 SCD is usually identified on routine newborn screening programs in the United States. Since 2006, universal newborn screening for SCD is performed in all 50 states. The sensitivity and specificity

TABLE 102-1 Clinical Features of Sickle Cell Trait and Common Types of Sickle Cell Disease

Type	Clinical Features
Sickle cell trait (SCT)	Rare painless hematuria; normal Hb level; heavy exercise under extreme conditions can provoke gross hematuria and complications (normal Hb)
Sickle cell anemia (SCA- HbSS)	Pain episodes, microvascular disruption of organs (spleen, liver, bone marrow, kidney, brain, and lung), gallstones, priapism, leg ulcers; anemia (Hb 6-9 g/dL [60-90 g/L; 3.72-5.59 mmol/L])
Sickle cell hemoglobin C (HbSC)	Painless hematuria and rare aseptic necrosis of bone; pain episodes are less common and occur later in life; other complications are ocular disease and pregnancy-related problems; mild anemia (Hb 9-14 g/dL [90-140 g/L; 5.59-8.69 mmol/L])
Sickle cell β^+-thalassemia (HbSβ^+-thal)	Rare pain; milder severity than HbSS because production of some HbA; Hb 9-12 g/dL (90-120 g/L; 5.59-7.45 mmol/L) with microcytosis
Sickle cell β^0-thalassemia (HbSβ^0-thal)	No HbA production; severity similar to SCA; Hb 7-9 g/dL (70-90 g/L; 4.34-5.59 mmol/L) with microcytosis

Hb, hemoglobin; HbA, hemoglobin A.

Data from references 1, 2, 13, 14 and 22.

of screening methods such as isoelectric focusing high-performance liquid chromatography and hemoglobin electrophoresis approaches 100%. For infants with a positive screening result, a second test should be performed before 2 months of age to confirm the diagnosis. More than 98% newborns in the United States are screened for SCD to identify the disease. Despite universal screening, some infants with SCD escape identification at birth because of extreme prematurity, prior blood transfusion, or inability to contact family.[2,19,21]

SCD involves multiple organ systems, and its clinical manifestations vary greatly between genotypes (Table 102-1).[1,2,13,22] Persons with SCT are usually asymptomatic and SCT is not considered a disease. However, under certain extreme situations where hemoglobin oxygenation is altered, RBC sickling can occur. Sickling of RBCs in the renal medulla, an area with low-oxygen tension, can result in the inability to concentrate urine. Individuals with such impairment can be at risk of dehydration. Microscopic hematuria has been observed, and gross hematuria can occur after heavy exercise. Other reported complications associated with SCT are venous thromboembolism, particularly pulmonary embolism, renal medullary carcinoma and chronic kidney disease.[14,17] Individuals with SCT should be cautious when participating in exercise under extreme conditions, such as athletic or military training. The US Sudden Death in Athletes Registry reported that 0.9% of 2,462 deaths occurred in athletes with SCT. The events in those 23 athletes with SCT were sudden cardiovascular collapse followed by several minutes of gradually worsening symptoms including dyspnea, fatigue and weakness during or after vigorous physical activity.[23] Preventive strategies such as gradual conditioning, adequate rest and hydration are recommended to minimize risk of sudden death in personnel undergoing athletic or military training.[17,23]

The cardinal features of SCD are hemolytic anemia and vaso-occlusion. In individuals with HbSS, anemia usually develops from 4 to 6 months after birth. The delay is due to the presence of HbF in fetal RBCs. HbF production is gradually replaced by HbS, leading to the clinical manifestations of the disease, such as pain and swelling of the hands and feet, commonly referred to as *hand-and-foot syndrome* or *dactylitis* in infants.[1,2]

The common clinical signs and symptoms associated with HbSS include chronic anemia and pallor; fever; arthralgia; scleral icterus; abdominal pain; weakness; anorexia; fatigue; enlargement of the liver, spleen, and heart; and hematuria. Laboratory findings include low hemoglobin level around 6 to 9 g/dL (60-90 g/L; 3.72-5.59 mmol/L), elevated reticulocytes of 10% to 25%, and elevated platelet and white blood cell (WBC) counts. Mean corpuscular volume (MCV) is normal. The peripheral blood smear demonstrates sickled red cell forms.[1,2,14]

Individuals with HbSC disease present with less severe symptoms than that of HbSS and can be characterized primarily by mild anemia (hemoglobin levels of 9-14 g/dL [90-140 g/L; 5.59-8.69 mmol/L] and reticulocytes of 5%-10%), infrequent episodes of pain, persistence of splenomegaly into adult life, and excessive target cells in the peripheral blood smear. In individuals with heterozygous HbS-β-thalassemia syndrome, severity of disease depends on the thalassemia gene involved.[1,2]

Predictors for severe disease in children have not been established. Dactylitis before 1 year of age, average hemoglobin less than 7 g/dL (70 g/L; 4.34 mmol/L) in the second year of life, and leukocytosis in the absence of infection are markers of disease severity previously described but not validated in a subsequent study.[24] The Cooperative Study of Sickle Cell Disease recently reported that reticulocytosis is associated with increased risk of death and stroke in infants.[25] Early acute chest syndrome during the first 3 years of life is a predictor for recurrent episodes throughout childhood. Children with concomitant SCD and asthma have increased frequencies of acute chest syndrome and pain episodes and increased mortality.[26] Factors associated with decreased survival in adults with SCD include frequency of sickle cell pain, elevated WBC, cerebrovascular events, renal failure, proteinuria and pulmonary hypertension.[26,27] With improved survival for SCD, chronic manifestations of the disease contribute to the increased morbidity later in life.

COMPLICATIONS

Acute Complications

Fever and Infection

Functional asplenia and failure to make antibodies against encapsulated organisms contribute to the high risk of overwhelming sepsis in individuals with SCD. Penicillin prophylaxis and vaccination have significantly reduced the overall risk of *Streptococcus pneumonia* bacteremia, but nonvaccine serotypes of *Streptococcus pneumonia* has been reported.[2] Children with SCD remain at a greater risk of invasive pneumococcal infections when compared to those with other underlying diseases or healthy children.[28] This is not specific to SCD but to the presence of vascular device and is not due to asplenia. Would like to rephrase and move.[29] Other encapsulated organisms are *Haemophilus influenzae, Neisseria meningitidis,* and *Salmonella*, with the latter known to cause osteomyelitis and pneumonia in SCD. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* should be considered in older children with infiltrates on chest radiograph. Viral infections (eg, influenza and parvovirus B19) can result in severe morbidity.[1,2] In children with SCD admitted for bacteremia, coagulase-negative *Staphylococcus* was associated with central venous access;[29] and should be considered for those with central line placed for chronic transfusion. In adults, overt pneumococcal bacteremia is less common and pathogens such as *Staphylococcus aureus* and gram-negative organisms are associated with immunosuppression, indwelling catheter and bone and joint infections.[30]

All SCD patients with fever greater than 38.5°C (101.3°F) must be evaluated to determine the risk of infection or sepsis; and those with temperature 39.5°C (103.1°F) and appear ill should be hospitalized. Evaluation should include physical examination, complete blood count with reticulocyte count, blood culture, chest radiograph, urinalysis, and urine culture. Lumbar puncture may be

TABLE 102-2 Acute Sickle Cell Complications

Vasoocclusive pain episodes[a]
Clinical features: Acute painful infarction without changes in Hb; almost all patients with SCA will have episodes of acute pain. Recurrent acute pain results in bone, joint, and organ damage and chronic pain. Vasoocclusive episodes most commonly involve the bones, liver, spleen, brain, lungs, and penis. Acute long bone pains can be accompanied by signs of inflammation, making it difficult to differentiate from osteomyelitis. Abdominal involvement can resemble a surgical abdomen. Precipitating factors include infection, extreme weather conditions, dehydration, and stresses.
Signs and symptoms: Deep throbbing pain; local tenderness, erythema, and swelling can be seen. Fever and leukocytosis are common. Dactylitis usually occurs in young infants. Jaundice and increased transaminases can be present if liver is involved.
Evaluation: Frequent physical examination, CBC, reticulocyte count, and urinalysis. Based on symptomatology, the following may be needed: needle aspiration to rule out osteomyelitis, abdominal studies (radiograph, computed tomography scan, etc.), liver function tests, bilirubin, culture, and chest radiograph.
Aplastic crisis[b]
Clinical features: Acute decrease in Hb with decreased reticulocyte count (usually <1%); transient suppression of RBC production in response to bacterial or viral infection, most common being parvovirus B19.
Signs and symptoms: Headache, fatigue, dyspnea, pallor, and tachycardia; can also present with fever, upper respiratory or gastrointestinal infection symptoms.
Evaluation: CBC, reticulocyte count, radiograph, cultures (blood, urine, and throat), evaluation of viral infection (eg, parvovirus titers).
Acute splenic sequestration[c]
Clinical features: Acute exacerbation of anemia due to sequestration of large blood volume by the spleen. More commonly seen in patients with functioning spleens (eg, infants with HbSS and older children and rarely adults with HbSC disease); onset often is associated with viral or bacterial infections; recurrences are common and can be fatal.
Signs and symptoms: Sudden onset of fatigue, dyspnea, and distended abdomen; rapid decrease in Hb and Hct with elevated reticulocyte count, abdominal pain, splenomegaly, vomiting, hypotension, and shock.
Evaluation: Close monitoring of vital signs, spleen size, and oxygen saturation, CBC, reticulocyte count, and cultures.

CBC, complete blood count; Hb, hemoglobin; HbSC, sickle cell hemoglobin C; HbSS, Homozygous; Hct, hematocrit; RBC, red blood cell.

[c]*Data from references 1, 2, 14, 22 and 39.*

needed, especially in young and toxic-appearing children. Fever in a patient with SCD should be considered a medical emergency with rapid administration of intravenous antibiotics due to risk of overwhelming sepsis.[1,22]

Children with SCD may experience a severe complication due to infection that results in impaired production of RBCs. An aplastic crisis is characterized by a decrease in the reticulocyte count and the rapid development of severe anemia (Table 102-2). The bone marrow becomes hypoplastic and is most often associated with a viral infection, particularly parvovirus B19.[1,2,14]

Neurologic

Neurologic abnormalities and cognitive deficits are well documented in patients with SCD. Vasoocclusive processes can lead to cerebrovascular occlusion that manifests as signs and symptoms of overt stroke, such as headache, paralysis, aphasia, visual disturbances, facial droop and convulsions. The risk of stroke is highest for HbSS and lowest for HbSβ^+-thal. The incidence of cerebral infarct in HbSS is 11% by age 20 years and 24% by age 45 years with a recurrence rate as high as 70% in 3 years. The highest risk occurs during the first decades, in particular ages 2 to 5. The risk is lowest before age 2 secondary to the protective effect of HbF. Ischemic strokes occur in 54% of cerebrovascular accidents with the highest risk before age 10 years and after 30 years of age; whereas hemorrhagic strokes are more common when patients are in their 20s and is associated with poor outcome.[1,2,7,31,32]

In addition to neurologic examination, evaluation of acute events include computed tomography (CT) scan and magnetic resonance imaging (MRI). Asymptomatic or silent infarcts are detected by screening MRI; and transcranial Doppler ultrasound (TCD) is important in primary stroke prevention and is used. In addition, electroencephalography (EEG) can be used if there is a history of seizure.[1,2,22]

About 10% to 30% of SCD who have HbSS with no prior history of stroke have been found to have changes on MRI of the brain consistent with infarction or ischemia. Silent cerebral infarcts can be associated with increased risk of stroke, decreased neurocognitive functions, behavioral changes and poor academic performances. Ongoing intermittent cerebral ischemia episodes have been found in asymptomatic children without concurrent illness.[33] Finally, lower intelligence, visual-motor impairments and neuropsychological dysfunctions have been reported in patients not affected by acute or silent strokes and are associated with severity of anemia.[1,2,31,33]

Acute Chest Syndrome

Acute chest syndrome (ACS) is the second most common cause of hospitalization and responsible for about 25% of deaths among individuals with SCD. ACS is defined as a new pulmonary infiltrate associated with one or more of the following: cough, dyspnea, tachypnea, chest pain, fever, wheezing, and new-onset hypoxia. As many as one-half of individuals with SCD experience at least one episode of ACS.[2,18,34]

Risk factors for ACS and recurrence include young age (peak incidence between age 2 and 4 years), lower HbF, higher leukocytes, history of asthma or bronchial hyper-responsiveness, and smoke exposure. Genotype and haplotype also influence the occurrence. Patients with HbSS and HbSβ^0-thal have higher incidence than those with HbSC and HbSβ^+-thal. The prevalence is higher with African haplotypes than that of Saudi Arabia.[1,18,26]

The primary etiology for ACS is pulmonary vascular occlusion. Infections, fat emboli released from bone marrow or direct adhesion of RBCs to the pulmonary vasculature lead to the inflammation and injury of the lung. The most common cause of ACS is infection. Viral causes are more common in children than adults. Bacteria that cause community acquired pneumonias can be the pathogens, which include *Mycoplasma pneumonia, Chlamydia pneumoniae,* and *Streptococcus pneumoniae*.[2,18,34]

ACS is more common in children but more severe in adults. Hypoxia is a predictor for severity and outcome. In addition to physical examinations, evaluations may include complete blood count and chest radiographs. In severe cases, CT scan, perfusion scintigraphy, transthoracic echocardiography and bronchoscopy may also be considered to exclude other etiologies. Pulmonary changes often involve the lower lobes of the lungs and may cause pleural effusions. Bilateral infiltrates or multiple lobe involvement may be an indication of poor prognosis.[2,18,26] Pulmonary manifestations must be recognized early and managed aggressively as ACS can rapidly progress to pulmonary failure and death.[26]

Priapism

Stasis and sickling of RBCs within the sinusoids of the corpora cavernosa is the primary mechanism of priapism, a sustained painful erection. In recent years, a better understanding of pathophysiology of priapism has identified other mechanisms at molecular level, such as abnormal NO signaling as result of chronic NO depletion. Stuttering priapism is repeated intermittent attacks up to several hours

before remission; ischemic priapism is a persistent painful erection greater than 4 hours and should be considered as an emergency. Thirty percent to 45% of males with SCD will present with at least one episode of priapism during their lifetime and the first episodes often occur during childhood. Impotence has been reported after repeated episodes and is directly related to the duration prior to treatment.[1,35,36]

Sickle Cell Pain

Acute episodes of pain are the most common symptoms and reason for seeking treatment in SCD. Sickle cell pain may be caused by bone or muscle infarction due to vasoocclusion (see Table 102-2). Although fever, infections, dehydration, hypoxia, acidosis, and sudden temperature alterations can precipitate pain, multiple factors often contribute to its development.[2,37,38] The back, chest and extremities are the most common locations of pain but pain can occur in any location such as abdomen or head and lead to confusion with other acute complications such as stroke.[1,22]

Individuals with HbSS experience more frequent episodes of pain than those with HbSC or other variants. Risk factors associated with painful episodes include older age, iron overload, higher Hb and lower HbF.[1,2,14,38] Biomarkers for severity of pain during vasoocclusion episodes include elevated C-reactive protein and lactate dehydrogenase (LDH).[4] Dactylitis (hand-and-foot syndrome) is a subtype of sickle cell pain, occurring in infancy and early childhood and is characterized by redness and swelling of the dorsal aspects of the hands, feet, fingers, and toes. The episodes are painful but usually do not result in permanent damage.[1,2]

Splenic Sequestration

Splenic sequestration is the sudden massive enlargement of the spleen resulting from the sequestration of sickled RBCs in the splenic parenchyma (see Table 102-2). Hematocrit and hemoglobin concentrations dramatically fall, with reticulocytosis and no evidence of marrow failure or accelerated hemolysis. The trapping of the sickled RBCs by the spleen also leads to a decrease in circulating blood volume, which can result in hypotension and shock. The condition is most often seen in infants and children because their spleens are intact, and can cause sudden death in young children. Splenic enlargement may also be acutely painful due to rapid capsular expansion. Over time, repeated splenic infarctions lead to autosplenectomy and the spleen can no longer become engorged. Sequestration usually occurs between one to 4 years of age and is uncommon beyond 5 year for children with HbSS and HbSβ^0-thal because autoinfarction usually is completed by then. For HbSC and HbSβ^+-thal, autoinfarction is delayed and sequestration can occur even during adulthood.[1,2,22,39]

Chronic Complications

Pulmonary

Over 90% of children survive into adulthood, increasing the contribution of pulmonary manifestations to the morbidity and mortality of SCD. Physical exam and history should be performed to identify signs and symptoms of respiratory conditions such as asthma, restrictive lung disease and chronic obstructive pulmonary disease. Pulmonary function testing is recommended to determine the cause in symptomatic patients but not as a routine screening tool.

Pulmonary hypertension, defined as a resting mean pulmonary arterial pressure (PAP) 25 mmHg or greater by right heart catheterization, is associated with increased morbidity and mortality in SCD. Symptoms of pulmonary hypertension include shortness of breath during normal activities, fatigue, syncope, and peripheral edema. A less invasive test, tricuspid regurgitant jet velocity by Doppler echocardiography, is frequently performed initially to estimate PAP. Serum NT-pro-BNP measurement is an alternative test that can be used in patients with normal renal function when Doppler echocardiography is not an option. The American Thoracic Society recommends assessment of mortality risk using noninvasive (indirect) or invasive direct measurement to guide management of pulmonary hypertension (Table 102-3).[22,26,40,41]

The prevalence of asthma in children with SCD is similar to that of general population. Symptoms of asthma exacerbation can overlap with ACS making it difficult to differentiate the two. Asthma and wheezing in individuals with SCD have been associated with ACS and vasoocclusive pain episodes and increased mortality. Early screening for asthma and other signs of respiratory conditions has been recommended.[1,22] In general, the national asthma education and prevention program asthma management guideline should be utilized in the management of asthma in children with SCD. Inhaled corticosteroids are first line for persistent symptoms.[42]

Skeletal and Skin Diseases

Bone diseases are common in SCD and vitamin D level has been suggested to be the biomarker.[4] Osteonecrosis, particularly of the femoral or humeral heads, causes permanent damage and disability.[14,22,43,44] Low bone mineral density can occur early with a prevalence of over 70% reported in adults with SCD.[43] Osteopenia and osteoporosis associated with low bone formation has been reported in both males and females with SCD.[43,44] Children with SCD also have an increased incidence of osteomyelitis; the organism most

TABLE 102-3 Risk Stratification and Management Recommendation for Pulmonary Hypertension

	Recommendations	Strength	Evidence Quality
Increased risk for mortality[a]	Hydroxyurea	Strong	Moderate
Increased risk for mortality, unresponsive or not candidates for hydroxyurea	Chronic transfusion therapy	Weak	Low
RHC-confirmed PH, venous thromboembolism, no risk factors for hemorrhage	Indefinite anticoagulant therapy	Weak	Low
Elevated TRV alone Elevated NT-pro-BNP alone	No PAH therapy[b]	Strong	Moderate
RHC-confirmed marked elevation of pulmonary vascular resistance, normal pulmonary artery wedge pressure, presence of related symptoms	• A trial of prostacyclin agonist or endothelin receptor antagonist • Phosphodiesterase-5 inhibitor should not be used as first-line therapy	Weak Moderate	Very low Moderate

[a]Increased risk for mortality: (1) Tricuspid regurgitant jet velocity (TRV) greater than or equal to 2.5 m/s, (2) an N-terminal pro-brain natriuretic peptide (NT-pro-BNP) level greater than or equal to 16 pg/mL (ng/L; 1.9 pmol/L) or (3) right heart catheterization (RHC)-confirmed pulmonary hypertension (PH).

[b]PAH therapy: (1) prostacyclin agonist (epoprostenol, treprostinil, iloprost), (2) soluble guanylate cyclase stimulator (riociguat), (3) endothelin receptor antagonist (bosentan, macitentan, ambrisentan), (4) phosphodiesterase-5 inhibitor (sildenafil, vardenafil, tadalafil).

Data from references 40 and 41.

often responsible is *Salmonella*.[30,44] In addition to necrosis of joints, chronic leg ulcers most commonly seen in the medial and lateral malleolus (ankles) can become a difficult and painful problem for adult. Ulcers are often seen after trauma or infection and are usually slow to heal.[22]

Ocular Manifestations

Ocular problems seen in patients with SCD include transient monocular blindness, visual field defects from retinal hemorrhage, retinal detachment, vitreous hemorrhage, venous microaneurysms, and neovascularization. The incidence of proliferative sickle retinopathy and vitreous hemorrhage is up to 50%. Vasoocclusion in the eye can occur as early as 20 months of age, and clinically detectable retinal diseases usually occur during adolescence and early adulthood. Despite the less systemic manifestations, individuals with HbSC develop serious retinal complications more often and earlier than those with HbSS. Annual retinal examination is recommended for patients with SCD to prevent blindness from retinopathy and other complications.[22,45]

Hepatobiliary Diseases

Cholelithiasis is a common complication of SCD resulting from chronic hemolysis and increased bilirubin production, and leading to biliary sludge and/or stone formation. The risk of gallstones increases with age: 12% for age 2 to 4 years, 43% by age 15 to 18 years and 70% to 75% in adults. Cholecystitis, exemplified by pain in the right upper quadrant, can be confused with an acute sickle pain episode in the abdomen. Mild baseline hepatomegaly and elevation of lever function tests are found in individuals with SCD. Cirrhosis occurred in 18% of young adults with SCD. Causes for development of chronic hepatic disease include repeated occlusion in the liver, iron overload, and hepatitis.[22,46]

Cardiac Diseases

Cardiovascular complications associated with anemia, including cardiac enlargement and various murmurs, can occur in patients with SCD. Patients experience various degrees of exertional dyspnea, tachycardia, and palpitation because of the decreased oxygen-carrying capacity of the blood. Left ventricular diastolic dysfunction has been reported in 18% of adults with SCD and is associated with increased mortality, especially in patients with pulmonary hypertension. Left ventricular stiffness and left ventricular hypertrophy have been reported, and the progression is speculated to lead to diastolic dysfunction later in life. Acute myocardial infarction in adults with SCD may be under-recognized due to the high incidence of sickle cell acute chest pain.[7,47,48]

Renal Diseases

Renal dysfunction in SCD begins during infancy as evidenced by glomerular hyperfiltration. Other manifestations include inability to concentrate urine, hematuria, tubular acidosis, papillary necrosis, glomerulonephritis, microalbuminuria, and proteinuria. Enuresis, as a result of increased urine production, occurs in 42% of children ages 6 to 8 and 9% in young adults age 18 to 20. Microalbuminuria is typically the first sign of chronic kidney disease, which has been associated with increased mortality.[22,49,50]

Growth and Development

Delayed growth and sexual maturation are common in patients with SCD. Despite normal birth weight and length, growth retardation occurs between 6 months and 4 years with height, weight and bone mass index being affected. The poor growth cannot be explained by nutritional factors alone. Alternations in growth factors as well as increased metabolic rate are factors contributing to the growth failure. Pubertal delay by 1 to 2 years is common in adolescents with SCD and fertility problems have been reported in both men and women with SCD.[14,51-53]

Psychiatric

Depression and anxiety are more common in children and adults with SCD than in the general population and have a significant impact on quality of life.[54,55] Depression is associated with pain episodes in children with SCD. In addition, depression is associated with social support for parents as well as individuals with SCD.[54] DSM-IV psychiatric diagnoses in adolescents with SCD include attention-deficit-hyperactivity, oppositional defiant, conduct, major depressive and anxiety disorders.[56]

Pregnancy

Pregnancy introduces an increased risk for the mother with SCD and for the fetus. Some women experience increased pain episodes during pregnancy and the anemia of SCD can lead to intrauterine growth retardation. Preterm labor and premature delivery are common in mothers with SCD, and the risk of spontaneous abortion is increased. The incidence of cesarean delivery and pregnancy-related complications are higher when compared to mothers who do not have SCD.[22,57,58]

TREATMENT

Desired Outcomes

The goal of treatment is to reduce hospitalizations, complications, and mortality. Treatment for SCD involves the use of general measures to meet the unique demands for increased erythropoiesis. Additional interventions can be aimed at preventing or treating complications of the disease. When an acute complication occurs, the type and severity of the episode determines the appropriate therapeutic plan.

With availability of public health programs and comprehensive care, most children in developed countries survive through childhood.[2,14] The median survival rate is estimated to be 42 years for males and 48 years for females for HbSS, and 60 years for males and 68 years for females for HbSC.[12,59] With increased life expectancy, outcome evaluation for management of SCD therefore should include assessment of health-related quality of care in both adults and children.

Patients with SCD require lifelong multidisciplinary care. All patients with SCD should receive regularly scheduled comprehensive medical evaluations. Because of the complexity of the disease, a multidisciplinary team is needed to provide high quality medical care, education, counseling, and psychosocial support. Appropriate comprehensive care can have a positive impact on both longevity and quality of life. This care includes the use of evidence based treatment combining general symptomatic supportive care, preventative medical therapies and specific disease modifying therapies aimed at altering hematologic capacity and function.

Routine Health Maintenance

SCD is a complex chronic disease involving multiple organs. In addition to the preventive care recommended for the general population, individuals with SCD also need health maintenance and screenings that are focused on minimizing complications from the disease (Table 102-4).

Immunizations

Administration of routine immunizations is crucial preventive care in managing SCD. Children 6 months and older and adults with SCD should receive influenza vaccine annually. The most updated immunization and catch-up schedules are provided by the Centers for Disease Control and Prevention (http://www.cdc.gov/vaccines/schedules.)

TABLE 102-4 Health Maintenance

Invasive Pneumococcal Infection Prevention[a]
1. Oral penicillin until age 5 for children with HbSS
   a. Discontinue penicillin prophylaxis at age 5 unless have had splenectomy or invasive pneumococcal infection
2. Consider no penicillin prophylaxis for children with HbSC disease and HbS—thal unless they have had a splenectomy

Immunization[b]
1. All individuals should receive immunization according to The Advisory Committee on Immunization Practices
2. Pneumococcal Vaccine
   a. All infants should receive complete series of PCV13.
   b. All children should receive PPSV23 at age 2 years and second dose at age 5 years.
   c. Children age 6-18 years with functional or anatomic asplenia should receive 1 dose of PCV13.
   d. Adults (age ≥ 19 years) with functional or anatomic asplenia.
      i. Not previously received PCV13 or PPSV23
         1. One dose PCV13; followed by PPSV23 at least 8 weeks later
      ii. Previously received PPSV23
         1. One dose PCV13 at least 1 year after last PPSV23
      iii. For individual age 19-64 years, a second dose of PPSV23 should be 5 years after first dose and no sooner than 8 weeks after PCV13
3. Haemophilus Influenza (Hib) Vaccine
   a. Children age greater than 5 years who have not previously received Hib vaccine should receive one dose
4. Meningococcal Vaccine (indicated for persons have functional or anatomic asplenia)
   a. 4-dose primary series to be administered with Hib-MenCY-TT (2, 4, 6, and 12-15 months) or MenACWY-CRM (2, 4, 6, and 12 months)
   b. Booster dose to be administered with MenACWY-CRM or MenACWY-D
      i. Primary series completed prior to age 7: booster dose 3 years after primary series and repeat every 5 years thereafter
      ii. Primary series completed age 7 or older: booster dose 5 years after primary series and repeat every 5 years thereafter
   c. Unvaccinated children 7-23 months: 2 doses of MenACWY-CRM with second dose at least 12 weeks after the first dose AND after first birthday
   d. Unvaccinated children age 2 years or older and adults: 2 doses of MenACWY-CRM or MenACWY-D 8-12 weeks apart
      i. MenACWY-D to be given at least 4 weeks after completion of all PCV13 doses
   e. Adults previously vaccinated should receive MenACWY-CRM or MenACWY-D every 5 years
5. Influenza vaccine annually for age ≥ 6 months

Renal[c]
1. Screen for proteinuria by age 10 and annually if negative
2. Initiate ACE inhibitor for adults with microalbuminuria or proteinuria without apparent cause

Pulmonary Hypertension (PH)[d]
1. Noninvasive tests (Doppler echocardiography or alternatively, serum NT-pro-BNP measurement) can be used to assess mortality risk
2. Echocardiogram to screen for PH and associated cardiac problems by age 8 for those with frequent cardiorespiratory symptoms
3. The optimal frequency for Doppler echocardiography is unknown but every 1-3 years seems to be reasonable
4. Children with evidence of PH by echocardiogram should be further evaluated: pulmonary function test, polysomnography, oxygenation assessment and thromboembolic disease
5. Cardiac catheterization should be performed before initiation of PAH-specific therapy

Ophthalmological Evaluation[c]
1. Eye examination begins at age 10 and rescreen at 1-2 year intervals

Stroke Prevention[c]
1. Children with SCA: transcranial Doppler (TCD) annually beginning at age 2 until at least age 16
2. Chronic transfusion therapy for stroke prevention in children with elevated (>200 cm/s) TCD results

PCV13, 13-valent conjugate pneumococcal vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine; ACE Inhibitor, angiotensin converting enzyme inhibitor; NT-pro-BNP, N-terminal pro-brain natriuretic peptide; PAH, pulmonary artery hypertension; PH, pulmonary hypertension.

Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly *S. pneumoniae*. Prior to the routine use of penicillin prophylaxis and the development of pneumococcal vaccines, invasive pneumococcal disease was 20- to 100-fold more common in children with SCD than in healthy children. Reduced mortality has been associated with the introduction of pneumococcal vaccines.[2,30]

Two different pneumococcal vaccines are available. The 13-valent pneumococcal conjugate vaccine (PCV13; Prevnar®) induces good antibody responses in infants and children less than 2 years of age. Immunization with the PCV13 is recommended for all children, regardless of SCD status, younger than 24 months of age. Infants should receive the first dose after 6 weeks of age. Two additional doses should be given at 2-month intervals, followed by a fourth dose at age 12 to 15 months. One dose of PCV13 should be given to children age 6 to 18 years and adults with functional or anatomic asplenia (see Table 102-4). The 23-valent pneumococcal polysaccharide vaccine (PPSV23; Pneumovax®23) is recommended for all children with functional or acquired asplenia but must be given after 2 years of age because of poor antibody response. To cover different serotypes, PPSV23 should be given starting at 2 years of age, and be administered 2 months after the last dose of the PCV13. A booster dose of PPSV23 is recommended 5 years after the first dose.[22,60,61]

The risk of meningococcal disease is also higher in SCD and vaccination is recommended for individuals with functional or acquired asplenia. Three different meningococcal vaccines are available: Meningococcal groups C and Y and *Haemophilus* b tetanus toxoid conjugate vaccine (Hib-MenCY-TT), and quadrivalent (serogroups A, C, Y, and W-135) meningococcal conjugate vaccines, MenACWY-CRM and MenACWY-D. Infants with functional asplenia should receive 4-dose series with Hib-MenCY-TT at 2, 4, 6, and 12 through 15 months or MenACWY-CRM at 2, 4, 6, and 12 months. If the first dose of Hib-MenCY-TT is given at or after 12 months of age, 2 doses should be given at least 8 weeks apart. Children over 2 years and adults with functional or acquired asplenia should receive a primary immunization series with two doses of the quadrivalent vaccine given 8 weeks apart. MenACWY-D should be

given at age 2 years or older and at least 4 weeks after completion of all PCV13. A booster is recommended every 5 years for individuals with SCD.[22,62,63]

Penicillin

4 Penicillin prophylaxis until at least 5 years of age is recommended in children with SCD HbSS or HbSβ^0-thal, even if they have received PCV13 or PPSV23 immunization, as prophylaxis against invasive pneumococcal infections. An effective regimen that reduces the risk of pneumococcal infections by 84% is penicillin V potassium at a dosage of 125 mg orally twice daily until the age of 3 years, followed by 250 mg twice daily until the age of 5 years. Individuals who are allergic to penicillin can be given erythromycin 20 mg/kg per day. Penicillin prophylaxis is not routinely given in older children, based on a study demonstrating no benefit over placebo beyond the age of 5 years. However, continuation of oral pneumococcal prophylaxis should be considered on a case-by-case basis, and is recommended for anyone with a history of invasive pneumococcal infection or surgical splenectomy.[22,24]

Clinical **Controversy...**

The need for routine penicillin prophylaxis in HbSC and HbSβ^+-thal patients is controversial because these patients have less severe disease. The original trial showing decreased morbidity from invasive infection included children with HbSS or SCA. But some clinicians recommend that children with any genotype should start penicillin prophylaxis as severe and fatal pneumococcal infections can occur with HbSC and HbSβ^+-thal.

Fetal Hemoglobin Inducers

HbF reduces polymer formation of HbS due to its high-oxygen affinity. Increased HbF levels significantly correlate with decreased RBC sickling and RBC adhesion and observational studies show a relationship between HbF concentration and severity of SCD. Individuals with SCD and low HbF levels experience more frequent pain and higher mortality. HbF levels of 20% or greater reduce the risk of acute sickle cell complications. Based on these observations, HbF induction has become a treatment modality for patients with SCD.

Hydroxyurea

Hydroxyurea (HU), a chemotherapeutic agent, stimulates HbF production and increases the number of HbF-containing reticulocytes and intracellular HbF. The antineoplastic activity of HU is related to inhibition of DNA synthesis by blocking the conversion of ribonucleoside to deoxyribonucleotides. The exact mechanism of HbF production is unknown, but is postulated that the cytotoxic effect in the bone marrow stimulates stress erythropoiesis and triggers rapid erythroid regeneration and shifts erythrocyte hemoglobin production to HbF. In addition, HU increases NO levels, reduces neutrophils and monocytes, has antioxidant properties, alters the RBC membrane, increases RBC deformability by increasing intracellular water content, and decreases RBC adhesion to the endothelium.[1,22,24]

HU can decrease the frequency of acute sickle cell pain and is FDA approved for adults with SCD based on the results of the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH Trial), a double-blind, placebo-controlled randomized controlled trial. In that study, HU significantly reduced the frequency of painful episodes, risk of ACS, need for blood transfusions, and number of hospitalizations. The incidence of death, stroke, and hepatic sequestration in the HU and placebo groups was not significantly different during the evaluation period. However, a follow-up study showed a 40% reduction in mortality with HU over a 9-year period. The original 299 patients from the MSH study were followed for 17.5 years and the results suggest improved survival with the long-term use of HU.[2,7,64,65]

Studies in pediatric patients have demonstrated similar results to the MSH Trial with no adverse effects on growth and development. In addition, some patients treated with HU therapy had possible recovery or preservation of splenic and brain functions, including cognitive performances. The Transcranial Doppler with Transfusions Converting to Hydroxyurea study (TWiTCH) closed early after interim analysis found that HU was not inferior to chronic blood transfusions to prevent primary stroke. However, the Stroke with Transfusions Changing to Hydroxyurea (SWiTCH) trial also closed early when the interim analysis showed that HU was inferior to chronic transfusions to prevent recurrent stroke. Therefore, chronic transfusions with iron chelation remain the best therapy to prevent stroke.[2,7,24] Initiating HU early and prior to development of complications may be beneficial. The Pediatric HU Phase III Clinical Trial (BABY HUG) evaluated HU therapy in young children ages 9 to 18 months.[66] Infants were randomized between HU and a placebo; the primary endpoints were splenic and renal function. Investigators found no significant difference in the primary endpoints but did find fewer episodes of pain and dactylitis with no significant toxicities. HU reduced the risk of painful events, ACS, renal enlargement, hospitalizations, and transfusions. In addition, improved urine concentration ability as demonstrated by higher urine osmolality was reported.[66-68] In a retrospective study of children aged 3 to 18 years with SCD, significant reduction in mortality, fewer hospitalizations and emergency visits and shorter admissions were reported.[69]

The most common adverse effect of HU is bone marrow suppression, resulting in neutropenia, thrombocytopenia, anemia, and decreased reticulocyte count. These hematologic adverse effects usually recover within 2 weeks of therapy discontinuation. Other side effects include dry skin and hyperpigmentation of skin or nails.[2,67,68,70] Long-term adverse effects of HU therapy in patients with SCD are not fully known although no serious adverse effects were reported in the long term (17.5 years) follow-up study of the MSH trial.[65] Studies in children have not demonstrated delays in growth or puberty, increased risk of infections or genotoxicity.[70,71] Myelodysplasia, acute leukemia, and chronic opportunistic infection associated with T-lymphocyte abnormalities have been reported in other patient populations treated with higher doses of HU. Reproductive toxicity is also a concern. High-dose HU has been shown to be teratogenic in animals, but normal pregnancies have been reported in women with SCD who received HU during pregnancy.[53]

Although HU is only FDA approved for adults with SCD, the National Institutes of Health (NIH) has supported its use in children and adolescents (**Table 102-5**).[22] Clinical indications for HU include frequent painful episodes, severe symptomatic anemia, a history of ACS, or other severe vasoocclusive complications. The starting dose for adult is 15 mg/kg per day rounded to the nearest 500 mg as a single daily dose (**Fig. 102-6**). A lower dose of 5 to 10 mg/kg per day is used for patients with chronic disease. The Baby HUG study found that children can be safely started at 20 mg/kg. Dosage can be increased by 5 mg/kg up to a maximum of 35 mg/kg in 8 week intervals if the patient does not demonstrate significant adverse effects and blood counts are stable. HU dosage should be individualized based on response and toxicity. In general, 3 to 6 months of therapy are required before improvement is observed. Medication adherence can be an issue. Since the MCV generally increases as the level of HbF increases, monitoring MCV is an inexpensive and convenient method to monitor response and adherence.[2,22,66,72]

5 Patients receiving HU should be closely monitored for toxicity. Blood counts should be checked every 4 weeks during dose titration and every 8 weeks thereafter. Treatment should be interrupted if hematologic indices fall below the following values: absolute neutrophil count, 2,000 cells/mm^3 (2 × 10^9/L); platelet count,

TABLE 102-5 Recommendations on Hydroxyurea Therapy

	Recommendation	Strength	Evidence Quality
Adults with HbSS or Sβ⁰-thalassemia			
1. Three or more sickle cell associated moderate to severe pain crises per year	Treat with hydroxyurea	Strong	High
2. Sickle cell associated pain that interferes with daily activities and quality of life		Strong	Moderate
3. History of severe and/or recurrent ACS		Strong	Moderate
4. Severe symptomatic chronic anemia that interferes with daily activities or quality of life		Strong	Moderate
Infants 9 months of age and older, children, and adolescents with HbSS or Sβ⁰-thalassemia regardless clinical severity	Offer hydroxyurea	Strong	High (age 9-42 months); Moderate (>42 months)
Chronic kidney disease and taking erythropoietin	Hydroxyurea can be added	Weak	Low
HbSC or HbSβ⁺-thalassemia with recurrent sickle cell associated pain that interferes with daily activities or quality of life	Consider hydroxyurea	Moderate	Low
History of stroke and unable to implement chronic transfusion	Initiate hydroxyurea	Moderate	Low

Data from references 22 and 64.

80,000 cells/mm^3 (80 × 10^9/L); hemoglobin, 5 g/dL (50 g/L; 3.1 mmol/L); or reticulocytes, 80,000 cells/mm^3 (80 × 10^9/L) if the hemoglobin concentration is less than 9 g/dL (90 g/L; 5.59 mmol/L). Other laboratory abnormalities warranting temporary discontinuation of therapy are a 50% increase in serum creatinine and a 100% increase in transaminases. After recovery has occurred, treatment should be resumed at a dose that is 5 mg/kg per day lower than the dose associated with toxicity. If no toxicity occurs after 12 weeks with the lower dose, the dose can be increased by 2.5 to 5 mg/kg per day. If the increased dose produces hematologic toxicity, the patient should be maintained at the last tolerated dose with no further escalation except for normal growth or weight gain.[22,64,72]

Chronic Transfusion Therapy

RBC transfusions play an important role in the management of SCD. In acute illness, transfusions can be life saving and the guidelines for acute transfusion are discussed in a later section. Chronic transfusion programs can prevent serious complications of SCD. The primary indication for chronic transfusion is primary and secondary stroke prevention and amelioration of organ damage.[1,2,73] Blood transfusions can be administered as a simple transfusion, a manual exchange or an automated exchange called erythrocytapheresis. Exchange transfusion frequently requires permanent venous access and is associated with higher cost but has the advantage of increasing normal (donor) HbA, limiting volume, minimizing hyperviscosity and transfusional iron overload.[22]

6 In children with an overt stroke, chronic transfusions are used as secondary stroke prevention and reduce stroke recurrence from about 50% to about 10% over 3 years. An initial stroke in SCD can be devastating and transfusions can be given for primary stroke prevention. Prophylactic transfusions significantly reduced the incidence of first stroke over a 2-year period in children 2 to 16 years of age who were at an increased risk for stroke based on TCD. The risk of stroke was reduced from 16% in patients receiving usual care to 2% in those who received prophylactic transfusions.[1,4,73] Chronic transfusions should be considered in selected children and adults with previous stroke or children with abnormal TCD measurements.[22] Chronic transfusions have also been used in patients with severe or recurrent ACS, debilitating pain, splenic sequestration, recurrent priapism, chronic organ failure, intractable leg ulcers, severe chronic anemia with cardiac failure, and complicated pregnancies, although data supporting the efficacy of chronic transfusion in these situations are limited.[1,74]

The goal of transfusions is to achieve and maintain an HbS concentration of less than 30% of total hemoglobin in the primary and secondary prevention of neurologic complications. Transfusions are usually given every 3 to 4 weeks, but the frequency of transfusion is adjusted to maintain the desired HbS levels. The risk of recurrent stroke decreases after 2 years of transfusion therapy and, in the absence of recurrent stroke, many clinicians will liberalize the HbS goal to less than 50%.[2,14] The optimal duration of primary prophylactic transfusion therapy in children with abnormal TCD is not clear, but discontinuation of transfusions has been associated with a 50% stroke recurrence rate within 12 months and abnormal blood flow velocity on TCD in children with SCD. The results of the TWiTCH trial suggest that some patients can safely transition to HU therapy after normalization of TCD and no evidence of cerebral vasculopathy with at least a 6-month overlap in transfusions and HU therapy. For secondary stroke prevention, transfusions should be continued indefinitely.[2,14,73] A pilot study suggested that HU could be started prior to discontinuation of transfusion for secondary stroke prevention with at least a 6-month overlap with transfusions. However, the phase III trial of switching HU for transfusion in secondary stroke prevention, the SWiTCH trial, was closed early due to an increased risk of recurrent strokes in the HU arm when compared to the transfusions arm.[14,31] The NIH recommends HU for prevention of recurrent stroke only if implementation of a transfusion program is not possible.[22]

Although the benefits of transfusion therapy are clear in some clinical situations, its role in other situations such as an acute pain episode remains controversial.[22] The risks of transfusion therapy must be weighed against possible benefits. The risks associated with transfusion therapy include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and nonhemolytic transfusion reactions. The use of leukocyte-reduced RBC transfusions in chronically transfused patients can reduce the risk of nonhemolytic transfusion reactions and viral transmission.[2,14] Transfusion-related infections also remain a concern. All patients should be immunized with hepatitis A and B vaccines. Other viruses that can be transmitted through blood products are parvovirus B19, hepatitis,[74] and cytomegalovirus. The risk of contracting human immunodeficiency virus from blood transfusions, although still of concern, has decreased with routine blood screening.[2,30]

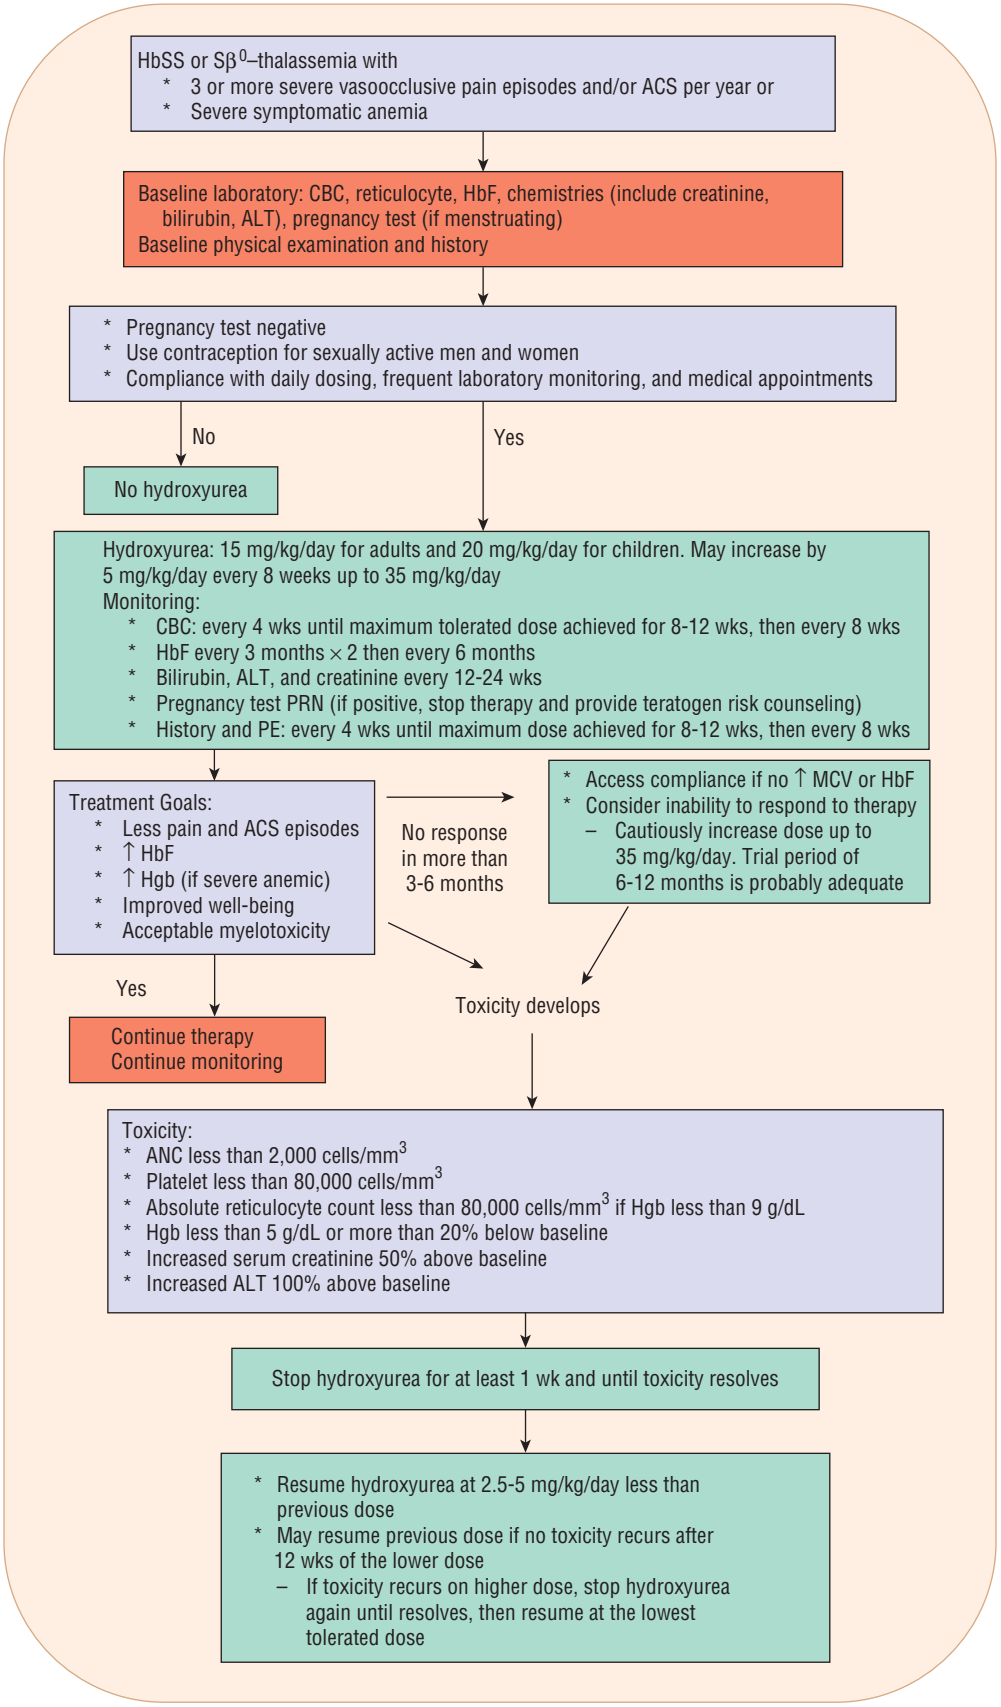

FIGURE 102-6 Hydroxyurea use in sickle cell disease. (ACS, acute chest syndrome; ALT, alanine aminotransferase; ANC, absolute neutrophil count; CBC, complete blood cell count; Hb, hemoglobin; HbF, fetal hemoglobin; HbSS, homozygous sickle cell hemoglobin; HbSSβ^0, sickle cell β^0-thalassemia; MCV, mean corpuscular volume; PE, physical examination; PRN, as needed; RBC, red blood cell) *(Data from references 1, 22 and 64.)*

Alloimmunization or alloantibody formation occurs in 19% to 37% of SCD patients who receive RBC transfusions and results from antigen differences on the red cell surface between the primarily Caucasian donor pool and recipients with SCD. Alloimmunization can make it difficult to find cross-matched blood and cause delayed hemolytic transfusion reactions. To prevent alloimmunization, patients receiving chronic transfusions should receive the best cross-matched blood including extended typing of other red cell antigens especially C, E, and Kell or full RBC phenotyping.[22,73,74]

The development of alloimmunization can be life threatening for individuals with SCD. Delayed hemolytic transfusion reactions (DHTR) usually occur within 7 to 10 days after transfusion but can occur as early as 2 days or as late as 20 days after transfusion. During a DHTR, patients develop symptoms consistent with hemolysis such as worsening pain, especially abdominal pain, severe anemia due to hemolysis of the transfused unit and reticulocytopenia, further aggravating the anemia. Subsequent transfusions can further worsen the clinical situation because of the presence of multiple antibodies making cross-matching difficult. Life-threatening events can be treated with steroids and intravenous immunoglobulin. Recombinant erythropoietin has been used in patients with reticulocytopenia.[73] Recovery, as evidenced by reticulocytosis with a gradual increase in the hemoglobin level, may occur only after further transfusions are withheld. Although some patients tolerate further transfusions after recovery, especially if the donor unit is negative for the offending alloantibody, others cannot avoid recurrent transfusions and may experience another hemolytic transfusion reaction. Rituximab has been used in two patients to prevent recurrent DHTR. It is generally preferable to prevent the development of DHTR by performing RBC phenotyping and, at a minimum, transfusing individuals with blood that is C, E, and Kell negative.[2,22,74]

Transfusional iron overload is another complication of RBC transfusions, and patients should be counseled to avoid excess dietary iron.[73,74] Abnormal liver biopsy results showing mild to moderate inflammation or fibrosis have been reported. Iron overload assessments include liver function test annually or semiannually and serum ferritin. Iron overload can be confirmed by liver biopsy or less invasively by MRI.[22,75] Three chelating agents are available. Deferoxamine has been used as a chelating agent for decades but must be administered by subcutaneous or intravenous infusion. Oral chelation agents, deferasirox and deferiprone have been shown to be equally effective as deferoxamine with demonstrated acceptable safety profile in long-term studies up to 5 years.[7,75-77] Deferasirox is given once daily (20-30 mg/kg) and the most common side effects are transient skin rash and gastrointestinal symptoms such as nausea, vomiting, diarrhea, and abdominal pain. Deferiprone has good oral bioavailability but a short half-life. The usual dose for deferiprone is 75 to 100 mg/kg per day in three divided dose. Similar to deferasirox, the common adverse effects for deferiprone are rashes and gastrointestinal symptoms but the most concerning side effects are neutropenia and agranulocytosis.[75-77]

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation (HSCT) is currently the only therapy that can cure patients with SCD. The overall survival rate and disease-free survival rate for children and young adults with sibling matched donors, has been reported at 95% to 98% and 87% to 92%, respectively.[78,79] The reported incidences of acute and chronic GVHD ranged from 5% to 17% and 0% to 3%, respectively. Other complications included seizures, marrow rejection, and sepsis. Improved growth, stabilization or improvement of CNS abnormalities and recovery of splenic dysfunction were observed in posttransplant SCD patients, but gonadal failure and delayed sexual development in females requiring hormonal replacement have been reported.[80]

The optimal candidates for unrelated matched allogeneic HSCT are SCD patients who are younger than 16 years of age, have a severe form of SCD and complications such as refractory pain, stroke, or recurrent ACS. Because allogeneic HSCT performed in young children before organ damage and alloimmunization occur is associated with increased success, counseling and screening for sibling matched donors during the first year of life is now recommended. The risks associated with allogeneic HSCT must be carefully considered, as the transplant-related mortality rate is about 5% to 10%, and graft rejection is about 10%. Other risks associated with allogeneic HSCT include secondary malignancies. Neurologic events, such as intracranial hemorrhage and seizures during transplant, were seen more frequently in patients with a history of stroke.[81-83]

Unfortunately, many children who are eligible for HSCT do not have an HLA-matched sibling donor and unrelated HLA-matched transplants are associated with higher transplant-related mortality. Umbilical cord blood is another potential donor source with some advantages over marrow donors including a lower incidence of severe GVHD and a larger donor pool from which to select donors, but such advantages are offset by longer time to engraftment and a higher rate of graft rejection.[80,82] Use of nonmyeloablative allogeneic HSCT in adults and pediatric patients reported mixed donor-recipient chimerism and reversal of SCD in several clinical trials and has the advantage of less acute toxicity.[78-80]

Clinical **Controversy...**

Consideration of HSCT before disease complications develop rather than waiting for severe problems to manifest has been advocated for asymptomatic individuals with HLA-identical sibling.

Treatment of Complications

Parents and older children should be educated on the signs and symptoms of complications and conditions that require urgent evaluation. During acute illness, patients should be evaluated promptly because deterioration can occur rapidly. Fluid balance should be maintained because dehydration and fluid overload can worsen complications associated with SCD. Oxygen saturation by pulse oximetry should be maintained at least 92% or at baseline. New or increasing supplemental oxygen requirements should be investigated.

Episodic Transfusions for Acute Complications

Indications for acute blood transfusions include (1) acute exacerbation of baseline anemia, such as aplastic crisis if the anemia is severe, hepatic or splenic sequestration, or severe hemolysis; (2) ACS, stroke, intrahepatic cholestasis, or acute multisystem organ failure; and (3) preparation for procedures that require the use of general anesthesia.[22] Patients in whom chronic transfusions can be useful include primary or secondary stroke prevention, patients with complicated obstetric problems, refractory leg ulcers, or refractory and protracted painful episodes. Acute transfusion is not indicated for priapism, uncomplicated pain or asymptomatic anemia. Simple transfusion or partial exchange transfusion can be used though red cell exchange has been shown to have superior outcomes when compared to simple transfusion in overt stroke. If simple transfusion is used, volume overload leading to congestive heart failure can occur if anemia is corrected too rapidly in patients with severe anemia. In addition, increases in hemoglobin levels to greater than 10 g/dL (100 g/L; 6.21 mmol/L) can cause hyperviscosity and should be avoided.[14,22]

Infection and Fever

Patients with SCD should be evaluated as soon as possible for any fever greater than 38.5°C (101.3°F). Criteria for hospitalization

include an infant younger than 1 year, history of previous bacteremia or sepsis, temperature greater than 39.5°C (103.1°F), WBC greater than 30,000 cells/mm^3 (30 × 10^9/L) or less than 5,000 cells/mm^3 (5 × 10^9/L) and/or platelets less than 100,000 cells/mm^3 (100 × 10^9/L), and evidence of other acute complications or toxic appearance. Outpatient management can be considered in older nontoxic children with reliable family caregivers. Antibiotic choice should provide adequate coverage for encapsulated organisms.[2,22,30]

7 Ceftriaxone should be used for outpatient management because it provides coverage for 24 hours. If admitted, cefotaxime can also be used. For patients with cephalosporin allergy, clindamycin can be used. Vancomycin should be considered for acutely ill children or if *Staphylococcus* is suspected. A macrolide antibiotic should be added if *Mycoplasma pneumoniae* is suspected such as in ACS. Penicillin prophylaxis should be discontinued while the patient is receiving broad-spectrum antibiotics. Acetaminophen or ibuprofen can be used for fever control. Increased fluid requirements may be present because of poor oral intake and/or increased insensible losses contributing to dehydration.[1,30]

Cerebrovascular Accidents

Patients with acute neurologic events must be hospitalized and monitored closely. Physical and neurologic examination should be performed every 2 hours. Acute treatment for children should include exchange transfusion to maintain hemoglobin at about 10 g/dL (100 g/L; 6.21 mmol/L) and HbS less than 30%, anticonvulsants for patients with a seizure history, and therapy for increased intracranial pressure if needed. Chronic transfusion therapy should be initiated for children with ischemic stroke as discussed earlier. In adults presenting with ischemic stroke related to atherosclerotic disease and not occlusion by sickled red cells, thrombolytic therapy should be considered if it is less than 3 hours since the onset of symptoms.[1,2,32]

Acute Chest Syndrome

Patients with ACS should use incentive spirometry frequently (eg, at least every 2 hours while awake) to reduce atelectasis development. In addition, proper management of pain is important. The goal is to provide relief while avoiding analgesic-induced hypoventilation. Appropriate fluid therapy is important as overhydration can cause pulmonary edema and exacerbate respiratory distress. Early use of broad-spectrum antibiotics, including a macrolide or quinolone in adults, is also recommended. Studies indicate that infection is the most common cause of ACS and can involve gram-positive, gram-negative, or atypical bacteria. Oxygen therapy is indicated for all patients who are hypoxic or in acute distress. In a patient with a history of reactive airway disease, asthma or wheezing on examination, a trial of bronchodilators is appropriate. Transfusions are indicated for severe ACS with worsening hypoxia and increased work of breathing.[1,14,18]

Steroids can decrease inflammation and endothelial cell adhesion. Glucocorticoids can decrease the duration of hospitalization and need for transfusions and other supportive care but can also increase the readmission rate for other sickle cell-related complications. Another potential therapy is the use of NO, which relaxes and dilates blood vessels. Its hematologic effects include inhibition of platelet aggregation and reduction in the polymerization tendency of HbS. Marked improvement of pulmonary status and cardiac output were reported in case reports of patients with ACS.[1,14,34]

Priapism

Stuttering priapism, episodes that last a few minutes to 2 hours, may resolve spontaneously with exercise, warm bath and oral analgesics. Prolonged episodes lasting more than 2 to 3 hours require prompt medical attention. The initial goals of treatment are to provide appropriate analgesic therapy, reduce anxiety, produce detumescence, and preserve testicular function and fertility. Treatment given within 4 to 6 hours can usually reduce erection. Aggressive hydration and adequate pain control should be initiated. Use of ice packs is not recommended. Heat (hot water bottles, hot packs, or sitz baths) can provide comfort without precipitating pain crisis. Although transfusions have been given to these patients, transfusions are not recommended for this use because they have not been shown to be efficacious and are associated with severe neurologic sequelae.[1,24]

Clinicians have used both vasoconstrictors and vasodilators in the treatment of priapism. Vasoconstrictors, such as diluted phenylephrine (10 mcg/mL) or epinephrine (1:1,000,000), are thought to work by forcing blood out of the corpus cavernosum into the venous return. In one uncontrolled open-label study, aspiration followed by intrapenile irrigation with a 1:1,000,000 solution of epinephrine was effective and well tolerated with 37 of 39 episodes experiencing resolution. Detumescence can be achieved more rapidly using penile irrigation than simple transfusion but the procedure should be performed by an urologist with experience in the treatment of priapism.[36,84]

Vasodilators, such as terbutaline and hydralazine, relax the smooth muscle of the vasculature. This relaxation allows oxygenated arterial blood to enter the corpus cavernosum, which displaces or washes out the damaged sickle cells that are stagnant in the corpus cavernosum. Terbutaline has been used to treat priapism, but it has not been formally studied in patients with SCD.[36,84] In one case report, a single oral sildenafil dose at onset of priapism aborted episodes. However, long-term studies of sildenafil have shown an increase in the frequency of pain episodes.[84,85] Surgical interventions used in severe refractory priapism have included a variety of shunt procedures. These surgical procedures have been successful in some cases, but they have a high failure rate and potential serious complications, which include impotence, skin sloughing, cellulitis, and urethral fistulas.[36,84]

Modalities to prevent priapism are limited and not well studied. Pseudoephedrine (30 or 60 mg/day given orally at bedtime) and leuprolide, a gonadotropin-releasing hormone, have been used to decrease the number of recurrent episodes of priapism. HU therapy can also be used, but the effect of HU on risk of priapism has not been formally investigated. Finally, antiandrogens (bicalutamide and finasteride) have been used in SCD for treatment of recurrent or refractory priapism without major side effects.[84] The role of chronic transfusion in preventing priapism remains unclear and transfusion is not recommended for long-term management.[22,84]

Clinical **Controversy...**

Some clinicians transfuse patients to maintain an HbS level less than 30% to prevent recurrent priapism. Duration of such regimens should be limited to 6 to 12 months. Clinical practice guidelines do not recommend chronic transfusion to prevent recurrent priapism.

Aplastic Crisis

Treatment of aplastic crisis is primarily supportive, and most patients recover spontaneously within 5 to 10 days. The only treatment may be blood transfusion if the anemia is severe or symptomatic. The reticulocyte count is used to detect the suppression of red cell production and the need for transfusion. The most common cause, parvovirus B19, is contagious and infected patients should be placed in isolation. In addition, contact with pregnant healthcare providers should be avoided because parvovirus infection during the midtrimester of pregnancy can result in hydrops fetalis and stillbirth.[1,2,30]

Splenic Sequestration

Splenic sequestration is a major cause of mortality in young children with SCD. The sequestration of RBCs in the spleen can result

in a rapid drop of hemoglobin, leading to hypovolemia, shock, and death. Immediate treatment with fluid resuscitation and blood transfusions is indicated to correct hypovolemia. Broad-spectrum antibiotic therapy, which includes coverage for *S. pneumoniae* and *H. influenzae*, can also be beneficial if the patient is febrile as infection can precipitate sequestration.[14,22]

Recurrent episodes occur in about half of patients and are associated with increased mortality. Options for management of recurrence include observation and splenectomy.[22] Increased risk of invasive infection after splenectomy is a concern in very young children, but most experts agree individuals with HbSS develop splenic dysfunction as early as 6 months of age and have acquired asplenia by 5 years of age and by 10 to 12 years for those with HbSC. Splenectomy is probably indicated, even after a single sequestration crisis, if that sequestration was life threatening. Splenectomy should be considered after repetitive episodes, even if they are less serious. For children younger than 2 years of age, chronic blood transfusions are recommended by some experts to prevent sequestration and delay splenectomy until the age of 2 years, when the risk of post-splenectomy septicemia is lower and pneumococcal vaccination has been completed. Finally, splenectomy should also be considered for patients with chronic hypersplenism.[1,2,22,39]

Acute Sickle Cell Pain

Hydration and analgesia are the mainstays of treatment for vaso-occlusive (painful) episodes (Table 102-6). Patients with mild pain crisis can be treated as outpatients with rest, increased fluid intake, warm compresses, and oral analgesics. Hospitalization is necessary for moderate-to-severe pain or when oral analgesics fail to relieve pain. A pain episode may be precipitated by several risk factors including infection. In the setting of pain and fever, an infectious etiology should be evaluated, and appropriate empiric therapy should be initiated in patients. In patients with severe symptomatic anemia, transfusions may be indicated. Fluid replacement given intravenously or orally to correct or prevent hydration at 1 to 1.5 times the maintenance requirement is recommended. Close monitoring of fluid status is essential as aggressive hydration, particularly with sodium-containing fluids, can lead to volume overload, ACS, and heart failure.[1,22,24]

The frequency and severity of acute pain episodes associated with SCD are variable. Pain should be assessed and analgesic therapy should be tailored for each patient and each individual episode. Several verbal and nonverbal pain assessment tools are available and should be used to measure the intensity of pain. Unfortunately, they have not been validated for sickle cell pain. However, pain scales validated for use in children, such as the Wong-Baker FACES scale should be used in pediatric patients with SCD pain. The healthcare provider should choose one tool appropriate for age and use it routinely to assess pain. Other useful information to guide choice of analgesics should include previous effective agents and their dosages, response to therapy and previous clinical course, and duration of pain episodes.[86-88]

8 Aggressive therapy that relieves pain and enables the patient to attain maximum functional ability should be initiated in patients with acute pain. Mild-to-moderate pain should be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen, unless there are contraindications to their use. Ketorolac may be useful for patients requiring intravenous therapy. Because of increased risk of gastrointestinal bleeding, it is recommended to limit the duration of therapy to 5 days or less. Ketorolac has also been associated with acute nonreversible kidney failure in a patient with SCD and should be used with caution and renal function monitored appropriately. When acetaminophen is used, it is important to monitor the total dose of acetaminophen administered in patients who may also be receiving the agent for fever or another acetaminophen-containing product for pain. If mild-to-moderate pain persists, an opioid should be added.[14,22,86,87]

Severe pain should be treated aggressively until the pain is tolerable. Commonly used opioids include morphine, hydromorphone, fentanyl, and methadone. The weak opioids, codeine, and hydrocodone, are used to manage mild-to-moderate pain usually in the outpatient setting. Meperidine has no advantages as an analgesic and many disadvantages. Meperidine toxicity is caused by accumulation of the metabolite normeperidine which can cause central nervous system side effects, ranging from dysphoria to seizures. Effective combination therapy, such as an NSAID and an opioid, can enhance analgesic efficacy while decreasing side effects.

Both prior history and current assessment should be considered in the management of acute sickle cell pain. For patients whose typical pain improves in a short time, preparations with a short duration of action are appropriate. For patients whose pain requires many days to resolve, sustained-release preparations combined with a short-acting product for breakthrough pain are more appropriate. If the patient has been on long-term opioid therapy at home, tolerance can develop. In these cases, the acute pain can be treated with an opioid of different potency or a larger dose of the same medication. Intravenous administration provides a rapid onset of action and therefore is preferred for severe pain. Intramuscular injections should be avoided. Children may actually deny pain due to fear of injections. Analgesics should be titrated to pain relief. In patients with continuous pain, the analgesic should be given as a scheduled dose or continuous infusion. Continuous infusion has the advantage of less fluctuation of blood levels between dosing intervals. As needed dosing is only indicated for breakthrough pain. Patient-controlled analgesia (PCA) is commonly prescribed for severe pain episodes. When used properly, PCA allows patients to have control over pain therapy and minimizes the lag time between perception

TABLE 102-6 Management of Acute Pain of Sickle Cell Disease

Principles
1. Treat underlying precipitating factors
2. Avoid delays in analgesia administration
a. Initiate analgesic within 30 minutes of triage or 60 minutes of registration
3. Use pain scale to assess severity
4. Choice of initial analgesic should be based on previous pain pattern, history of response, current status, and other medical conditions
5. Schedule pain medication; avoid as-needed dosing
6. Provide rescue dose for breakthrough pain
7. If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics
8. Frequently assess to evaluate pain severity and side effects; titrate dose as needed
9. Treating adverse effects of opioids is part of pain management
10. Consider nonpharmacologic intervention (eg, relaxation techniques, guided imagery, deep breathing)
11. Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a product with a rapid onset is also needed for breakthrough pain
Analgesic regimens
Mild-to-moderate pain: nonopioid ± weak opioid
Moderate-to-severe pain: weak opioid or low dose of a strong opioid ± nonopioid
Severe pain: strong opioid + nonopioid
Other adjunct therapy
Hydration, heating pads, relaxation, and distraction
Laxatives for constipation
Antihistamine for itching
Antiemetics for nausea or vomiting

Data from references 86-88.

of pain and administration of analgesics. Studies have shown PCA use reduced cumulative dosage required for pain control. The transdermal fentanyl patch has also been used successfully, but its role in sickle cell acute pain crisis is unclear because of its slow onset of onset of pain relief (12-16 hours) and fixed dosage form, which makes it difficult to titrate the dose. Other alternative pain management techniques such as physical therapy, massage, biofeedback, and relaxation therapy can be helpful as adjunct therapy.[86-88]

Suboptimal pain relief has been reported in both emergency room and hospitalized patients. The most common cause of suboptimal pain control in children and adults with SCD is the suspicion of addiction.[22] This obstacle is especially common in adolescents. In one study, 53% of emergency physicians believed that 20% of SCD patients are psychologically addicted to opioid analgesics. Another barrier to effective pain control is the difference in perception between patients, family, and healthcare providers. Patients with SCD have been reported to experience pain over 50% of days, and they develop coping strategies including flat affect. Patients who have inadequate pain control can exhibit anxiety and drug-seeking behavior for fear of pain. Tolerance to opioids may also be misinterpreted as drug addiction by healthcare providers and families. Aggressive pain control, frequent monitoring of pain during episodes, and tapering medication according to response are factors that minimize physical dependence. The use of a protocol has been shown to result in optimal management of pain control in SCD.[24,86-89]

With better understanding of NO and inflammation on vasculopathy, therapy targeting blood rheology, endothelium adhesion or inflammation have been explored as adjunct therapy. Inhaled NO has been studied as therapy to abort pain at onset of episodes. Significant reduction of pain scores in adult patients received inhaled NO in the emergency room. However, no differences in duration of episodes, hospital stay, or opioid use when given to hospitalized adult and pediatric patients were observed.[90,91] In a randomized controlled trial in children hospitalized for painful episodes, arginine, the precursor for NO, reduced total opioid use by more than 50%. Length of hospital stay was not reduced significantly but the pain scores were significantly lower at discharge when compared to placebo.[92] Systemic corticosteroids, methylprednisolone and dexamethasone have also been evaluated as an adjunct therapy for pain control. Shorter duration of analgesic therapy and duration of hospitalization were reported but increased risk of readmission was also reported.[93]

Chronic Sickle Cell Pain

As the number of adults living with SCD increases due to improved survival, the prevalence of disease morbidities including chronic pain also increases. Most of the published research has focused on the prevention of pain and the management of acute pain episodes. The mechanisms of chronic pain development in SCD are poorly understood and no systematic studies have evaluated risk factors for chronic pain development. Central sensitization and peripheral neural sensitization have been hypothesized to play a role in the development of chronic SCD pain.[37,38,94] Currently, there are no published reports of other medications such as selective serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors and anticonvulsants commonly used to treat chronic pain in patients with SCD. Treatment of chronic pain in SCD requires a multidisciplinary approach and most physicians with expertise in treating SCD recommend following established guidelines for chronic pain.[95]

PERSONALIZED PHARMACOTHERAPY

The mainstay of treatment in SCD involves medical therapy both for supportive care and disease modification. Classically, pharmacotherapy is individualized by weight-based dosing. However, new research is evaluating approaches to further personalize therapy. For example, many adults with SCD have abnormal renal function due to intrarenal sickling. HU, the most important disease modifying medication, is renally excreted with urinary recovery of 40% of the administered dose in adults with SCD. A lower initial dose of 5 to 10 mg/kg per day is recommended for individuals with creatinine clearance of less than 60 mL/min (1 mL/s).[22] Pharmacokinetic differences between adult and pediatric patients were not reported in initial studies. As a result, investigators designed a prospective clinical trial, the Hydroxyurea Study of Long-Term Effects (HUSTLE, NCT00305175), to evaluate interpatient variability among children taking HU. For the first-dose pharmacokinetic studies, 51 of 87 patients showed a "fast" absorption profile with an earlier and higher maximum concentration after a single dose of 20 mg/kg. Although several parameters were associated with maximum tolerated dose (MTD) and HbF at MTD, the investigators concluded that standardized dose titration to myelosuppression remains the best option.[96]

Adults and children with SCD require the use of acute and chronic pain medications including opioids to control painful episodes. Some patients have clinically demonstrated inadequate relief to analgesic dosing with codeine. Children who failed oral therapy with codeine were found to carry a polymorphism in the *CYP2D6* gene resulting in a poor metabolizer phenotype. The CYP2D6 isoenzyme mediates the metabolism of codeine to morphine. These results have led to early discontinuation of codeine analgesics in children with SCD if no response is seen after their first dose and use of alternative oral analgesics for the treatment of pain at home. Often in treating individuals with SCD, analgesia is not obtained even with very high intravenous opioid doses. A recent review highlighted several enzymes that play a role in morphine metabolism that may be altered in patients with SCD including UGT2B7, a morphine-metabolizing enzyme; OPRM1, a mu opioid receptor or ABCB1, a transporter protein at the blood brain barrier. However, further investigation is needed and genetic testing has not been used to guide morphine dosing.[97,98]

The concept of individualized therapy in SCD is being tested with the identification of single nucleotide polymorphisms (SNPs) associated with severity of disease and HbF responses to HU therapy. Increases in HbF with HU appeared to be related to baseline levels suggesting that genomic profiles may contribute to the differences. Genome-wide association studies have identified several loci in HbF expression. BCL11A is a transcription factor that regulates hemoglobin switching and could account for the variability of HbF levels between individuals with high and low HbF. Different biomarkers have been studied in SCD to identify complications and phenotypic variability. The potential use of biomarkers and genome-based modification of phenotype in SCD may allow a personalized therapeutic approach in the future.[97]

EVALUATION OF THERAPEUTIC OUTCOMES

9 SCD is a complex disorder that requires multidisciplinary comprehensive care. All patients should receive regular medical evaluation to provide preventive care, establish baseline symptoms and laboratory values, monitor changes, and provide education appropriate for age. For infants younger than 1-year-old, medical evaluations every 2 to 4 months are recommended. Beyond 2 years of age, evaluation can be extended to every 6 to 12 months with modifications depending on severity of the illness.

Routine laboratory evaluation including complete blood cell counts and reticulocyte counts every 3 to 6 months up to 2 years of age, then every 6 to 12 months; HbF level should be screened annually until 2 years of age. Evaluation of renal, hepatobiliary, and pulmonary function should be done annually. TCD screening is recommended to start at age 2 years and performed annually for children with HbSS and HbSβ. Ophthalmologic examination

to screen for retinopathy is recommended at around age 10 to 12 years for those with HbSC and 14 years for HbSS. In patients with recurrent ACS, pulmonary function tests should be done to establish baseline values and identify declines in lung function as well as an evaluation by pulmonology to screen for lower airway hyper-responsiveness.

It is essential that immunizations and prophylactic antibiotics be given. When infections do occur, appropriate antibiotic therapy should be initiated, and the patient should be monitored for laboratory and clinical improvement. The efficacy of HU can be measured as a decrease in the number, severity, and duration of sickle cell pain episodes. HbF concentrations or MCV values can also provide some indication of the patient's response to therapy. When painful episodes do occur, the effectiveness of analgesics can be measured by subjective assessments made by the patient, and healthcare practitioners. The success of poststroke blood transfusions can be measured by clinical progression or the occurrence of subsequent strokes. Finally, indicators can be used for measurements of quality of care for children with SCD.

ABBREVIATIONS

ACS	acute chest syndrome
CT	computed tomography
ET-1	endothelin 1
GVHD	graft-versus-host disease
HbA	hemoglobin A
HbAS	one normal (hemoglobin A) and one sickle cell hemoglobin (hemoglobin S) gene
HbC	hemoglobin C
HbF	fetal hemoglobin
HbS	sickle cell hemoglobin
HbSβ^+-thal	hemoglobin sickle cell β^+-thalassemia
HbSβ^0-thal	hemoglobin sickle cell β^0-thalassemia
HbSC	sickle cell hemoglobin C
HbSS	homozygous sickle cell hemoglobin (hemoglobin S)
HLA	human leukocyte antigen
HPFH	hereditary persistence of fetal hemoglobin
HSCT	hematopoietic stem cell transplantation
HU	hydroxyurea
ISC	irreversibly sickled cell
MCHC	mean corpuscular hemoglobin concentration
MCV	mean corpuscular volume
MRI	magnetic resonance imaging
MSH	Multicenter Study of Hydroxyurea in Sickle Cell Anemia
MTD	maximum tolerated dose
NIH	National Institutes of Health
NO	nitric oxide
NSAID	nonsteroidal anti-inflammatory drug
NT-pro-BNP	N-terminal pro-brain natriuretic peptide
PAH	pulmonary artery hypertension
PAP	pulmonary arterial pressure
PCA	patient-controlled analgesia
PCV7	7-valent pneumococcal conjugate vaccine
PCV13	13-valent pneumococcal conjugate vaccine
PPSV23	23-valent pneumococcal polysaccharide vaccine
RBC	red blood cell
SCA	sickle cell anemia
SCD	sickle cell disease
SCT	sickle cell trait
TCD	transcranial Doppler ultrasound
VCAM-1	vascular cell adhesion molecule 1
WBC	white blood cell

Drug-Induced Hematologic Disorders

e103

Elisa M. Greene and Tracy M. Hagemann

KEY CONCEPTS

1. The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.
2. Drug-induced hematologic disorders are generally rare adverse effects associated with drug therapy.
3. The incidence of rare adverse drug reactions (ADRs) is usually established by postmarketing surveillance and reporting.
4. Rechallenging a patient with an agent suspected of inducing a blood disorder is not generally recommended.
5. Drug-induced hematologic disorders can occur by two mechanisms: direct drug or metabolite toxicity or an immune reaction.
6. The primary treatment of drug-induced hematologic disorders is removal of the drug in question and symptomatic support of the patient.

INTRODUCTION

1 Hematologic disorders have long been a potential risk of modern pharmacotherapy. Granulocytopenia (agranulocytosis) was reported in association with one of medicine's early therapeutic agents, sulfanilamide, in 1938.[1] Some agents cause predictable hematologic disease (eg, antineoplastics), but others induce idiosyncratic reactions not directly related to the drugs' pharmacology. The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.

2 The incidence of idiosyncratic drug-induced hematologic disorders varies depending on the condition and the associated drug. Few epidemiologic studies have evaluated the actual incidence of these adverse reactions, but these reactions appear to be rare. Women are generally more susceptible than men to the hematologic effects of drugs. The incidence varies based on geography, which suggests that genetic differences may be important determinants of susceptibility. Drug-induced thrombocytopenia is the most common drug-induced hematologic disorder, with reports suggesting that between 0.1% and 5% of patients who receive heparin develop heparin-induced thrombocytopenia (HIT).[2,3] The Berlin Case-Control Surveillance Study was conducted from 2000 to 2009 to assess the incidence and risks of drug-induced hematologic disorders and found that almost 30% of all cases of blood dyscrasias were "possibly" attributable to drug therapy.[4]

Although drug-induced hematologic disorders are less common than other types of adverse reactions, they are associated with significant morbidity and mortality. Aplastic anemia is the leading cause of death followed by thrombocytopenia, agranulocytosis, and hemolytic anemia.[5] Similar to most other adverse drug reactions (ADRs), drug-induced hematologic disorders are more common in elderly adults than in the young; the risk of death also appears to be greater with increasing age.

3 The MedWatch program supported by the Food and Drug Administration[6] is the most common avenue for postmarketing surveillance to establish the incidence of ADRs. Many facilities have similar drug-reporting programs to follow ADR trends and to determine whether an association between a drug and an ADR is causal or coincidental. These programs enable practitioners to confirm that an adverse event is the result of drug therapy rather than one of many other potential causes; general guidelines are readily available.[7,8]

4 Because drug-induced blood disorders are potentially dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis is not recommended. In vitro studies with the offending agent and cells or plasma from the patient's blood can be performed to determine causality.[9] These methods are often expensive, however, and require facilities and expertise that are not generally available. Laboratory confirmation of drug causation is not always necessary to warrant interruption or discontinuation of therapy. Therefore, it is extremely important that practitioners be able to clinically evaluate suspect drugs quickly and to interrupt therapy when necessary.

Through the use of surveillance programs, lists of drugs that may be associated with adverse events have been published. These lists include a large number of commonly used drugs. Although these lists may help clinicians identify specific drug causes of adverse events, the large number of agents implicated may make this a difficult process. The absence of a drug from such a list should not discourage the investigation and reporting of a suspected agent associated with an adverse event. It is imperative that clinicians use a rational approach to determine causality and identify the agents associated with a reaction. The clinician should focus on the issue, perform a rigorous investigation, develop appropriate criteria, use objective criteria to grade the response, and complete a quantitative summary. A complete, thorough, and detailed drug and exposure history must be obtained from the patient in order to best determine any potential for drug causation.

Laboratory Tests to Direct Antimicrobial Pharmacotherapy

e104

Michael J. Rybak, Jeffrey R. Aeschlimann, and Kerry L. LaPlante

KEY CONCEPTS

1. Understanding the difference between normal host flora and typical pathogens will help to determine whether a patient is truly infected or merely colonized.
2. Direct examination of tissue and body fluids by Gram stain provides rapid information about the causative pathogen.
3. Isolation of the offending organism by culture or rapid diagnostic testing assists in the diagnosis of infection and allows for more definitive directed treatment.
4. Development of molecular testing systems (or rapid diagnostic testing) has improved our ability to diagnose infection and determine the antimicrobial susceptibilities for numerous pathogens, including fastidious or slow growing mycobacteria and viruses.
5. Although highly standardized, in vitro antimicrobial susceptibility testing has limitations and often cannot truly mimic the conditions found at the site of an infection. This can cause discordance between in vitro susceptibility results and in vivo response to therapy.
6. Laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases.
7. When used appropriately, rapid automated susceptibility test systems appear to improve therapeutic outcomes of patients with infection, especially when they are linked with other clinical information systems.
8. Laboratory tests such as the minimum inhibitory and minimum bactericidal concentration tests, time-kill tests, postantibiotic effect tests, and antimicrobial combination testing are important for the clinician to understand because they help to determine antimicrobial pharmacodynamic properties.
9. Routine monitoring of serum concentrations is currently used for a select few antimicrobials (eg, aminoglycosides and vancomycin) in an attempt to minimize toxicity and maximize efficacy.
10. Appropriate timing for the collection of serum samples when measuring antimicrobial serum concentrations is crucial to ensure that proper data are generated on the pharmacokinetics of antimicrobials.
11. Monitoring of aminoglycoside serum concentrations and the use of extended-interval doses can help to maximize the probability of therapeutic success and minimize the probability of aminoglycoside-related toxicity for certain infections.
12. Vancomycin and aminoglycoside serum concentration monitoring should be routinely done to ensure adequate serum concentrations, minimize toxicity, and avoid the potential for resistance.
13. Antimicrobial pharmacodynamics have become a crucial consideration for the selection of both empirical and pathogen-directed therapy in the current era of antimicrobial resistance.
14. Optimization of antimicrobial pharmacodynamic parameters such as the ratio of the peak serum concentration to minimum inhibitory concentration (MIC) or the time that the antibiotic serum concentration remains above the MIC and area above the curve over MIC can improve infection treatment outcomes.

Selection of an appropriate antimicrobial therapeutic regimen for a given infection requires knowledge of the infecting pathogen, host characteristics, and the drug's expected activity against the pathogen. The most fundamental aspect of therapy starts with an appropriate diagnosis. A vast array of laboratory tests including rapid diagnostic technology is available to assist in verifying the presence of infection and for monitoring the response to therapy. Although rigorous standardization of these tests is desirable, many of the tests may be difficult to interpret correctly and therefore, often they should be considered complementary to sound clinical judgment. Organism susceptibility to the administered antimicrobials is key to determining the outcome from therapy. Host characteristics, however, such as immune status, infection site location, and body organ function, play a significant role in selecting the most appropriate antimicrobial for a given individual.[1] This chapter reviews the routine laboratory tests that are used to assist in the diagnosis and treatment of infection.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com.**

Antimicrobial Regimen Selection

105

Grace C. Lee and David S. Burgess

KEY CONCEPTS

1. Every attempt should be made to obtain specimens for culture and sensitivity testing prior to initiating antibiotics.
2. Empirical antibiotic therapy should be based on knowledge of likely pathogens for the site of infection, information from patient history (eg, recent hospitalizations, work-related exposure, travel, and pets), and local susceptibility.
3. Patients with delayed dermatologic reactions (ie, rash) to penicillin generally can receive cephalosporins. Patients with type I hypersensitivity reactions (ie, anaphylaxis) to penicillins should not receive cephalosporins. Alternatives to the cephalosporins include aztreonam, quinolones, sulfonamide antibiotics, or vancomycin based on type of coverage indicated.
4. Creatinine clearance should be estimated for every patient who is to receive antibiotics and the antibiotic dose interval adjusted accordingly. Hepatic function should be considered for drugs eliminated through the hepatobiliary system, such as clindamycin, erythromycin, and metronidazole.
5. All concomitant drugs and nutritional supplements should be reviewed when an antibiotic is added to a patient's therapy to ensure drug–drug interactions will be avoided.
6. Combination antibiotic therapy may be indicated for polymicrobial infections (eg, intra-abdominal and gynecologic infections), to produce synergistic killing (such as *β*-lactam plus aminoglycoside vs *Pseudomonas aeruginosa*), or to prevent the emergence of resistance.
7. All patients receiving antibiotics should be monitored for resolution of infectious signs and symptoms (eg, decreasing temperature and white blood cell count) and adverse drug events.
8. Antibiotics with the narrowest effective spectrum of activity are preferred. Antibiotic route of administration should be evaluated daily, and conversion from IV to oral therapy should be attempted as signs of infection improve for patients with functioning GI tracts (general exceptions are endocarditis and CNS infections).
9. Patients not responding to an appropriate antibiotic treatment in 2 to 3 days should be reevaluated to ensure (a) the correct diagnosis, (b) that therapeutic drug concentrations are being achieved, (c) that the patient is not immunosuppressed, (d) that the patient does not have an isolated infection (ie, abscess and foreign body), or (e) that resistance has not developed.
10. The main goals of antimicrobial stewardship programs (ASPs) are to optimize antimicrobial selection, dosing, duration, and route of administration while minimizing adverse drug events and the emergence of antimicrobial resistance.

Antimicrobials are among the most widely used classes of drugs. In the United States, expenditures for antimicrobial agents exceed $10 billion annually. Approximately 20% to 40% of hospitalized patients receive antibiotics. The use of antibiotics is the main driver in creating selective pressure for the emergence of antimicrobial resistant pathogens; nevertheless, antibiotic overuse remains common. Selecting appropriate antimicrobial agent(s) to treat an infection has proven to be a challenging task.[1,2] Although the choice of a single agent or a combination of agents should be individualized for each patient, certain general principles of therapy should guide the selection of specific drugs (**Table 105-1**).

The initial selection of antimicrobial therapy is nearly always empirical, which is prior to documentation and identification of the offending organism. Infectious diseases generally are acute, and a delay in antimicrobial therapy can result in serious morbidity or even mortality. Thus, empirical antimicrobial therapy selection should be based on information gathered from the patient's history and physical examination and results of Gram stains or of rapidly performed tests on specimens from the infected site. This information, combined with knowledge of the most likely offending organism(s) and an institution's local susceptibility patterns, should result in a rational selection of antibiotics to treat the patient. This chapter introduces a systematic approach to the selection of antimicrobial therapeutic regimens.

CONFIRMING THE PRESENCE OF INFECTION

An infectious disease diagnosis is determined by assessing the presence of signs and symptoms of an infection, determining the site of infection, and establishing a microbiological diagnosis, when possible.

Fever

The presence of a temperature greater than the expected 37°C (98.6°F) "normal" body temperature is considered a hallmark of infectious diseases. Body temperature is controlled by the hypothalamus. In addition, the circadian rhythm, a built-in temperature cycle, is also operational. The daily temperature rhythm can vary for each individual. In a healthy person, the internal thermostat is set between the morning low temperature and the afternoon peak as controlled by the circadian rhythm. During fever, the hypothalamus is reset at a higher temperature level.

Fever is defined as a controlled elevation of body temperature above the normal range. The average normal body temperature range taken orally is 36.7°C to 37°C (98°F-98.6°F). Body temperatures obtained rectally generally are 0.6°C (1°F) higher and axillary temperatures are 0.6°C (1°F) lower than oral temperatures, respectively. Skin temperatures are also less than the oral temperature but can vary depending on the specific measurement method.

Clinical assessment
Laboratory tests
Assessment of therapeutic failure

Fever can be a manifestation of disease states other than infection. Collagen vascular (autoimmune) disorders and several malignancies can have fever as a manifestation. Fever of unknown or undetermined origin is a diagnostic dilemma and is reviewed extensively elsewhere.[3]

Many drugs have been identified as causes of fever. *Drug-induced fever* is defined as persistent fever in the absence of infection or other underlying condition. The fever must coincide temporally with the administration of the offending agent and disappear promptly on its withdrawal, after which the temperature remains normal. Possible mechanisms of drug-induced fever are either a hypersensitivity reaction or development of antigen–antibody complexes that result in the stimulation of macrophages and the release of interleukin 1 (IL-1). While fever is not a common drug effect (accounting for no more than 5% of all drug reactions), it should be suspected when obvious reasons for fever are not present. Almost any medication can produce fever, but β-lactam antibiotics, anticonvulsants, allopurinol, hydralazine, nitrofurantoin, sulfonamides, phenothiazines, and methyldopa appear to be responsible more often than others.

Noninfectious etiologies of fever can be referred to as "false-positives." Although these certainly can confuse the clinician, even more troublesome are false-negatives: the absence of fever in a patient with signs and symptoms consistent with an infectious disease. Careful questioning of the patient or family is vital to assess the ingestion of any medication that can mask fever (eg, aspirin, acetaminophen, nonsteroidal anti-inflammatory agents, and corticosteroids). The use of antipyretics should be discouraged during the treatment of infection unless absolutely necessary because they can mask a poor therapeutic response. Moreover, elevated body temperature, unless very high (greater than 40.5°C [greater than 105°F]), is not harmful and may be beneficial.

Signs and Symptoms

White Blood Cell Count

Most infections result in elevated white blood cell (WBC) counts (leukocytosis) because of the increased production and mobilization of granulocytes (neutrophils, basophils, and eosinophils), lymphocytes, or both to ingest and destroy invading microbes. The generally accepted range of normal values for WBC counts is between 4,000 and 10,000 cells/mm^3 (4×10^9 and 10×10^9/L). Values above or below this range hold important prognostic and diagnostic value.

Bacterial infections are associated with elevated granulocyte counts, often with immature forms (band neutrophils) seen in peripheral blood smears. Mature neutrophils are also referred to as *segmented neutrophils* or *polymorphonuclear* (PMN) *leukocytes*. The presence of immature forms (left shift) is an indication of an increased bone marrow response to the infection. With infection, peripheral WBC counts can be very high, but they are rarely higher than 30,000 to 40,000 cells/mm^3 (30×10^9/L-40×10^9/L). Because leukocytosis indicates the normal host response to infection, low leukocyte counts after the onset of infection indicate an abnormal response and generally are associated with a poor prognosis.

The most common granulocyte defect is neutropenia, a decrease in absolute numbers of circulating neutrophils. A thorough description of the consequences of neutropenia is given in Chapter e99. Lymphocytosis, even with normal or slightly elevated total WBC counts, generally is associated with tuberculosis and viral or fungal infections. Increases in monocytes can be associated with tuberculosis or lymphoma, and increases in eosinophils can be associated with allergic reactions to drugs or infections caused by metazoa. Many types of infections can be accompanied by a completely normal WBC count and differential.

Local Signs

The classic signs of pain and inflammation can manifest as swelling, erythema, tenderness, and purulent drainage. Unfortunately, these are only visible if the infection is superficial or in a bone or joint. The manifestations of inflammation in deep-seated infections (eg, meningitis, pneumonia, endocarditis, and urinary tract infection) must be ascertained by examining tissues or fluids. For example, the presence of neutrophils in spinal fluid, lung secretions (sputum), or urine is highly suggestive of a bacterial infection.

Symptoms referable to an organ system must be sought out carefully because not only do they help in establishing the presence of infection, but they also aid in narrowing the list of potential pathogens. For example, a febrile patient with complaints of flank pain and dysuria can well have pyelonephritis. In this situation, enteric Gram-negative bacilli, especially *Escherichia coli*, are the predominant pathogens. If a febrile patient has no symptoms suggestive of an organ system but only constitutional complaints, the list of possible infectious diseases is lengthy.[3] A febrile individual with cough and sputum production probably has a pulmonary infection. What is not so evident, however, is the etiologic organism in this situation, because it can be caused by bacteria, mycobacteria, viruses, *Chlamydia*, or mycoplasmas.[4] In this situation, attention to the patient's history and background disease states is important. Even more important is a careful examination of the infected material (in this case sputum) to ascertain the identity of the pathogen.

IDENTIFICATION OF THE PATHOGEN

Microbiological Studies

1 Identification and antimicrobial susceptibility of a suspected pathogen are the most important factors in determining the choice of antimicrobial therapy. Generally, infected body materials must be sampled, if at all possible or practical, before or concurrently with institution of any antimicrobial therapy for two reasons. First, a Gram stain of the material might reveal bacteria, or an acid-fast stain might detect mycobacteria or actinomycetes. Second, the premature use of antimicrobials can suppress the growth of pathogens which might result in false-negative cultures results or alterations in the cellular and chemical composition of infected fluids. This is particularly true in patients with vertebral osteomyelitis, urinary tract infections, subacute endocarditis, meningitis, and septic arthritis.[5-9]

Blood cultures usually should be performed in the acutely ill febrile patient. Blood culture collection should coincide with sharp elevations in temperature, suggesting the possibility of

microorganisms or microbial antigens in the bloodstream. Ideally, blood should be obtained from peripheral sites as two sets (one set consists of an aerobic bottle and one set an anaerobic bottle) from two different sites approximately 1 hour apart. In selected infections, bacteremia is qualitatively continuous (eg, endocarditis), so cultures can be obtained at any time.[9]

In addition to the infected materials produced by the patient (eg, blood, sputum, urine, stool, and wound or sinus drainage), other less accessible fluids or tissues must be obtained if they are suspected to be the infected site (eg, spinal fluid in meningitis and joint fluid in arthritis). Abscesses and cellulitic areas also should be aspirated.

When a pathogenic microorganism is identified, the next step for the majority of clinical microbiological laboratories is antimicrobial susceptibility testing which measures the ability of a select organism to grow in the presence of an antimicrobial agent. These methods are described in detail in Chapter e25. Once a microorganism is identified and its susceptibilities are known, specific definitive antimicrobial therapy should be promptly administered.

Over the last decade, there has been an explosion in the development of rapid diagnostic methods that provide simultaneous organism identification and resistance marker detection. These methods include nonamplified probe technologies (peptide nucleic-acid-fluorescence in situ hybridization), proteomics, and nucleic acid amplification methods combined with microarray technologies. These tests can significantly reduce time to organism identification; thereby, can reduce time to effective antimicrobial therapy, overall antimicrobial use, and health outcomes among patients with infectious diseases.[10-12]

Interpreting Results

After a positive Gram stain, culture results, or both are obtained, the clinician must be cautious in determining whether the organism recovered is a true pathogen, a contaminant, or a part of the normal flora (see Chapter e25). The latter consideration is especially problematic with cultures obtained from the skin, oropharynx, nose, ears, eyes, throat, and perineum. These surfaces are heavily colonized with a wide variety of bacteria, some of which can be pathogenic in certain settings. For example, coagulase-negative staphylococci are found in cultures of all the aforementioned sites, yet are seldom regarded as pathogens unless recovered from blood, venous access catheters, or prosthetic devices.

Importantly, cultures of specimens from purportedly infected sites that are obtained by sampling from or through one of these contaminated areas might contain significant numbers of the normal flora. For urine cultures, the urinalysis should be used in combination with culture results to assess the presence of WBCs, nitrite, and leukocyte esterase to help confirm infection and rule out colonization.[13]

Particularly problematic are expectorated sputum specimens that must be evaluated carefully by determination of the presence of squamous epithelial cells and leukocytes.[4] A predominance of epithelial cells in sputum specimens reduces the likelihood that recovered bacteria are pathogenic, especially when multiple types of organisms are seen on Gram stain. In contrast, the discovery of leukocytes in large numbers with one predominant type of organism is a more reliable indicator of a valid collection. In general, however, sputum evaluation has poor sensitivity and specificity as a diagnostic test.

Gram-staining techniques, culture methods, and serologic identification, as well as susceptibility testing, are discussed in detail in Chapter e25. Emphasis must be placed on the proper collection and handling of specimens and careful assessment of Gram stain or other test results in guiding the clinician toward appropriate selection of initial antimicrobial therapy.[14]

SELECTION OF PRESUMPTIVE THERAPY

2 In many instances, empiric therapy must be instituted before microbiological results are available. To select rational antimicrobial therapy for a given clinical situation, a variety of factors must be considered. These include the severity and acuity of the disease, local epidemiology and antibiogram, patient history, host factors, factors related to the drugs used, and the necessity for using multiple agents. In addition, there are generally accepted drugs of choice for the treatment of most pathogens (see **Appendix 105-1**).

Antibiogram

Drugs of choice are compiled from a variety of sources and are intended as guidelines rather than as specific rules for antimicrobial use. These choices are influenced by local antimicrobial susceptibility data rather than information published by other institutions or national compilations. Each institution should publish an annual summary of antibiotic susceptibilities (antibiogram) for organisms cultured from patients. Antibiograms contain both the number of nonduplicate isolates for common species and the percentage susceptible to the antibiotics tested. To further guide empirical antibiotic therapy, some hospitals publish unit-specific antibiograms in unique patient care areas, such as intensive care units or burn units.

Susceptibility of bacteria can differ substantially among hospitals within a community. For example, the prevalence of hospital-acquired methicillin-resistant *Staphylococcus aureus* (HA-MRSA) in some centers is quite high, whereas in other centers the problem might be nonexistent. This particular situation will influence the selection of therapy for possible *S. aureus* infection, where the clinician must choose either a β-lactam or vancomycin. The problem of differing susceptibilities is not limited only to Gram-positive bacteria but also is evident in Gram-negative organisms, and all drug classes are affected.

Patient History

Empirical therapy is directed at organisms that are known to cause the infection in question. These organisms are discussed for different sites of infection in Chapters 83 to e103. To define the most likely infecting organisms, a careful history and physical examination must be performed. The place where the infection was acquired should be determined, for example, the home (community acquired), nursing home environment, or hospital acquired (nosocomial). Nursing home patients can be exposed to potentially more resistant organisms because they are often surrounded by ill patients who are receiving antibiotics. Important considerations when selecting empiric antimicrobial therapy include: 1) prior knowledge of colonization or infections, 2) previous antimicrobial use, 3) the site of infection and the organisms most likely pathogens, and 4) local antibiogram and resistance patterns for important pathogens. Other questions to ask infected patients regarding the history of present illness include: 1) Are any other people sick at home, especially children? 2) Are any unusual pets kept in the home? 3) Where are you employed (ie, are you exposed to contaminated meat or infectious biohazards)? and 4) Has there been any recent travel (ie, to endemic areas of fungal infections or developing countries)?

Host Factors

Several host factors should be considered when evaluating a patient for antimicrobial therapy. The most important factors are drug allergies, age, pregnancy, genetic or metabolic abnormalities, renal and hepatic function, site of infection, concomitant drug therapy, and underlying disease states.

Allergy

3 Allergy to an antimicrobial agent generally precludes its use. Careful assessment of allergy histories must be performed because many patients confuse common adverse drug effects (ie, GI disturbance) with true allergic reactions.[15-17] Among the most commonly cited antimicrobial allergies are those to penicillin, penicillin-related compounds, or both. In the absence of complete penicillin skin testing capabilities, a rule of thumb for giving cephalosporins to patients allergic to penicillin is to avoid giving them to patients who give a good history for immediate or accelerated reactions (eg, anaphylaxis, laryngospasm) and to give them under close supervision in patients with a history of delayed reactions, such as a rash.[18] If a Gram-negative infection is suspected or documented, therapy with a monobactam may be appropriate because cross-reactivity with other β-lactams is nonexistent.

Age

The patient's age is an important factor both in trying to identify the likely etiologic agent and in assessing the patient's ability to eliminate the drug(s) to be used. The best example of an age determinant of organisms is in bacterial meningitis, where the pathogens differ as the patient grows from the neonatal period through infancy and childhood into adulthood.[5,19]

For neonates, hepatic and liver functions are not well developed. Therefore, bilirubin excretion is decreased resulting in increased concentration of unconjugated bilirubin that can cause kernicterus. Neonates (especially when premature) can develop kernicterus when given sulfonamides. This results from displacement of bilirubin from serum albumin. In addition, neonates have more body water content that results in a larger volume of distribution leading to adjustments in antibiotic dosing regimens. Additional special drug considerations for pediatric patients include low frequency of adverse effects and compliance-enhancing features (eg, absorption not affected by food, once- to twice-daily dosing, and good taste).[7,20,21]

The major physiologic change in persons older than 65 years of age is a decline in the number of functioning nephrons that, in turn, results in decreased renal function.[22] This is usually manifested by an increased incidence of side effects caused by antimicrobials that are eliminated renally. For example, renal toxicity caused by aminoglycosides may be apparent much sooner during therapy in older adults than in younger patients.

Pregnancy

During pregnancy, not only is the fetus at risk for drug teratogenicity, but the pharmacokinetic disposition of certain drugs can be altered.[23] Penicillins, cephalosporins, and aminoglycosides are cleared from the peripheral circulation more rapidly during pregnancy. This is probably a result of marked increases in intravascular volume, glomerular filtration rate, and hepatic and metabolic activities. The net result is that maternal serum antimicrobial concentrations can be as much as 50% lower during this period than in the nonpregnant state. Increased dosages of certain compounds might be necessary to achieve therapeutic levels during late pregnancy.[24]

Metabolic or Genetic Variation

Inherited or acquired metabolic abnormalities will influence the therapy of infectious diseases in a variety of ways. For example, patients with impaired peripheral vascular flow may not absorb drugs given by intramuscular injection. In addition, certain metabolic states can predispose patients to enhanced drug toxicity. For instance, patients who are phenotypically slow acetylators of isoniazid are at greater risk for peripheral neuropathy.[25] Patients with severe deficiency of glucose-6-phosphate dehydrogenase can develop significant hemolysis when exposed to such drugs as sulfonamides, nitrofurantoin, nalidixic acid, antimalarials, and dapsone. Although mild deficiencies are found in African Americans, the more severe forms of the disease generally are confined to persons of eastern Mediterranean origin. Another example is the antiretroviral drug abacavir, which is associated with a severe hypersensitivity reaction, consisting of fever, rash, abdominal pain, and respiratory distress. This risk has been associated with the presence of a human leukocyte antigen allele HLA-B*5701. Routine screening for the presence of this allele before initiating treatment with abacavir is a recommendation in the current HIV treatment guidelines. Furthermore, the hepatic cytochrome P450 system is a major pathway for a large number of antimicrobials. While differential host expressions of these enzymes occur, insufficient clinical data are currently available to recommend routine screening for antimicrobial therapy.

Organ Dysfunction

4 Patients with diminished renal or hepatic function or both will accumulate certain drugs unless the dosage is adjusted. It is common for patents requiring antimicrobial therapy to have some degree of renal impairment. Because many of the commonly used antimicrobials are primarily cleared by the kidneys, it is imperative to adjust the dosing regimen or therapy.[26,27] Recommendations for dosing antibiotics in patients with liver dysfunction are not as formalized as guidelines for patients with renal dysfunction. Antibiotics that should be adjusted in severe liver disease include clindamycin, erythromycin, metronidazole, and rifampin. Significant accumulation can occur when both liver dysfunction and renal dysfunction are present for the following drugs: cefotaxime, nafcillin, piperacillin, and sulfamethoxazole.[28]

Concomitant Drugs

5 Any concomitant therapy that the patient is receiving can influence the drug selection, dose, and monitoring. For instance, administration of isoniazid to a patient who is also receiving phenytoin can result in phenytoin toxicity secondary to inhibition of phenytoin metabolism by isoniazid. Furthermore, drugs that possess similar adverse effect profiles can increase the risk for effects (ie, two drugs that cause nephrotoxicity or neutropenia). A detailed review of drug interactions is beyond the scope of this chapter, but an excellent textbook on this subject is available.[29] Lists of potentially severe drug–drug interactions are provided in **Table 105-2**.

Concomitant Disease States

Concomitant disease states can influence the selection of therapy. Certain diseases will predispose patients to a particular infectious disease or will alter the type of infecting organism. For example, patients with diabetes mellitus and the resulting peripheral vascular disease often develop infections of the lower extremity soft tissue. Moreover, the alterations in peripheral blood flow associated with the disease and perhaps altered immunity make such infections more difficult to treat than in nondiabetics. Patients with chronic lung disease or cystic fibrosis develop frequent pulmonary infections that can be caused by somewhat different microorganisms than are found in otherwise normal hosts.

Patients with immunosuppressive diseases, such as malignancies or acquired immunologic deficiencies, are highly predisposed to infections, and the types of causative or pathogenic organisms can be vastly different from what would be expected (see Chapter e99). For instance, patients undergoing chemotherapy for acute forms of leukemia often are profoundly granulocytopenic and are predisposed to infections caused by bacteria and fungi.[30] Patients with the acquired immunodeficiency syndrome (AIDS) often become infected with an enormous variety of organisms (see Chapter e103).

TABLE 105-2 Major Drug Interactions with Antimicrobials

Antimicrobial	Other Agent(s)	Mechanism of Action/Effect	Clinical Management
Aminoglycosides	Neuromuscular blocking agents	Additive adverse effects	Avoid
	Nephrotoxins (N) or ototoxins (O) (eg, amphotericin B [N], cisplatin [N/O], cyclosporine [N], furosemide [O], NSAIDs [N], radiocontrast [N], vancomycin [N])	Additive adverse effects	Monitor aminoglycoside SDC and renal function
Amphotericin B	Nephrotoxins (eg, aminoglycosides, cidofovir, cyclosporine, foscarnet, pentamidine)	Additive adverse effects	Monitor renal function
Azoles	See Chapter 98		
Chloramphenicol	Phenytoin, tolbutamide, ethanol	Decreased metabolism of other agents	Monitor phenytoin SDC, blood glucose
Foscarnet	Pentamidine IV	Increased risk of severe nephrotoxicity/hypocalcemia	Monitor renal function/serum calcium
Isoniazid	Carbamazepine, phenytoin	Decreased metabolism of other agents (nausea, vomiting, nystagmus, ataxia)	Monitor drug SDC
Macrolides/azalides	Digoxin	Decreased digoxin bioavailability and metabolism	Monitor digoxin SDC; avoid if possible
	Theophylline	Decreased metabolism of theophylline	Monitor theophylline SDC
Metronidazole	Ethanol (drugs containing ethanol)	Disulfiram-like reaction	Avoid
Penicillins and cephalosporins	Probenecid, aspirin	Blocked excretion of β-lactams	Use if prolonged high concentration of β-lactam desirable
Ciprofloxacin/norfloxacin	Theophylline	Decreased metabolism of theophylline	Monitor theophylline
Quinolones	Classes Ia and III antiarrhythmics	Increased Q-T interval	Avoid
	Multivalent cations (antacids, iron, sucralfate, zinc, vitamins, dairy, citric acid), didanosine	Decreased absorption of quinolone	Separate by 2 hours
Rifampin	Azoles, cyclosporine, methadone propranolol, PIs, oral contraceptives, tacrolimus, warfarin	Increased metabolism of other agent	Avoid if possible
Sulfonamides	Sulfonylureas, phenytoin, warfarin	Decreased metabolism of other agent	Monitor blood glucose, SDC, PT
Tetracyclines	Antacids, iron, calcium, sucralfate	Decreased absorption of tetracycline	Separate by 2 hours
	Digoxin	Decreased digoxin bioavailability	Monitor digoxin SDC; avoid if possible

PI, protease inhibitor; PT, prothrombin time; SDC, serum drug concentrations.

Azalides: azithromycin; azoles: fluconazole, itraconazole, ketoconazole, and voriconazole; macrolides: erythromycin and clarithromycin; protease inhibitors: amprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, and saquinavir; quinolones: ciprofloxacin, gemifloxacin, levofloxacin, and moxifloxacin.

Many factors predisposing to infection are related to disruption of the host's integumentary barriers. For example, trauma, burns, and iatrogenic wounds induced in surgery can lead to a substantial risk of infection depending on the severity and location of the injury or disruption. For a complete discussion of the various risks involved in surgical procedures, see Chapter 100.

Drug Factors

Pharmacokinetic and Pharmacodynamic Considerations

Integration of both pharmacokinetic and pharmacodynamic properties of an agent is important when choosing antimicrobial therapy to ensure efficacy and to prevent resistance.[31] Early researchers relied solely on pharmacokinetic properties such as the area under the (drug concentration) curve (AUC), maximum observed concentration (peak), and drug half-life to optimize therapy. Pharmacodynamics is the study of the relationship between drug concentration and the effects on the microorganism. There is an important relationship between both pharmacokinetic and microbiologic parameters that has resulted in measurements such as AUC:minimal inhibitory concentration (MIC) ratio, peak:MIC ratio, and time (T) the concentration is above MIC ($T > MIC$).[32-35]

Aminoglycosides exhibit concentration-dependent bactericidal effects. An example of the integration of pharmacokinetics and microbiologic activity is the use of high-dose, once-daily aminoglycosides. For these regimens, the drug is given as a single large daily dose to maximize the peak:MIC ratio. Aminoglycosides also possess a postantibiotic effect (persistent suppression of organism growth after concentrations decrease below the MIC) that appears to contribute to the success of high-dose, once-daily administration. Fluoroquinolones exhibit concentration-dependent killing activity, but optimal killing appears to be characterized by the AUC:MIC ratio.

β-Lactams display time-dependent bactericidal effects. Killing activity is enhanced only marginally if drug concentration exceeds the MIC. Therefore, the important pharmacodynamic relationship for these antimicrobials is the duration that drug concentrations exceed the MIC ($T > MIC$). Effective dosing regimens require serum drug concentrations to exceed the MIC for at least 40% to 50% of the dosing interval. Frequent small doses, continuous infusion, or prolonged infusion of β-lactams appears to be correlated with positive outcomes.

A detailed discussion on antimicrobial pharmacokinetics–pharmacodynamics is beyond the scope of this chapter. However, excellent sources of information on this topic are available.[31,32,35]

Tissue Penetration

The importance of tissue penetration varies with site of infection. Some of the difficulties in interpreting data include a lack of correlation with clinical outcomes and poor understanding of whether the antimicrobial agents are present in a biologically active form. An example of the former problem is the recognized efficacy of drugs with low biliary fluid concentrations in the treatment of cholecystitis, cholangitis, or both and the absence of the enhanced efficacy

of drugs whose primary route of elimination is biliary excretion of active drug. An example of the latter difficulty is with penetration to deep infections, such as abscesses, where various factors such as acid pH, WBC products, and various enzymes can inactivate even high concentrations of certain drugs.

The CNS is one body site where antimicrobial penetration is relatively well defined, and correlations with clinical outcomes are established.[5,36] CSF concentrations of antimicrobial agents necessary to cure bacterial meningitis have been defined, and drugs that do not reach significant concentrations in the CSF should be either avoided or instilled directly, if feasible.

Caution must be exercised when selecting an antimicrobial agent for clinical use on the basis of tissue or fluid penetration. Body fluids where drug concentration data are clinically relevant include CSF, urine, synovial fluid, and peritoneal fluid. Apart from these areas, more attention should be paid to clinical efficacy, antimicrobial spectrum, toxicity, and cost than to comparative data on penetration into a given body site.

The proper route of administration for an antimicrobial depends on the site of infection. Parenteral therapy is warranted when patients are being treated for febrile neutropenia or deep-seated infections such as meningitis, endocarditis, and osteomyelitis. Severe pneumonia often is treated initially with IV antibiotics and switched to oral therapy as clinical improvement is evident.[4,37,38] Patients treated in the ambulatory setting for upper respiratory tract infections (eg, pharyngitis, bronchitis, sinusitis, and otitis media), lower respiratory tract infections, skin and soft-tissue infections, uncomplicated urinary tract infections, and selected sexually transmitted diseases can usually receive oral therapy.

Drug Toxicity

It is incumbent on health professionals to avoid toxic drugs whenever possible. Antibiotics associated with CNS toxicities, usually when not dose-adjusted for renal function, include penicillins, cephalosporins, quinolones, and imipenem. Hematologic toxicities generally are manifested with prolonged use of nafcillin (neutropenia), piperacillin (platelet dysfunction), cefotetan (hypoprothrombinemia), chloramphenicol (bone marrow suppression, both idiosyncratic and dose-related toxicity), and trimethoprim (megaloblastic anemia). Reversible nephrotoxicity classically is associated with aminoglycosides and vancomycin. Irreversible ototoxicity can occur with aminoglycosides. In the outpatient setting, patients must be counseled regarding photosensitivity with azithromycin, quinolones, tetracyclines, pyrazinamide, sulfamethoxazole, and trimethoprim. Lastly, all antibiotics have been implicated in causing diarrhea and colitis secondary to *Clostridium difficile* (see Chapter 91).[39] List of potential antibiotic adverse drug reactions is provided in Table 105-3.

Aside from consideration of drug toxicity, some antimicrobial use requires more intensive risk–benefit analysis. An example of this is the decision to use isoniazid prophylactically to prevent tuberculosis. Because the hepatotoxicity of isoniazid increases in frequency with age, older persons (greater than 45 years of age) who are candidates for isoniazid prophylaxis (positive skin test) must have additional risk factors for tuberculosis to balance the potential toxic effects. These include evidence of recent skin test conversion, immunosuppression, or previous gastrectomy. Older patients without additional risk factors are more likely to suffer toxicity from isoniazid than derive benefit from its use.

Combination Antimicrobial Therapy

6 In selecting a drug regimen for a given patient, consideration must be given to the necessity of using more than one drug. Inappropriate or inadequate antimicrobial therapy has been associated with increased morbidity and mortality.[40] Combinations of antimicrobials generally are used to broaden the spectrum of coverage for empirical therapy, achieve synergistic activity against the infecting organism, and prevent the emergence of resistance.

Broadening the Spectrum of Coverage

Increasing the coverage of antimicrobial therapy generally is necessary in two scenarios. First is in mixed infections where multiple organisms are likely to be present. This is the case in intra-abdominal and female pelvic infections, in which a variety of aerobic and anaerobic bacteria can produce disease.[41] Traditionally, a combination of a drug active against aerobic Gram-negative bacilli (such as an aminoglycoside) and a drug active against anaerobic bacteria (such as metronidazole or clindamycin) is selected. Newer compounds, which possess good activity against both of these types of organisms, such as the β-lactam/β-lactamase inhibitor combinations, carbapenems, or glycylcyclines, might be adequate to replace the combination and thereby reduce the cost of therapy. The second scenario is for critically ill patients with presumed health care-associated infections in which an increased spectrum of activity is desirable.[37] Health care-associated infections are frequently caused by multi-drug resistant pathogens; combination therapy is used in this setting to ensure that at least one of the antimicrobials will be active against the pathogen(s).

Synergism

The achievement of synergistic antimicrobial activity is advantageous for infections caused by enteric Gram-negative bacilli in immunosuppressed patients. Laboratory tests to identify synergy between antibiotic combinations are described in Chapter 24. Traditionally, combinations of aminoglycosides and β-lactams have been used because these drugs together generally act synergistically against a wide variety of bacteria. However, the data supporting superior efficacy of synergistic over nonsynergistic combinations are weak. At best, synergistic combinations appear to produce better results in infections caused by *Pseudomonas aeruginosa* and *Enterococcus* species.[33,42-44]

The most obvious example of the use of synergy is the treatment of enterococcal endocarditis. The causative organism is usually only inhibited by penicillins, but it is killed rapidly by the addition of streptomycin or gentamicin to a penicillin. The need for bactericidal activity in the treatment of endocarditis underscores the need for these synergistic combinations.[9,45]

Preventing Resistance

The use of antimicrobial combinations to prevent the emergence of resistance is applied widely but not often realized. The only circumstance where this has been clearly effective is in the treatment of tuberculosis. The prevalence of resistance to a first-line drug such as isoniazid or rifampin in a population of organisms may be as high as 1 in 10^6 to 10^8. Because the bacterial load in a patient with active tuberculosis often exceeds this, two drugs are given to reduce the likelihood of encountering resistance to less than 1 in 10. There is ample evidence from in vitro data and experimental bacterial infections that combinations of drugs with different mechanisms are effective in the prevention of the emergence of resistance. Data from clinical trials, however, either are conflicting or do not convincingly support this concept.[42]

Clinical **Controversy...**

Rapid initiation of appropriate antibiotic therapy is associated with improved outcomes among patients with infections. Therefore, there is a great need for reliable methods to rapidly screen patient risk factors for infections due to multi-drug resistant pathogens. However, prediction tools or criteria definitions may lack sensitivity and or specificity, and may lead to inadequate therapy or to

TABLE 105-3 Antimicrobial Adverse Drug Reactions

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
Penicillins	Hypersensitivity reactions and rash, drug fever, diarrhea, emesis, abdominal pain, hepatitis, interstitial nephritis, leukopenia, thrombocytopenia, Coomb's positive-hemolytic anemia, *C. difficile* colitis, electrolyte abnormalities, seizures	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria). During prolonged therapy and/or high-dose regimens, periodically monitor renal function, hepatic function, and CBC	Most serious reaction is immediate IgE-mediated anaphylaxis. Incidence is 0.05%, but 5%-10% can be fatal
Cephalosporins	Hypersensitivity reactions and rash, drug fever, diarrhea, interstitial nephritis, Coomb's positive-hemolytic anemia, leukopenia, thrombocytopenia, coagulopathy, hepatitis, *C. difficile* colitis	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria) and rash, renal function, hepatic function, and CBC	Patients with a history of IgE-mediated allergic reactions to penicillins should not receive a cephalosporin
Carbapenems	Hypersensitivity reactions and rash, headache, nausea, diarrhea, seizures, drug fever, eosinophilia, thrombocytopenia, hepatitis, *C. difficile* colitis	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria) and rash, renal function, hepatic function, and CBC	Skin test cross-sensitivity with penicillin reported to be up to 50%, but clinically significant cross-sensitivity reactions in penicillin-allergic patients reported to be as low as 1% Highest incidence of seizures with use of imipenem–cilastatin. More frequent in patients who are elderly, have history of seizure disorders and renal dysfunction
Monobactams	Rash, diarrhea, nausea, hepatitis, thrombocytopenia, *C. difficile* colitis	Monitor renal and hepatic function	May be used in patients with allergy to penicillins/cephalosporins
Aminoglycosides	Tubular necrosis and renal failure, vestibular and cochlear toxicity, neuromuscular blockade, vertigo, anemia, hypersensitivity	Monitor renal function, SDC, serum calcium, magnesium, sodium. Monitor for nausea, vomiting, nystagmus, and vertigo	Nephrotoxicity can be reversible. More frequent in patients with the following risk factors: elderly, history of renal dysfunction, concomitant administration of nephrotoxic drug (ie, cyclosporine, amphotericin B, radiocontrast, vancomycin), and duration of therapy Ototoxicities can be irreversible
Glycopeptides	Red man syndrome, phlebitis, renal dysfunction, neutropenia, leukopenia, eosinophilia, thrombocytopenia, drug fever	Monitor renal function, CBC, and SDC	Red man syndrome is associated with rapid infusion and nonspecific histamine release. May be prevented by prolonging infusions to over at least 60 minutes and pretreatment with antihistamines
Lipopeptides (daptomycin)	Hepatotoxicity, CPK elevation with or without myopathy, diarrhea, eosinophilic pneumonia, *C. difficile* colitis	Monitor LFTs, development of muscle pain/weakness, or neuropathy Obtain serum CPK levels at baseline and weekly (or more frequently in patients with prior or concomitant statin, renal dysfunction, or patients with elevations in CPK)	CPK elevation is dose-dependent. Obtain baseline and weekly CPK levels. Discontinue daptomycin if CPK exceeds 10 times normal level or if patient develops myopathy and CPK >1,000 international units/L (>16.7 μkat/L). Consider stopping statin therapy during treatment with daptomycin
Oxazolidinones	Myelosuppression (thrombocytopenia, leukopenia, and anemia), peripheral neuropathy, optic neuropathy, blindness, lactic acidosis, diarrhea, nausea, serotonin syndrome, interstitial nephritis	Monitor for signs and symptoms of serotonin syndrome particularly in patients with prior or concomitant serotonergic agents, CBC with differential. For prolonged therapy, perform visual function tests, monitor visual acuity and visual field defect	Myelosuppression is reversible and associated with treatment duration >2 weeks
Tetracyclines	GI upset, nausea, vomiting, diarrhea, hepatotoxicity, esophageal ulcerations, photosensitivity, azotemia, visual disturbances, vertigo, hyperpigmentation, deposition on teeth, hemolytic anemia, pseudotumor cerebri, pancreatitis, *C. difficile* colitis	Monitor CBC with differential, LFTs, and renal function	Doxycycline preferred in patients with renal dysfunction Vestibular symptoms more frequent in women than in men Avoid use during pregnancy and in children
Chloramphenicol	Myelosuppression, aplastic anemia, "gray baby syndrome," optic neuritis, peripheral neuropathy, digital paresthesias, GI upset, *C. difficile* colitis, hypersensitivity	Obtain baseline CBC with differential and every 2 days during therapy. Monitor SDC (particularly in children and in patients with hepatic or renal insufficiency), liver and renal function	Bone marrow suppression associated with doses >4 g/day. Serum levels >50 mcg/mL (mg/L; 155 μmol/L) are associated with increased risk for "gray baby syndrome"
Rifamycines	Discoloration of urine, tears, contact lens, sweat, hepatotoxicity, GI upset, flu-like syndrome, hypersensitivity, thrombocytopenia, leukopenia, drug fever, interstitial nephritis, thrombocytopenia	Monitor LFTs, bilirubin, renal function, CBC at baseline; continue to monitor every 2-4 weeks in patients with hepatic impairment or receiving concomitant hepatotoxic drugs	Increased potential for hepatitis with concomitant hepatotoxic drugs (ie, TB drugs)

(*continued*)

TABLE 105-3 Antimicrobial Adverse Drug Reactions (*Continued*)

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
Macrolides/azalide	GI intolerance, diarrhea, prolonged QTc, cholestatic hepatitis, reversible ototoxicity, torsade de pointes, rash, hypothermia, exacerbation of myasthenia gravis	Monitor LFTs and ECG in high-risk patients	
Clindamycin	Diarrhea, *C. difficile* colitis, nausea, vomiting, generalized rash, hypersensitivity	For prolonged therapy, monitor liver and renal function	
Fluoroquinolones	GI intolerance, headache, malaise, insomnia, dizziness, photosensitivity, QTc prolongation, tendon rupture, peripheral neuropathy, crystalluria, seizure, interstitial nephritis, Stevens-Johnson syndrome, allergic pneumonitis, *C. difficile* colitis	Monitor renal function, encephalopathic changes (eg, confusion, hallucinations, and tremor)	Tendon rupture more frequently seen in the elderly and kidney, heart, and lung transplant recipients, and with concurrent use of corticosteroids
Polymyxins	Nephrotoxicity, neurotoxicity (paresthesia, vertigo, ataxia, blurred vision, slurred speech), neuromuscular blockade, bronchospasm (administered via inhalation)	Obtain baseline renal function tests and regularly during therapy. Monitor for signs of neuromuscular blockade (eg, respiratory depression, apnea, muscle weakness)	Nephrotoxicity is dose-dependent
Sulfonamides and trimethoprim	GI intolerance, rash, hyperkalemia, bone marrow suppression (anemia with folate deficiency, thrombocytopenia, and leukopenia), serum sickness, hepatitis, photosensitivity, crystalluria with azotemia, urolithiasis, methemoglobinemia, Stevens-Johnson syndrome, toxic epidermal necrolysis, aseptic meningitis, pancreatitis, interstitial nephritis, Sweet syndrome, neurologic toxicity	Monitor for hypersensitivity reactions and rash, CBC, renal and hepatic function, serum potassium, serum glucose	HIV-infected patients are at increased risk for developing adverse drug reactions Methemoglobinemia due to severe G6PD deficiency
Metronidazole	GI intolerance, headache, metallic taste, dark urine, peripheral neuropathy, disulfiram reactions with alcohol, insomnia, stomatitis, aseptic meningitis, dysarthria	Monitor hepatic function, mental/neurologic status	Peripheral neuropathy is reversible and associated with prolonged treatment

CBC, complete blood count; CPK, creatine phosphokinase; LFT, liver function test; SDC, serum drug concentrations; TB, tuberculosis.

overuse of broad-spectrum antibiotic therapy. For example, there have been numerous studies evaluating the utility of the healthcare-associated pneumonia (HCAP) criteria in guiding empiric broad-spectrum therapy. Despite evidence of high sensitivity in identifying potential multi-drug resistant pathogens, other studies have demonstrated that HCAP criteria have low specificity for identifying specific organisms, such as MRSA or Pseudomonas, and may lead to overuse of antibiotics. Currently, whether the HCAP criteria appropriately guide broad-spectrum empiric therapy remains a debate.

Disadvantages of Combination Therapy

Although there are potentially beneficial effects from combining drugs, there also are potential disadvantages, including increased cost, greater risk of drug toxicity such as nephrotoxicity with aminoglycosides, amphotericin, and possibly vancomycin, and superinfection with even more resistant bacteria.[42,44,46]

The combination of two or more antibiotics can result in antagonistic effects. For example, the effect of antagonism may be evident when one drug induces β-lactamase production and another drug is β-lactamase unstable. Cefoxitin and imipenem are examples of drugs capable of inducing β-lactamases and may result in more rapid inactivation of penicillins when used together.

MONITORING THERAPEUTIC RESPONSE

7 After antimicrobial therapy has been instituted, the patient must be monitored carefully for a therapeutic response. Culture and sensitivity reports from specimens sent to the microbiology laboratory must be reviewed and the therapy changed accordingly. Use of agents with the narrowest spectrum of activity against identified pathogens is recommended. If anaerobes are suspected, even if they are not identified, anti-anaerobic therapy should be continued.

Patient monitoring should include many of the same parameters used to diagnose the infection. The WBC count and temperature should start to normalize. Physical complaints from the patient also should diminish (ie, decreased pain, shortness of breath, cough, or sputum production). Appetite should improve. However, radiologic improvement can lag behind clinical improvement.

Determinations of serum (or other fluid) levels of antimicrobials can be useful in ensuring outcome, preventing toxicity, or both. There are only a few antimicrobials that require serum concentration monitoring and then only in selected situations. These include the aminoglycosides, vancomycin, flucytosine, and chloramphenicol. Achievement of adequate aminoglycoside concentrations within the first few days of therapy of Gram-negative infection has been correlated with better therapeutic outcome.[47]

Changes in the volume of distribution can have a significant impact on the efficacy, safety, or both of therapy. An unexpectedly low volume of distribution (such as in the dehydrated

patient) will result in higher, potentially toxic drug concentrations, whereas a larger-than-expected volume of distribution (such as in patients with edema or ascites) will result in low, potentially subtherapeutic concentrations. The most effective methods use measured serum concentrations of the drugs rather than estimations from renal function tests to assess true drug clearance from the body.

8 As patients improve clinically, the route of administration should be reevaluated. Streamlining therapy from parenteral to oral (switch therapy) has become an accepted practice for many infections.[5] Criteria that should be present to justify a switch to oral therapy include (a) overall clinical improvement, (b) lack of fever for 8 to 24 hours, (c) decreased WBC count, and (d) a functioning GI tract. Drugs that exhibit excellent oral bioavailability when compared with IV formulations include ciprofloxacin, clindamycin, doxycycline, levofloxacin, metronidazole, moxifloxacin, linezolid, and trimethoprim–sulfamethoxazole.

FAILURE OF ANTIMICROBIAL THERAPY

9 A variety of factors may be responsible for an apparent lack of response to therapy. Patients who fail to respond over 2 to 3 days require a thorough reevaluation. It is possible that the disease is not infectious or is nonbacterial in origin, or there is an undetected pathogen in a polymicrobial infection. Other factors include those directly related to drug selection, the host, or the pathogen. Laboratory error in identification, susceptibility testing, or both (presence of inoculum effect or resistant subpopulations) is a rare cause of antimicrobial failure.

Failures Caused by Drug Selection

Factors related directly to the drug selection include an inappropriate drug selection, dosage, or route of administration. Malabsorption of a drug product because of GI disease (such as a short-bowel syndrome) or a drug interaction (such as complexation of fluoroquinolones with multivalent cations resulting in reduced absorption) can lead to potentially subtherapeutic serum concentrations. Accelerated drug elimination is also possible. This can occur in patients with cystic fibrosis or during pregnancy, when more rapid clearance or larger volumes of distribution can result in low serum concentrations, particularly for aminoglycosides. A common cause of failure of therapy is poor penetration into the site of infection. This is especially true for sites such as the CNS, eye, and prostate gland. Drug failure also can result from drugs that are highly protein bound or that are chemically inactivated at the site of infection.

Failures Caused by Host Factors

Host defenses must be considered when evaluating a patient who is not responding to antimicrobial therapy. Patients who are immunosuppressed (eg, granulocytopenia from chemotherapy or AIDS) may respond poorly to therapy because their defenses are inadequate to eradicate the infection despite seemingly adequate drug regimens. A good example is the poor response of infection in granulocytopenic patients that is seen when their WBC counts remain low during therapy. This contrasts with a much better response when granulocyte counts increase during therapy.

Other host factors are related to the need for surgical drainage of abscesses or removal of foreign bodies, necrotic tissue, or both. If these situations are not corrected, they result in persistent infection and, occasionally, bacteremia despite adequate antimicrobial therapy.

Failures Caused by Microorganisms

There are two types of resistance, intrinsic and acquired resistance. Intrinsic resistance is when the antimicrobial agent never had activity against the bacterial species. For example, Gram-negative bacteria are naturally resistant to vancomycin because the drug cannot penetrate the outer membrane of Gram-negative bacteria. Acquired resistance is when the antimicrobial agent was originally active against the bacterial species but the genetic makeup of the bacteria has changed so the drug can no longer be effective.[48]

The strategies used by bacteria to develop acquired resistance are primarily classified into four general mechanisms of resistance: (a) alteration in the target site, (b) change in membrane permeability, (c) efflux pump, and (d) drug inactivation. Bacteria can use one or more of these mechanisms against a specific antibiotic class. Furthermore, a single mechanism of resistance can result in resistance to multiple related or unrelated classes of antibiotics.

Drug inactivation through either β-lactamases or aminoglycoside-modifying enzymes is the predominant mechanism of resistance. For example, β-lactamases can be either plasmid or chromosomally mediated. In addition, the expression of β-lactamases can be induced or constitutive. There are now multiple types and classes of β-lactamases identified, which is beyond the scope of this chapter. However, there are several outstanding papers discussing all of the different types of β-lactamases.[49-51]

The increase in resistance among bacteria is believed to be a result of continued overuse of antimicrobials in the community, as well as in hospitals, and the increasing prevalence of immunosuppressed patients receiving long-term suppressive antimicrobials for the prevention of infections. These resistance patterns are regionally variable, and susceptibility patterns in the community (or hospital) should be monitored closely to promote rational antimicrobial selection.[48]

Enterococci have been isolated with multiple resistance patterns. They may be resistant to β-lactams (by virtue of β-lactamase production, altered penicillin-binding proteins [PBPs], or both), vancomycin (via alterations in peptidoglycan synthesis), and high levels of aminoglycosides (via enzymatic degradation). Pneumococci resistant to penicillins, certain cephalosporins, and macrolides are increasingly common. These organisms generally are susceptible to vancomycin, the new fluoroquinolones, and cefotaxime or ceftriaxone. However, antimicrobial agents such as linezolid, daptomycin, telavancin, and tigecycline have been targeted at resistant Gram-positive bacteria.

Treatment of an infection caused by *Enterobacter*, *Citrobacter*, *Serratia*, or *P. aeruginosa* with a third-generation cephalosporin or aztreonam may produce an initial clinical response by eradicating all the susceptible bacteria in the population. Within a few days, however, the highly resistant subpopulations have a selective advantage and can overgrow the infection site to produce a relapse. These bacteria usually retain susceptibility to aminoglycosides, carbapenems, and fluoroquinolones but are resistant to all other β-lactams. Host defenses are extremely important in this scenario. Debilitated patients with pulmonary infections, abscesses, or osteomyelitis are at high risk for drug failure. In these situations, a combination regimen to prevent the emergence of resistance or the use of carbapenem or a fluoroquinolone may be warranted for empirical therapy.

ANTIMICROBIAL STEWARDSHIP

The importance of the selection and continuation of appropriate antimicrobial therapy in acute care hospitals are part of a wide movement that is referred to as 'antimicrobial stewardship'. Antimicrobial stewardship programs are aimed at "optimizing antimicrobial selection, dosing, route, and duration of therapy to maximize clinical cure or prevention of infection while limiting the unintended consequences, such as the emergence of resistance, adverse drug events, and cost."

Many institutions have developed an antibiotic stewardship program. The team is generally a multidisciplinary group including representation from microbiology, infection control, administration, information technology, pharmacy including infectious disease-trained clinical pharmacists, and physicians from several disciplines, including infectious disease. Components of antimicrobial stewardship activities include formulary restriction, prospective audit and feedback of antimicrobial prescriptions to clinicians, education, use of clinical order sets and guidelines, de-escalation of therapy, and intravenous to oral antimicrobial conversion.[52,53]

Antibiotic Formulary

One of the main roles of an antimicrobial stewardship team is to decide which antibiotics to include on their formularies. The decision to have a formulary remains controversial; however, restricting choices does encourage familiarity with a core of antibiotics for residents and attending physicians. Open formularies allow the empirical use of any commercially available antibiotics, with recommended guidelines for changes when culture and sensitivity results are finalized. The implementation of the guidelines and restrictions requires the cooperation of the entire medical staff. Education is vital to the success of the antibiotic formulary.

Keeping Current

Attention must be paid to the literature on antimicrobials to assist in the selection of therapy. Evidence-based practice guidelines from the Infectious Diseases Society of America can aid clinicians to direct appropriate therapy for specific infectious disease syndromes. In addition, the results from prospective, controlled, randomized clinical trials should be evaluated whenever possible when considering appropriate antimicrobial therapy. Results from prelicensing open trials offer only limited information that can be useful in this regard because patients in these trials generally are not seriously ill and are not infected with multiple resistant bacteria. Other confounding factors found in most clinical situations are excluded by virtue of the study design. Therefore, comparative data in more seriously ill patients are essential for the appropriate application of new agents.

Postmarketing trials are also important because results can demonstrate superiority of one regimen over another, in efficacy, safety, or cost-effectiveness. Appropriate antimicrobial therapy can change as new organisms are discovered, susceptibility patterns change, new drugs become available, and new clinical trial results are published. Classical thinking in the treatment of infectious diseases will continue to change and evolve to maintain antimicrobial efficacy. Optimal use of modern antimicrobials is just beginning to be defined.

ABBREVIATIONS

AIDS	acquired immunodeficiency syndrome
AST	antimicrobial susceptibility testing
AUC	area under the curve
CSF	cerebrospinal fluid
HA-MRSA	hospital-acquired methicillin-resistant *Staphylococcus aureus*
IL-1	interleukin 1
MIC	minimal inhibitory concentration
PBP	penicillin-binding protein
PMN	polymorphonuclear
WBC	white blood cell

Appendix 105-1

Drugs of Choice, First Choice, *Alternative(s)*

GRAM-POSITIVE COCCI

Enterococcus faecalis (generally not as resistant to antibiotics as *Enterococcus faecium*)

- Serious infection (endocarditis, meningitis, pyelonephritis with bacteremia)
  - Ampicillin (or penicillin G) + (gentamicin or streptomycin)
  - Vancomycin + (gentamicin or streptomycin), daptomycin, linezolid, tedizolid, telavancin, tigecycline[a]
- Urinary tract infection
  - Ampicillin, amoxicillin
  - *Fosfomycin* or *nitrofurantoin*

E. faecium (generally more resistant to antibiotics than *E. faecalis*)

- Recommend consultation with infectious disease specialist
  - Linezolid, quinupristin/dalfopristin, daptomycin, tigecycline[a]

Staphylococcus aureus/*Staphylococcus epidermidis*

- Methicillin (oxacillin)-sensitive
  - Nafcillin or oxacillin
  - *FGC,[b,c] trimethoprim–sulfamethoxazole, clindamycin, BL/BLI[d]*
- Hospital-acquired methicillin (oxacillin)–resistant
  - Vancomycin ± (gentamicin or rifampin)
  - *Ceftaroline, daptomycin, linezolid, telavancin, tigecycline,[a] trimethoprim–sulfamethoxazole, quinupristin–dalfopristin*
- Community-acquired methicillin (oxacillin)–resistant
  - Clindamycin, trimethoprim–sulfamethoxazole, doxycycline[a]
  - *Ceftaroline, dalbavancin, daptomycin, linezolid, oritivancin, tedizolid, telavancin, tigecycline,[a]* or *vancomycin*

Streptococcus (groups A, B, C, G, and *Streptococcus bovis*)

- Penicillin G or V or ampicillin
- *FGC,[b,c] erythromycin, azithromycin, clarithromycin*

Streptococcus pneumoniae

- Penicillin-sensitive (minimal inhibitory concentration [MIC] <0.1 mcg/mL [mg/L])
  - Penicillin G or V or ampicillin
  - *FGC,[b,c] doxycycline,[a] azithromycin, clarithromycin, erythromycin*
- Penicillin intermediate (MIC 0.1-1 mcg/mL [mg/L])
  - High-dose penicillin (12 million units/day for adults) or ceftriaxone[c] or cefotaxime[c]
  - *Levofloxacin,[a] moxifloxacin,[a] gemifloxacin,[a] or vancomycin*
- Penicillin-resistant (MIC ≥1.0 mcg/mL [mg/L])
  - Recommend consultation with infectious disease specialist.
    - *Vancomycin ± rifampin*
    - *Per sensitivities: ceftaroline, cefotaxime, ceftriaxone,[c] levofloxacin,[a] moxifloxacin,[a] or gemifloxacin[a]*

Streptococcus, viridans group

- Penicillin G ± gentamicin[e]
- *Cefotaxime,[c] ceftriaxone,[c] erythromycin, azithromycin, clarithromycin*, or *vancomycin ± gentamicin*

GRAM-NEGATIVE COCCI

Moraxella (Branhamella) catarrhalis

- Amoxicillin–clavulanate, ampicillin–sulbactam
- *Trimethoprim–sulfamethoxazole, erythromycin, azithromycin, clarithromycin, doxycycline,[a] SGC,[c,f] cefotaxime,[c] ceftriaxone,[c]* or *TGCPO[c,g]*

Neisseria gonorrhoeae (also give concomitant treatment for *Chlamydia trachomatis*)

- Disseminated gonococcal infection
  - Ceftriaxone[c] or cefotaxime[c]
  - *Oral follow up: cefpodoxime,[c] ciprofloxacin,[a]* or *levofloxacin[a]*
- Uncomplicated infection
  - Ceftriaxone,[c] cefotaxime,[c] or cefpodoxime[c]
  - *Ciprofloxacin[a]* or *levofloxacin[a]*

Neisseria meningitides

- Penicillin G
- *Cefotaxime[c]* or *ceftriaxone[c]*

GRAM-POSITIVE BACILLI

Clostridium perfringens

- Penicillin G ± clindamycin
- *Metronidazole,[a] clindamycin, doxycycline,[a] cefazolin,[c] carbapenem[h,i]*

Clostridium difficile

- Oral metronidazole[a]
- *Oral vancomycin* or *fidaxomicin*

GRAM-NEGATIVE BACILLI

Acinetobacter spp.

- Doripenem, imipenem, or meropenem ± aminoglycoside[j] (amikacin usually most effective)
- *Ampicillin–sulbactam, polymyxins,[i]* or *tigecycline[a]*

Bacteroides fragilis (and others)

- Metronidazole[a]
- *BL/BLI,[d] clindamycin, cefoxitin,[c] cefotetan,[c] ceftolozane-azobactam, ceftazidime-avibactam*, or *carbapenem[h,i]*

Enterobacter spp.

- Carbapenem[h] or cefepime ± aminoglycoside[j]
- *ceftolozane-tazobactam, ceftazidime-avibactam, ciprofloxacin,[a] levofloxacin,[a] piperacillin–tazobactam, ticarcillin–clavulanate*

Escherichia coli

- Meningitis
  - Cefotaxime,[c] ceftriaxone,[c] meropenem
- Systemic infection
  - Cefotaxime[c] or ceftriaxone[c]
  - *BL/BLI,[d] fluoroquinolone,[a,k] carbapenem[h,i]*
- Urinary tract infection
  - Most oral agents: check sensitivities
  - Ampicillin, amoxicillin–clavulanate, doxycycline,[a] or cephalexin[c]
  - *Aminoglycoside,[j] FGC,[b,c] nitrofurantoin, fluoroquinolone[a,k]*

Gardnerella vaginalis

- Metronidazole[a]
- *Clindamycin*

Haemophilus influenzae

- Meningitis
  - Cefotaxime[c] or ceftriaxone[c]
  - *Meropenem[i]*

- Other infections
  - BL/BLI,[d] or if β-lactamase-negative, ampicillin or amoxicillin
  - *Trimethoprim–sulfamethoxazole, cefuroxime,[c] azithromycin, clarithromycin*, or *fluoroquinolone*[a,k]

Klebsiella pneumoniae

- BL/BLI,[d] cefotaxime,[c] ceftriaxone,[c] cefepime[c]
- Carbapenem,[h,i] *ceftolozane-tazobactam, ceftazidime-avibactam*, fluoroquinolone[a,k]

Legionella spp.

- Azithromycin, erythromycin ± rifampin, or fluoroquinolone[a,k]
- Trimethoprim–sulfamethoxazole, clarithromycin, or doxycycline[a]

Pasteurella multocida

- Penicillin G, ampicillin, amoxicillin
- *Doxycycline,[a] BL/BLI,[d] trimethoprim–sulfamethoxazole* or *ceftriaxone*[c]

Proteus mirabilis

- Ampicillin
- *Trimethoprim–sulfamethoxazole*

Proteus (indole-positive) (including *Providencia rettgeri*, *Morganella morganii*, and *Proteus vulgaris*)

- Cefotaxime,[c] ceftriaxone,[c] or fluoroquinolone[a,k]
- *BL/BLI,[d] aztreonam,[l] aminoglycosides,[j] carbapenem,[h,i] ceftolozane-tazobactam, ceftazidime-avibactam*

Providencia stuartii

- Amikacin, cefotaxime,[c] ceftriaxone,[c] fluoroquinolone[a,k]
- *Trimethoprim–sulfamethoxazole, aztreonam,[l] carbapenem*[h,i]

Pseudomonas aeruginosa

- Urinary tract infection only
  - Aminoglycoside[j]
  - *Ciprofloxacin,[a] levofloxacin*[a]
- Systemic infection
  - Cefepime,[c] ceftazidime,[c] doripenem,[i] imipenem,[i] meropenem,[i] piperacillin–tazobactam, or ticarcillin–clavulanate + aminoglycoside[j]
  - *Aztreonam,[l] ceftolozane-tazobactam, ceftazidime-avibactam, ciprofloxacin,[a] levofloxacin,[a] polymyxin*[i]

Salmonella typhi

- Ciprofloxacin,[a] levofloxacin,[c] ceftriaxone,[c] cefotaxime[c]
- *Trimethoprim–sulfamethoxazole*

Serratia marcescens

- Ceftriaxone,[c] cefotaxime,[c] cefepime,[c] ciprofloxacin,[a] levofloxacin[a]
- *Aztreonam,[l] carbapenem,[h,i] piperacillin–tazobactam, ticarcillin–clavulanate*

Stenotrophomonas (Xanthomonas) maltophilia (generally very resistant to all antimicrobials)

- Trimethoprim–sulfamethoxazole.
- *Check sensitivities to ceftazidime,[c] doxycycline,[a] minocycline,[a]* and *ticarcillin–clavulanate*

MISCELLANEOUS MICROORGANISMS

Chlamydia pneumoniae

- Doxycycline[a]
- *Azithromycin, clarithromycin, erythromycin, or fluoroquinolone*[a,k]

C. trachomatis

- Azithromycin or doxycycline[a]
- *Levofloxacin,[a] erythromycin*

Mycoplasma pneumoniae

- Azithromycin, clarithromycin, erythromycin, fluoroquinolone[a,k]
- *Doxycycline*[a]

SPIROCHETES

Treponema pallidum

- Neurosyphilis
  - Penicillin G
  - *Ceftriaxone*[c]
- *Primary* or *secondary*
  - Benzathine, penicillin G
  - *Ceftriaxone*[c] or *doxycycline*[a]

Borrelia burgdorferi (choice depends on stage of disease)

- Ceftriaxone[c] or cefuroxime axetil,[c] doxycycline,[a] amoxicillin
- *High-dose penicillin, cefotaxime*[c]

---

[a]Not for use in pregnant patients or children.
[b]First-generation cephalosporins—IV: cefazolin; orally: cephalexin, cephradine, or cefadroxil.
[c]Some penicillin-allergic patients may react to cephalosporins.
[d]β-Lactam/β-lactamase inhibitor combination—IV: ampicillin–sulbactam, piperacillin–tazobactam, and ticarcillin–clavulanate; orally: amoxicillin–clavulanate.
[e]Gentamicin should be added if tolerance or moderately susceptible (MIC >0.1 mcg/mL [mg/L]) organisms are encountered; streptomycin is used but can be more toxic.
[f]Second-generation cephalosporins—IV: cefuroxime; orally: cefaclor, cefditoren, cefprozil, cefuroxime axetil, and loracarbef.
[g]Third-generation cephalosporins—orally: cefdinir, cefixime, cefetamet, cefpodoxime proxetil, and ceftibuten.
[h]Carbapenem: doripenem, ertapenem, imipenem/cilastatin, and meropenem.
[i]Reserve for serious infection.
[j]Aminoglycosides: gentamicin, tobramycin, and amikacin; use per sensitivities.
[k]Fluoroquinolones IV/orally: ciprofloxacin, levofloxacin, and moxifloxacin.
[l]Generally reserved for patients with hypersensitivity reactions to penicillin.

Central Nervous System Infections

106

Ramy H. Elshaboury, Aileen S. Ahiskali, Jessica S. Holt, and John C. Rotschafer

KEY CONCEPTS

1. The four most common pathogens of acute bacterial meningitis in the United States are *Streptococcus pneumoniae*, group B *Streptococcus*, *Neisseria meningitidis*, and *Haemophilus influenzae* type b, although routine vaccinations are having a dramatic effect on the incidence and distribution of these pathogens.
2. In cases of bacterial meningitis, initial findings can include (a) presenting signs and symptoms: fever, headache, nuchal rigidity (the classic triad), Brudzinski's or Kernig's sign, and altered mental status; and (b) abnormal cerebrospinal fluid (CSF) chemistries: elevated white blood cell (WBC) count (greater than 1,000 cells/mm^3[greater than 1×10^2/L]), elevated protein (greater than 50 mg/dL [greater than 500 mg/L]), and decreased glucose levels (less than 45 mg/dL [less than 2.5 mmol/L]).
3. Two main microbiologic tests that should be obtained include a gram stain and culture of the CSF. Molecular testing such as polymerase chain reaction (PCR), latex coagglutination, and enzyme immunoassay (EIA) tests can provide for the rapid identification of several causes of meningitis.
4. Three primary goals of treatment in meningitis include (a) eradication of infection, (b) amelioration of signs and symptoms, and (c) prevention of the development of neurologic sequelae, such as seizures, deafness, coma, and death.
5. When selecting antibiotics, the clinician must consider the antibiotic concentration at the site of infection as well as the spectrum of antibacterial activity. Empirical choices should be based on age, predisposing conditions, vaccination history, and comorbidities. (a) Ceftriaxone or cefotaxime and vancomycin are reasonable initial choices for empirical coverage of community-acquired meningitis in adult patients. (b) *Listeria monocytogenes* is a common pathogen in infants and elderly; therefore, ampicillin with or without gentamicin should be empirically added to antimicrobial regimens.
6. Empirical coverage with an appropriate antibiotic should be started as soon as possible when clinical suspicion of meningitis exists. If there is a delay in obtaining a lumbar puncture (even 30-60 minutes), or if the patient is to undergo neuroimaging, the first dose of an antibiotic should not be withheld.
7. Antibiotic dosages for the treatment of meningitis should be optimized to ensure adequate CNS therapeutic concentrations.
8. The duration of antibiotic treatment for meningitis has not been standardized; however, it is generally based on the causative organism and the individual case, and may range from 7 to 21 days.
9. Close contacts and relatives of the index case should be assessed for appropriate chemoprophylaxis and vaccinations, particularly for *N. meningitidis* and *H. influenzae* meningitis.
10. Steroid treatment includes dexamethasone of 0.15 mg/kg per dose given four times daily for 4 days in infants and children older than 2 months of age with proven or strongly suspected bacterial meningitis. Steroids should be started prior to the first dose of antibiotics.

Central nervous system (CNS) infections are caused by a variety of pathogens, including bacteria, viruses, fungi, and parasites. Infections are the result of hematogenous spread from a primary infection site, seeding from a parameningeal focus, reactivation from a latent site, trauma, or congenital defects within the CNS. Newer diagnostic techniques have enabled more rapid and definitive diagnoses, thus diminishing the number of unknown "aseptic meningitis" diagnoses and improving targeted therapy. Bacteria resistant to multiple antibiotics present new challenges in the management of CNS infections. This chapter presents the etiology, pathophysiology, therapy, and prophylaxis of these infections, concentrating predominantly on bacterial meningitis.

EPIDEMIOLOGY

Approximately 4,100 cases of acute community-acquired bacterial meningitis, excluding epidemics, occurred annually in the United States between 2003 and 2007, resulting in approximately 500 deaths.[1] Risk factors and mortality rates widely vary depending on the causative microorganism and age group, and as high as 20% (range 12.3%-35.3%) of survivors will experience one or more neurologic disabilities.[2] Neurologic sequelae frequently associated with bacterial meningitis include seizures, sensorineural hearing loss, and hydrocephalus. While risk for the development of neurologic sequelae depends on the infecting organism, pneumococcal meningitis is typically associated with the highest risk.[2,3] Despite the availability of antimicrobial therapy against the most common CNS pathogens, CNS infections continue to pose significant morbidity and mortality.

ETIOLOGY

1 CNS infections are caused by a variety of microorganisms. Historically, infections were primarily community-acquired; however, an increasing number of cases are now nosocomial.[4] *Haemophilus*

influenzae type b (Hib) was the most commonly identified cause of bacterial meningitis until the introduction of the Hib conjugate vaccine in 1990,[5] when *Streptococcus pneumoniae* became the most commonly identified cause.[1,6] Between 2003 and 2007 in the United States, *S. pneumoniae* accounted for 58% of all bacterial meningitis cases, followed by group B *Streptococcus* (18.1%), *Neisseria meningitidis* (13.9%), *H. influenzae* (6.7%), and *L. monocytogenes* (3.4%).[1] Other causative organisms included gram-negative organisms and *Staphylococcus* spp.[4,6]

Following the release of the pneumococcal heptavalent protein-polysaccharide conjugate vaccine (PCV7) in 2000, the rate of invasive pneumococcal disease (IPD), including pneumococcal meningitis, steadily dropped from 24.3 cases per 100,000 people in 1999 to 17.3 cases per 100,000 in 2001 and 13.5 cases per 100,000 in 2007.[7] The largest impact was in children younger than 2 years of age, where a nearly 70% decline in infection rate was reported as a result of implementation in the routine childhood vaccination schedule. This positive effect carried into the adult population with significant reduction in IPD across all age groups, despite stagnant adult vaccination coverage.[8] Further reductions in IPD in the United States and Europe were also noted following the introduction of the 13-valent pneumococcal conjugate vaccine (PCV13) in 2010 for routine childhood vaccination, and later for high-risk and older adults.[9,10] Widespread availability of childhood vaccination against Hib starting in 1980s in the United States has also resulted in a dramatic reduction of invasive infections, including meningitis, in the past 20 to 30 years. Finally, targeted meningococcal vaccination for high-risk infants, adolescents, and adults have similarly impacted the epidemiology and risk of meningococcal meningitis, and further changes are expected following the availability of meningococcal group B vaccines in the United States.[11] As a result of the rapid decline of acute community-acquired bacterial meningitis rates in children, the median age of patients increased from 30.3 years in 1998 to 41.3 years in 2007 in the United States.[1]

Both the Hib and pneumococcal vaccines are of limited availability in low-income and developing countries where cost is often prohibitive. Thus rates of invasive disease, neurologic sequelae, and case fatalities among children and adults continue to be substantially higher than western developed countries.[2]

ANATOMY AND PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM

Meninges

The skull and vertebrae protect the CNS from blunt or penetrating trauma (Fig. 106-1). The brain is suspended in these structures by cerebrospinal fluid (CSF) and is surrounded by the meninges. The meninges are made up of three separate membranes: dura mater, arachnoid, and pia mater.[12] Dura mater, or pachymeninges, lies directly beneath and is adherent to the skull. The other two membranes are referred to collectively as leptomeninges. Pia mater lies directly over brain tissue. Arachnoid, the middle layer, lies between the dura mater and the pia mater. The subarachnoid space, located between the arachnoid and the pia mater, is the conduit for CSF. By definition, meningitis refers to inflammation of the subarachnoid space or spinal fluid, whereas encephalitis is an inflammation of the brain tissue itself. Since infectious microorganisms frequently are an underlying cause of these inflammatory processes, the terms meningitis, encephalitis, or meningoencephalitis are frequently used to denote an infectious process.

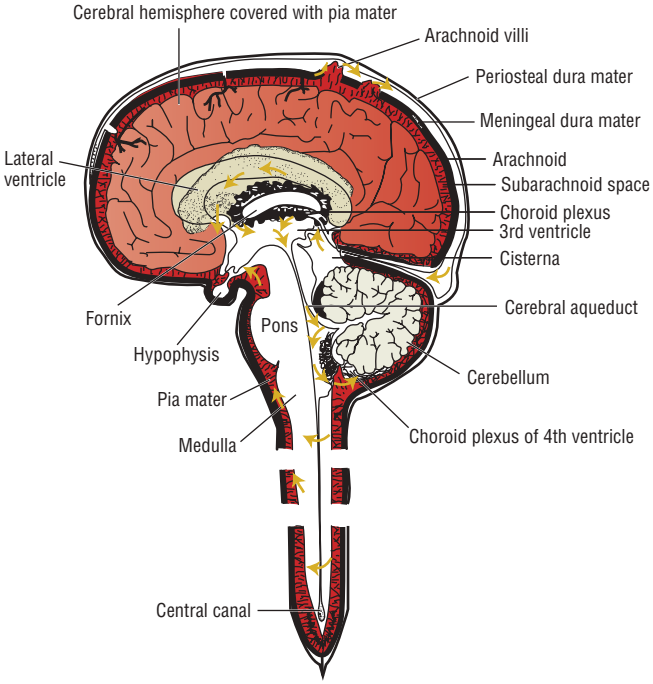

FIGURE 106-1 Diagram of the central nervous system.

Cerebrospinal Fluid

Approximately 85% of the CSF is produced within the third, fourth, and lateral ventricles by the choroid plexus (Fig. 106-1). CSF volume in the CNS is related to patient age: infants have approximately 40 to 60 mL of CSF, older children have 60 to 100 mL, while adults have 115 to 160 mL. Normally, CSF is produced at the rate of approximately 500 mL/day and flows unidirectionally downward through the spinal cord. The CSF is removed by the arachnoid villi and vertebral venous plexus located in the spinal cord and does not recommunicate with the point of production.[12]

2 The CSF normally is clear, with a protein content of less than 50 mg/dL (500 mg/L), a glucose concentration of approximately 50% to 60% of the simultaneous peripheral serum glucose concentration, and a pH of approximately 7.4. Also, it typically contains fewer than five WBCs per cubic millimeter (fewer than 5×10^6/L), all of which should be lymphocytes (Table 106-1).[13-17] As meninges become inflamed, the constituency of the CSF changes, and these abnormalities can be used diagnostically as markers of CNS infections.

TABLE 106-1 Mean Values of the Components of Normal and Abnormal Cerebrospinal Fluid[13-17]

Type	Normal	Bacterial	Viral	Fungal	Tuberculosis
WBC (cells/mm^3 or 10^6/L)	<5 (<30 in newborns)	1,000-5,000	5-500	100-400	25-500
Differential[a]	Monocytes	Neutrophils	Lymphocytes	Lymphocytes	Variable
Protein (mg/dL)	<50 (<500 mg/L)	Elevated	Mild elevation	Elevated	Elevated
Glucose (mg/dL)	45-80 (2.5-4.4 mmol/L)	Low	Normal	Low	Low
CSF/blood glucose ratio	50%-60%	Decreased	Normal	Decreased	Decreased

[a]Initial cerebrospinal fluid (CSF), while blood cell (WBC) count may reveal a predominance of polymorphonuclear neutrophils (PMNs).

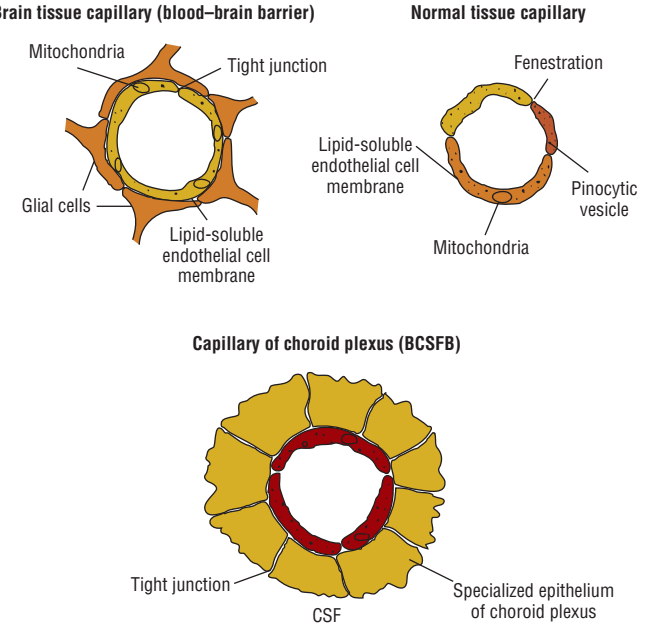

FIGURE 106-2 Schematic representation of a blood–cerebrospinal fluid barrier capillary, brain tissue capillary, and normal tissue capillary (*below*).

Blood–Brain Barrier/Blood–CSF Barrier

Natural barriers to the exchange of drugs and endogenous compounds among the blood, brain, and CSF are the blood–brain barrier (BBB) and the blood–CSF barrier (BCSFB) (Fig. 106-2). The BBB consists of tightly joined capillary endothelial cells. Drug entry into brain tissue is accomplished by direct passage through the capillary endothelial cells and further penetration of the glial cells that envelop the capillary structure.[12] Passage of drugs into the CSF is controlled by the BCSFB. This barrier is created by ependymal cells of the choroid plexus, which function as an active-transport system similar to the renal tubular epithelial cells. The inflammatory process associated with meningitis can also inhibit the active-transport system of the choroid plexus.[18]

PATHOPHYSIOLOGY OF THE CNS INFECTION

The development of bacterial meningitis occurs following bacterial invasion of the host and CNS, bacterial multiplication with subsequent inflammation of the CNS; specifically the subarachnoid and the ventricular spaces; pathophysiologic alterations owing to progressive inflammation, and the resulting neuronal damage.[14] The critical first step in the acquisition of acute bacterial meningitis is nasopharyngeal colonization of the host. Immunoglobulins (Igs), such as secretory IgA, are found in high concentrations within nasopharyngeal secretions and work to inhibit bacterial colonization. However, this mucus barrier is deteriorated by IgA proteases secreted by bacteria, which then extend pili allowing adherence to the host cell surface receptors. Bacterial pathogens tightly attach to nasopharyngeal epithelial cells and are then phagocytized into the host's bloodstream. After accessing the patient's bloodstream, bacteria must overcome the host's defense mechanisms. Commonly, CNS bacterial pathogens produce an extensive polysaccharide capsule resistant to neutrophil phagocytosis and complement opsonization. Therefore, *H. influenzae*, Escherichia *coli*, and *N. meningitidis* strains lacking polysaccharide capsules are unable to cause meningitis. Capsular polysaccharides activate the alternate complement pathway, which promotes phagocytosis and clearance of infecting pathogens. Patients unable to activate the alternative complement pathway, such as asplenic and sickle cell patients, are predisposed to bacterial infections caused by encapsulated microorganisms and therefore are at increased risk for meningitis.[14]

Although the exact site and mechanism of bacterial invasion into the CNS is unknown, studies suggest invasion into the subarachnoid space occurs by continuous exposure of the CNS to large bacterial inoculum. Bacteremia with inoculum densities of at least 10^3 colony-forming units (CFU)/mL [10^6 CFU/L] appears to be essential for subarachnoid space invasion.[19] Although several sites of bacterial invasion have been theorized, the most plausible sites are the choroid plexus and/or the cerebral microvasculature. Host defense mechanisms within the subarachnoid space are inadequate to combat bacterial pathogens; therefore, bacteria replicate freely within the CSF until either overgrowth occurs or an effective antibiotic regimen is administered that terminates the process.

The effects of meningitis, namely, inflammation within the subarachnoid space and the ensuing neurologic damage, are not necessarily a direct result of the pathogens themselves. The neurologic sequelae occur due to the activation of the host's inflammatory pathways, a process induced by the pathogen or its products. Bacterial cell lysis and subsequent death can result in the release of cell-wall components, such as lipopolysaccharide (LPS), lipid A (endotoxin), lipoteichoic acid, teichoic acid, and peptidoglycan, depending on whether the pathogen is gram-positive or gram-negative (Fig. 106-3). These cell-wall components cause capillary endothelial cells and CNS macrophages to release cytokines (interleukin-1 [IL-1] and tumor necrosis factor [TNF]) and other inflammatory mediators (IL-6, IL-8, platelet-activating factor [PAF], nitric oxide, arachidonic acid metabolites [eg, prostaglandin and prostacycline], and macrophage-derived proteins). Proteolytic products and toxic oxygen radicals are

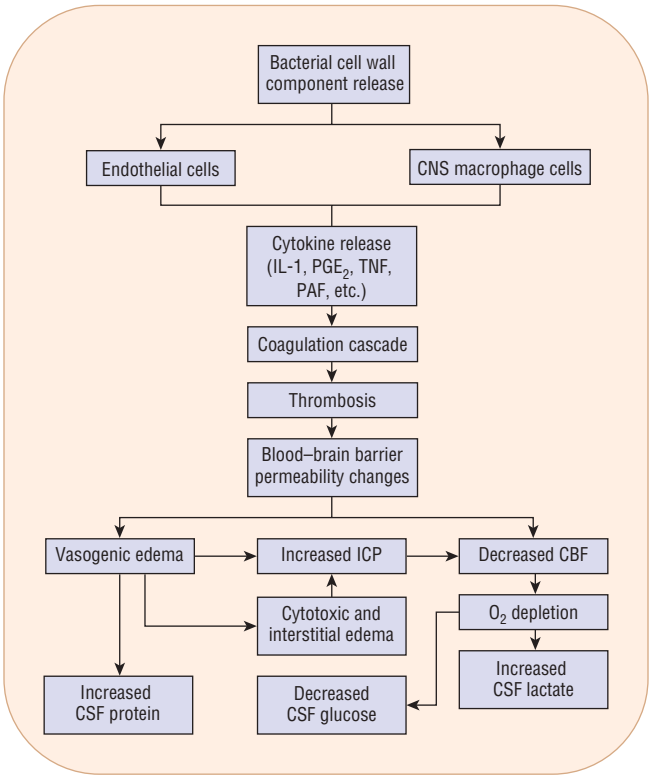

FIGURE 106-3 Hypothetical schema of pathophysiologic events that occur during bacterial meningitis. CBF, cerebral blood flow; CSF, cerebrospinal fluid; ICP, intracranial pressure; IL-1, interleukin-1; PAF, platelet-activating factor; PGE_2, prostaglandin E_2; TNF, tumor necrosis factor.

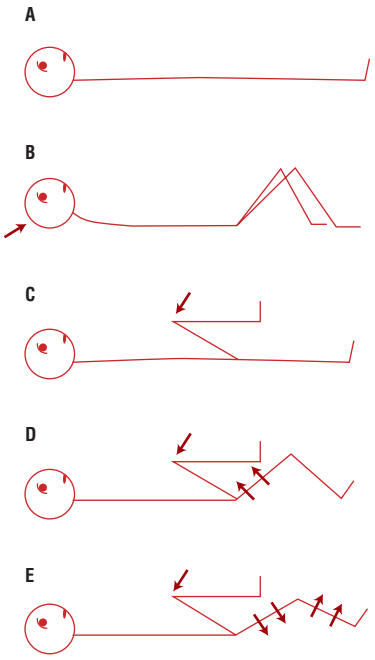

FIGURE 106-4 (A and B) Brudzinski's neck signs. (B) Hip and knee flexion occurs as a result of flexion of the neck. (C to E) Brudzinski's leg signs. (C) Patient's leg is flexed by examiner (*arrow*). (D) The contralateral leg begins to flex—identical contralateral sign (*arrows*). (E) The contralateral leg now begins to extend spontaneously, resembling a little kick (*arrows*).

released from the capillary endothelium, causing an alteration in the permeability of the BBB. PAF activates the coagulation cascade, and arachidonic acid metabolites stimulate vasodilation. These events propagate other sequential events that lead to cerebral edema, elevated intracranial pressure (ICP), CSF pleocytosis, decreased cerebral blood flow, cerebral ischemia, and death.[14,19]

CLINCAL PRESENTATION AND DIAGNOSIS

Clinical presentation varies with age, and generally, the younger the patient, the more atypical and the less pronounced the clinical picture is. Patients may receive antibiotics in the outpatient setting before a diagnosis of meningitis is made, thus delaying presentation to the hospital. Subsequently, prior antibiotic therapy may cause the gram stain and CSF culture to be negative, but rarely affects CSF protein or glucose.

Signs and Symptoms

2 Classic signs and symptoms include fever, nuchal rigidity, altered mental status (*the classic triad*), chills, vomiting, photophobia, and severe headache; Kernig's and Brudzinski's signs may also be present but are poorly sensitive and frequently absent in children (**Figs. 106-4 and 106-5**). Additionally, clinical signs and symptoms in young children may include bulging fontanelle, apneas, purpuric rash, irritability, refusal to eat, and convulsions.[20] Ultimately, almost all patients exhibit at least two of these symptoms: fever, nuchal rigidity, headache, and altered mental status.[3] Purpuric and petechial skin lesions may indicate meningococcal involvement, although lesions may also be present with *H. influenzae* meningitis and skin rashes rarely occur with pneumococcal meningitis.[5] Waterhouse–Friderichsen syndrome, a rapid eruption of multiple hemorrhagic lesions associated with a shock-like state, is associated with meningococcal meningitis. *H. influenzae* and meningococcal meningitis both can cause involvement of the joints during the illness. Finally, history of head trauma with or without skull fracture or presence of a chronically draining ear may be associated with pneumococcal involvement.

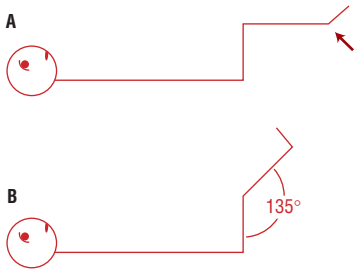

FIGURE 106-5 Kernig's sign. (A) Knees are raised to form a 90-degree angle relative to the trunk, and the examiner attempts to extend the knees. (B) Once the knee angle reaches approximately 135 degrees, contracture or extensor spasm occurs.

Bacterial Meningitis Score

Bacterial Meningitis Score is a validated clinical decision tool aimed to identify children older than 2 months with CSF pleocytosis who are at low risk of acute bacterial meningitis.[21,22] This tool incorporates clinical features such as positive CSF gram stain, presence of seizure, serum absolute neutrophil count 10,000 cells/mm^3 or more (10×10^9/L or more), CSF protein 80 mg/dL or more (800 mg/L or more), and CSF neutrophil count 1,000 cells/mm^3 or more (1×10^9/L or more). Treatment is recommended when one or more criteria are present. Certain pediatric patients are excluded including those with purpura, CSF shunt, recent neurosurgery, Lyme disease (LD), and those who received oral or intravenous antibiotics within 72 hours. This scoring tool was validated in several studies showing high accuracy in excluding acute bacterial meningitis. One meta-analysis of eight validation studies between 2002 and 2012 showed the tool to be highly accurate, with combined sensitivity of 99.3%, specificity of 62.1%, and negative predictive value of 99.7%.[22]

Laboratory Tests

Several tubes of CSF are collected via lumbar puncture for chemistry, cytology, microbiology, and hematology tests. Theoretically, the first tube has a higher likelihood of being contaminated with both blood and bacteria during the puncture, although the total volume is more important in practice than the tube cultured. CSF should not be refrigerated or stored on ice. Analysis of CSF chemistries includes measurement of glucose and total protein concentrations. An elevated CSF protein of more than or equal to 50 mg/dL (500 mg/L or more) and a CSF glucose concentration of less than 50% of the simultaneously obtained peripheral value suggest bacterial meningitis (Table 106-1).[13-17] The values for CSF glucose, protein, and WBC found with bacterial meningitis overlap significantly with those with viral, tuberculous, and fungal meningitis (Table 106-1).[13-17] Therefore, CSF WBC counts and CSF glucose and protein concentrations cannot always distinguish the different etiologies of meningitis.

Other Diagnostic Tests[13,15,23,24]

In patients presenting with new-onset seizures, signs of space-occupying lesions, or moderate to severe impairment of consciousness, cranial imaging via magnetic resonance imaging (MRI) or cranial computed tomography (CT) should precede a lumbar puncture. MRI is generally preferred, as it more clearly identifies areas of cerebral edemas. In these instances, the withdrawal of CSF fluid from a lumbar puncture reduces counterpressure that may result in compression of the brain with risk of brain herniation complicating the clinical course. Neuroimaging should not, however, delay initiation of appropriate antibiotic therapy as doing so can result in a poor outcome in this disease.[25,26] Finally, MRI is considered the preferred imaging modality for the diagnosis of encephalitis due to higher specificity and sensitivity than CT.[15]

Blood and other specimens should be cultured according to clinical judgment as meningitis frequently can arise via hematogenous dissemination or can be associated with infections at other sites. 3 Gram stain and culture of the CSF should be performed for suspected meningitis, and gram stain continues to be the most rapid and accurate method for presumptive diagnosis. When performed before antibiotic therapy is initiated, gram stain is both rapid and sensitive and can confirm the diagnosis of bacterial meningitis in 75% to 90% of cases. However, the sensitivity of the gram stain decreases to 40% from 60% in patients who received prior outpatient antibiotic therapy. Procalcitonin (PCT) has emerged as a predictive biomarker for invasive infections, including meningitis, owing to specificity to bacterial infections. Elevation of serum PCT levels was mostly studied in lower respiratory tract and blood stream infections, but some data support its association with bacterial meningitis.[27] Utility of PCT in predicting bacterial meningitis and differentiating bacterial from viral etiologies is controversial, and more studies are needed to confirm the impact of serum PCT monitoring on clinical outcomes.

Polymerase chain reaction (PCR) techniques can be used to diagnose meningitis caused by *N. meningitidis*, *S. pneumoniae*, and Hib. PCR is considered to be highly sensitive and specific, but expense and availability can be limiting. A multiplex PCR system with a meningitis panel is currently under review by the U.S. Food and Drug Administration (FDA) for approval. The panel includes tests for six bacterial, eight viral, and two yeast targets, with a turnaround time of appoximately 1 hour. Latex fixation, latex coagglutination, and enzyme immunoassay (EIA) tests provide for the rapid identification of several bacterial causes of meningitis, including *S. pneumoniae*, *N. meningitidis*, and Hib. Rapid-identification latex tests work by bringing potential capsular antigens of the pathogen causing meningitis in contact with a specific antibody, causing an antigen-antibody reaction. This capsular antigen-antibody reaction can be quickly observed visually without waiting for culture results. The sensitivity and specificity of latex fixation and coagglutination tests can vary with the manufacturer of the antibody, density of the antigen present in the CSF, and pathogen being tested. Latex agglutination is considered most useful for patients who have been previously treated with antimicrobials and whose CSF gram stain and culture remain negative.[15]

Diagnosis of tuberculosis meningitis employs acid-fast stain, culture, and PCR of the CSF. Also, PCR testing of the CSF is the preferred method for diagnosing most viral meningitis/encephalitis infections. Finally, the standard diagnostic tests for fungal meningitis include culture, direct microscopic examination of stained and unstained specimens of CSF, antigen detection of cryptococcal or histoplasmal antigens, and antibody assay of serum and/or CSF.

TABLE 106-2 Bacterial Meningitis: Most Likely Etiologies and Empirical Therapy by Age Group[13-15]

Age	Most Likely Organisms	Empirical Therapy[a]
<1 month	*S. agalactiae* Gram-negative enterics[b] *L. monocytogenes*	Ampicillin + cefotaxime *or* ampicillin + aminoglycoside
1-23 months	*S. pneumoniae* *N. meningitidis* *H. influenzae* *S. agalactiae*	Vancomycin[c] + 3rd generation cephalosporin (cefotaxime *or* ceftriaxone)
2-50 years	*N. meningitidis* *S. pneumoniae*	Vancomycin[c] + 3rd generation cephalosporin (cefotaxime *or* ceftriaxone)
>50 years	*S. pneumoniae* *N. meningitidis* Gram-negative enterics[b] *L. monocytogenes*	Vancomycin[c] + ampicillin + 3rd generation cephalosporin (cefotaxime *or* ceftriaxone)

[a]All recommendations are A-III.

[b]*E. coli*, *Klebsiella* spp, Enterobacter spp common.

[c]Vancomycin use should be based on local incidence of penicillin-resistant *S. pneumoniae* and until cefotaxime or ceftriaxone minimum inhibitory concentration results are available.

Strength of recommendation: (A) Good evidence to support a recommendation for use; should always be offered. (B) Moderate evidence to support a recommendation for use; should generally be offered.[15]

Quality of evidence: (I) Evidence from 1or more properly randomized, controlled trial. (II) Evidence from 1 or more well-designed clinical trial, without randomization; from cohort or case-controlled analytic studies (preferably from 1 or more center) or from multiple time-series. (III) Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.[15]

TREATMENT

Desired Outcome

4 Goals for the treatment of CNS infections should include eradication of infection, amelioration of signs and symptoms, prevention or reduction of morbidity and mortality, initiation of appropriate antimicrobials and supportive care, and prevention of disease through timely introduction of vaccination and chemoprophylaxis. Understanding antibiotic selection and the issues surrounding antibiotic penetration will assist in meeting the goals of treatment.

General Approach to Treatment and Nonpharmacologic and Supportive Therapy

Until a pathogen is identified, prompt empirical antibiotic coverage is often needed. 5 Based on the patient's profile (ie, allergies, age, and concurrent medical conditions), extent of antibiotic CNS penetration,[28] and spectrum of activity; appropriate recommendations can be made, and therapy should last at least 48 to 72 hours or until the diagnosis of bacterial meningitis can be ruled out (Tables 106-2 and 106-3).[13-15,28] 6 The first dose of antibiotics should not be withheld, even when lumbar puncture is delayed or neuroimaging is being performed, as changes in the CSF after antibiotic administration usually take up to 12 to 24 hours to occur. Continued therapy should be based on the assessment of clinical improvement, culture, and susceptibility testing results. Once a pathogen is identified, antibiotic therapy should be tailored to the specific pathogen (Tables 106-4 and 106-5).[13,15,24] Throughout the course of treatment, efficacy parameters such as signs and symptoms, microbiologic findings, and CSF examination should be followed to evaluate the success of meeting the desired outcomes.

Supportive care, particularly early in the course of treatment, is critically important. Administration of fluids, electrolytes, antipyretics, and analgesics are indicated for patients presenting with a possible CNS infection. Additionally, venous thromboembolism prophylaxis and ICP monitoring are often needed. Patients may require the administration of osmotic diuretics such as mannitol 25% or hypertonic 3% saline to maintain an ICP of less than 15 mm Hg (less than 2 kPa) and a cerebral perfusion pressure of 60 mm Hg or more (8 kPa or more). Other supportive care measures may include respiratory and circulatory supports, gastrointestinal (GI) care and maintaining normal body temperature. Although supportive care is important initially, appropriate antibiotic therapy (empirical or definitive) should be started as soon as possible.[25,26]

7 Several factors influence the transfer of antibiotic from capillary blood into the CNS. Notably, antibiotic penetration is increased through inflamed meninges due to damage to tight junctions between capillary endothelial cells and reduction of the activity of energy-dependent efflux pumps in the choroid plexus responsible for movement of penicillins and, to a lesser extent, fluoroquinolones and aminoglycosides (Table 106-3).[28] Antibiotics having low molecular weights are passed more easily through biologic barriers than compounds of higher molecular weight. Furthermore, only nonionized antibiotics at physiologic or pathologic pH are capable of diffusion. Highly lipid-soluble compounds penetrate more readily than water-soluble compounds. Antibiotics not extensively bound

TABLE 106-3 Penetration of Antimicrobial Agents into the CSF[a,28]

Therapeutic Levels in CSF With or Without Inflammation	
Acyclovir	Levofloxacin
Chloramphenicol	Linezolid
Ciprofloxacin	Metronidazole
Fluconazole	Moxifloxacin
Flucytosine	Pyrazinamide
Foscarnet	Rifampin
Fosfomycin	Sulfonamides
Ganciclovir	Trimethoprim
Isoniazid	Voriconazole
Therapeutic Levels in CSF With Inflammation of Meninges	
Ampicillin ± sulbactam	Imipenem
Aztreonam	Meropenem
Cefepime	Nafcillin
Cefotaxime	Ofloxacin
Ceftazidime	Penicillin G
Ceftriaxone	Piperacillin/tazobactam[b]
Cefuroxime	Pyrimethamine
Colistin	Quinupristin/dalfopristin
Daptomycin	Ticarcillin ± clavulanic acid[b]
Ethambutol	Vancomycin
Nontherapeutic Levels in CSF With or Without Inflammation	
Aminoglycosides	Cephalosporins (second generation)[d]
Amphotericin B	Doxycycline[e]
β-Lactamase inhibitors[c]	Itraconazole[f]
Cephalosporins (first generation)	

[a]Using recommended CNS dosing and compared to MIC of target pathogens.

[b]May not achieve therapeutic levels against organisms with higher MIC, as in *P. aeruginosa*. Tazobactam does not penetrate BBB.

[c]Includes clavulanic acid, sulbactam, and tazobactam.

[d]Cefuroxime is an exception.

[e]Documented effectiveness for *B. burgdorferi*.

[f]Achieves therapeutic concentrations for *Cryptococcus neoformans* therapy.

to plasma proteins provide a larger free fraction of drug capable of passing into the CSF. Passage of large, polar antibiotics into the CSF may be assisted, however, by a carrier transport system. Antibiotic dosages in the treatment of CNS infections must be optimized to ensure adequate penetration to the site of infection.

Problems of CSF penetration were traditionally overcome by direct instillation of antibiotics intrathecally, intracisternally, or intraventricularly. Advantages of direct instillation, however, must be weighed against the risks of invasive CNS procedures and adverse effects. Intrathecal administration of antibiotics is unlikely to produce therapeutic concentrations in the ventricles possibly owing to the unidirectional flow of CSF.[4] Although intraventricular administration from a therapeutic standpoint may be preferred over intrathecal administration, the former requires neurosurgical placement of a subcutaneous reservoir. Intraventricular delivery may be necessary in patients who have shunt infections that are difficult to eradicate or who cannot undergo surgical interventions.[15] Antimicrobial agents often utilized for bacterial meningitis treatment have adequate CSF penetration, which has limited the need for direct CNS instillation. The European Guidelines for meningitis treatment recommend considering the use of intrathecal or intraventricular antibiotics only in patients who fail conventional treatment.[13]

8 Although the length of treatment for bacterial meningitis is generally based on the causative organism, there is no universally accepted standard (Table 106-4).[13,15,17] Meningitis caused by *S. pneumoniae* has been treated successfully with 10 to 14 days of antibiotic therapy, while cases caused by *N. meningitidis* or *H. influenzae* usually can be treated with a 7-day course. In contrast, a longer duration (21 days or more) has been recommended for patients with *L. monocytogenes*, gram-negative or pseudomonal meningitis. Nonetheless, antibiotic treatments for bacterial meningitis should be individualized, and some patients may require enduring courses.

Causative Organisms

Streptococcus pneumoniae (Pneumococcus or Diplococcus)

1 *S. pneumoniae* is the leading cause of meningitis in patients 2 months of age or older, and causes over 50% of all cases of bacterial meningitis in the United States with an overall case-fatality rate of approximately 18%.[1] Despite the decline in rates of pneumococcal meningitis since the introduction of PCV7 vaccination in 2000, case-fatality rate did not significantly change from pre-PCV7 era. Approximately 50% of cases are secondary infections resulting from primary infections of parameningeal foci, such as the ear or paranasal sinuses. Pneumonia, endocarditis, CSF leak secondary to head trauma, splenectomy, alcoholism, sickle cell disease, and bone-marrow transplantation may predispose the patient to the development of pneumococcal meningitis.

Neurologic complications, such as coma, hearing impairment, and seizures, are common with pneumococcal meningitis. The prognosis of pneumococcal meningitis depends on a variety of factors, including chronic comorbidities, low Glasgow Coma Scale Score, focal neurological deficits on admission, low CSF leukocyte count, pneumonia, bacteremia, and intracranial and systemic complications.[29]

Based on resistance patterns and the fact that sufficient CSF concentrations of penicillin are difficult to achieve with standard intravenous doses, penicillin should not be used as empirical therapy if *S. pneumoniae* is a suspected pathogen. Furthermore, appropriate Clinical Laboratory Standards Institute (CLSI)-approved testing of all CSF isolates for penicillin resistance is recommended. Ceftriaxone and cefotaxime have served as alternatives to penicillin in the treatment of penicillin-resistant pneumococci. Of note, higher cephalosporins minimum inhibitory concentration (MIC) and higher cephalosporin resistance rates were shown in penicillin-resistant isolates.[30] Therapeutic approaches to cephalosporin-resistant pneumococcus include the addition of vancomycin and rifampin. However, only data from animal and experimental trials supporting the use of rifampin are available.[31] 6 Therefore, the combination of vancomycin and ceftriaxone has been suggested as empirical treatment until the results of antimicrobial susceptibility testing are available. Vancomycin should not be used alone even for highly penicillin- and cephalosporin-resistant strains.[13,15] Finally, some pneumococcal strains exhibit tolerance to vancomycin and were linked to increased meningitis mortality.[32,33]

Given the limited therapeutic options for penicillin- and cephalosporin-resistant pneumococcal meningitis, newer agents have been evaluated. Meropenem is approved by the US FDA for the treatment of bacterial meningitis in children aged 3 months and older and has shown similar clinical and microbiologic efficacies to cefotaxime or ceftriaxone. Meropenem is currently recommended as an alternative to a third-generation cephalosporin in penicillin nonsusceptible isolates. Some caution is warranted with the use of imipenem for CNS infections because of the possibility of drug-induced seizures, especially when dosing is not adjusted for declining renal function. Of note, seizures may be caused by meningitis itself or by imipenem, and the cause is often difficult to differentiate. The newer fluoroquinolones (levofloxacin and moxifloxacin) represent another therapeutic option with favorable activity against

TABLE 106-4 Antimicrobial Agents of First Choice and Alternative Choice in the Treatment of Meningitis Caused by Gram-Positive and Gram-Negative Microorganisms[13,15,17]

Organism	Antibiotics of First Choice	Alternative Antibiotics	Recommended Duration of Therapy
Gram-Positive Organisms			
Streptococcus pneumoniae[a]			10-14 days
Penicillin susceptible MIC ≤ 0.06 mcg/mL (mg/L)	Penicillin G or Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Cefepime (B-II), or Meropenem (B-II)	
Penicillin resistant MIC > 0.06 mcg/mL (mg/L)	Vancomycin[b,c] + Cefotaxime or Ceftriaxone (A-III)	Moxifloxacin (B-II)	
Ceftriaxone resistant MIC > 0.5 mcg/mL (mg/L)	Vancomycin[b,c] + Cefotaxime or Ceftriaxone (A-III)	Moxifloxacin (B-II)	
Staphylococcus aureus			14-21 days
Methicillin susceptible	Nafcillin or Oxacillin (A-III)	Vancomycin (A-III) or Meropenem (B-III)	
Methicillin resistant	Vancomycin[b,c] (A-III)	TMP-SMX or Linezolid (B-III)	
Group B *Streptococcus*	Penicillin G or Ampicillin (A-III) ± Gentamicin[b,c]	Ceftriaxone or Cefotaxime (B-III)	14-21 days
S. epidermidis	Vancomycin[b,c] (A-III)	Linezolid (B-III)	14-21 days[d]
L. monocytogenes	Penicillin G or Ampicillin ± Gentamicin[b,c,e] (A-III)	Trimethoprim-sulfamethoxazole (A-III), Meropenem (B-III)	≥21 days
Gram-Negative Organisms			
Neisseria meningitis			7-10 days
Penicillin susceptible	Penicillin G or Ampicillin (A-III)	Cefotaxime or Ceftriaxone (A-III)	
Penicillin resistant	Cefotaxime or Ceftriaxone (A-III)	Meropenem or Moxifloxacin (A-III)	
Haemophilus influenzae			7-10 days
β-lactamase negative	Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Cefepime (A-III) or Moxifloxacin (A-III)	
β-lactamase positive	Cefotaxime or Ceftriaxone (A-I)	Cefepime (A-I) or Moxifloxacin (A-III)	
Enterobacteriaceae[f]	Cefotaxime or Ceftriaxone (A-II)	Cefepime (A-III), Moxifloxacin (A-III), Meropenem (A-III) or Aztreonam (A-III)	21 days
Pseudomonas aeruginosa	Cefepime or Ceftazidime (A-II) ± Tobramycin[b,c] (A-III)	Ciprofloxacin (A-III), Meropenem (A-III), Piperacillin plus Tobramycin[a,b] (A-III), Colistin sulfomethate[g] (B-III), Aztreonam (A-III)	21 days

[a]European Guidelines recommend considering the addition of rifampin to vancomycin therapy.

[b]Direct CNS administration maybe considered if failed conventional treatment.

[c]Monitor serum drug levels.

[d]Based on clinical experience; no clear recommendations.

[e]European guidelines recommend adding gentamicin for the first 7 days of treatment.

[f]Includes *E. coli and Klebsiella* spp.

[g]Should be reserved for multidrug-resistant pseudomonal or *Actinetobacter* infections for which all other therapeutic options have been exhausted.

See Table 106-2 footnotes for rating scale of evidence.

multidrug-resistant pneumococci and good penetration into the CSF.[31,34]

Intravenous linezolid, daptomycin, and ceftaroline have also emerged as viable therapeutic options for treating multidrug-resistant gram-positive infections. Linezolid in combination with ceftriaxone has been used to treat a limited number of cases of pneumococcal meningitis with outcomes similar to standard treatment.[35] Daptomycin was as effective or better than ceftriaxone plus vancomycin for pneumococcal strains exhibiting penicillin and ceftriaxone resistance, respectively, in a rabbit model.[36] Additionally, daptomycin may reduce the inflammatory response caused by cell-wall components in pneumococcal meningitis compared with ceftriaxone in animal models.[37] Finally, ceftaroline achieved 14% penetration into inflamed meninges and 3% into uninflamed meninges in an experimental rabbit meningitis model.[38]

Pneumococcal vaccines help in reducing the risk of IPD. Virtually all serotypes of *S. pneumoniae* exhibiting intermediate or complete resistance to penicillin are included in the 23-serotype pneumococcal polysaccharide vaccine (PPV23). Due to low vaccination rates among people 65 years of age and older, the U.S. Centers for Disease Control and Prevention (CDC) issued stronger recommendations for the use of the PPV, calling for vaccination of the following high-risk groups: persons over the age of 65 years; persons aged 2 to 64 years who have a chronic illness, who live in high-risk environments (eg, Alaskan natives and residents of long-term care facilities), and who lack a functioning spleen (eg, sickle cell disease and splenectomy); and immunocompromised persons over the age of 2 years, including those with human immunodeficiency virus (HIV) infection.[39] Additionally, the question of whether or not college students living in dormitories, a possible high-risk environment, should be vaccinated remains debatable.

Use of the heptavalent pneumococcal conjugate vaccine (PCV7), introduced in 2000, significantly reduced the incidence of invasive pneumococcal infections, including sepsis and meningitis.[7,40] In the decade following its introduction, rate of invasive disease caused by non-PCV7 strains increased considerably, especially serotype 19A, leading to the development of a newer vaccine with expanded coverage.[7] In 2010, the FDA approved a PCV13 in replacement of PCV7, leading to a rapid and significant reduction of IPD in children younger than 5 years of age. In the first 3 years after the introduction of PCV13 in the United States, investigators estimated over 30,000 cases of IPD and 3,000 deaths were averted.[9] In 2011, the FDA

TABLE 106-5 Dosing of Antimicrobial Agents by Age Group Antimicrobial[13,15]

Agent	Infants and Children	Adults	Monitoring/Comments
Antibacterial			
Ampicillin	75 mg/kg every 6 h	2 g every 4 h	
Aztreonam	—	2 g every 6-8 h	Alternative for penicillin allergy
Cefepime	50 mg/kg every 8 h	2 g every 8 h	Consider prolonged infusion
Cefotaxime	75 mg/kg every 6-8 h	2 g every 4-6 h	Preferred in neonates
Ceftazidime	50 mg/kg every 8 h	2 g every 8 h	
Ceftriaxone	100 mg/kg daily	2 g every 12 h	Avoid in neonates
Ciprofloxacin	10 mg/kg every 8 h	400 mg every 8-12 h	Consider higher doses for *P. aeruginosa*
Colistin	5 mg/kg/day	5 mg/kg/day	Consider intraventricular doses Only for MDR organisms Monitor renal function
Gentamicin	2.5 mg/kg every 8 h	2 mg/kg every 8 h *or* 5-7 mg/kg daily	TDM is recommended Monitor renal function
Levofloxacin	—	750 mg daily	May prolong QTc
Linezolid	10 mg/kg every 8 h	600 mg every 12 h	May cause thrombocytopenia and peripheral neuropathy
Meropenem	40 mg/kg every 8 h	2 g every 8 h	Consider prolonged infusion
Moxifloxacin	—	400 mg daily	May prolong QTc
Oxacillin/Nafcillin	50 mg/kg every 6 h	2 g every 4 h	Nafcillin preferred if renal dysfunction
Penicillin G	0.05 million Units/kg every 4 h	4 million Units every 4 h	
Polymyxin B	—	1.25-1.5 mg/kg every 12 h	Only for MDR organisms No data in pediatric patients
Tobramycin	2.5 mg/kg every 8 h	2.5 mg/kg every 8 h *or* 5-7 mg/kg daily	TDM is recommended Monitor renal function
Trimethoprim-sulfmathoxazole	5 mg/kg every 6-12 h	5 mg/kg every 6-12 h	Dose based on trimethoprim
Vancomycin	15 mg/kg every 6 h	15-20 mg/kg every 8-12 h	TDM is recommended Monitor renal function
Antimycobacterials			
Isoniazid	10-15 mg/kg daily	5 mg/kg daily	Supplemental vitamin B_6 is recommended
Rifampin	10-20 mg/kg daily (max 600 mg daily)	600 mg daily	Many drug-drug interactions
Pyrazinamide	15-30 mg/kg daily	15-30 mg/kg daily	Rarely causes hepatotoxicity
Ethambutol	15-25 mg/kg daily	15-25 mg/kg daily	May cause neutropenia
Antifungals			
Amphotericin B	1 mg/kg daily	0.7-1 mg/kg daily	Monitor renal function Maintain adequate hydration
Lipid amphotericin B	5 mg/kg once daily	3-5 mg/kg daily	Monitor renal function Maintain adequate hydration
Flucytosine	25 mg/kg every 6 h	25 mg/kg every 6 h	Consider TDM to avoid bone marrow suppression
Fluconazole	6-12 mg/kg daily	800-1,200 mg daily	Monitor liver function
Itraconazole			Consider TDM Suspension form is preferred
Posaconazole	—	400 mg every 12 h	Variable absorption No data in pediatric patients
Voriconazole	7 mg/kg every 12 h	6 mg/kg every 12 h × 2 doses then 4 mg/kg every 12 h	Consider TDM Many drug-drug interactions Monitor liver function
Antivirals			
Acyclovir	10-20 mg/kg every 8 h	10-20 mg/kg every 8 h	Monitor renal function Maintain adequate hydration
Ganciclovir	—	5 mg/kg every 12 h	Monitor renal function
Foscarnet	—	60 mg/kg every 8 h *or* 90 mg/kg every 12 h	Monitor renal function Maintain adequate hydration

TDM, therapeutic drug monitoring.

approved the use of PCV13 in adults 50 years and older as it produced antibody levels that were either comparable to or higher than the levels achieved by PPV23, for the 12 common serotypes included in PCV13. The Advisory Committee on Immunization Practices (ACIP) in 2014 recommended routine use of PCV13 in series with PPV23 for all adults 65 years of age or older.[41] Although the total number of pneumococcal meningitis cases in the United States remained the same with PCV13, the proportion of PCV13 serotypes and antibiotic-resistant strains significantly decreased, mainly serotype 19A.[42] PCV13 is recommended for all healthy infants younger than 2 years of age to be immunized at 2, 4, 6, and 12 to 15 months; all adults of 65 years or older; and high-risk individuals.[39,41,43] High-risk persons include those with cochlear implants, CSF leaks, who lack a functioning spleen, and immunocompromised persons.

Neisseria meningitidis (Meningococcus)

1 *N. meningitidis* is a leading cause of bacterial meningitis among children and young adults in the United States and around the world.[1,44] Five of the thirteen serogroups of *N. meningitidis* (A, B, C, Y, and W-135) are primarily responsible for invasive meningococcal disease. Clusters of disease, defined as two or more cases of the same serogroup that are closer in time and space than expected for the population or group under observation, generally are associated with crowding as in schools, dormitories, and military barracks.[45] Other significant risk factors for meningococcal disease include complement deficiency, persons without a functioning spleen, and active smokers.[11] Serogroups B, C, and Y cause the majority of disease in the United States, while serogroup A, although associated with meningococcal outbreaks in Africa and Asia, is a rare cause of disease in the United States.[46] Routine vaccine recommendations has significantly decreased the prevalence of serogroup C meningococcal disease; however, this led to a surge in serogroup B infections, especially in infants.[47] Overall incidence of meningococcal disease in the United States has been declining since the late 1990s; however, incidence remains highest in infants aged older than 1 year with a second peak in adolescents and young adults 16 to 23 years of age. *N. meningitidis* accounted for 13.9% of all meningitis cases in the United States during 2003 to 2007, with a case-fatality rate of approximately 10%.[1]

Initially, patients are colonized and, at some point, develop bacteremia, which most likely occurs prior to hospital admission. Meningitis occurs after the bacteria seed into the meninges. After the acute phase of meningitis has resolved, there is a unique immune reaction that distinguishes meningococcal meningitis from other bacterial causes. 2 The patient develops a characteristic immunologic reaction of fever, arthritis (usually involving large joints), and pericarditis approximately 10 to 14 days after the onset of disease despite successful treatment. At this time, examination of the synovial fluid may reveal a large number of polymorphonuclear cells, elevated protein concentrations, normal glucose concentrations, and sterile cultures. The reaction may last a week or longer, and no additional antibiotic therapy is required; however, patients may benefit from nonsteroidal anti-inflammatory agents and supportive care.[5,48]

Seizures and coma are uncommon with meningococcal meningitis. Also, patients may develop deafness and transiently impaired ocular movements. Deafness unilaterally or, more commonly, bilaterally may develop early or late in the disease course. Hearing loss secondary to sensory nerve damage (sensorineural hearing) is usually permanent, whereas conductive hearing impairment, such as damage to the tympanic membrane, is often reversible. The presence of petechiae may be the primary clue that the underlying pathogen is *N. meningitidis*. Approximately 60% of adults and up to 90% of pediatric patients with meningococcal meningitis have purpuric lesions, petechiae, or both.[5] Patients may have an obvious or subclinical picture of disseminated intravascular coagulation (DIC), which may progress to infarction of the adrenal glands and renal cortex and cause widespread thrombosis and rapid death.

6 Third-generation cephalosporins (ie, cefotaxime and ceftriaxone) are the recommended empiric treatment for meningococcal meningitis (Table 106-4).[13,15,17] When final culture results are available, penicillin G or ampicillin is recommended for penicillin-susceptible isolates. Meropenem and fluoroquinolones are also suitable alternatives for the treatment of penicillin nonsusceptible meningococci.[13,15]

N. meningitidis is spread by direct person-to-person close contact, including respiratory droplets and pharyngeal secretions. Close contacts of patients contracting meningococcal meningitis are at an increased risk of developing meningitis. Close contacts include daycare center contacts, members of the household, or anyone who has been exposed to respiratory or oral secretions through activities such as coughing, sneezing, or kissing. Secondary cases of meningitis usually develop within the first week following exposure, but may take up to 60 days after contact with the index case.[11] Young children are at the greatest risk of contracting *N. meningitidis*; however, all ages are at risk, especially close contacts exposed via household, daycare, or military contact.

9 Prophylaxis of close contacts should be started only after consultation with the local health department. In general, rifampin, ceftriaxone, ciprofloxacin, or azithromycin are given for prophylaxis. A systematic review of available data suggests an increased rate of rifampin-resistant isolates.[49] Also, cases of ciprofloxacin-resistant isolates were reported in North America. Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to current recommendations from the CDC.[11]

Until recently, only two meningococcal vaccines were available in the United States; but as of 2015, six products became available. Two quadrivalent meningococcal conjugate vaccines are available with antigens to serogroups A, C, W-135, and Y. In 2012, a bivalent conjugate combination vaccine was licensed in the United States, and contains antigens to serogroups C and Y, and *H. influenzae* type b. Until late 2014, serogroup B meningococcal vaccines (MenBs) were unavailable in the United States. Following an outbreak of meningococcal meningitis due to serogroup B on two college campuses in 2013, two MenB vaccines were subsequently granted breakthrough therapy designations for rapid approval. In 2015, ACIP recommended routine administration for persons 10 to 25 years of age identified as being at increased risk due to serogroup B meningococcal disease outbreak or certain medical conditions (complement deficiencies and functional/anatomic asplenia). For full details of vaccination recommendation in various age groups and for those with significant risk factors, readers should refer to current recommendations from the ACIP.

Haemophilus influenzae type b

1 Historically, *H. influenzae* type b was the most common cause of community-acquired bacterial meningitis in children 6 months to 3 years of age. Since the introduction of effective vaccines, the incidence of Hib disease in the Unite States has declined dramatically.[5,50] Widespread vaccination of infants and children has effectively decreased the incidence of bacterial meningitis due to Hib in children between the ages of 1 month and 5 years, resulting in a significant decline in all cases of bacterial meningitis.[1] In children older than 3 years and adults, meningitis caused by Hib may indicate a parameningeal focus of infection, such as middle ear infection, paranasal sinus infection, or CSF leakage. Spread of the organism occurs either through direct spread from infected sinuses, draining of these areas via the veins, or bacteremia originating from the local focus of infection.[51]

6 Third-generation cephalosporins (cefotaxime and ceftriaxone) are the drugs of choice for empirical therapy for *H. influenzae* type b meningitis as they are active against β-lactamase–producing and non–β-lactamase–producing strains.[15] In addition, they are relatively free of toxicity and do not require serum concentration

monitoring. Cefepime and fluoroquinolones are suitable alternatives regardless of β-lactamase activity.

9 Prophylaxis is to protect close contacts from the index case by eliminating nasopharyngeal and oropharyngeal carriages of *H. influenzae*. Invasive disease should be reported to the local public health department and the CDC. Prophylaxis of close contacts should be started only after consultation with the local health department. Widespread vaccination has limited the need for chemoprophylaxis. Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to the recommendations of the American Academy of Pediatrics.

Vaccination includes a series of doses and usually is begun in children at 2 months of age. In addition to pediatric immunization, the vaccine also should be considered in patients older than 5 years of age with the following underlying conditions: sickle cell disease, asplenia, and immunocompromising diseases. As noted earlier, a bivalent conjugate combination vaccine, MenHibrix®, containing antigens to meningococcal serogroups C and Y, and *H. influenzae* type b became available in 2012. Refer to chapter in this text for further information on vaccine dosing and administration schedules.

Streptococcus agalactiae (Streptococcus Group B)

1 Streptococcus group B (GBS) is a leading cause of neonatal meningitis in the United States and around the world.[1,52,53] The causative organism, *Streptococcus agalactiae*, is a gram-positive bacterium with β-hemolytic properties that is often implicated in neonatal sepsis, pneumonia, and meningitis. GI and genitourinary colonization in pregnant women is common, up to 25%.[54] Neonates acquire this infection through vertical transmission while passing through the vaginal canal during birth.

Early-onset infections are those occurring within the first week of life, while late-onset infections occur after the first week of the child's birth. Universal prenatal screening and intrapartum antimicrobial prophylaxis of colonized pregnant women have significantly decreased rate of early onset invasive disease.[55] While rates of GBS meningitis in the United States did not change significantly during 1998 to 2008, including cases in patients less than 2 months of age, most cases during 2002 to 2007 were late-onset infections that are not affected by intrapartum prophylaxis.[1,53] Furthermore, neonatal GBS meningitis survivors carry substantial long-term morbidity and up to 11% die before the age of 3 years.[54]

6 Ampicillin and penicillin G are the recommended agents for the treatment of presumed GBS. Addition of an aminoglycoside should also be considered for confirmed GBS meningitis. GBS continues to be susceptible to ampicillin and penicillin; however, reports of isolates with increased MIC have been published.[55]

Investigations are undergoing to develop vaccines to reduce maternal colonization and prevent fetal transmission of GBS. Clinical trials have shown promising results; however, to date there are no licensed vaccines available for GBS.

Listeria monocytogenes

L. monocytogenes is a gram-positive diphtheroid-like organism. This disease primarily affects neonates, alcoholics, immunocompromised adults, and the elderly; while infections in healthy individuals are rare. *L. monocytogenes* is implicated in approximately 10% of meningitis cases in those older than 65 years of age and carries a case-fatality rate of approximately 18% in the United States.[1]

Transmission usually involves colonization of the patient's GI tract with the organisms, which then penetrate the gut lumen. Soft cheeses and raw produce are common causes of listeriosis outbreaks. Coleslaw, unpasteurized milk, ready-to-eat foods, and raw beef and poultry have also been identified as sources of this foodborne pathogen.[14] If a sufficient cell-mediated immune response (T-lymphocytes, macrophages) is not produced, bacteremia, meningitis, meningoencephalitis, or cerebritis may develop. Infection of the CNS may be diffuse or localized, possibly involving the cerebral hemispheres, thalamus, and brain stem.

Incidence of *L. monocytogenes* meningitis tends to peak in the summer and early fall. As with gram-negative meningitis, presentation may be subtle and insidious, and clinical suspicion should prompt lumbar puncture. 2 *L. monocytogenes* produces primarily a mononuclear CSF response.[56] One common laboratory error seen with *L. monocytogenes* is a tendency to misidentify the organism on gram stain as a diphtheroid, streptococcus, or a poorly staining gram-negative rod.

Treatment of *L. monocytogenes* meningitis with penicillin G or ampicillin may result in only a bacteriostatic effect and possible persistence of infection. Usually the combination of penicillin G or ampicillin with an aminoglycoside results in a bactericidal effect. 8 Patients should be treated for a minimum of 3 weeks.[15] European Guidelines for meningitis treatment recommend considering combination therapy for the first 7 to 10 days of treatment, with the remaining course of therapy completed with penicillin G or ampicillin alone.[13] Despite in-vitro activity against *L. monocytogenes*, vancomycin was associated with high failure rates. Also, third-generation cephalosporins lack in-vitro activity against *L. monocytogenes*. Trimethoprim-sulfamethoxazole and meropenem may be effective alternatives as adequate CSF penetration is achieved.[13,15]

Gram-Negative Meningitis

Gram-negative bacilli, excluding *H. influenzae*, are an uncommon but increasing cause of nosocomial meningitis in adults.[57] The most common pathogens are *E. coli* and *Pseudomonas* species in adults, while neonates are also at risk for gram-negative meningitis with *E. coli* and *Klebsiella pneumoniae* responsible for 40% to 50% of cases.[58] A 2013 study identified urinary tract infections as the most important independent factor associated with higher risk of gram-negative meningitis in adults.[57] Several additional factors predispose patients to the development of gram-negative meningitis include: congenital defects involving the CNS, accidental cranial trauma, neurosurgery, the use of antimicrobial agents with exclusive gram-positive activity preoperatively in neurosurgery, any form of communication between the skin and subarachnoid space (such as a dermal sinus), diabetes, malignancy, cirrhosis, parameningeal infection, spinal anesthesia, advanced age, immunosuppression, and hospitalization in general.[57]

Elderly debilitated patients are at an increased risk of gram-negative meningitis but typically lack the classic signs and symptoms of the disease. Nuchal rigidity may be difficult to detect secondary to cervical arthritis. Presence of a low-grade fever and changes in mental status without other obvious cause should prompt consideration of meningitis and a lumbar puncture.

Treatment of gram-negative meningitis is complex because of the variety of organisms implicated in these cases. The treatment of meningitis due to *Pseudomonas aeruginosa* remains a unique problem because antibiotics showing good antibacterial activity, such as antipseudomonal penicillins and aminoglycosides, penetrate the CSF poorly.[28] Furthermore, many isolates of *P. aeruginosa* are resistant to multiple, if not all, commonly used agents, and this trend in resistance is increasing. 6 Initially, cases of *P. aeruginosa* meningitis should be treated with an extended-spectrum β-lactam such as ceftazidime or cefepime, or alternatively aztreonam, ciprofloxacin, or meropenem.[4,15] The addition of an aminoglycoside, usually tobramycin, to one of the aforementioned agents should also be considered. Since aminoglycosides penetrate the CSF poorly, their inclusion is predominant to aid in the treatment of extracerebral infections. If multidrug-resistant *P. aeruginosa* is suspected initially, intraventricular administration of an aminoglycoside should be considered along with intravenous administration. Preservative-free forms of gentamicin and tobramycin are available and should be used for direct administration into the CSF. Since CSF flows unidirectionally with gravity, intraventricular aminoglycoside administration is

more likely to produce therapeutic concentrations throughout the CSF than intrathecal administration. While intraventricular administration of aminoglycosides is considered for treatment of *P. aeruginosa* meningitis, this method produced higher mortality in a sample of infants treated for gram-negative bacillary meningitis.[59] Thus intraventricular administration of aminoglycosides to infants is not recommended routinely.

Multidrug-resistant *P. aeruginosa* and *Acinetobacter* infections are of concern to clinicians because of the limited therapeutic options available. This concern has led to the reemergence of the use of older antibiotics, such as colistin and polymyxin B. Colistin can be used, both intravenously and intrathecally, in the treatment of multidrug-resistant *P. aeruginosa* or *Acinetobacter* CNS infections.[60] Furthermore, synergistic activity with the combination of colistin and ceftazidime against multidrug-resistant *P. aeruginosa* was demonstrated in an *in vitro* model.[61] The use of colistin should be reserved for only the most severe cases. New cephalosporin-β-lactamase inhibitor combination agents (ceftolozane-tazobactam and ceftazidime-avibactam) have yet to be studied in patients with CNS infections, but may be future alternative therapies for multidrug resistant gram-negative organisms.

Other gram-negative organisms causing meningitis, excluding *P. aeruginosa* and *Acinetobacter* spp., most likely can be treated with a third- or fourth-generation cephalosporin, such as cefotaxime, ceftriaxone, ceftazidime, or cefepime. Ceftazidime, however, may not be the best choice of empirical antibiotic for situations where the offending organism is not known initially because of its lack of reliable gram-positive coverage. Cefotaxime should be used in place of ceftriaxone in the neonatal period because of the potential for the displacement of bilirubin from albumin-binding sites.

Trimethoprim-sulfamethoxazole is useful in the management of the Enterobacteriaceae family and also may be useful in the management of *L. monocytogenes*. One advantage of trimethoprim-sulfamethoxazole is that its penetration into the CSF does not depend on meningeal inflammation.[28] However, trimethoprim-sulfamethoxazole is not bactericidal which limits its routine use for the acute management of CNS infections. Fluoroquinolones exhibit good penetration into the CSF and are effective in animal models of both gram-negative and gram-positive meningitis; however, there are limited data on their efficacy in clinical practice. Ciprofloxacin is recommended as an alternative agent for the treatment of *E. coli*, other Enterobacteriaceae, and *P. aeruginosa*.[15] Cefepime, meropenem, and aztreonam represent other therapeutic options for the treatment of gram-negative bacterial meningitis.[13,15]

8 CSF cultures may remain positive for several days or more with a regimen that eventually will be curative. Therapeutic efficacy can be monitored through bacterial colony counts every 2 or 3 days, which should decrease progressively over the period of therapy. Therapy for gram-negative meningitis should be continued for a minimum of 21 days from the start of treatment with an effective agent.[13,15]

Clinical **Controversy...**

Multidrug resistant gram-negative meningitis is an ongoing concern due to the limited number of therapeutic options available. Therapy is often limited to older, and more toxic, antibiotics, such as colistin and polymyxin B. Although new agents with extended spectrum of activity have been developed, they are yet to be studied in patients with CNS infections. Two cephalosporin-β-lactamase inhibitor combination agents (ceftolozane-tazobactam and ceftazidime-avibactam) may be future alternative therapies for multidrug resistant gram-negative organisms, but currently lack data to support their use in clinical settings.

Bacillus anthracis

Bacillus anthracis is a large, endospore-forming, aerobic, gram-positive bacteria capable of producing infection via the cutaneous, pulmonary, or GI routes. Cases of meningitis have been reported following both cutaneous and inhalational infections. According to the CDC, and prior to the bioterrorism-related outbreak in 2001, only a handful of sporadic cases had occurred in the United States in the 20th century, with the last occurrence in 2011. Mortality rates due to uncomplicated cutaneous, GI and inhaled anthrax infections are estimated to be less than 2%, 40% or more, and 45%, respectively, while cases of anthrax meningitis are often fatal.[62]

The major neurologic complication of anthrax infection is fulminant, rapidly fatal hemorrhagic meningoencephalitis. The inhalational form of anthrax seems to be a potent inducer of neurologic symptoms, and death usually occurs within a week for those with neurologic complications.[62] *B. anthracis* typically is susceptible to penicillin, amoxicillin, erythromycin, doxycycline, and ciprofloxacin. The bioterrorism-related strain in 2001 was susceptible to fluoroquinolones, rifampin, tetracycline, vancomycin, imipenem, meropenem, chloramphenicol, clindamycin, and aminoglycoside; but resistant to third-generation cephalosporins and trimethoprim-sulfamethoxazole. Recommendations for the treatment of systemic anthrax with possible or confirmed meningitis call for the use of three active antibacterial agents. Empiric regimens that include high doses of intravenous fluoroquinolones (ciprofloxacin, levofloxacin, or moxifloxacin) along with a carbapenem (meropenem, doripenem, or imipenem) and a protein synthesis inhibitor (eg, linezolid or clindamycin) are recommended. Once penicillin susceptibility is confirmed, the carbapenem can be deescalated to intravenous penicillin G or Ampicillin.[62] Also, adjunctive corticosteroids should be considered for patients with suspected or confirmed anthrax meningitis. Doxycycline is not recommended for the treatment of anthrax meningitis owing to poor CNS penetration, compared to MIC of most bacterial pathogens, but can be utilized for cases of inhaled or cutaneous anthrax once CNS involvement has been ruled out.[62] Finally, in 2015 the U.S. FDA approved an intravenous anthrax immune globulin for the treatment of inhalation anthrax in adults and pediatric patients along with appropriate antibacterial treatments.

Dexamethasone as an Adjunctive Treatment for Bacterial Meningitis

In addition to antibiotics, dexamethasone is a commonly used adjunctive therapy in the treatment of meningitis. Corticosteroids inhibit the production of TNF and IL-1, both potent proinflammatory cytokines. In clinical trials that measured inflammatory mediators, lower levels of TNF, PAF, or IL-1 were detected in patients treated with dexamethasone.[63-65] A series of animal studies, however, suggest adjuvant dexamethasone may aggravate neuronal injury by increasing apoptosis, programmed cell death, in the hippocampus of infant rats with pneumococcal and in rabbits with *E. coli* meningitis.[66] A series of early clinical studies assessing the outcomes of dexamethasone therapy for the initial treatment of bacterial meningitis showed conflicting results.[67] Subsequently, a systematic review in 2004 indicated that treatment with corticosteroids reduced both mortality and neurological sequelae in adults with community-acquired bacterial meningitis.[68] However, large randomized clinical trials showed conflicting results. A fundamental problem with corticosteroid investigations to date is that the majority of patients in the trials had *H. influenzae* meningitis, which has decreased dramatically following the introduction of polysaccharide conjugate vaccines in early 1980s. Additionally, the majority of studies examining dexamethasone use for pneumococcal meningitis were conducted before widespread penicillin-resistant pneumococcus emerged or in parts of the world where penicillin resistance is minimal.

A systematic review of 25 randomized controlled trials involving 4,121 participants showed corticosteroid use in bacterial meningitis was associated with lower rates of severe hearing loss, any hearing loss, and neurological sequelae, but did not reduce overall mortality nor was associated with beneficial effects in low-income countries. Additionally, subgroup analyses showed reduced overall mortality in pneumococcal meningitis and severe hearing loss in children with *H. influenzae* meningitis.[69] While a previous meta-analysis of five randomized, double-blinded, placebo-controlled trials of dexamethasone for bacterial meningitis in patients of all ages showed that adjunctive dexamethasone did not seem to significantly reduce death or neurological disability.[70] Thus, adjunctive corticosteroid use in the management of bacterial meningitis remains controversial.

Most clinical trials on the use of adjunctive dexamethasone in bacterial meningitis have involved children. A retrospective analysis of pediatric patients with pneumococcal meningitis and one unblinded, noncontrolled trial suggested that adjunctive steroids may decrease the neurologic sequelae and mortality associated with *S. pneumoniae* meningitis.[63,71] Also, a meta-analysis in 1997 suggested benefits in *H. influenza* meningitis and, if commenced with or before antibiotics, suggested benefit for pneumococcal meningitis in childhood.[72] Finally, a large multicenter trial did not demonstrate reduction in mortality when adjunctive dexamethasone was used for children with meningococcal or pneumococcal meningitis, but potential benefit in preventing long-term hearing loss was observed.[73]

10 Current recommendations call for the use of adjunctive dexamethasone in infants and children (6 weeks of age and older) with *H. influenza* meningitis.[15] The recommended intravenous dose is 0.15 mg/kg every 6 hours for 2 to 4 days, initiated 10 to 20 minutes prior to or concomitant with, but not after, the first dose of antibiotics. Clinical outcome is unlikely to improve if dexamethasone is given after the first dose of antimicrobial and should therefore be avoided. For infants and children 6 weeks of age and older with pneumococcal meningitis, adjunctive dexamethasone may be considered after weighing the potential benefits and possible risks.[15,74] If adjunctive dexamethasone is used, careful monitoring of signs and symptoms of GI bleeding and hyperglycemia should be employed. Moreover, the use of dexamethasone may interfere with the interpretation of clinical response to treatment, such as resolution of fever.

If pneumococcal meningitis is suspected or proven, it is recommended that adults receive dexamethasone 0.15 mg/kg (up to 10 mg) every 6 hours for 2 to 4 days with the first dose administered 10 to 20 minutes prior to first dose of antibiotics. Similar to the pediatric population, clinical outcome is unlikely to improve if dexamethasone is given after the first dose of antibiotics and should therefore be avoided.[13,15] It is often difficult to ascertain the responsible pathogen on presentation; therefore, some clinicians recommend initiating dexamethasone in all adult patients presenting with community-acquired bacterial meningitis. Dexamethasone is not routinely recommended for patients with acute community-acquired bacterial meningitis due to other bacterial etiologies.[13,15]

Routine use of dexamethasone in meningitis is not without controversy. A potential concern is adjunctive dexamethasone therapy that may reduce the penetration of antibiotics into the CSF by inhibiting or reducing meningeal inflammation. In early experimental models of meningitis, steroids decreased the CSF concentrations of ampicillin, rifampin, vancomycin, and gentamicin.[65,75] Yet, ceftriaxone and vancomycin penetration into CSF was unaffected by concurrent dexamethasone administration in pediatric patients.[76,77] Appropriate concentrations of vancomycin in CSF may be obtained even when adjunctive dexamethasone is used, but the small number of subjects studied limits the generalization of these findings.[78]

Bacterial Brain Abscess

Approximately 1,500 to 2,500 cases of brain abscess occur annually in the United States, with decreasing incidence due to contiguous spread of infection from the oropharynx, middle ear, and paranasal sinuses and increasing incidence due to contiguous spread from cranial trauma or neurosurgical procedures.[79,80] Other sources of infection include hematogenous spread from distant foci of infection, such as endocarditis or intra-abdominal infection. Mortality rates have declined significantly in the past 50 years, with 70% of survivors expected to have no to minimal neurologic sequelae.[81]

2 The clinical presentation varies depending on the number, size, and location of the abscess(es). Headache, mental status changes, focal neurologic deficits, and fever are the most common symptoms of brain abscess, but seizures and nausea and vomiting may also be seen.[81,82] Diagnosis of brain abscess can be facilitated by CT or MRI, with preference given to MRI due to the ability to better differentiate cerebral tumor, stroke, and abscess. Lumbar puncture is not routinely recommended in patients with brain abscess, while CT-guided aspiration and biopsy can be both diagnostic and therapeutic.[81]

The etiology of brain abscess depends on the initial site of infection. Those arising from spread of infection from oropharynx, middle ear, and paranasal sinuses are commonly caused by streptococci and oral anaerobes (eg, *Actinomyces* spp., *Bacteroides* spp., *Fusobacterium* spp., *Peptostreptococcus*). Staphylococci, aerobic and gram-negative bacilli are commonly involved in postoperative abscesses or those following head trauma. *P. aeruginosa* and *Nocardia* spp. can also cause brain abscesses but are more commonly seen in immunocompromised patients.[81]

6 Because brain abscesses are commonly polymicrobial, empiric antimicrobial therapy should include antibiotics with activity against gram-positive, gram-negative, and anaerobic organisms. For example, the regimen could include vancomycin plus a third- or fourth-generation cephalosporin plus metronidazole, depending on risk factors. A carbapenem (such as meropenem) could replace the cephalosporin and metronidazole. De-escalation of therapy should occur once a causative organism is identified. While no consensus on treatment duration for brain abscesses exists, duration of therapy should be determined for each individual patient and should include consideration of the causative pathogen, size of abscess, use of surgical treatment, and response to therapy. Because seizure is a common complication of brain abscesses, anticonvulsant therapy is recommended for at least 1 year and may be discontinued when an EEG shows no epileptic activity. 10 The benefit of dexamethasone in the treatment of brain abscess is unclear and not routinely recommended, unless signs of cerebral edema are identified.[81]

Cryptococcus neoformans

Cryptococcus spp. are encapsulated soil yeasts acquired by inhalation of spores from the environment leading to CNS infection and less commonly pulmonary disease. The two main pathogenic species are *Cryptococcus neoformans* and *C. gattii*. While cryptococcal infections mainly affect persons with underlying impaired immunity such as HIV-positive (approximately 80%-95% of cases) and HIV-negative immunosuppressed patients, infections in nonimmunosuppressed individuals have been reported in North America.[83] Globally, approximately 958,000 cases of cryptococcal meningitis occur annually, mostly in Sub-Saharan Africa, resulting in an overall 3-months case-fatality rate of over 600,000.[84]

The incubation period in acquired immunodeficiency syndrome (AIDS) patients may be very short, as opposed to a relatively normal host, in whom it may be very long. Symptoms of *C. neoformans* meningitis are insidious and may be present for varying periods, depending on the host involved, before the definitive diagnosis is made. 2 Fever and a history of headaches are the most common symptoms, although altered mentation and evidence of focal neurologic deficits may be present. Examination of the CSF usually reveals mildly elevated WBCs, primarily lymphocytes (Table 106-1). 3 Diagnosis is based on the presence of a positive CSF, blood, sputum, or urine

culture for *C. neoformans*. Organisms may be seen by microscope when stained with India ink and are more likely to be seen in AIDS patients compared with other hosts. An additional rapid test helpful in diagnosis is latex agglutination, which detects the presence of cryptococcal antigens. Latex agglutination is associated with overall sensitivities and specificities of 93% to 100% and 93% to 98%, respectively.[83] A cryptococcal antigen detection test needs to be considered in any patient presenting initially with meningitis. Risk factors predictive of a poor outcome include lethargy at presentation, nonimmunosuppressed patients, high CSF cryptococcal antigen titer, low CSF WBC count, low CD4 cell count, fungemia, and elevated CSF pressure.[85-87]

Rapid sterilization of CNS through rapid fungicidal activity is the main approach of induction therapy, which ranges from 2 to 6 weeks, followed by consolidation therapy for 8 weeks.[88] Despite poor penetration into the CSF, amphotericin B has long been the drug of choice for the treatment of acute cryptococcal meningitis due to its rapid fungicidal activity.[85] A landmark clinical trial showed amphotericin B (1 mg/kg/day) combined with flucytosine (100 mg/kg/day) for 2 weeks was more effective than amphotericin alone for 4 weeks or in combination with fluconazole (400 mg twice daily) for 2 weeks in HIV-positive patients.[89] Additionally, this combination was associated with the most rapidly fungicidal activity, when compared with amphotericin alone, in combination with fluconazole or in combination with fluconazole and flucytosine.[90]

Clinical **Controversy...**

Timing of HAART initiation following acute cryptococcal meningitis in patients with HIV-AIDS remains an area of clinical controversy. Conflicting results from earlier studies prompted a recent prospective trial (COAT Trial) of adult HIV-positive patients with acute cryptococcal meningitis comparing early (1-2 weeks) and late (5 weeks) initiation of HAART following diagnosis. Late HAART initiation was associated with a significant reduction in 26-week mortality. Current HIV and cryptococcal meningitis treatment guidelines recommend a short delay (2-10 weeks) between diagnosis and HAART initiation; however, more definitive recommendations remain an area of clinical debate.

Unfortunately, in the AIDS population, flucytosine is often poorly tolerated, causing bone marrow suppression and GI distress. Careful monitoring of hematologic parameters, therapeutic drug monitoring (TDM) and dose adjustment for patients with renal insufficiency are recommended to avoid flucytosine-associated toxicities. Amphotericin B alone or in combination with high-dose fluconazole may be reasonable alternatives to standard treatment.[91,92] Lipid formulations of amphotericin B at higher doses (3-5 mg/kg/day) can be used for HIV-positive patients with or predisposed to renal dysfunction and are recommended for organ-transplant recipients.[88]

Azole therapy is the most studied alternative regimen for the treatment of *C. neoformans* meningitis in HIV-positive patients. Fluconazole and itraconazole have been studied as monotherapy with mixed results. If used alone or in combination with flucytosine, higher fluconazole doses of 800 to 2,000 mg/day are recommended due to higher success rates.[93] To note, the rate of fluconazole-resistant *C. neoformans* has been increasing in recent years.[94] Itraconazole has limited utility in induction therapy due to limited CSF levels of the active drug. Generally, itraconazole suspension is preferred due to better absorption, and TDM is recommended to ensure optimal drug levels.[88] Voriconazole in combination with amphotericin B showed similar rate of clearance of cryptococcal CFU in CSF samples compared with standard therapy.[91] Posaconazole has demonstrated clinical activity against cryptococcal and other fungal infections of the CNS in patients with refractory disease or otherwise intolerant to standard antifungal agents. Posaconazole appeared well tolerated at oral doses of 800 mg/day and may be an alternative in the treatment of fungal CNS infection due to *C. neoformans*.[95] More data are needed to determine what role the new azole antifungal agents will play in future treatment of cryptococcal meningitis. Also, widespread TDM of new azole antifungals will be needed to ensure adequate CNS therapeutic concentrations.

HIV-positive persons often require extended maintenance or suppressive therapy, minimum of 12 months, because of high relapse rates following primary therapy (induction and consolidation phases) for *C. neoformans*. A large multicenter, controlled trial compared fluconazole 200 mg/day and amphotericin B 1 mg/kg/wk in the prevention of relapse. Two percent of patients receiving fluconazole versus 18% of patients on amphotericin B relapsed. In addition, the amphotericin B group had significantly more frequent bacterial infections, bacteremia, and drug-related toxicity.[96] Fluconazole was also superior to itraconazole in the prevention of relapse.[97] Current guidelines recommend continuing maintenance therapy until immune reconstitution takes place. Guidelines for the prevention of opportunistic infections in HIV-infected persons are updated frequently and can be found at www.aidsinfo.nih.gov. Readers interested in treatment guidelines for cryptococcal meningitis in HIV-negative immunosuppressed, such as transplant recipients, and nonimmunosuppressed individuals are encouraged to review the Infectious Diseases Society of America Guidelines for the management of cryptococcal disease.[88]

Viral Encephalitis

Encephalitis is defined by the presence of an inflammatory process of the brain in association with clinical evidence of neurologic dysfunction.[24] Patients with metabolic disturbances, organ dysfunction, and noninfectious encephalitis, including postimmunization encephalitis or encephalomyelitis, can have similar clinical presentation to those with infectious encephalitis. Several infectious organisms have been identified to cause encephalitis, with viral etiologies being the most commonly diagnosed.[98,99] Additionally, meningoencephalitis is a term commonly used to describe meningeal inflammation along with encephalitis.

The epidemiology of viral encephalitis in the United States has changed dramatically since the mid-1960s because of the introduction of large-scale polio, rubella, varicella-zoster virus (VZV), and mumps immunization programs. Worldwide, mumps remains a causative agent of viral encephalitis in countries with low vaccination rates. Poliomyelitis, once a significant cause of encephalitis, is now confined to only a few less-developed countries. While a confirmed or probable pathogen is identified in less than 50% of cases, common causes of viral encephalitis and meningoencephalitis in the United States include herpes simplex virus (HSV), West Nile virus (WNV), and the enteroviruses.[98,99] Additionally, viral encephalitis is caused by a variety of other pathogens, such as arboviruses, adenoviruses, influenzae virus A and B, rotavirus, corona virus, cytomegalovirus (CMV), VZV, Epstein-Barr virus, and lymphocytic choriomeningitis. Collectively, about 20,000 encephalitis-associated hospitalizations are expected per year in the United States, with a case fatality rate of more than 5% and total health-care burden of nearly $2 billion.[56,99]

Viral encephalitis is acquired primarily by hematogenous spread or, alternatively, by neuronal spread of the causative pathogen. After entry into the host, viral replication occurs, resulting in dissemination through the reticuloendothelial system or vasculature. Infection of the capillary endothelial cells and choroid plexus may provide a conduit for CNS infections. Viruses such as polio, HSV, and VZV may also gain access to the CNS by axonal retrograde

transmission from peripheral nerve endings. Once a virus gains access to the CNS, the course of infection depends on the virulence of the particular virus and the host immune response. Subsequent neuronal injury is caused by direct cell damage due to viral replication, but inflammatory and immune-mediated responses also contribute to neurological damage.[16,17]

In contrast with purulent meningitis, host response to viral encephalitis is mediated primarily through cytotoxic T-lymphocytes. Increases in concentrations of IL-1, IL-6, and interferon (INF)-α, -β and -γ may occur. While cytokine assays are available for investigational use, they are not used routinely in the clinical diagnosis of viral encephalitis.[16,17] 2 The clinical syndrome associated with viral encephalitis generally is independent of viral etiology and may vary depending on the patient's age. Common signs in adults include headache, mild fever, nuchal rigidity, malaise, drowsiness, nausea, vomiting, and photophobia. Only fever and irritability may be evident in the infant, and acute bacterial meningitis must be ruled out as a cause of fever when no other localized findings are observed in a child. Duration of symptoms generally is 1 to 2 weeks, and specific manifestations outside the meninges can also occur depending on the viral etiology.

Laboratory examination of the CSF usually reveals a pleocytosis with 100 to 1,000 WBC/mm^3 (0.1-1 $\times$ 10^9/L), which are primarily lymphocytic; however, 20% to 75% of patients with viral encephalitis may have a predominance of polymorphonuclear cells on initial examination of the CSF. On repeat lumbar puncture, 90% of patients presenting initially with a predominance of neutrophils experience a shift to a predominance of mononuclear cells. Other laboratory findings include normal to mildly elevated protein concentrations and normal or mildly reduced glucose concentrations (see Table 106-1).[16,17]

3 As mentioned earlier, pathogens responsible for viral encephalitis are often not identified. Poor laboratory recovery of viral pathogens and limited treatment options for viral encephalitis made the need for specific identification of pathogens of questionable value. Advances in diagnostic laboratory techniques and the potential for decreased costs associated with longer duration of hospitalization for patients with unconfirmed viral encephalitis have led to a reevaluation of the need for confirmatory pathogen diagnosis. When clinical signs warrant pathogen identification, appropriate laboratory diagnostic techniques, including PCR and serologic testing, should be undertaken. Molecular methods are preferred to conventional laboratory tests, such as viral cultures and brain biopsy, in the diagnosis of viral encephalitis owing to improved sensitivity and specificity, higher yield and rapid results.[23,24]

Supportive and symptomatic treatments of patients with viral encephalitis are of great importance due to limited treatment options for most viral etiologies. Such treatments may include seizure control, hemodynamic management, venous thromboembolism prevention, ICP management, and secondary bacterial infection prevention. Corticosteroid therapy is generally not recommended in most viral encephalitis cases; however, treatment should be considered for patients with cerebral edema and increased ICP.[23,24]

Although there are numerous pathogenic causes of viral encephalitis, much of the clinical presentation, diagnosis, and treatment are similar. The most commonly isolated viral etiologies are described here. Both HSV type 1 (HSV1) and HSV type 2 (HSV2) are considered the most common treatable causes of viral encephalitis. HSV1 is associated with encephalitis in adults, whereas HSV2 is associated predominantly with encephalitis in newborns.[99,100] Sexually active adults acquire HSV meningitis during or after an attack of genital or rectal HSV, whereas neonates acquire the virus during passage through the vaginal canal of mothers with active HSV infection. HSV PCR testing on CSF specimens should be performed for all patients with presumed encephalitis. Moreover, repeat testing should be considered for patients with an initial negative test after 3 to 7 days.[24] Establishing the correct diagnosis as early as possible is paramount because of high mortality rate without treatment (approaches 70%), and unlike other viral etiologies, specific and effective therapy is available. As a result, empirical therapy of suspected HSV encephalitis, while laboratory results are pending, is necessary. Delaying antiviral therapy has been consistently associated with unfavorable outcomes and increased mortality across several studies. In one retrospective study of 184 patients with HSV encephalitis, administration of intravenous acyclovir within first day of hospital admission was associated with a lower mortality rate (13% vs 31%).[26] Additionally, a clinical decision to treat may need to be made regardless of test results.

Acyclovir is the drug of choice for HSV encephalitis. In adult patients with normal renal function, acyclovir is usually administered as 10 mg/kg intravenously every 8 hours for 2 to 3 weeks.[23,24] Higher doses of acyclovir (20 mg/kg every intravenously every 8 hours) have been used in neonates and are associated with lower mortality rates.[101] HSV resistance to acyclovir has been reported with increasing incidence, particularly in immunocompromised patients with prior or chronic exposures to acyclovir, ranging from 3.5% to 10% in immunocompromised patients.[102] The alternative treatment for acyclovir-resistant HSV is foscarnet. The dose for patients with normal renal function is 40 to 60 mg/kg infused over 1 hour every 8 to 12 hours for 3 weeks, with the higher dose typically reserved for HIV-infected individuals.[23] Ensuring adequate hydration is imperative to decrease risk of acyclovir- and foscarnet-induced nephrotoxicity. In addition, patients receiving foscarnet should be monitored for seizures related to alterations in plasma electrolyte levels. Finally, a recent prospective study examined the utility of long-term antiviral treatment on overall survival with no or mild neuropsychological impairment. Adult patients who completed standard initial HSV encephalitis treatment followed by an additional 3-month course of oral valacyclovir did not show improvements in neuropsychological testing 12 months later compared to placebo.[103]

Because of the recent epidemic in the United States, a separate discussion of the WNV is warranted. Although primarily mosquitoes transmit WNV, transmissions via blood products, organ transplantation, transplacental transfer, and breast milk have been documented. Similar to other arboviruses, the incubation period for WNV ranges from 3 days to 2 weeks. Infection with WNV is asymptomatic in most adults or causes a mild flu-like syndrome characterized by fever, malaise, myalgia, and lymphadenopathy. Among 41,762 reported cases of WNV in the United States between 1999 and 2014, the overall mortality rate was approximately 4% (9% in patients with neuroinvasive disease).[104] Many patients develop a maculopapular, erythematous rash, which is more common in children than in adults and is uncommon in other forms of viral encephalitis. The other neurologic manifestations include fever, nausea, vomiting, headache, altered mental status, movement disorders, and/or a syndrome much like poliomyelitis.[105] The primary risk factor for this manifestation seems to be advanced age, but alcohol abuse, diabetes, hypertension, immunosuppression, and cardiovascular disease were also identified as potential risk factors for neuroinvasive disease and worse outcomes.[105,106] The poliomyelitis syndrome is characterized by an early prodromic phase of fevers and weakness followed by the sudden onset of flaccid paralysis. CSF examination of WNV encephalitis typically shows pleocytosis and a slightly elevated CSF protein concentration. Several diagnostic methods have been developed for WNV, including a PCR assay and enzyme-linked immunosorbent assay (ELISA) tests. However, serologic tests (ELISA) can cross-react with other flaviviruses causing a false-positive result. Moreover, serum IgM antibodies for WNV can persist for up to 1 year, leading to confusion regarding whether the infection is an acute or previous infection. Ribavirin has shown inhibitory effects on the WNV in neural tissue cultures, but this has not been studied in controlled trials. Finally, DNA vaccines were studied in animals and have

shown positive results.[105] Treatment is typically supportive, including treatment for seizures and increased ICP, and in the majority of cases, the disease is self-limiting.[23,24]

CMV has emerged as a major cause of morbidity and mortality in immunocompromised patients, including HIV-infected individuals and transplant recipients on immunosuppressants. CNS infections with CMV are often difficult to treat, with higher failure rates and poor outcomes. Combination therapy with ganciclovir and foscarnet is recommended for induction treatment due to higher failure rates and lack of survival benefits when monotherapy with either agent is utilized.[23,24] In adult patients, ganciclovir 5 mg/kg every 12 hours and foscarnet 60 mg/kg every 8 hours (or 90 mg/kg every 12 hours) for 3 weeks are recommended during the induction phase, followed by maintenance phase with either agent. Other interventions that may improve survival outcomes include the initiation of highly active antiretroviral therapy (HAART) in untreated HIV-infected patients and reduction of immunosuppression intensity in transplant recipients.

HIV encephalitis is a common CNS complication associated with AIDS. Frequently, patients may complain of headache, photophobia, or stiff neck at the time of presumed seroconversion. As the disease progresses neurologic symptoms are frequently reported secondary to other opportunistic infections. Diagnosis of viral encephalitis is difficult because mental status and neurologic examinations are not sensitive enough to detect early changes. Direct evidence of HIV encephalitis can be obtained through CSF culture, p24 antigen testing, or qualitative or quantitative PCR for HIV RNA. Diagnostic workup of other potential copathogens, such as HSV, *Toxoplasma gondii*, *Mycobacterium tuberculosis*, *Aspergillus* spp, and *Cryptococcus*, should also be performed. Refer to chapter on HIV infection for a complete discussion of infectious complications in HIV-positive individuals.

Other Etiologies

Mycobacterium Tuberculosis

M. tuberculosis is the primary cause of tuberculous meningitis and remains the most life-threatening form of extrapulmonary tuberculosis. The incidence of tuberculosis, in general, has decreased to three cases per 100,000 individuals in the United States in 2013.[107]

The CDC recommends an initial regimen of four drugs for empirical treatment of *M. tuberculosis*. This regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol for the first 2 months, generally followed by isoniazid plus rifampin for the remaining duration of therapy.[108] The recommended therapy for HIV-positive individuals is the same as for immunocompetent patients, although rifabutin may be considered in place of other rifamycins in an effort to minimize drug interactions with protease inhibitors and nonnucleoside reverse-transcriptase inhibitors. Therapy in HIV-negative and HIV-positive patients should be individualized based on susceptibility patterns and guidelines from the CDC and the American Thoracic Society, which are updated frequently and available on the Internet (www.cdc.gov/nchstp/tb/pubs/mmwrhtml/maj_guide.htm). Patients with *M. tuberculosis* meningitis should be treated for 9 to 12 months or longer with multiple-drug therapy, and patients with rifampin-resistant strains may receive up to 18 to 24 months of therapy.

Treponema pallidum (Neurosyphilis)

Infection of the CNS by *Treponema pallidum* can occur at any stage of the disease although is most commonly seen in tertiary or latent syphilis many years, even decades, after the initial exposure. According to the CDC, incidence of late latent syphilis, which includes neurosyphilis, can develop in 15% of people who do not receive treatment for syphilis.[109] Patients with neurosyphilis may be asymptomatic, or present with signs and symptoms consistent with acute meningitis. Diagnosis is based on CSF findings, neurologic manifestations, and serologic evidence of exposure.[110] Aqueous penicillin G is recommended for treatment dosed either 3 to 4 million Units every 4 hours or 18 to 24 million units as a continuous infusion for a duration of 10 to 14 days.[109] If CSF pleocytosis is initially present, CSF examination should be repeated every 6 months until the cell count is normal. For further reading on the manifestations and treatment of syphilis we refer you to chapter on sexually transmitted infections in this text.

Toxoplasma gondii

Toxoplasmic encephalitis (TE) is caused by the protozoan *T. gondii*. Approximately 22.5% of the U.S. population 12 years and older have been infected with *T. gondii*. In other parts of the world, up to 95% of populations are infected. The primary routes of transmission are foodborne, animal-to-human (cats serving as the definitive host), mother-to-child (congenital), blood transfusions, and organ transplantation.[111] TE is typically caused by the reactivation of disease in immunocompromised patients, especially those with AIDS, or intrauterine infection in newborns. Clinical manifestations include extrapyramidal signs and symptoms, headache, seizures, confusion, hemiparesis, cranial nerve abnormalities, or fever.[24] In congenital toxoplasmosis, patients may also present with hydrocephalus, intracerebral calcification, microcephaly, convulsions, or chorioretinitis.[24,112] Definitive diagnosis of TE requires a clinical sample via a brain biopsy; therefore, TE is presumptively diagnosed on the basis of clinical symptoms, positive serology for antitoxoplasma IgG antibodies, and identification of space-occupying lesions on CT, MRI, or other radiologic imaging. In patients with AIDS, MRI typically shows multiple ring-enhancing lesions. *T. gondii* can also be detected by PCR in CSF; however, the sensitivity is low (50%) and the result is usually negative once treatment has started.[24,112,113] First-line treatment for TE in adults consists of pyrimethamine plus sulfadiazine plus leucovorin. Leucovorin is typically added to the treatment regimen to reduce the likelihood of hematologic toxicity associated with pyrimethamine. In patients who are unable to tolerate sulfadiazine, clindamycin may be used as an alternative. Other alternative treatment options include trimethoprim-sulfamethoxazole, atovaquone plus pyrimethamine plus leucovorin, atovaquone plus sulfadiazine, atovaquone monotherapy, or pyrimethamine plus leucovorin plus azithromycin. Treatment recommendations are the same in pediatric patients; however, several of the alternative regimens have not been studied in children.[24,112,113]

Borrelia burgdorferi

LD is caused by the spirochete *Borrelia burgdorferi* and is the most common tick-borne infection in North America and Europe.[114] Lyme neuroborreliosis (LNB) is an infectious disorder of the nervous system caused by *B. burgdorferi* and has been reported in up to 10% to 15% of patients with untreated LD. CNS involvement may include meningitis, myelitis, cerebral vasculitis, or encephalitis. Clinical manifestations include fever, headache, fatigue, photosensitivity, phonosensitivity, confusion, hemiparesis, cranial neuropathy (facial neuropathy being the most common), cerebellar ataxia, ocular flutter, apraxia, opsoclonus-myoclonus syndrome, or Parkinson-like symptoms. Poliomyelitis-like syndromes and acute stroke-like symptoms caused by cerebral vasculitis have been documented in single-case reports but are considered rare. Unlike the European LD, the North American LD is also characterized by a skin rash called erythema migrans.[114,115] Currently there is no international consensus for the diagnosis of LNB. Diagnosis is primarily based on the presence of neurological symptoms without other obvious reasons, CSF analysis (lymphocytic pleocytosis, moderately elevated protein, normal glucose), intrathecal *B. burgdorferi* antibody production, blood and CSF serologic testing (ELISA plus Western blot), and MRI demonstrating areas of inflammation.[24,114,115] PCR testing for

detection of *B. burgdorferi* in CSF has a sensitivity of less than 10% to 30% and has an unknown specificity, therefore is not routinely recommended. Parenteral treatment with ceftriaxone once daily is recommended as first-line treatment of LNB. Patients with cranial neuropathy without clinical signs of meningitis may be treated with oral amoxicillin, doxycycline, or cefuroxime axetil. The European Federation of Neurological Societies (EFNS) guidelines also recommend oral doxycycline as a first-line option for patients with symptoms confined to the meninges, cranial nerves, nerve roots, or peripheral nerves based on its CSF penetration, ability to achieve CSF concentrations above the MIC, and several Class III studies showing similar short- and long-term efficacy to various parenteral regimens.[115] Alternative parenteral options to ceftriaxone include cefotaxime or penicillin G. For patients intolerant to β-lactams, doxycycline oral or intravenous is suggested.

EVALUATION OF THERAPEUTIC OUTCOMES

Signs and Symptoms

Because of the potential for rapid deterioration associated with CNS infections, signs and symptoms of fever, headache, meningismus (eg, nuchal rigidity, Brudzinski's or Kernig's sign), vital signs, and signs of cerebral dysfunction should be evaluated every 4 hours for the initial 3 days and then daily thereafter. The Glasgow Coma Scale should be used in severely ill patients. Trends in improvement and resolution rather than single evaluations in time are more important in monitoring the signs and symptoms of meningitis.

Microbiologic Findings

CSF and blood samples for gram-stain, cultures, and sensitivity testing should be taken prior to starting antibiotic therapy. If lumbar puncture is delayed, however, antibiotics should be started. Although the CSF cultures may be negative, antibiotic therapy rarely interferes with the protein and/or glucose concentrations in the CSF. Furthermore, if the laboratory is made aware of the antibiotic therapy, steps can be taken to diminish the effects of the antibiotic during the detection process. Gram stain results can be obtained immediately and can guide empirical antibiotic treatment. Identification of the organism can be made within 24 hours, and sensitivities should be available within 48 hours. Repeat cultures should be performed to help determine if sterilization is achieved. A second tube of blood should be taken to allow for latex agglutination tests of antigens to common meningeal pathogens (*H. influenzae*, *S. pneumoniae*, *N. meningitidis*, *E. coli*, and group B *Streptococcus*) if the gram stain has not been helpful.

CSF Examination

In bacterial meningitis, the CSF WBC count usually is greater than 1,000 cells/mm^3 (1,000 × 10^6/L), the CSF protein concentration is elevated, and the CSF glucose concentration (hypoglycorachia) is often low (45 mg/dL or less [2.5 mmol/L or less] or 50%-60% of a simultaneous blood glucose value). Viral encephalitis, in contrast, results in relatively normal CSF protein and glucose levels and typically does not result in greater than 90% polymorphonuclear neutrophils (PMNs) in the CSF (Table 106-1).

ABBREVIATIONS

ACIP	Advisory Committee on Immunization Practices
AIDS	acquired immunodeficiency syndrome
BBB	blood–brain barrier
BCSFB	blood–cerebrospinal fluid barrier
CBF	cerebral blood flow
CDC	US Centers for Disease Control and Prevention
CFU	colony forming unit
CLSI	Clinical and Laboratory Standards Institute
CMV	cytomegalovirus
CNS	central nervous system
CSF	cerebrospinal fluid
CT	computed tomography
DIC	disseminated intravascular coagulation
EFNS	European Federation of Neurological Societies
EIA	enzyme immunoassay
ELISA	enzyme-linked immunosorbent assay
FDA	US Food and Drug Administration
GBS	group B *Streptococcus*
GI	gastrointestinal
HAART	highly active antiretroviral therapy
Hib	*Haemophilus influenzae* type b
HIV	human immunodeficiency virus
HSV	herpes simplex virus
ICP	intracranial pressure
Ig	immunoglobulin
IPD	invasive pneumococcal disease
IL-1	interleukin-1
INF	interferon
LNB	lyme neuroborreliosis
LPS	lipopolysaccharide
MenB	serogroup B meningococcal vaccine
MIC	minimum inhibitory concentration
MRI	magnetic resonance imaging
PAF	platelet-activating factor
PCR	polymerase chain reaction
PCT	procalcitonin
PCV7	heptavalent pneumococcal conjugate vaccine
PCV13	13-valent pneumococcal conjugate vaccine
PGE2	prostaglandin E_2
PMN	polymorphonuclear neutrophil
PPV23	23-valent pneumococcal polysaccharide vaccine
TDM	therapeutic drug monitoring
TE	toxoplasmic encephalitis
TNF	tumor necrosis factor
VZV	varicella-zoster virus
WBC	white blood cell
WNV	West Nile virus

Martha G. Blackford, Mark L. Glover, and Michael D. Reed

KEY CONCEPTS

1. Respiratory infections remain a major cause of morbidity from acute illness in the United States and likely represent the most common reasons why patients seek medical attention.
2. The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, whereas microbes less commonly gain access to the lungs via the blood from an extrapulmonary source or by inhalation of infected aerosol particles. The competency of a patient's immune status is an important factor influencing the susceptibility to infection, etiologic cause, and disease severity.
3. An appropriate treatment regimen for the patient with uncomplicated lower respiratory tract infection can be established by evaluating the patient history, physical examination, chest radiograph, and properly collected sputum for culture interpreted in light of current knowledge of the most common lung pathogens and their antibiotic susceptibility patterns within the community.
4. Acute bronchitis is caused most commonly by respiratory viruses and almost always is self-limiting. Therapy targets associated symptoms, such as lethargy, malaise, or fever and may include fluids for rehydration. Routine use of antibiotics should be avoided and medication to suppress cough is rarely indicated.
5. Chronic bronchitis is caused by several interacting factors, including inhalation of noxious agents (most prominent are cigarette smoke and exposure to occupational dusts, fumes, and environmental pollution) and host factors including genetic factors and bacterial (and possibly viral) infections. The hallmark of this disease is a chronic cough, accompanied by excessive production, and expectoration of sputum with a persistent presence of microorganisms in the patient's sputum.
6. Treatment of acute exacerbations of chronic bronchitis includes attempts to mobilize and enhance sputum expectoration (chest physiotherapy, humidification of inspired air), oxygen if needed, aerosolized bronchodilators in select patients with demonstrated benefit, and possibly antibiotics.
7. Respiratory syncytial virus is the most common cause of acute bronchiolitis, an infection that mostly affects infants during their first year of life. In the well infant, bronchiolitis usually is a self-limiting viral illness.
8. The most prominent pathogen causing community-acquired pneumonia in otherwise healthy adults is *Streptococcus pneumoniae*, whereas the most common pathogens causing hospital-acquired are *Staphylococcus aureus* and gram-negative aerobic bacilli. Anaerobic bacteria are the most common etiologic agents in pneumonia that follow aspiration of gastric or oropharyngeal contents.
9. Treatment of community-acquired pneumonia may consist of humidified oxygen for hypoxemia, bronchodilators when bronchospasm is present, rehydration fluids, and chest physiotherapy for marked accumulation of retained respiratory secretions. Antibiotic regimens should be selected based on presumed causative pathogens and pulmonary distribution characteristics and should be adjusted to provide optimal, targeted therapy against pathogens identified by culture (sputum or blood).
10. Treatment of hospital-acquired pneumonia requires aggressive therapy with careful consideration of the dominance and susceptibility patterns of the pathogens present within the institution.

1 Respiratory tract infections remain a major cause of morbidity from acute illness in the United States and most likely represent the single most common reason patients seek medical attention. This chapter focuses on bacterial and viral infections involving the lower respiratory tract, which includes the tracheobronchial tree and lung parenchyma.

2 The respiratory tract has an elaborate system of host defenses, including humoral immunity, cellular immunity, and anatomic mechanisms.[1] When functioning properly, respiratory tract host defenses are markedly effective in protecting against pathogen invasion and removing potentially infectious agents from the lungs. For the most part, infections in the lower respiratory tract occur only when these defense mechanisms are impaired, as in cases of dysgammaglobulinemia or compromised ciliary function, such as that caused by the chronic inflammation accompanying cigarette smoking. In addition, local defenses may be overwhelmed when a particularly virulent microorganism or excessive inoculum invades lung parenchyma. The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, which, after achieving sufficiently high concentrations, gain access to the lung via aspiration of oropharyngeal secretions. Less commonly, microbes enter the lung via the blood from an extrapulmonary source or by inhalation of infected aerosolized particles. The specific type of pulmonary infection caused by an invading microorganism is determined by a variety of host factors, including age, anatomic features of the airway, and specific characteristics of the infecting agent.

The most common infections involving the lower respiratory tract are bronchitis, bronchiolitis, and pneumonia. Bronchitis and bronchiolitis are inflammatory conditions of the large and small airways, respectively, of the tracheobronchial tree. The inflammatory process does not extend to the alveoli. Bronchitis frequently is classified as acute or chronic; acute bronchitis occurs in individuals of all ages, whereas chronic bronchitis primarily affects adults. Bronchiolitis is a disease of infancy.

Lower respiratory tract infections in children and adults most commonly result from either viral or bacterial invasion of lung parenchyma. The diagnosis of viral infections rests primarily on the recognition of a characteristic constellation of clinical signs and symptoms. Because treatment is largely supportive, only occasionally does the diagnosis require laboratory confirmation; this is achieved through serologic tests or identification of the organism by culture or antigen detection in respiratory secretions.[2] Laboratory techniques using polymerase chain reaction (PCR), microarrays, and multiplex ligation-dependent probe amplification, to name a few, have emerged as a means to identify specific pathogens rapidly and accurately.[3]

In contrast, because bacterial pneumonia usually necessitates expedient, effective, and specific antibiotic therapy, its management depends, in large part, on an understanding of the risk factors for acquiring pneumonia, predominant pathogens within the community, and, if necessary, isolation of the etiologic agent by culture from lung tissue or secretions.[4-6] The pharynx is colonized with many organisms that can cause pneumonia; therefore, culture of expectorated sputum can be misleading unless the specimen is examined to ensure that it has originated from the lower respiratory tract. The Gram stain provides the easiest method for distinguishing lower from upper respiratory tract secretions; moreover, through determination of the shape and color of the bacteria, the Gram stain frequently narrows the microbiologic differential diagnosis sufficiently to allow accurate initial therapy. Scanned under low-power microscopy, Gram-stained expectorated upper respiratory tract secretions contain many irregularly shaped epithelial cells with little evidence of inflammation and may not reflect the pathogen. In contrast, a lower-tract specimen from a patient with bacterial pneumonia usually contains multiple neutrophils per high-powered field and a single or predominant bacterial species. More aggressive procedures can be performed in an attempt to more accurately identify responsible pathogens including respiratory secretion samples obtained via bronchoscopy or bronchoalveolar lavage (BAL). Culture of specimens confirmed to originate from the lower tract by Gram stain or collection via BAL provides valuable diagnostic information for the majority of patients with bacterial pneumonia. In addition, pneumonia promotes the release of inflammatory mediators and acute-phase proteins, such as C-reactive protein, which is significantly elevated in serum in the presence of respiratory tract infections.[7] Unfortunately with the exception of pathogen identification by culture, elevations in C-reactive protein, changes in sputum color or peripheral white blood count, etc., are not specific for determining viral, bacterial, or fungal etiology. Newer genomic testing may add tremendously in determining the identity of responsible pathogen(s) and then selection of optimal antimicrobial therapy.

3 An appropriate treatment regimen for the patient with an uncomplicated lower respiratory tract infection usually can be established by history, physical examination, chest radiograph, and properly collected sputum cultures interpreted in light of the most common lung pathogens and their antibiotic susceptibility patterns within the community.[2,5] More sophisticated or invasive diagnostic methods (eg, computed tomography, bronchoscopy, and lung biopsy)[2] are reserved for severely ill patients who are unable to expectorate sputum or who are not responding to empirical therapy or for pulmonary infections occurring in immunocompromised patients.

BRONCHITIS

Acute Bronchitis

Epidemiology and Etiology

Acute bronchitis occurs year round, but more commonly during the winter months. Acute bronchitis is responsible for at least 10 million office and urgent care visits annually, underscoring its major financial impact on the healthcare system. Acute bronchitis is characterized by inflammation of the epithelium of the large airways resulting from infection or exposure to irritating environmental triggers (eg, air pollution and cigarette smoke). Acute (viral) infection and or smoking are the most common precipitants of attacks, which usually manifest initially as a persistent cough.

4 Respiratory viruses are the predominant infectious agents associated with acute bronchitis, accounting for 85% to 95% of occurrences. The most common infecting agents include influenza A and B, respiratory syncytial virus (RSV), and parainfluenza virus, whereas the common cold viruses (rhinovirus and coronavirus) and adenovirus are encountered less frequently. Although far less common, bacterial pathogens are involved in a minority of cases and involve pathogens often associated with community-acquired pneumonia (CAP), including *Mycoplasma pneumoniae*, *Streptococcus pneumonia, Haemophilus influenzae, Moraxella catarrhalis*, and less commonly *Chlamydophila pneumoniae* and *Bordetella pertussis*, the agent responsible for whooping cough. Although a primary bacterial etiology for acute bronchitis appears rare, secondary bacterial infection may be involved, particularly in patients with underlying disease(s).[8]

Pathogenesis

4 Since acute bronchitis is primarily a self-limiting illness and rarely a cause of death, few data describing the pathology are available. In general, infection of the trachea and bronchi yields inflammation-induced hyperemic and edematous mucous membranes with an increase in bronchial secretions. Destruction of respiratory epithelium can range from mild to extensive and may affect bronchial mucociliary function. In addition, the increase in desquamated epithelial cells and bronchial secretions, which can become thick and tenacious, further impairs mucociliary activity. The probability of permanent damage to the airways as a result of acute bronchitis remains unclear but appears unlikely. However, epidemiologic evaluations support the belief that recurrent acute respiratory infections may be associated with increased airway hyperreactivity and possibly the pathogenesis of asthma, chronic obstructive pulmonary disease (COPD), or possibly the asthma-COPD overlap syndrome.[9,10]

Clinical Presentation

Acute bronchitis usually begins as an upper respiratory infection with nonspecific complaints.[8,11] Cough is the hallmark of acute bronchitis and occurs early. The onset of cough may be insidious or abrupt, and the symptoms persist despite resolution of nasal or nasopharyngeal complaints; cough may persist for up to 3 or more weeks. Frequently, the cough initially is nonproductive, but then progresses, yielding mucopurulent sputum. In older children and adults, the sputum is raised and expectorated; in the young child, sputum often is swallowed and can result in gagging and vomiting. Substantial discomfort may result from the coughing. Dyspnea, cyanosis, or signs of airway obstruction are observed rarely unless the patient has underlying pulmonary disease, such as emphysema or COPD. Fever, when present, rarely exceeds 39°C (102.2°F) and appears most commonly with adenovirus, influenza virus, and *M. pneumoniae* infections. The diagnosis typically is made on the basis of a characteristic history and physical examination, and should be differentiated from asthma or bronchiolitis as these latter diseases are usually associated with wheezing, shortness of breath, and

hypoxemia. Bacterial cultures of expectorated sputum are of limited use because of the inability to avoid normal nasopharyngeal flora by the sampling technique. Similarly, viral cultures are unnecessary. In the absence of important risk factors, including COPD, congestive heart failure, or immune compromise, throat/sputum cultures have no role in the routine care of patients with acute bronchitis. As newer antigen-based PCR and genetic diagnostic tests for identifying specific pathogens become more routinely available,[12] specific etiologic causes of acute bronchitis will be identified. However, for the vast majority of affected patients, an etiologic diagnosis is unnecessary and will not change the prescribing of routine supportive care for the management of these patients.

TREATMENT

Desired Outcome

In the absence of a complicating bacterial superinfection, acute bronchitis almost always is self-limiting. The goals of therapy are to provide comfort to the patient and, in the unusually severe case, to treat associated dehydration and respiratory compromise.[8]

General Approach to Treatment

4 Treatment of acute bronchitis is symptomatic and supportive in nature. Reassurance and antipyretics frequently are all that are needed. Bedrest for comfort may be instituted as desired. Patients should be encouraged to drink fluids to prevent dehydration and possibly to decrease the viscosity of respiratory secretions. Mist therapy (use of a vaporizer) may promote the thinning and loosening of respiratory secretions.

Pharmacologic Therapy

Mild analgesic–antipyretic therapy often is helpful in relieving the associated lethargy, malaise, and fever. Aspirin or acetaminophen (650 mg/dose in adults [maximum less than 4 g/day] or 10-15 mg/kg/dose in children [maximum 60 mg/kg/day]) administered every 4 to 6 hours or ibuprofen (200-800 mg/dose in adults [maximum 3.2 g/day] or 10 mg/kg/dose in children [maximum 40 mg/kg/day]) should be administered every 6 to 8 hours. Aspirin should be avoided in children less than 19 years of age with a fever-causing illness and acetaminophen or ibuprofen used as the preferred agents because of a possible, but unclear and unproven, association between aspirin use and the possible development of Reye's syndrome.[13]

Use of ibuprofen as an antipyretic has increased. The drug's antipyretic efficacy appears identical to that of aspirin or acetaminophen, although its duration of antipyretic effect may be slightly longer (eg, 3-4 hours for aspirin and acetaminophen vs more than 5-6 hours for ibuprofen). A possible association with acetaminophen use during pregnancy or childhood and the subsequent development of asthma has raised some question as to the viability of routine acetaminophen use during childhood.[14] For these reasons, ibuprofen has become a preferred analgesic and antipyretic by many pediatric practitioners. However, caution should be exercised with the use of ibuprofen in patients younger than 6 months, elderly patients, and individuals with poor renal function. Aspirin, ibuprofen, and other nonsteroidal anti-inflammatory drugs inhibit prostaglandin synthesis and may adversely influence renal function in these predisposed patient populations.

Patients may present with mild-to-moderate wheezing. In otherwise healthy patients, no meaningful benefits have been described with the routine use of oral or aerosolized β_2-receptor agonists[15] and/or oral or aerosolized corticosteroids. Corticosteroids should be avoided in patients with acute bronchitis. A Cochrane review concluded (based on benefit vs potential for adverse effects) there is no evidence to support the use of β_2-receptor agonists in either pediatric or adult patients with acute bronchitis; however, in adults with airflow obstruction, there was a trend toward improvement.[15] Some clinicians, despite no data, may initiate a brief trial (eg, ~5-7 days) of β_2-receptor agonists and even oral or inhaled corticosteroid for patients with a persistent (>14-20 days), troublesome cough. This is rarely if ever necessary in patients with uncomplicated acute bronchitis and should be avoided. Cough may persist for 3+ weeks and airway hyperresponsiveness for 5-6 weeks in as many as 50% of affected patients. In contrast, COPD patients experiencing an acute exacerbation can (will) benefit from a short course of corticosteroid. Studies do not support the use of mucolytic agents in patients with acute bronchitis.

Patients suffering from acute bronchitis frequently medicate themselves with nonprescription cough and cold remedies containing various combinations of antihistamines, sympathomimetics, and antitussives despite the lack of definitive evidence supporting their effectiveness. The tendency of these agents to dehydrate bronchial secretions could aggravate and prolong the recovery process. Although not recommended for routine use, persistent, mild cough, which may be bothersome, can be treated with dextromethorphan; more severe coughs may require intermittent codeine or other similar agents.[16] In severe cases, the cough may be persistent enough to disrupt sleep, and use of a mild sedative-hypnotic, concomitantly with a cough suppressant (eg, codeine), may be desirable. However, antitussives should be used cautiously when the cough is productive. The primary or supplemental use of expectorants is questionable because their clinical effectiveness has not been well established.

Routine use of antibiotics for treatment of acute bronchitis should be strongly discouraged due to limited benefit.[8,17] In previously healthy patients who exhibit persistent fever or respiratory symptoms for more than 5 to 7 days or for predisposed patients (eg, elderly/frail, COPD, and immune compromised), the possibility of a concurrent bacterial infection should be suspected. When possible, antibiotic therapy should be directed toward anticipated respiratory pathogen(s) (eg, *S. pneumoniae* and *H. influenza*). *M. pneumoniae*, if suspected by history or if confirmed by culture serology or PCR, can be treated with azithromycin. Alternatively and empirically, a fluoroquinolone antibiotic with activity against these suspected pathogens (eg, levofloxacin) can be used, but due to the increasing rate of pathogen resistance to current antimicrobial drugs, the use of antibiotics in patients with acute bronchitis should be reserved for only those patients not responding adequately to supportive care and deemed at risk of associated complications. During known epidemics involving the influenza A virus, amantadine or rimantadine may have been effective in minimizing associated symptoms if administered early in the course of the disease, though treatment with these drugs, the adamantanes, is no longer recommended by the Centers for Disease Control and Prevention due to increasing influenza resistance and associated adverse effects.[18] The neuraminidase inhibitors (eg, zanamivir and oseltamivir) are active against both influenza A and B viral infections and may reduce the severity and duration of the influenza episode if administered promptly during the onset of the viral infection and are the preferred treatment (see Chapter 109).[19] Unfortunately, the incidence of influenza virus resistance to available antiviral drugs is increasing,[20] necessitating reconsideration of how we administer antiviral drugs for prophylaxis and treatment. The concept of antiviral drug combinations has emerged as a successful approach to effectively treat systemic viral infections.[21]

Chronic Bronchitis

Epidemiology and Etiology

Chronic bronchitis, most often a component of COPD, is a clinical diagnosis for a nonspecific, heterogenic disease that primarily

affects adults. An in-depth presentation of the spectrum and management of COPD is given in Chapter 27; this section will focus solely on chronic bronchitis. In developed countries, the prevalence of chronic bronchitis is slightly higher in men than in women and possibly more common in Whites. Depending on the definition used for chronic bronchitis, it is estimated that 3.4% to 22% of adults have chronic bronchitis and that 14% to 74% of COPD patients suffer from chronic bronchitis.[22]

5 Chronic bronchitis is defined clinically as the presence of a chronic cough productive of sputum lasting more than 3 consecutive months of the year for 2 consecutive years without an underlying etiology of bronchiectasis or tuberculosis. The disease is a result of several contributing factors; the most prominent include cigarette smoking, exposure to occupational dusts, fumes, and environmental pollution, and host factors (eg, genetic factors and bacterial [and possibly viral] infections). The contribution of each of these factors and of others (either alone or in combination) to chronic bronchitis is unknown.[23] Cigarette smoke is a well-known airway irritant and is a predominant factor in the etiology of chronic bronchitis. Although previously assumed the most common etiologic cause of chronic bronchitis, more strict prohibition of public smoking, and the resultant decrease in chronic tobacco smokers, particularly in developed countries, underscores the importance of other factors as causes of this chronic disease. Approximately 4% to 22% of patients with chronic bronchitis report never smoking.[22] Additional airway irritants including occupational dust, chemicals, or air pollution, either alone or more likely in combination, are also responsible for the pathogenesis of chronic bronchitis.[22,23] Furthermore, genome-wide association studies have begun to expand our understanding of the molecular pathways that may have clinical relevance in this very heterogeneous disease; see Chapter 27. Lastly, the influence of recurrent respiratory tract infections during childhood or young adult life on the later development of chronic bronchitis remains obscure, but recurrent respiratory infections may predispose individuals to the development of chronic bronchitis. Whether these recurrent respiratory tract infections are a result of unrecognized anatomic abnormalities of the airways or impaired pulmonary defense mechanisms is unclear.

Numerous consensus statements and published authoritative guidelines define chronic bronchitis and emphysema as the two main components of COPD/chronic obstructive lung disease.[24-26] The Global Initiative for Chronic Obstruction Lung Disease (GOLD) guidelines document does not distinguish these two diagnoses (eg, emphysema or chronic bronchitis) in the definition of COPD, but it does define COPD as a disease characterized by airflow obstruction that is not fully reversible and progressive. The GOLD guidelines (www.goldcopd.com) provide a COPD classification scoring system according to severity that can be helpful in staging patients for intensity of therapy, acute/chronic therapy, and prognosis. Unfortunately, differences in definitions between authoritative organizations may cause confusion in the assignment of patients in clinical trials and thus in assessment and application of study results to clinical care.

Pathogenesis

Chronic inhalation of an irritating noxious substance compromises the normal secretory and mucociliary function of bronchial mucosa.[27] Bronchial biopsy specimens in bronchitic patients underscore the importance of T-cell derived proinflammatory cytokines (eg, interleukins IL-4, 5, 13, and interferon gamma) in the pathogenesis and propagation of the observed inflammatory changes. In chronic bronchitis, the bronchial wall is thickened, and the number of mucus-secreting goblet cells on the surface epithelium of both larger and smaller bronchi is increased markedly. In contrast, goblet cells generally are absent from the smaller bronchi of normal individuals. In addition to the increased number of goblet cells, hypertrophy of the mucous glands and dilation of the mucous gland ducts are observed. As a result of these changes, chronic bronchitics have substantially more mucus in their peripheral airways, further impairing normal lung defenses. This increased quantity (overproduction and hypersecretion) of tenacious secretions within the bronchial tree frequently causes mucous plugging of the smaller airways. Accompanying these changes are squamous cell metaplasia of the surface epithelium, edema, and increased vascularity of the basement membrane of larger airways and variable chronic inflammatory cell infiltration. In addition, the amounts of several proteases derived from inflammatory cells are increased and due to COPD-induced defective antiproteases lead to continued destruction of connective tissue. Continued progression of this pathology can result in residual scarring of small bronchi and peribronchial fibrosis augmenting airway obstruction and weakening of bronchial walls.[22]

Clinical Presentation

5 The hallmark of chronic bronchitis is a cough that may range from a mild to a severe and incessant coughing productive of purulent sputum. Coughing may be precipitated by multiple stimuli, including simple, normal conversation. Expectoration of the largest quantity of sputum usually occurs on arising in the morning, although many patients expectorate sputum throughout the day. The expectorated sputum usually is tenacious and can vary in color from white to yellow-green. Patients with chronic bronchitis often expectorate as much as 100 mL/day more than normal. As a result, many patients complain of a frequent bad taste in their mouth and of halitosis. It is important to recognize that sputum color provides no prognostic indication of infection or cause of an infectious disease exacerbation, that is, viral versus bacterial cause. Although sputum color of more green and yellow can be a predictor of potentially pathogenic bacteria this is unreliable clinically.[28] The diagnosis of an acute exacerbation requires consideration of a number of different factors all occurring within a discrete timeframe, (eg, increased/worsening respiratory symptoms including dyspnea, sputum volume and/or clearance, cough, etc). The tracking of the number of acute exacerbations and their consequences (decline in forced expiratory volume in 1 second (FEV1), persistent/worsening of symptoms annually is extremely important for prognostication and defining ongoing treatment strategies. Each acute exacerbation of chronic bronchitis results in continual declines in lung function.

The diagnosis of chronic bronchitis is based primarily on clinical assessment and history. Any patient who reports coughing sputum on most days for at least 3 consecutive months each year for 2 consecutive years presumptively has chronic bronchitis.[22] The diagnosis of chronic bronchitis is made only when the possibilities of bronchiectasis, cardiac failure, cystic fibrosis, and lung carcinoma, amongst others, have been effectively excluded. In an attempt to be more specific in the diagnosis, some investigators have added the criteria of lost wages for 3 or more weeks. In addition, many clinicians attempt to subdivide their patients based on severity of disease to guide therapeutic interventions. Two primary classification proposals are most often used in an attempt to determine the severity of the underlying disease as well as the occurrence/impending occurrence of an acute exacerbation of chronic bronchitis; for disease severity and acute exacerbations the prognostic tools advocated by GOLD are very helpful including classification based on spirometry ("mild" postbronchodilator FEV1 greater than or equal to 80% predicted to "very severe" postbronchodilator FEV1 less than 30% predicted: see Chapter 27); the COPD assessment test (8-item measure of health status), the Clinical COPD Questionnaire (a measure of clinical control) and the Modified Medical Research Council Questionnaire to predict future mortality. The other simple classification system is that proposed by Anthonisen and colleagues in 1987[29] that is still used to categorize patients in many therapeutic clinical trials. The use of patient symptom diaries can also be

TABLE 107-1 Clinical Presentation of Chronic Bronchitis

Signs and symptoms
Excessive sputum expectoration
Cough
Cyanosis (advanced disease)
Physical examination
Chest auscultation usually reveals inspiratory and expiratory rales, rhonchi, and mild wheezing with an expiratory phase that is frequently prolonged
Hyperresonance on percussion with obliteration of the area of cardiac dullness
Normal vesicular breathing sounds are diminished
Clubbing of digits (advanced disease)
Obesity
Chest radiograph
Increase in anteroposterior diameter of the thoracic cage (barrel chest)
Depressed diaphragm with limited mobility
Laboratory tests
Erythrocytosis (advanced disease), that is, increased hematocrit
Pulmonary function tests
Decreased vital capacity
Prolonged expiratory flow

helpful in compliant patients. The importance of accurate classification for grouping patients of similar disease involvement cannot be overemphasized with respect to assessing publications outlining treatment strategies for these patients. Although gross, these classifications attempt to capture specific phenotypes of chronic bronchitis patients. The typical clinical presentation of chronic bronchitis is listed in Table 107-1. Comparison of the trends in changes in a patient's physical activity, symptoms, and clinical/physical findings from the patient's "routine" is extremely helpful in determining the presence and severity of an acute exacerbation.

In more advanced stages of chronic bronchitis, physical findings associated with cor pulmonale, including cardiac enlargement, hepatomegaly, and edema of the lower extremities, are observed. In general, chronic bronchitics tend to maintain at least normal body weight and commonly are obese. Radiographic studies are of limited value in either the diagnosis or follow-up of a patient. The microscopic and laboratory assessments of sputum are used in the overall evaluation of patients with chronic bronchitis. Gram staining of the sputum often reveals a mixture of both gram-positive and gram-negative bacteria, reflecting normal oropharyngeal flora and chronic tracheal colonization (in order of frequency) by nontypable *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*. Table 107-2 lists the most common bacterial isolates identified from sputum culture for patients experiencing an acute exacerbation of chronic bronchitis. For patients with more severe airflow disease (eg, FEV_1 less than 40% predicted), enteric gram-negative bacilli, *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas aeruginosa* may be significant pathogens during acute exacerbations.

TABLE 107-2 Common Bacterial Pathogens Isolated from Sputum of Patients with Acute Exacerbation of Chronic Bronchitis

Pathogen	Percent of Cultures
H. influenzae[a,b]	45
M. catarrhalis[a]	30
S. pneumoniae[c]	20
E. coli, *Enterobacter* species, *Klebsiella* species, *P. aeruginosa*	5

[a]Often β-lactamase positive.

[b]Vast majority are nontypable strains.

[c]More than 25% of strains may have intermediate or high resistance to penicillin.

TREATMENT

Desired Outcome

The goals of therapy for chronic bronchitis are twofold: to reduce the severity of chronic symptoms and to ameliorate acute exacerbations and achieve prolonged exacerbation-free intervals.

General Approach to Treatment

The approach to treatment of chronic bronchitis is multifactorial.[22] First and foremost, attempts must be made to reduce the patient's exposure to known bronchial irritants (eg, smoking and workplace pollution). A complete occupational and environmental history for determination of exposure to noxious, irritating gases as well as preference toward cigarette smoking must be assessed. Often easier discussed than accomplished, honest, yet reasonable attempts should be made with the patient to reduce or eliminate the number of cigarettes smoked daily and to reduce exposure to secondhand smoke. An organized, coordinated, smoking cessation program, including counseling, possibly hypnotherapy, and the adjunctive use of nicotine substitutes (eg, nicotine gum or patch) or other pharmacotherapy (eg, bupropion and varenicline) may promote the reduction or complete withdrawal from cigarette smoking. Often just as difficult is modification of exposure to irritating substances within the home and workplace.

The importance of pulmonary rehabilitation has been realized in improving the quality of life for patients with chronic respiratory diseases.[30] Pulmonary rehabilitation is broadly defined as an interdisciplinary program individualized for patients with chronic respiratory impairment designed to optimize each patient's physical and social performance and autonomy. A personalized exercise training program including resistance and aerobic exercise are central to these programs. Pulmonary rehabilitation programs relieve dyspnea and fatigue, improve a patient's emotional function, and enhance their sense of control over their disease and life. These improvements are often moderately large and clinically relevant.[30] The challenge for the future is to determine what components of a comprehensive pulmonary rehabilitation program provide the greatest benefit.

6 Measures to provide chest physiotherapy (eg, pulmonary "toilet") can be instituted.[31] Clearly the cost-effectiveness of chest physiotherapy needs to be better described but their short-term effects have been demonstrated and may be of symptomatic value to many patients experiencing an acute exacerbation of the chronic bronchitis. During acute pulmonary exacerbations of the disease, the patient's ability to mobilize and expectorate sputum may be reduced dramatically. In these instances, attempts at postural drainage techniques, with instruction and or active participation from a respiratory therapist, may assist in promoting clearance of pulmonary secretions. In addition, humidification of inspired air may promote the hydration (liquefaction) of tenacious secretions, allowing for removal that is more productive. Use of aerosolized mucolytic aerosols, such as *N*-acetylcysteine (NAC) and DNAse, is of questionable therapeutic value, particularly considering their propensity to induce bronchospasm (NAC) and their excessive cost. NAC cleaves the disulfide bonds of mucous, decreasing its elastic property that is important for upward mobility and then expectoration. A Cochrane meta-analysis of aerosol mucolytic therapy in subjects with chronic bronchitis or COPD found that treatment with mucolytics was associated with a small reduction in acute exacerbations and did not cause any harm, improve quality of life, or slow the decline of lung function.[32] The clinical benefit may be greater for chronic bronchitics/COPD patients who have frequent or prolonged exacerbations and are unable to utilize inhaled corticosteroids or long-acting β_2-agonists.[32] Although limited data are available, chronic use of oral or aerosolized bronchodilators may be of benefit by increasing

mucociliary and cough clearance. For patients with moderate to severe COPD, combination therapy with a long-acting β_2-agonist and inhaled corticosteroid led to decreased exacerbations and rescue medication use, while it also improved quality of life, lung function, and symptom scores compared with long-acting β_2-agonist monotherapy.

Pharmacologic Therapy

Patients should be up to date with vaccinations, particularly pneumococcal and an annual influenza vaccine; however, the clinical utility of vaccination against haemophilus disease is questionable. For patients who consistently demonstrate clinical limitation in airflow, a therapeutic challenge of a short-acting β_2-agonist bronchodilator (eg, as albuterol aerosol) should be considered. Pulmonary function tests should be performed before and after β_2-agonist aerosol administration for more objective determination of a patient's propensity to benefit from supplemental aerosol therapy. Sufficient published experience supports the use of inhalation therapy with a β_2-agonist for patients with chronic bronchitis (COPD) to improve pulmonary function and exercise tolerance and to reduce the sense of breathlessness.[22] Regular use of a long-acting β-receptor agonist aerosol (eg, salmeterol and formoterol) in responsive patients are more effective and probably more convenient than short-acting β_2-receptor agonists.[33] The aerosol route for β_2-receptor agonist and/or corticosteroid administration is favored over systemic formulations for improved patient acceptance and compliance and to minimize the number and magnitude of associated adverse effects. Chronic inhalation of a long-acting β-receptor agonist (LABA) and a poorly absorbed corticosteroid combination (eg, salmeterol/fluticasone and formoterol/mometasone) has been associated with improved pulmonary function and quality of life.[34] However, chronic use of aerosolized corticosteroid is associated with increased side effects including hoarseness, sore throat, thrush, pneumonia, and osteoporosis. Nevertheless, caution should be exercised in withdrawing inhaled glucocorticoid administration in patients with severe COPD receiving triple inhalation therapy as it may lead to increased frequency of acute exacerbations and a greater decrease in lung function.

Published experience with inhaled anticholinergic drugs, including ipratropium and tiotropium, is increasing and defining an important role in the chronic management of patients with chronic bronchitis and COPD.[35] Numerous studies are now available demonstrating the clinical effectiveness of inhaled long-acting muscarinic antagonists (LAMAs) alone or more frequently when administered in combination with a LABA, in improving lung function and real benefits in symptom control and reductions in the number of acute exacerbations. Triple combination inhalation therapy (eg, LABA + LAMA + an inhaled corticosteroid) is being evaluated in patients with more severe COPD with promising findings.[36] The exact role of triple therapy remains to be defined. Although once prescribed extensively for patients with chronic bronchitis, chronic theophylline therapy is used with decreasing frequency in favor of aerosolized β_2-receptor agonists, LABA, LAMA, etc. Nevertheless, long-acting theophylline remains an effective "add on" therapy for many patients, particularly those with more severe chronic bronchitis/COPD due to the drugs beneficial effects of bronchodilation, improved ciliary function and increased beat frequency, possibly increased mucus hydration, and low cost.[22]

Phosphodiesterase 4 inhibitors (PDE-4), compared with the nonselective phosphodiesterase inhibitor theophylline, only affect phosphodiesterase in the airway smooth muscle, immune (eosinophils, monocytes, and neutrophils), and proinflammatory cells. Roflumilast is a highly specific (second generation) PDE-4 inhibitor which is most often reserved for use in patients with moderate to severe COPD. Considering that many of the published studies assessing the viability of second-generation PDE-4 inhibitors in patients with COPD involved patients with chronic cough and increased sputum production, it is inferred that these drugs would be of value in patients with chronic bronchitis as well. The GOLD guidelines suggest roflumilast reduces exacerbations in COPD patients with chronic bronchitics treated with oral glucocorticosteroids. A review of clinical trials and observational studies found that roflumilast only provides a net benefit to patients at high risk of severe exacerbations.[37] A lower 30-day readmission rate in patients hospitalized for COPD with roflumilast therapy was reported.[38] Others have found that PDE-4 inhibitors improved lung function over placebo and reduced the likelihood of exacerbations; they had little impact on a patient's symptoms or quality of life. Nevertheless, the major limitation to the use of PDE-4 inhibitors is their side effect profiles. Patients receiving roflumilast often experience nausea, vomiting, headache, decreased appetite, sleep disturbances, and an increased risk of psychiatric events.[39] The exact role of roflumilast in chronic lung disease is evolving but many guidelines suggest its greatest use is in the more severely affected patients.

Use of antimicrobials for treatment of chronic bronchitis has been controversial, but is becoming more accepted in specific circumstances. Numerous comparative evaluations, including placebo-controlled studies of antibiotic administration with acute and chronic treatment of chronic bronchitics, have suggested clinical benefit. The antibiotics selected most frequently possess variable in vitro activity against the common sputum isolates *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, and *M. pneumoniae*. Conflicting published results appear independent of the antibiotic used or the regimen compared. A wide disparity that existed in the published results from older studies, served as the basis for the enormous controversy that surrounded the use of antibiotics for the treatment of acute exacerbations of chronic bronchitis. Overall, good clinical results have been observed with the use of standard antibiotic regimens (eg, macrolides, azalides, oral cephalosporins, and the combination drug amoxicillin/clavulanate, trimethoprim/sulfamethoxazole, and tetracyclines) as well as with the use of fluoroquinolones.[40-45] The goal is to select the most effective antibiotic drug for the patient based on their history of previous exacerbations and response to drug therapy. The introduction of genome expression profiling of sputum and other biologic fluids can facilitate specific pathogen diagnosis and focused therapy.[46]

A useful paradigm for the assessment and treatment of acute exacerbations of chronic bronchitis and antibiotic decision making is shown in **Fig. 107-1**. Many clinicians use the so-called Anthonisen criteria to determine if antibiotic therapy is indicated.[29] With the Anthonisen criteria, if a patient exhibits two of the following three criteria during an acute exacerbation of chronic bronchitis (AECB), the patient will most likely benefit from antibiotic therapy and, thus, should receive a treatment course: (a) increase in shortness of breath; (b) increase in sputum volume; and (c) production of purulent sputum. There are greater healthcare costs for patients who are noncompliant with their antibiotic regimen for their AECB.

The increasing resistance of the common bacterial pathogens to first-line agents further complicates antibiotic selection. As many as 30% to 40% of *H. influenzae* isolates and 95% to 100% of *M. catarrhalis* isolates produce β-lactamases. Moreover, up to 40% of *S. pneumoniae* isolates demonstrate resistance to penicillin (minimum inhibitory concentration [MIC] = 0.1-2 mg/L), with approximately 20% of isolates being highly resistant (MIC greater than 2 mg/L). Concern regarding *S. pneumoniae* resistance is increasing, and resistance is now greater than or equal to 30% for macrolides. Despite these changes in bacterial susceptibility, the current recommendation is to initiate therapy with first-line antimicrobial agents in less severely affected patients (see Fig. 107-1). Trimethoprim/sulfamethoxazole has been extremely useful for patients with less-severe disease.[47] For patients with more moderate to severe disease, many clinicians will begin antibiotic therapy with the second-line

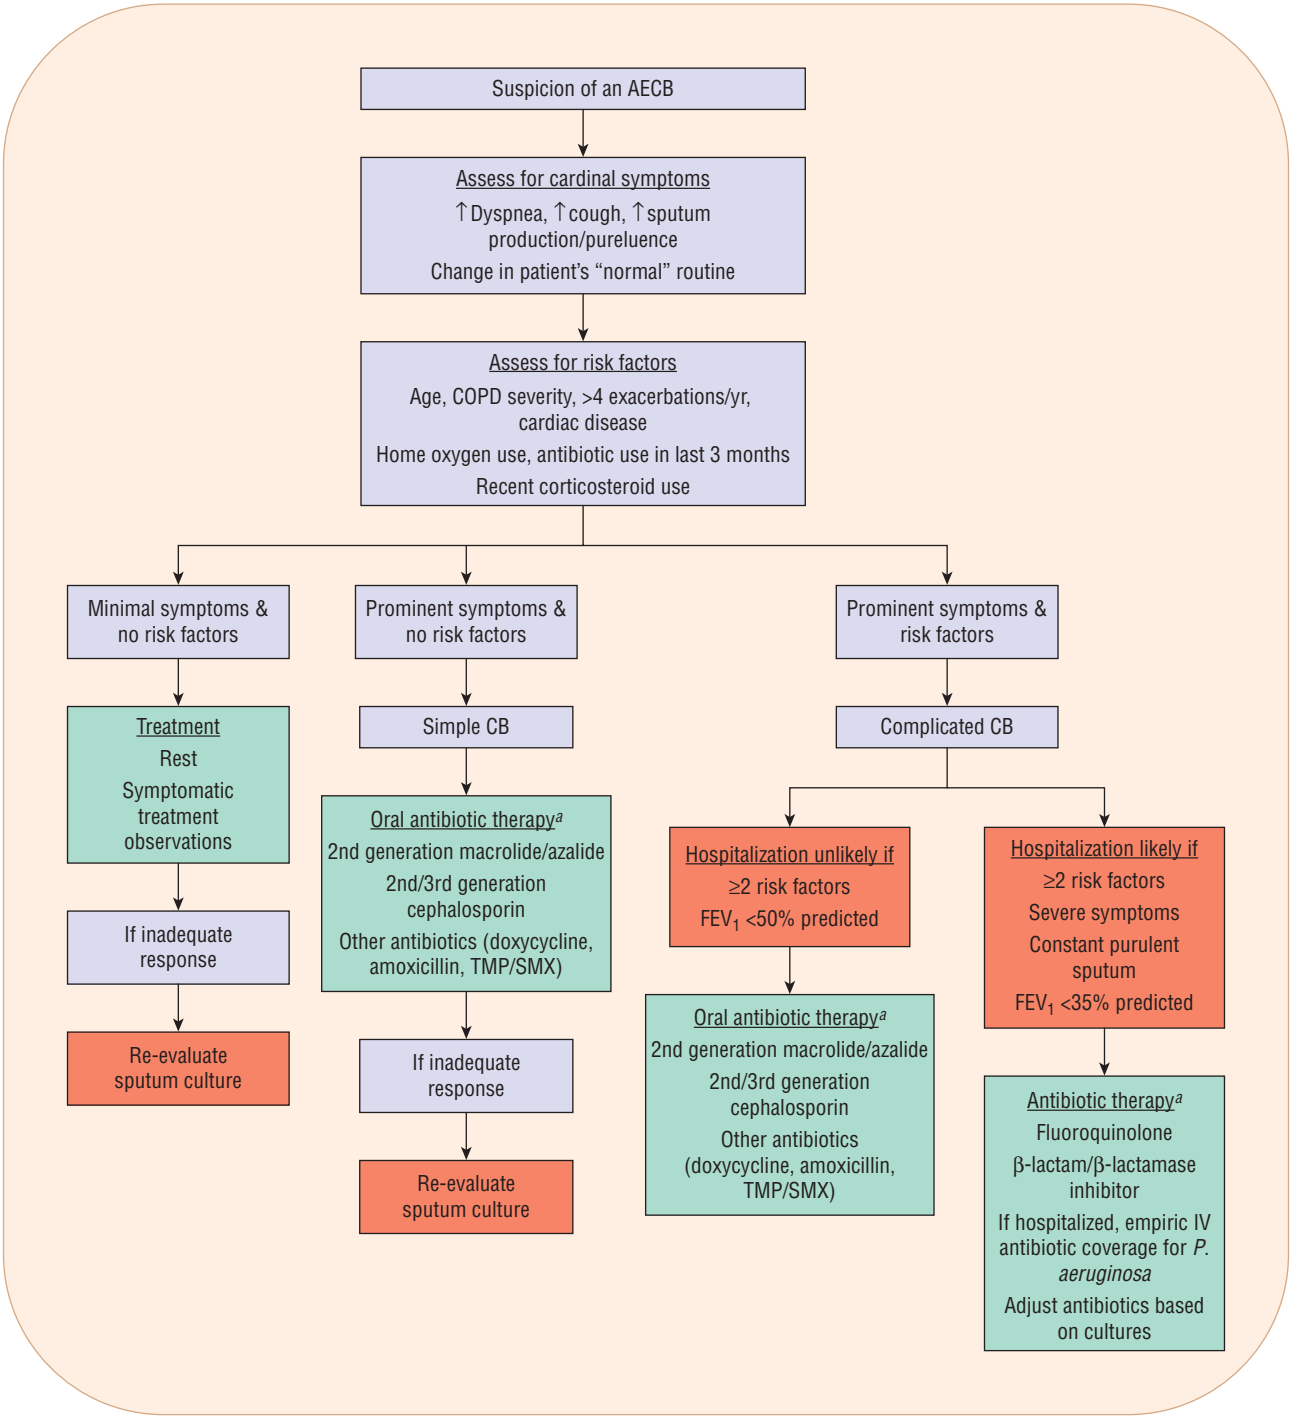

FIGURE 107-1 Clinical algorithm for the diagnosis and treatment of chronic bronchitic patients with an acute exacerbation incorporating the principles of the clinical classification system. (AECB, acute exacerbation of chronic bronchitis; COPD, chronic obstructive pulmonary disease; CB, chronic bronchitis; TMP/SMX, trimethoprim/sulfamethoxazole.) [a]See Table 107-3 for commonly used antibiotics and doses. *(Adapted from reference 110.)*

agents, amoxicillin/clavulanate, a macrolide (such as azithromycin or clarithromycin, although they are being used less frequently), and more frequently with a fluoroquinolone, such as levofloxacin and moxifloxacin (see Fig. 107-1).

Regardless of the antibiotic selected, predetermined outcome measures should be monitored closely for each patient to determine the success or failure of the therapeutic intervention. Oral antibiotics with broader antibacterial spectra (eg, amoxicillin/clavulanate and fluoroquinolones) that possess potent in vitro activity against sputum isolates are increasingly becoming first-line antibiotics as initial therapy for treatment of acute exacerbations of chronic bronchitis.

An important clinical outcome variable directing drug selection and criteria for beginning antibiotics in individual patients is the infection-free period when chronic bronchitics are off antibiotics. The length of the infection-free time period and the change in the number of physician office visits and hospital admissions with a particular antibiotic regimen are extremely important to identify, whenever possible, for each patient. The antibiotic regimen that results in the longest infection-free period defines the "regimen of choice" for specific patients for future acute exacerbations of their disease. Trials of long-term prophylactic antibiotic use may provide a slight benefit in decreasing exacerbation rates, but does not appear

TABLE 107-3 Oral Antibiotics Commonly Used for the Treatment of Acute Respiratory Exacerbations in Chronic Bronchitis

Antibiotic	Brand Name	Usual Adult Dose (mg)	Dose Schedule (Doses/Day)
Preferred Drugs			
Ampicillin	–	250-500	4-3
Amoxicillin	–	500-875	3-2
Amoxicillin/clavulanate	Augmentin®	500-875	3-2
Ciprofloxacin	Cipro®	500-750	2
Levofloxacin	Levaquin®	500-750	1
Moxifloxacin	Avelox®	400	1
Doxycycline	Monodox®	100	2
Minocycline	Minocin®	100	2
Tetracycline HCl	–	500	4
Trimethoprim/sulfamethoxazole[a]	Bactrim DS™/Septra DS®	1 DS	2
Supplemental Drugs			
Azithromycin	Zithromax®	250-500	1
Erythromycin	Ery-Tab®/Erythrocin®	500	4
Clarithromycin	Biaxin®	250-500	2
Cephalexin	Keflex®	500	4

[a]DS, double-strength tablet (160-mg trimethoprim/800-mg sulfamethoxazole).

to decrease mortality, but does markedly increase the emergence and colonization of antibiotic-resistant pathogens. For this reason, most guidelines do not currently support this indication. However, chronic macrolide/azalide use reduces the incidence of acute exacerbations in COPD patients in a clinically significant manner[48,49] (macrolide and anti-inflammatory activity addressed later).

Antibiotics that are effective against responsible pathogens, demonstrate the least risk of drug interactions, and can be administered in a manner that promotes compliance should be selected. Antibiotics, commonly used for treatment of these patients with chronic bronchitis, and their respective adult starting doses are listed in Table 107-3. Doses of antibiotics should be adjusted as needed to the desired clinical effect and the lowest incidence of acceptable side effects. A frequently used clinical strategy to enhance the duration of symptom-free periods incorporates higher-dose antibiotic regimens using the upper limit of the recommended daily antibiotic dose for a period of 5 to 7 days. More clinicians are electing to limit their antibiotic treatment regimen to 5 days as compelling data continue to support equal efficacy, less exposure potentially reducing bacterial resistance development and possibly less side effects with short-duration antibiotic therapy versus longer treatment regimens (greater than 7 days).[41,42]

With the exception of long-term macrolide/azalide administration, chronic antibiotic therapy is rarely indicated in the management of patients with chronic bronchitis. Such approaches lead to marked increase in cost and occurrence of multidrug resistant (MDR) pathogens. Conversely, long-term macrolide (erythromycin, clarithromycin, and roxithromycin) or azalide (azithromycin) administration has been associated with a clinically significant reduction in the incidence of acute exacerbations in patients with chronic bronchitis and COPD.[48-50] The benefit of these drugs is attributed to their antibacterial, anti-inflammatory, and immunomodulatory activity. These drugs reduce bacterial adherence and toxin production, inhibit biofilm function, and reduce the generation of oxygen free radicals, modulate mucin gene protein production controlling mucus hypersecretion, and improve mucociliary clearance. These drugs also decrease neutrophil chemotaxis, promote downregulation of adhesion molecule expression, and inhibit transcription factors leading to decreased production of pro-inflammatory cytokines.[50]

The importance of multifactorial cellular oxidative stress in the pathogenesis of chronic bronchitis and COPD has prompted the study of the efficacy of antioxidants and in particular, the oral administration of NAC, other mucolytic agents and antioxidants.[32,51,52] Some guidelines suggest their use for more severely affected patients. Studies with oral NAC have suggested a dose-dependent response with 600 mg once to twice daily and it may slightly decrease the exacerbation rate in COPD patients not using inhaled steroids; however, there does not appear to any effect on lung function. The exact role of antioxidant in the care of these patients remains to be defined—no specific recommendations can be provided until more data are available regarding which specific compound (as well as dose and duration of therapy) is optimal.

BRONCHIOLITIS

Epidemiology and Etiology

7 Bronchiolitis is an acute viral infection of the lower respiratory tract that affects approximately 50% of children during the first year of life and 100% by age 2 years. The occurrence of bronchiolitis peaks during the winter months and persists through early spring. Bronchiolitis remains the major reason for hospital admission during the first year of life. The incidence of bronchiolitis appears to be more common in males than in females.[53]

Respiratory syncytial virus is the most common cause of bronchiolitis, accounting for up to 75% of all cases. During epidemic periods, the incidence of RSV-induced bronchiolitis may approach 90% of cases. Other detectable viruses include parainfluenza, adenovirus, and influenza. Bacteria serve as secondary pathogens in a minority of cases.[53,54]

Clinical Presentation

The clinical presentation of bronchiolitis (Table 107-4) is often preceded by 1 to 4 days of symptoms (eg, nasal congestion, rhinorrhea, cough, and low-grade fever) indicative of an upper respiratory tract infection. Due to limited oral intake because of coughing combined with fever, vomiting, and diarrhea, infants frequently are dehydrated. The increased work of breathing and tachypnea most likely contribute to increased fluid loss. In most cases, bronchiolitis

TABLE 107-4 Clinical Presentation of Bronchiolitis

Signs and symptoms
Prodrome with irritability, restlessness, and mild fever
Cough and coryza
Vomiting, diarrhea, noisy breathing, and increased respiratory rate as symptoms progress
Labored breathing with retractions of the chest wall, nasal flaring, and grunting
Physical examination
Tachycardia and respiratory rate of 40-80/min in hospitalized infants
Wheezing and inspiratory rales
Mild conjunctivitis in one third of patients
Otitis media in 5%-10% of patients
Laboratory tests
Peripheral white blood cell count normal or slightly elevated
Abnormal arterial blood gases (hypoxemia and, rarely, hypercarbia)

is self-limiting and typically symptoms improve within 7 to 10 days with resolution within 28 days without the need for hospitalization. In patients who require hospitalization, the average length of stay is approximately 3 days.[54]

The diagnosis of bronchiolitis is based primarily on history and clinical findings. It is important for the clinician to attempt to differentiate between bronchiolitis and a host of other clinical entities affecting infants, which may produce a similar picture of dyspnea and wheezing. Asthma, congestive heart failure, anatomic airway abnormalities, cystic fibrosis, foreign bodies, and gastroesophageal reflux are the primary disease entities that may present with wheezing in children. Isolation of a viral pathogen in the respiratory secretions of a wheezing child establishes a presumptive diagnosis of infectious bronchiolitis. However, the ability to identify specific viral pathogens often is hindered by the limited availability of special virology laboratories. In addition, in the elderly and in immunocompromised patients, antigen detection lacks adequate sensitivity, and patients frequently seek medical care after the acute stage of the infection, thus compromising the ability of the available tests to diagnose RSV. However, the proliferation of commercial enzyme-linked immunosorbent assays and fluorescent antibody staining techniques of nasopharyngeal secretions has increased the ability to identify viral antigens within several hours. Identification of RSV by PCR should be available from most clinical laboratories, but its relevance to the clinical management of bronchiolitis remains obscure and therefore routine testing is not recommended.[53,54]

Multiple clinical laboratory determinations have been used to assist in the management of cases of bronchiolitis. Radiographic evaluation of the chest in children with bronchiolitis yields variable findings and rarely alters therapeutic decisions. Thus, the routine use of chest radiography is not recommend; however, in hospitalized patients who fail to demonstrate expected improvement, they may help to distinguish bronchiolitis from other entities characterized by wheezing so that appropriate treatment may be initiated. In children requiring hospitalization, abnormalities in blood gas tensions are frequent and appear to relate to disease severity. Hypoxemia is common and increases the respiratory drive, whereas hypercarbia is seen in only the most severe cases. Despite the presence of moderate degrees of hypoxemia, clinical cyanosis is unusual.[54]

TREATMENT

Desired Outcome

7 In the well infant, bronchiolitis usually is a self-limiting illness, and reassurance, antipyretics, and adequate fluid intake usually are all that are necessary while waiting for resolution of the underlying viral infection. In-hospital support is necessary for the child suffering from respiratory failure or marked dehydration; underlying cardiac and pulmonary diseases potentiate these conditions.[54]

General Approach to Treatment

7 Almost all otherwise healthy babies with bronchiolitis can be followed as outpatients. Such infants are treated for fever, provided generous amounts of oral fluids, and observed closely for evidence of respiratory deterioration.[55] In severely affected children, the mainstays of therapy for bronchiolitis are oxygen therapy and IV fluids. In a subset of patients, aerosolized bronchodilators may have a role. For selected infants, particularly those with underlying pulmonary disease, cardiac disease, or both, therapy with the antiviral agent ribavirin can be considered.[54]

Pharmacologic Therapy

7 Aerosolized β_2-adrenergic therapy appears to offer little benefit for the majority of patients and may even be detrimental.[53,56,57] However, this therapy may offer some benefit to the child with a predisposition toward bronchospasm. In addition, although clinical trials have demonstrated varied results, nebulized epinephrine seems to be more efficacious than albuterol in hospitalized patients with bronchiolitis.[53,58] For such patients, bronchodilator therapy may be offered initially, but should not be pursued in the absence of a clear-cut clinical benefit. Furthermore, given their overall ineffectiveness, neither aerosolized β_2-adrenergic nor nebulized epinephrine therapies are recommended by the American Academy of Pediatrics for the treatment of bronchiolitis.[57]

Similarly, controlled trials of corticosteroids in bronchiolitic infants have not shown therapeutic effects or significant harmful effects, though viral shedding may be prolonged.[54,57] As a result, the routine use of systemically administered corticosteroids is not recommended by the American Academy of Pediatrics and is therefore discouraged.[57] Conversely, the combined use of oral dexamethasone with nebulized epinephrine may act synergistically to reduce hospital admissions and shorten the time to discharge and the duration of symptoms; however, more trials are needed to confirm these findings.[58,59] Although placing children with bronchiolitis in mist tents has been common practice, no data have documented the effectiveness of this practice.

The American Academy of Pediatric guidelines support the use of nebulized hypertonic saline (eg, 3% saline) for the treatment of bronchiolitis in hospitalized infants and children. As such, although nebulized hypertonic saline has proven to be safe and effective for the symptomatic improvement in patients with bronchiolitis after 1 day of use, the benefit of a reduction in length of hospital stay appears to be limited to patients whose mean length of hospital stay generally exceeds 3 days. Thus, this latter benefit may be less applicable to patients in the United States where the mean length of hospital stay due to bronchiolitis is approximately 3 days.[56,57]

Ribavirin may offer benefit to a subset of infants with bronchiolitis. Ribavirin, a synthetic nucleoside, possesses in vitro antiviral properties against a variety of RNA and DNA viruses, including influenza A, influenza B, parainfluenza, and adenovirus, it is approved only in aerosolized form against RSV. Use of the aerosol drug formulation requires special equipment (small-particle aerosol generator) and specially trained personnel for administration via oxygen hood or mist tent. Special care must be taken to avoid drug particle deposition and the resulting clogging of respiratory tubing and valves in mechanical ventilators. Among hospital admissions for RSV infection, ribavirin therapy failed to decrease length of hospital stay, number of days in the intensive care unit, or number of days receiving mechanical ventilation. Consequently, the American Academy of Pediatrics does not recommend the routine use of ribavirin in children with

bronchiolitis[57] and most experts recommend reserving use of ribavirin for severely ill patients.

Clinical **Controversy...**

Despite the overall lack of demonstrated benefit of aerosolized β_2-adrenergic agonist, nebulized epinephrine, and corticosteroids in clinical trials, they continue to be prescribed to some patients presenting with bronchiolitis.

For infants with underlying pulmonary or cardiovascular disease, prophylaxis against RSV may be warranted. When administered monthly during the RSV season, both RSV immune globulin and palivizumab (a monoclonal antibody for RSV) may decrease the number of RSV episodes and the need for hospitalization. Between the two, palivizumab is preferred, given its ease of administration, lack of administration-related adverse effects, and noninterference with select immunizations.[60] Despite continuing research, there is no vaccine marketed for RSV.

PNEUMONIA

Epidemiology

Pneumonia remains one of the most common causes of severe sepsis and infectious cause of death in children and adults in the United States, with a mortality rate of 30% to 40%.[5,61] Pneumonia occurs throughout the year, with the relative prevalence of disease resulting from different etiologic agents varying with the seasons. It occurs in persons of all ages, although the clinical manifestations are most severe in the very young, the elderly, and the chronically ill.

Pathogenesis

Microorganisms gain access to the lower respiratory tract by three routes. They may be inhaled as aerosolized particles, enter the lung via the bloodstream from an extrapulmonary site of infection or via aspiration of oropharyngeal contents. Aspiration is a common occurrence in both healthy and ill people during sleep and is a major mechanism by which pulmonary pathogens gain access to the lower airways and alveoli. When pulmonary defense mechanisms are functioning optimally, aspirated microorganisms are cleared from the region before infection can become established; however, aspiration of potential pathogens from the oropharynx can result in pneumonia if lung defenses are impaired. Factors that promote aspiration, such as altered sensorium and neuromuscular disease, may result in an increase in the size of the inoculum delivered to the lower respiratory tract, thereby overwhelming local defense mechanisms. Lung infections with viruses suppress the antibacterial activity of the lung by impairing alveolar macrophage function and mucociliary clearance, thus setting the stage for secondary bacterial pneumonia. Mucociliary transport is also depressed by ethanol and narcotics and by obstruction of bronchi by mucus, tumor, or extrinsic compression. All these factors can severely impair pulmonary clearance of aspirated bacteria. Any alteration of the normal lung microbiome by infection and/or disease can evolve to pneumonia requiring antimicrobial treatment.[62]

8 The most prominent pathogen causing CAP in otherwise healthy adults is *S. pneumoniae* and accounts for up to 35% (12%-68%) of all acute cases. Other common pathogens include *H. influenza* (2.5%-45%), the atypical pathogens *M. pneumoniae*, *Legionella species*, and *C. pneumoniae* (~20%), and a variety of viruses including influenza.[63,64] Healthcare-associated pneumonia was a classification that has been used to distinguish nonhospitalized patients at risk for MDR pathogens from those with CAP however this has fallen out of use.[4,6,65] The term *atypical* may be applied to pneumonia to indicate that the pneumonia may be caused by an atypical pathogen (eg, bilateral lobar pneumonia with a negative sputum Gram stain).[66]

Gram-negative aerobic bacilli, *S. aureus*, and MDR pathogens are the leading causative agents in hospital-acquired pneumonia (HAP).[6] Anaerobic bacteria are the most common etiologic agents in pneumonia that follows the aspiration of gastric or oropharyngeal contents. Ventilator-associated pneumonia (VAP) is also associated with MDR pathogens.

Pneumonia in infants and children is caused by a wider range of microorganisms, and, unlike adults, nonbacterial pathogens predominate. Most pneumonias occurring in the pediatric age group are caused by viruses, especially RSV, parainfluenza, and adenovirus.[5] *M. pneumoniae* is an important pathogen in older children. Beyond the neonatal period, *S. pneumoniae* is the major bacterial pathogen in childhood pneumonia, followed by group A *Streptococcus* and *S. aureus*. *H. influenzae* type b, once a major childhood pathogen, has become an infrequent cause of pneumonia since the introduction of active vaccination against this organism in the late 1980s.

Based on the differences in severity and outcome for patients with CAP, genetic factors likely play a role.[67,68] Multiple variations in genes affecting inflammation, cough and airway protection, pattern recognition molecules, and organ function along with environmental factors may alter a patient's response to CAP. In the future, when disease response is better associated with specific genetic polymorphisms, therapy should become better targeted.

Clinical Presentation

Bacterial pneumonia is caused most commonly by gram-positive streptococci and staphylococci and by gram-negative organisms that normally inhabit the GI tract (enterics) or soil and water (nonenterics). In addition, *Legionella*, itself a weakly staining gram-negative nonenteric organism, accounts for a small percentage of CAP and HAP, although the true incidence may be underreported.[66] Finally, *M. tuberculosis*, an acid-fast staining bacillus, still remains an important cause of pneumonia in urban centers throughout the United States even though the incidence is much lower compared to other countries.[69,70]

Even though a wide array of gram-positive and gram-negative organisms can cause pneumonia, they usually present a similar clinical appearance (Table 107-5); thus, the epidemiologic and clinical clues will render one more likely than the other. *S. pneumoniae*,

TABLE 107-5 Clinical Presentation of Pneumonia

Signs and symptoms
Abrupt onset of fever, chills, dyspnea, and productive cough
Rust-colored sputum or hemoptysis
Pleuritic chest pain
Physical examination
Tachypnea and tachycardia
Dullness to percussion
Increased tactile fremitus, whisper pectoriloquy, and egophony
Chest wall retractions and grunting respirations
Diminished breath sounds over affected area
Inspiratory crackles during lung expansion
Chest radiograph
Dense lobar or segmental infiltrate
Laboratory tests
Leukocytosis with predominance of polymorphonuclear cells
Low oxygen saturation on arterial blood gas or pulse oximetry

S. aureus, the enteric gram-negative rods, and occasionally other organisms may produce local irritation or destruction of blood vessels leading to rust-colored sputum or hemoptysis. Pleural effusions, both sterile and emphysematous, may be associated with many of these entities, as evidenced by distant breath sounds and a wide area of dulled percussion. The chest radiograph and sputum examination and culture are the most useful diagnostic tests for gram-positive and gram-negative bacterial pneumonia, especially for hospitalized patients; urine antigen testing for *L. pneumophila* and *S. pneumoniae* is recommended for patients with severe CAP.[4,71] Typically, the chest radiograph reveals a dense lobar or segmental infiltrate. However, patchy consolidation may be seen occasionally with virtually all these pathogens. Occasionally, pneumonia resulting from hematogenous spread of the organisms results in a diffuse, alveolar pattern on chest radiograph. Gram stain of the expectorated sputum demonstrates many polymorphonuclear cells per high-powered field in the presence of a predominant organism, which is reflected as heavy growth of a single species on culture. Other laboratory tests are less sensitive or specific. Blood cultures may be helpful in identifying the offending organism, but are positive in only a minority of patients. The complete blood count usually reflects a leukocytosis with a predominance of polymorphonuclear cells; in some instances, particularly with *S. pneumoniae*, elevation of the white blood cell (WBC) count may be pronounced. Normal or mildly elevated WBC counts, however, do not exclude bacterial pneumonic disease. The patient also may be hypoxic, as reflected by low oxygen saturation on arterial blood gas or pulse oximetry.

Community-Acquired Pneumonia

8 *S. pneumoniae* is the most common community-acquired bacterial pneumonia in adult and pediatric patients.[4,5,64] It is particularly prevalent and severe for patients with splenic dysfunction, diabetes mellitus, chronic cardiopulmonary or renal disease, or HIV infection. Community-acquired disease with *S. aureus* is identified most frequently in young infants, patients with cystic fibrosis, and those recovering from an antecedent respiratory viral infection. Group A *Streptococcus* is an uncommon cause of CAP, but when it does occur, it frequently follows a viral respiratory tract infection. Only occasionally is it associated with streptococcal pharyngitis. The organism is pyogenic, and the presentation can be severe. Community-acquired enteric gram-negative pneumonia is identified most frequently among patients with chronic illness, especially alcoholism and diabetes mellitus. In preschool-aged children, viral pathogens more commonly cause CAP compared with bacterial pathogens.[5]

Severity scores (eg, CRB65, CURB-65, and PSI), with varying strengths and weaknesses, assist healthcare professionals in predicting intensive care hospitalization and outcomes for patients with CAP.[4,71-73] Definitions of severe CAP may vary depending on the institution; however, patients with severe CAP are more likely to require intensive care or mechanical ventilation, or develop complications with sepsis, bacteremia, or multiorgan failure. Severe CAP may also be difficult to distinguish from HCAP or HAP; however, the pathogens, *S. pneumoniae*, *H. influenzae*, and anaerobic bacteria are not usually MDR. Patients at greater risk for severe CAP are those with underlying medical conditions or at risk for aspiration, animal exposure, or exposure to other infected patients or seasonal epidemics.[65]

Hospital-Acquired Pneumonia

After the urinary tract and the bloodstream, the lungs are the most frequent site for infections acquired in the hospital. HAP is seen most commonly in critically ill patients and is usually caused by bacteria.[6] Factors predisposing patients to the development of HAP include the severity of illness, duration of hospitalization, supine positioning, witnessed aspiration, coma, acute respiratory distress syndrome, patient transport, and prior antibiotic exposure (Table 107-6). The strongest predisposing factor, however, is mechanical ventilation (intubation). The length of stay for hospital admissions is increased by a mean of 7 to 9 days for patients who develop HAP.[6,65]

The organisms most commonly associated with HAP are *S. aureus* and enteric (eg, *K. pneumoniae* or *E. coli*) and nonenteric (eg, *P. aeruginosa*) gram-negative bacilli, organisms that colonize the pharynx of the hospitalized, critically ill patient. Patients with longer lengths of hospital admission or IV antibiotic use within the previous 90 days prior to the development of HAP are more likely to have MDR organisms.[6] The diagnosis of HAP usually is established by the presence of a new infiltrate on chest radiograph, fever, worsening respiratory status, and the appearance of thick, neutrophil-laden respiratory secretions. The diagnosis often is difficult to make in the intensively ill patient with underlying lung pathology that itself can be associated with an abnormal changing radiograph, as occurs

TABLE 107-6 Pneumonia Classifications and Risk Factors

Type of Pneumonia	Definition	Risk Factors
Community acquired (CAP)	Pneumonia developing in patients with no contact to a medical facility	• Age >65 years • Diabetes mellitus • Asplenia • Chronic cardiovascular, pulmonary, renal and/or liver disease • Smoking and/or alcohol abuse
Hospital acquired (HAP)	Pneumonia developing >48 hours after hospital admission	• Witnessed aspiration • COPD, ARDS, or coma • Administration of antacids, H_2-antagonists, or proton pump inhibitor • Supine position • Enteral nutrition, nasogastric t ube • Reintubation, tracheostomy, or patient transport • Head trauma, ICP monitoring • Age >60 years • MDR risk (eg. MRSA, MDR *Pseudomonas*) if IV antibiotic use within 90 days
Ventilator associated (VAP)	Pneumonia developing >48 hours after intubation and mechanical ventilation	• Same as hospital acquired • MDR risk with septic shock, ARDS, acute renal replacement therapy, or 5+ days of hospitalization

ARDS, adult respiratory distress syndrome; CAP, community-acquired pneumonia; COPD, chronic obstructive pulmonary disease; HAP, hospital-acquired pneumonia; ICP, intracranial pressure; MDR, multidrug resistant; MRSA, methicillin-resistant S. aureus VAP, ventilator-associated pneumonia.

with congestive heart failure or chronic lung disease. If a patient develops fever, leukocytosis, and purulent sputum, and has positive sputum/tracheal cultures, but radiographic imaging does not indicate new infiltrates, the patient may have tracheobronchitis as opposed to HAP.[6] Broad-spectrum antibiotics frequently are started empirically even in equivocal circumstances, with bronchoscopy reserved for poorly responsive patients.[6]

Ventilator-Associated Pneumonia

VAP is defined as pneumonia occurring more than 48 hours postendotracheal intubation. The risk for developing pneumonia in the hospital increases by 6 to 21 times after a patient is intubated because the natural airway defenses against the migration of upper respiratory tract organisms into the lower tract are bypassed.[6] This situation is exacerbated by the wide use of acid-reducing drugs (eg, H_2-receptor blocking agents and proton pump inhibitors) in the intensive care unit, which increases the pH of gastric secretions and may promote the proliferation of microorganisms in the upper GI tract. Subclinical microaspirations are events that occur routinely in intubated patients and result in the inoculation of bacteria-contaminated gastric contents into the lung and a higher incidence of nosocomial pneumonia.[75] Pneumonia that develops within 4 days of hospitalization is more likely to be caused by an antibiotic sensitive organism such as *S. pneumoniae*, *S. aureus*, or *Haemophilus* species, whereas infections developing later are more likely to be MDR (eg, *P. aeruginosa*, MRSA, and *Acinetobacter* species). Outbreaks of VAP may be caused occasionally by contaminated respiratory therapy equipment.

To date, there is no "gold standard" for diagnosing VAP; thus, an accurate diagnosis is challenging. Most intensivists agree that VAP should be suspected if new or persistent infiltrates are found on chest radiograph along with two or more of the following: purulent tracheal secretions, leukocytosis or leucopenia, and body temperature greater than 38.3°C (100.9°F).[75,76] Noninvasive sampling techniques are recommended over invasive techniques (eg, bronchoalveolar lavage) for obtaining samples of lower respiratory tract secretions for culture and sensitivity testing.[6]

Special Populations

Pneumonia in the HIV-Infected Patient A broad range of pathogens can cause pneumonia in HIV infection (Table 107-7) including opportunistic infections such as *P. jiroveci* and *Mycobacterium* species.[77] These patients may be afflicted with pneumonia multiple times, particularly in the advanced stages of the disease, and a given episode may be caused by more than one species. The clinical presentation of pneumonia in HIV-infected persons frequently is not helpful in distinguishing one pathogen from another. The pneumonia usually is subacute in onset and consists of fever, nonproductive cough, and dyspnea. Radiographically, most of these entities produce a multilobular or diffuse pattern. Some practitioners initially treat the HIV-infected patient with pneumonia empirically; however, given the wide array of possible pathogens, more frequently a specific microbiologic diagnosis is aggressively pursued early in the patient's course through sputum induction or bronchoalveolar lavage to allow a rational choice of an antimicrobial regimen. The diagnosis and treatment of HIV-infected patients with pulmonary disease is discussed in detail in Chapter 126.

Pneumonia in the Neutropenic Host Neutropenia in the cancer patient is a common complication of aggressive chemotherapy, but occasionally results from the cancer itself. The risk of infection for the cytopenic patient is increased significantly when the absolute neutrophil count falls less than 500 cell/mm^3 (0.500 × 10^9/L) and the neutropenia persists for more than 7 days. For many patients, the duration of chemotherapy-induced cytopenia can be reduced by judicious application of colony-stimulating factors.[78]

The organisms that cause pneumonia in the cytopenic cancer patient include a broad range of bacteria and fungi. The most prominent among these are gram-positive bacteria (staphylococci and streptococci); others include enteric and nonenteric (particularly *P. aeruginosa*) gram-negative rods as well as the fungi (*Candida*, *Aspergillus*). The chest radiograph may reveal the lobar pattern typical of bacterial infection in the normal host, or it may exhibit a diffuse pattern. The pneumonia may remain invisible by chest radiograph until the neutropenia resolves. Noninfectious entities that may cause pulmonary symptoms include toxicity from radiation or chemotherapy or infiltration of the lung parenchyma by the tumor itself.

Common Pathogens

Gram-Positive Bacteria

S. aureus is a prominent cause of HAP and may result from hematogenous spread from a distant source. It is characteristically severe and accompanied by the formation of pneumatoceles (air-containing cavities within the lung). Infections caused by MDR organisms, such as MRSA and vancomycin-intermediate and vancomycin-resistant *S. aureus* are increasing among patients with HAP. IV antibiotic use within the past 90 days increases the risk for MRSA and other MDR pathogens causing HAP and VAP.6 Group B *Streptococcus*, although rare in adults, is the most common cause of bacterial pneumonia among neonates and typically causes a clinical and radiographic picture nearly indistinguishable from hyaline membrane disease.[79]

Enteric Gram-Negative Bacteria

The enteric gram-negative bacteria are leading causes of HAP because the upper respiratory tract becomes rapidly colonized with gram-negative organisms after hospitalization, particularly among critically ill patients and those receiving antibiotics.[80] *K. pneumoniae* is the most frequently encountered pathogen among the gram-negative enteric bacteria, although the relative prominence of these organisms varies among hospitals. The gram-negative bacilli are associated with high mortality, sometimes exceeding 50%; their potential to produce significant morbidity and mortality has been enhanced by the emergence of highly MDR organisms in some hospital settings.[6]

Nonenteric Gram-Negative Bacteria

The most prominent nonenteric gram-negative rods associated with pneumonia include *P. aeruginosa*, *H. influenzae*, and *M. catarrhalis*. Like the enteric gram-negative organisms, *P. aeruginosa* is a frequent cause of HAP and is particularly prominent among neutropenic and burn patients.[6] In addition, cystic fibrosis patients suffer from chronic, multilobar infections with *P. aeruginosa*, as well as other *Pseudomonas* species, and *S. maltophilia* is an emerging pathogen[81]; these infections are punctuated with acute exacerbations. Dual coverage for *P. aeruginosa* is only suggested if patients are at risk for antimicrobial resistance, if resistance is >10% towards a monotherapy agent based on antibiogram, or if resistance patterns are not known.[6] *H. influenzae* type b has been a prominent pathogen in childhood pneumonia. The incidence of all invasive disease due to this organism in the pediatric age group has dropped dramatically since the introduction of the conjugated *Haemophilus* vaccines in the late 1980s. However, two different clinical presentations of *H. influenzae* pneumonia continue to be observed in adults. The most common by far is the bronchopneumonia form, which develops most frequently for patients with underlying chronic lung disease and is believed to represent, in most patients, an exacerbation of chronic bronchitis. In the second form of *H. influenzae* pneumonia, segmental or lobar involvement predominates. The course of this illness is more acute, with sudden onset of cough, fever, and pleuritic chest pain. Finally, *M. catarrhalis*, an important cause of otitis media and sinusitis, is an increasingly important cause of lower respiratory tract infections in immunocompromised and hospitalized patients.

Anaerobic Bacteria

Anaerobic pneumonitis is most likely to occur in individuals predisposed to aspiration by impaired consciousness or dysphagia as the source for the anaerobic bacteria is generally the oral cavity/gingival crevice.[82] Bronchogenic carcinoma is an associated underlying condition. A variety of gram-positive and gram-negative anaerobic bacteria indigenous to the upper airway may cause pneumonitis when large quantities of oropharyngeal secretions are aspirated into the lower airways. The most common organisms identified are *B. melaninogenicus*, *Fusobacteria*, and anaerobic streptococci; polymicrobial infections with anaerobes and aerobes, such as *S. aureus*, *S. pneumoniae*, and gram-negative bacilli, are common.[82]

Early in the infection, clinical symptoms are similar to CAP with patients presenting with cough, low-grade fever, pulmonary infiltrates, and leukocytosis. The course of anaerobic pneumonia is typically indolent and patients are unlikely to have rigors. Other characteristic features are lung abscess, necrotizing pneumonia, and empyema. Anaerobic infections should be suspected if patients are predisposed to aspiration or have a chronic course, putrid sputum/breath, pulmonary necrosis, or empyema.[82] Chest radiographs reveal infiltrates typically located in dependent lung segments, and lung abscesses develop in 20% of patients 1 to 2 weeks into the course of the illness.

Atypical Pneumonia

Legionella species, *Mycoplasma* species, *Chlamydia* species, viruses, and fungi are recognized causes of pneumonia syndromes in all age groups. The designation *atypical pneumonia* has been used to describe pneumonia caused by many of these agents, since it is distinct from the typical bacterial pneumonia course seen most commonly in adults.[67]

Legionella pneumophila

Of the several *Legionella* species known to cause pneumonia in humans, *L. pneumophila* is by far the most important, accounting for 2% to 9% of all CAPs in North America and Europe.[66,83,84] *Legionella*, a small, gram-negative, non–spore-forming bacilli, is an aquatic organism that is transmitted by inhalation of aerosols containing the organism or by microaspiration of contaminated water. Outbreaks of illness caused by *L. pneumophila* have been linked to excavation sites and to contaminated water from air conditioners and showers. Person-to-person transmission has not been demonstrated. In addition to epidemics, *L. pneumophila* causes sporadic illness that peaks in summer and fall. Individuals who are more than 50 years of age, have chronic lung disease, smoke cigarettes, or immunocompromised are at increased risk.[66,83,84]

Infection with *L. pneumophila* is characterized by multisystem involvement and the severity of the infection can range from mild to severe rapidly progressive pneumonia.[73,83] It has a gradual onset with prominent constitutional symptoms (eg, malaise, lethargy, weakness, and anorexia) occurring early in the course of the illness. A dry, nonproductive cough is present initially and becomes productive of mucoid or purulent sputum over several days. Fevers exceeding 38.8°C (101.8°F) develop in more than half of patients (greater than 20% with fevers exceeding 40°C[104°F]) and typically are unremitting and associated with a relative bradycardia. Pleuritic chest pain and progressive dyspnea may be seen. Along with pneumonia, extrapulmonary symptoms, particularly diarrhea, nausea, vomiting, and neurologic symptoms (headache, hallucinations, seizures, and focal neurologic findings), should increase the suspicion for *L. pneumophila*; the GI symptoms may remain evident throughout the course of the illness.[83,84] Myalgias, arthralgias, and chills also occur. Substantial changes in the patient's mental status, often out of proportion to the degree of fever, are seen in approximately one fourth of patients. Chest radiographs initially reveal patchy alveolar infiltrates that may be bilateral and asymmetric. Pulmonary infiltrates may worsen even when the patient is receiving appropriate antibiotics. Progression to lobar or multilobar consolidation is frequent, as are small pleural effusions.

Laboratory findings include leukocytosis with a predominance of mature and immature granulocytes in 50% to 75% of patients. Urinalysis may reveal proteinuria, hematuria, and casts; abnormal liver function tests, increases in serum creatine phosphokinase, hyponatremia, and hypophosphatemia (typically occurring early in infection) have been reported in patients with *L. pneumophila*.[83] Because *L. pneumophila* stains poorly, routine microscopic examination of sputum is of little diagnostic value. Although it exhibits slow growth and has highly selective growth requirements, *L. pneumophila* has been isolated successfully from tissue using a specialized medium. Direct fluorescent antibody examination of respiratory tract secretions, lung tissue, or pleural fluid is the most rapid means of establishing the diagnosis. The sensitivity of this method approaches 70% for sputum and 90% for lung tissue, and diagnostic specificity is high for both. Commercially available urine antigen tests have been developed for *L. pneumophila* (primarily Lp1, the most virulent strain) that allow for detection within 2 to 3 days from the onset of symptoms. These tests are 56% to

99% sensitive and remain positive for weeks even after effective antibiotics have been started. Thus, routine testing in the United States is not recommended, but should be considered for patients not responding to outpatient therapy, those with severe pneumonia, and those with risk factors mentioned above.[83]

M. pneumoniae

The mycoplasmas are included in their own taxonomy labeled *Mollicutes*. Although their small size and filterability are similar to viruses, the structure of their ribosomal RNA indicates that they have evolved from bacteria, and, unlike any virus, they contain cytoplasm and can replicate in an extracellular environment. They are distinguished from eubacteria by their low genetic content and have a parasitic relationship with their hosts.[66] In addition, the mycoplasmas lack a cell wall and are surrounded instead by a lipid membrane. The latter characteristic explains the resistance of these pathogens to cell wall–active antibiotics.

M. pneumoniae causes human disease throughout the year, with a slightly increased incidence in fall and early winter. During the summer months when other causes of pneumonia are less common, *M. pneumoniae* is responsible for a greater proportion of cases. Both infection and disease from *M. pneumoniae* are common, with 10% to 30% of the cases of CAP in children and young adults attributed to this organism.[85] In enclosed populations, such as military recruits and college dormitory residents, it may cause more than 50% of the cases of CAP. Infection is spread by close person-to-person contact and the incubation period is 2 to 3 weeks. *M. pneumoniae* infections are unusual in children younger than 5 years old and show a peak incidence in older children and young adults. Only 3% to 10% of persons infected with *M. pneumoniae* develop pneumonia, with the majority of respiratory tract involvement manifested as pharyngitis and tracheobronchitis. Asymptomatic infection is common.

M. pneumoniae usually presents with a gradual onset of fever, headache, and malaise, with the appearance 3 to 5 days after the onset of illness of a persistent, hacking cough that initially is nonproductive. Sore throat, ear pain, and rhinorrhea often are present. Chills are seen only occasionally and pleuritic pain is uncommon. Lung findings generally are limited to rales and rhonchi; findings of consolidation are rare. Nonpulmonary manifestations of *M. pneumoniae* are extremely common and include nausea, vomiting, diarrhea, myalgias, arthralgias, polyarticular arthritis, and skin rashes (eg, mucositis and Steven's Johnson Syndrome); myocarditis, pericarditis, hemolytic anemia, meningoencephalitis, cranial neuropathies, and Guillain-Barré syndrome have also been reported.[66,86,87] Systemic symptoms generally clear in 1 to 2 weeks, whereas respiratory symptoms may persist for up to 4 weeks. Although the course of mycoplasma pneumonia usually is benign and self-limited, severe respiratory disease may develop in patients with sickle cell disease, agammaglobulinemia, COPD, and in those who have undergone a splenectomy.[66]

Radiographic and CT findings generally are more impressive than the patient's physical findings and include patchy or interstitial infiltrates, consolidations, centrilobular nodules, and bronchial wall thickening.[88] Small unilateral, transient pleural effusions are common; large effusions and empyema are rare. Radiographic abnormalities resolve slowly and 4 to 6 weeks may be required for complete resolution.

Sputum Gram stain may reveal mononuclear or polymorphonuclear leukocytes, with no predominant organism. Although *M. pneumoniae* can be cultured from respiratory secretions using specialized medium, its growth is slow as 2 to 3 weeks may be necessary for culture identification. Indirect evidence of infection by *M. pneumoniae* is the presence of elevated levels of serum cold hemagglutinins. These immunoglobulin M antibodies develop in approximately half of patients with mycoplasmal pneumonia and can be elevated in other illnesses, especially viral infections. A definitive diagnosis also can be made by demonstrating a fourfold or greater rise in serum antibodies to *M. pneumoniae*.[88] However, because this test also requires 2 to 4 weeks for results, the diagnosis of mycoplasmal pneumonia during the acute phase of the illness must be based on the characteristic history, appropriate clinical setting, and typical physical findings.

C. pneumoniae

C. pneumoniae has received the new taxonomic classification of *Chlamydophila*; however, it may still be referred to as *Chlamydia pneumoniae* in some references.[89] *C. pneumoniae*, formally designated the Taiwan acute respiratory agent after the laboratory designations for the first two isolates, is antigenically similar to *C. psittaci*. *C. pneumoniae* infection is ubiquitous worldwide; approximately 80% of the population has been infected by adulthood,[66] but only a small percentage of infections result in clinically apparent pneumonia. Conversely, approximately 5% to 15% of pneumonia is associated with this pathogen.[89] Primary infection with *Chlamydia* pneumonia typically occurs in young adults and is characterized by mild respiratory symptoms with a gradual onset (eg, incubation period about 21 days). Constitutional manifestations, particularly fever, headache, and hoarseness, are common.[66] The radiographic findings are nonspecific and usually consist of multilobular interstitial infiltrates with circumscribed lesions. Immunity is incomplete, and reinfection with *C. pneumoniae* is common, particularly among the elderly. Definitive diagnosis of *C. pneumoniae*–associated pneumonia depends on identification of the organism in sputum. Culture of this organism is difficult and commercially available antigen detection systems are insensitive.

Viral Pneumonia

Viruses are an uncommon cause of pneumonia in adults, except in the immunosuppressed.[6] When viral pneumonia does occur, the influenza virus (usually type A) is the most common cause in the adult civilian population[4]; other viruses causing adult CAP include RSV, adenoviruses, parainfluenza, and human metapneumovirus.[4] In contrast, viruses are by far the most common agents producing pneumonia in infants and young children with a prevalence of up to 80% in those less than 2 years of age, with RSV accounting for most cases. Other common viruses in children include parainfluenza, adenovirus, human metapneumovirus, bocavirus, and rhinovirus.[5,53,66]

Viral respiratory tract infections occur more commonly in the winter and typically spread rapidly from person to person through susceptible populations. Underlying cardiac or pulmonary disease predisposes one to an increased incidence and severity of viral lower respiratory tract infection, especially with influenza virus in adults and RSV in children. Radiographic findings are nonspecific, include bronchial wall thickening and perihilar, and diffuse interstitial infiltrates. Pleural effusions may be seen, especially in adenovirus and parainfluenza pneumonia.

The clinical pictures produced by respiratory viruses are sufficiently variable and overlap to such a degree that an etiologic diagnosis cannot be made confidently based on clinical grounds alone. Although virus isolation in tissue culture is still considered the gold standard, it is time consuming and technically demanding; a period of 7 or more days often is required for virus identification[3] and thus this method usually cannot be used for definitive diagnosis during the acute phase of illness. Serologic tests for virus-specific antibodies are used often in epidemiologic and surveillance studies of viral infections since the diagnostic fourfold rise in titer between acute and convalescent phase sera may require 2 to 3 weeks to develop.[3] Rapid antigen testing for the influenza virus (some tests distinguishing types A and B) and RSV is available; however, cost, high false-positive rates, and 50% to 70% sensitivity are considerations for its utility during nonpeak seasons.[3,4,6] Viral testing with molecular techniques provides increased utility for patient care with high

sensitivity, rapid results, and the ability to detect new and emerging pathogens. Although not universally available in the United States, these include real-time PCR, solid and liquid microarrays, mass spectrometry, target-enriched multiplexing PCR, and multiplex ligation-dependent probe amplification, to name a few.[3]

Viruses that have emerged in recent decades and caused significant outbreaks include avian influenza H5N1, severe acute respiratory syndrome coronavirus (SARS-CoV), swine influenza H1N1, variant influenza A H3N2, and Middle Eastern respiratory syndrome coronavirus (see Chapter 109 for further discussion of these viruses).[90,91] In general, signs and symptoms of these viral infections are similar to other viral subtypes; however, there have been unique differences with several of the strains. Pneumonia, respiratory distress syndrome, lymphopenia, and clotting abnormalities tend to occur rapidly in patients infected with H5N1. The H1N1 virus affected normally healthy young adults as opposed to other flu viruses, which tend to be more severe in the young and the elderly, and resulted in serious infections requiring hospitalization and death. The SARS-CoV is an extremely contagious atypical pneumonia[92,93] causing high fever, myalgias, headache, diarrhea, and a dry nonproductive cough, however, for unclear reasons, SARS appears to be less severe for pediatric patients.

Tuberculosis

The acid-fast bacillus *M. tuberculosis* causes tuberculosis and is spread person to person by inhalation of droplets. After years of steady decline, the number of cases of pneumonia caused by *M. tuberculosis* in the United States began to increase in the middle to late 1980s. The new epidemic was a consequence of an increased incidence among prison inmates, IV drug abusers, immigrants, and, most prominently, HIV-infected patients. It is most prominent in urban neighborhoods afflicted with crowded conditions and poor access to healthcare; thus, groups prone to tuberculosis include the homeless and patients in chronic care facilities and homes for the elderly. Unlike previous eras in which tuberculosis was seen most frequently in elderly men, infection currently is identified in increasing numbers of young minority adults. Multidrug resistant strains of *M. tuberculosis* have become more common and treatment regimens for these patients should involve consultation with a specialist. (See Chapter 112 for a detailed discussion of tuberculosis pathophysiology, diagnosis, and treatment.)

TREATMENT

Desired Outcome

Eradication of the offending organism through selection of the appropriate antibiotic and subsequent complete clinical cure are the goals of therapy for all bacterial infections. Therapy should minimize associated morbidity, including one or both of the following: reversible or irreversible disease and drug-induced organ toxicity (eg, renal, lung, or hepatic dysfunction). Most cases of viral pneumonia are self-limiting, although therapy of influenza pneumonia with specific antiviral agents (oseltamivir and zanamivir) may hasten recovery. All efforts should focus on the design of the most cost-effective approach to therapy. Whenever possible, the oral (vs parenteral) route for drug administration should be selected, encouraging outpatient management rather than hospitalization. Optimal treatment of infection/lower respiratory tract infection requires a rapid and accurate diagnosis, rapid initiation of effective antimicrobial therapy, and proper antimicrobial stewardship. The sooner proper antimicrobial therapy is instituted, the better the outcome. Comprehensive principles of optimal antimicrobial therapy and infectious diseases stewardship are discussed in detail in Chapter 105.

General Approach to Treatment

9 The first priority in assessing the patient with pneumonia is to evaluate the adequacy of respiratory function and to determine the presence of signs of systemic illness, specifically dehydration or sepsis with resulting circulatory collapse. Oxygen or, in severe cases, mechanical ventilation and fluid resuscitation should be provided as necessary. Further supportive care of the patient with pneumonia includes humidified oxygen for hypoxemia, administration of bronchodilators (albuterol) when bronchospasm is present, and chest physiotherapy with postural drainage if evidence of retained secretions. Additional therapeutic adjuncts include adequate hydration (IV if necessary), optimal nutritional support, and control of fever. Appropriate sputum samples may be obtained to determine the microbiologic etiology. In more severely ill—hospitalized patients cultures of lower respiratory tract secretions obtained by protected specimen brush bronchoscopy or via BAL along with blood cultures can be helpful in identifying causative pathogens. Rehydration should be provided to replace losses that may have occurred as a result of fever, poor intake, and/or associated vomiting. Selection of an appropriate antimicrobial must be made based on the patient's probable or documented microbiology and its distribution in the respiratory tract, side effects, and cost. Respiratory tract infection diagnosis and treatment guideline reports have been published by authoritative professional organizations that focus on proper treatment regimens and should be consulted for evidence-based treatment recommendations across the spectrum of community- and/or hospital-associated pneumonias.[94]

An increasingly important challenge to effective treatment of lower respiratory tract infections is the ability of bacteria and fungi to form biofilms—colonies of organisms protected by an extracellular polymer matrix of polysaccharides and extracellular DNA. These are complex, multicellular structures that adhere to surfaces (anatomical or devices, eg, indwelling IV lines) and are responsible for the chronicity and poor microbial eradication rates of many hospital-acquired as well as chronic infections, for example, cystic fibrosis (see Chapter 29). Biofilms display specific properties and serve as a reservoir for pathogen dissemination and resultant systemic infection. The colonies of pathogens they harbor can be resistant to antimicrobial drug (eg, aminoglycosides) and immune cell penetration—biofilms may contain single or mixed microbial communities. Other drug classes like fluoroquinolones may penetrate certain biofilms well, but still do not eradicate 100% of the biofilm microorganisms. Biofilm-based microorganisms can produce a number of small, diffusible "communication" molecules—some are signaling molecules regulating cell density within the biofilm and other intracellular functions. An in depth assessment of biofilms is beyond the scope of this chapter, but a good understanding of their many characteristics and approaches to combat them are pivotal to the design of effective treatment of (lower respiratory tract) infections.[95]

Clinical **Controversy...**

Various adjunctive therapy options have been studied for their potential benefits in CAP in recent years. Drugs that have been studied include corticosteroids, prostaglandin inhibitors, statins, immunoglobulin therapy, mediator-specific immunomodulators, angiotensinogen-converting enzyme inhibitors, and oral hypoglycemic agents. Proposed mechanisms for some of the drugs have centered on protective effects (eg, vasodilation and cough reflex) and antiinflammatory effects. Due to differences in study design and patient populations, the actual benefits of these therapies in the treatment of CAP remains undetermined.[96]

Pharmacologic Therapy

Antibiotic Concentrations

Antibiotic concentrations in respiratory secretions in excess of the pathogen MIC are necessary for successful treatment of pulmonary infections.[97] The concept of a blood–bronchus barrier, analogous but dissimilar to the blood–brain barrier, has been used to describe the characteristics of drug penetration into pulmonary secretions. The ability of a drug to penetrate respiratory secretions depends on multiple physicochemical factors, including molecular size, lipid solubility, and degree of ionization at serum and biologic fluid pH and the extent of protein binding. Studies performed in animals and cystic fibrosis patients suggest that larger molecular size favors the accumulation of drugs in bronchial secretions. This finding contrasts with data on drug penetration of other physiologic compartments, such as the cerebrospinal fluid, and may be a result of the trapping of lower-molecular-weight compounds in mucin pores. Nevertheless, the rate at which a drug may accumulate in certain respiratory secretions appears to remain an important factor relative to the drug's clinical efficacy in treating pulmonary infections. The unionized form of drug and lipid solubility also appears to favor drug penetration. Of note, the pH of the infected bronchi often is more acidic than that of normal tissue and blood. These factors combined underscore the importance of considering the inhaled route of antimicrobial drugs for the treatment of patients with moderate to severe pneumonia, particularly in high-risk patient groups.[98]

Clinical **Controversy...**

Prior to the availability of newer β-lactam and fluoroquinolone antibiotics possessing consistently potent activity against multiple gram-negative pathogens, some investigators promoted the administration of antibiotics by direct endotracheal instillation. This method of drug administration attempts to provide increased topical concentrations of antibiotics that do not appear to penetrate respiratory secretions effectively while reducing the likelihood of systemic toxicity. In addition, greater local concentrations of antibiotics, particularly of the polymyxins (eg, colistin) and aminoglycosides are believed to overcome partially the substantial decrease in antibiotic bioactivity observed when these agents interact with the purulent material present in infectious foci. Despite these potential theoretical advantages, the role of antibiotic aerosols or direct endotracheal instillation in clinical practice remains controversial and guidelines do not recommend the routine use of aerosolized antibiotics.[6, 99-102] Nevertheless, positive efficacy and safety data combined with the increasing incidence of serious infections caused by MDR pathogens is fostering the continued study of antibiotic aerosols.

Limited data are available for assessing the influence of drug protein binding on the rate and amount of respiratory secretion penetration. Clearly, it is the free antibiotic fraction reaching the infected site capable of binding to the bacterial cell target that is responsible for antibacterial activity. Given that the degree of protein binding influences a drug's ability to traverse membranes, a similar relationship would be expected within the lung. However, focusing on the absolute amount of an antibiotic bound to plasma/tissue proteins without accounting for the drug's overall antibacterial potency is errant. To completely assess an antibiotic's therapeutic potential in the treatment of pneumonia or any infectious process, it is prudent to assess the antibiotic's integrated pharmacokinetic-pharmacodynamic (PK-PD) characteristics (eg, bacterial killing may be concentration dependent, time dependent, or a hybrid) that account for the drug's degree of binding to serum proteins, tissue distribution, and in vitro potency. These concepts relating to antibiotic activity and overall drug penetration of respiratory secretions underscore the importance of applying the well-defined concepts of antimicrobial PK and PD to the design of optimal antibiotic dosing regimens. A primary example of effectively applying antibiotic PK-PD–designed optimal dosing is reflected in the clinical practice of administering certain antibiotics (once daily dosing of aminoglycosides) to achieve high peak serum concentrations on the assumption that higher (and possibly more effective) biologic fluid concentrations of the drug will be achieved. The aminoglycosides are large polar molecules that diffuse poorly into tissue and respiratory secretions; however, with increasing concentrations obtained with once-daily dosing, increased target-tissue concentrations would be expected with increasing individual doses. Further, recognizing that the peak drug concentration-to-pathogen MIC ratio (Cmax:MIC) is the primary PK-PD correlate for aminoglycosides and that the target Cmax:MIC ratio for aminoglycosides is approximately 10, the single daily dose strategy is most likely to achieve the desired PK-PD target at the desired anatomic site. Similar is the case for the so-called respiratory fluoroquinolones (eg, levofloxacin, moxifloxacin, and gemifloxacin) higher individual dose therapy targeting a greater Cmax:MIC ratio or the more commonly targeted area under the concentration–time curve (AUC)-to-pathogen MIC ratio, that is, AUC:MIC, for fluoroquinolones. The target 24-hour AUC:MIC ratio for fluoroquinolones was originally greater than 35 (possible minimum of 25) for gram-positive and greater than 125 (possible minimum of 100) for gram-negative pathogens. However, with the increasing incidence of antibiotic-resistant bacteria many clinicians are targeting higher ratios of greater than 100 to 200 to suppress possibly resistant mutants of gram-negative pathogens. For greatest probability of success, the antibiotic concentrations projected in these PK-PD correlates should include the expected free (not protein-bound) antibiotic concentration. Conversely, concentration-dependent killing characteristics best correlate with successful therapy with the β-lactam/-carbapenem and macrolide classes of antimicrobials (see Chapter e104 and Chapter 105 for more in-depth discussion of antibiotic concepts).[99,103]

Sputum collection and gram-staining and culture can still be helpful in determining the causative pathogens for respiratory tract infections since it may serve as a reservoir for pathogen growth and possibly represent the PD interface for pulmonary infections. Investigators have assessed antibiotic concentrations in sputum, frequently describing sputum drug concentrations as a ratio of serum to sputum drug concentration; however, caution should be exercised in the interpretation of these data. Data describing sputum drug concentrations is often difficult to interpret because of differences in analytic techniques, method of sputum sampling, and random nature of sampling times relative to drug dose. To more accurately describe the distribution characteristics of antimicrobial agents in sputum, research studies should be designed to allow sequential repeated sputum sampling over a specified dosage interval under both first-dose and steady-state conditions. Thus, until greater sophistication is achieved in our understanding of the relationships between antibiotic concentrations in specific anatomic sites, plasma (blood)-based integrated PK-PD correlates should be used for antibiotic and dose selection.

Recognizing the many deficiencies of using sputum drug concentration correlates for prognosticating antibacterial therapy, most investigators now prefer the determination of drug concentrations in pulmonary epithelial lining fluid and alveolar macrophages.[97] Assessing drug concentrations in specific

compartments may provide greater insight into drug selection and efficacy (eg, epithelial lining fluid may reflect the extracellular fluid space and thus the important site for extracellular pathogens, *S. pneumoniae*, *M. catarrhalis*, and *H. influenza*). Although characterizing antimicrobial disposition into these compartments is desirable, access to obtain these samples requires invasive procedures (eg, BAL).

Selection of Antimicrobial Agents

Treatment of bacterial pneumonia, like the treatment of most infectious diseases, initially involves the empirical use of a relatively broad-spectrum antibiotic that is effective against probable pathogens after appropriate cultures and specimens for laboratory evaluation have been obtained.[63,94] Therapy should be narrowed to cover specific pathogens after the results of cultures are known. Multiple factors that help to define the potential pathogens involved include patient age, previous and current medication history, underlying disease(s), major organ function, and present clinical status. These factors must be evaluated to select an appropriate and effective empirical antibiotic regimen as well as the most appropriate route for drug administration (oral vs parenteral). (For a more detailed discussion on the principles of antibiotic selection, see Chapter 105.)

Many antibiotics are effective in the treatment of bacterial pneumonia. Superiority of one antibiotic over another when both demonstrate similar dose-normalized in vitro activity and tissue distribution characteristics is difficult to define. Our opinions on appropriate empirical choices for the treatment of bacterial pneumonias relative to a patient's underlying disease are listed in Table 107-8 for adults and Table 107-9 for children. A complete listing of antimicrobial agents for specific pathogens is beyond the scope of this chapter and is presented in Chapter 105.

TABLE 107-8 Evidence-Based Empirical Antimicrobial Therapy for Pneumonia in Adults[a]

Clinical Setting	Usual Pathogens	Empirical Therapy
Outpatient/Community Acquired		
Previously healthy	*S. pneumoniae*, *M. pneumoniae*, *H. influenzae*, *C. pneumoniae*, *M. catarrhalis*	Macrolide/azalide,[b] or tetracycline[c]
Comorbidities (diabetes, heart/lung/liver/renal disease, and alcoholism)	Viral MDR S. pneumoniae	Oseltamivir or zanamivir if <48° from onset of symptoms Fluoroquinolone[d] or β-lactam + macrolide[b]
Elderly Regions with >25% rate of macrolide-resistant *S. pneumoniae*	*S. pneumoniae*, gram-negative bacilli	Piperacillin/tazobactam or cephalosporin[e] or carbapenem[f] Fluoroquinolone[d] or β-lactam + macrolide[b]/tetracycline
Inpatient/Community Acquired		
Non-ICU	*S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, *C. pneumoniae*, *Legionella* sp.	Fluoroquinolone[d] or β-lactam + macrolide[b]/tetracycline
ICU	*S. pneumoniae*, *S. aureus*, *Legionella* sp., gram-negative bacilli, *H. influenzae*	β-Lactam + macrolide[b]/fluoroquinolone[d]
	If *P. aeruginosa* suspected	Piperacillin/tazobactam or meropenem or cefepime + fluoroquinolone[d]/AMG/azithromycin; or β-lactam + AMG + azithromycin/respiratory fluoroquinolone[d]
	If MRSA suspected	Above + vancomycin or linezolid
	Viral	Oseltamivir or zanamivir ± antibiotics for 2° infection
Hospital Acquired or Ventilator Associated		
No risk factors for MDR pathogens (single agent *Pseudomonal* coverage)	*S. pneumoniae*, *H. influenzae*, MSSA, enteric gram-negative bacilli	Piperacillin/tazobactam, cefepime, levofloxacin, imipenem or meropenem
Risk factors for MDR pathogen (dual agent *Pseudomonal* coverage)	*P. aeruginosa*, *K. pneumoniae* (ESBL), *Acinetobacter* sp.	Antipseudomonal cephalosporin[e] or antipseudomonal carbapenem or β-lactam/β-lactamase + antipseudomonal fluoroquinolone[d] or AMG[g]
	If MRSA or *Legionella* sp. suspected	Above + vancomycin or linezolid
Aspiration	*S. aereus*, enteric gram-negative bacilli Anaerobes	Penicillin or clindamycin or piperacillin/tazobactam + AMG[g] Clindamycin, β-lactam/β-lactamase, or carbapenem
Atypical Pneumonia[h]		
Legionella pneumophila		Fluoroquinolone,[d] doxycycline, or azithromycin
Mycoplasma pneumonia		Fluoroquinolone,[d] doxycycline, or azithromycin
Chlamydophila pneumonia		Fluoroquinolone,[d] doxycycline, or azithromycin
SARS		Fluoroquinolone[d] or macrolides[b]
Avian influenza		Oseltamivir
H1N1 influenza		Oseltamivir

MRSA, methicillin-resistant *Staphylococcus aureus*; AMG, aminoglycoside; SARS, severe acute respiratory syndrome; ESBL, extended-spectrum β-lactamases; MDR, multidrug resistant; MSSA, methicillin-sensitive *Staphylococcus aureus*.

[a]See the section Selection of Antimicrobial Agents.

[b]Macrolide/azalide: erythromycin, clarithromycin, and azithromycin.

[c]Tetracycline: tetracycline, HC1, and doxycycline.

[d]Fluoroquinolone: ciprofloxacin, levofloxacin, and moxifloxacin.

[e]Antipseudomonal cephalosporin: cefepime and ceftazidime.

[f]Antipseudomonal carbapenem: imipenem and meropenem.

[g]Aminoglycoside: amikacin, gentamicin, and tobramycin.

[h]For tuberculosis, see Chapter 112.

Data from references 4, 6, 66.

TABLE 107-9 Empirical Antimicrobial Therapy for Pneumonia in Pediatric Patients[a]

Clinical Setting	Usual Pathogen(s)	Empirical Therapy
Outpatient/Community Acquired		
<1 month	Group B *Streptococcus*, *H. influenzae* (nontypable), *E. coli*, *S. aureus*, *Listeria* CMV, RSV, adenovirus	Ampicillin/sulbactam, cephalosporin,[b] carbapenem[c] Ribavirin for RSV[d]
1-3 months	*C. pneumoniae*, possibly *Ureaplasma*, CMV, *Pneumocystis carinii* (afebrile pneumonia syndrome) *S. pneumoniae*, *S. aureus*	Macrolide/azalide,[e] trimethoprim–sulfamethoxazole Semisynthetic penicillin[f] or cephalosporin[g]
Preschool-aged children	Viral (rhinovirus, RSV, influenza A and B, parainfluenzae, adenovirus, human metapneumovirus, coronavirus)	Antimicrobial therapy not routinely required
Previously healthy, fully immunized infants and preschool children with suspected mild–moderate bacterial CAP	*S. pneumoniae* *M. pneumoniae*, other atypical	Amoxicillin, cephalosporin[b,g] Macrolide/azalide or fluoroquinolone
Previously healthy, fully immunized school-aged children and adolescents with mild–moderate CAP	*S. pneumoniae* *M. pneumoniae*, other atypical	Amoxicillin, cephalosporin,[b,g] or fluoroquinolone Macrolide/azalide, fluoroquinolone, or tetracycline
Moderate–severe CAP during influenza virus outbreak	Influenza A and B, other viruses	Oseltamivir or zanamivir
Inpatient/Community Acquired		
Fully immunized infants and school-aged children	*S. pneumoniae* CA-MRSA *M. pneumoniae*, *C. pneumoniae*	Ampicillin, penicillin G, cephalosporin[b] β-Lactam + vancomycin/clindamycin β-Lactam + macrolide/fluoroquinolone/ doxycycline
Not fully immunized infants and children; regions with invasive penicillin-resistant pneumococcal strains; patients with life-threatening infections	*S. pneumoniae*, *PCN resistant* MRSA *M. pneumoniae*, other atypical pathogens	Cephalosporin[b] Add vancomycin/clindamycin Macrolide/azalide[e] + β-lactam/doxycycline/ fluoroquinolone

CMV, cytomegalovirus; RSV, respiratory syncytial virus; CAP, community-acquired pneumonia; MRSA, methicillin resistant *Staphylococcus aureus*.

[a]See the section Selection of Antimicrobial Agents.

[b]Third-generation cephalosporin: ceftriaxone and cefotaxime. Note that cephalosporins are not active against *Listeria*.

[c]Carbapenem: imipenem–cilastatin and meropenem.

[d]See text for details regarding possible ribavirin treatment for RSV infection.

[e]Macrolide/azalide: erythromycin and clarithromycin/azithromycin.

[f]Semisynthetic penicillin: nafcillin, and oxacillin.

[g]Second-generation cephalosporin: cefuroxime and cefprozil.

Data from reference 5.

A patient's medical history of responding or not responding to one of these antibiotics in the recent past will assist greatly in the decision to continue their use. For infected patients with risk factors, regardless of whether the patient resides in the community, long-term care facility, or acute care hospital, the fluoroquinolone antibiotics represent important treatment tools based on their highly favorable PK (tissue and intracellular distribution) and PD (potency, broad spectrum) characteristics combined with ease of administration (IV, oral) and patient tolerability. Furthermore, optimal dosing directed by the projected 24-hour free fluoroquinolone AUC-to-pathogen MIC ratio (see earlier) has fostered maximal bacteriologic kill and enhanced patient safety.

Table 107-10 lists dosages for selected antibiotics used for the treatment of bacterial pneumonia. The large number of expensive drugs mandates critical evaluation for formulary selection and clinical use. Similarities of in vitro activity, resistance to bacterial-inactivating enzymes, and overall effectiveness often make rational therapeutic decisions difficult and even appear random. However, some general principles can be applied to guide rational antibiotic choice, including direct comparison of the antibiotic's likely attainment of the defined PK-PD target correlate for specific bacterial species within the infected site. An understanding and application of inherent drug characteristics appears to be of the utmost importance for the selection of an optimal therapeutic regimen. Thus, whenever possible, identification of the causative pathogen and expected/defined antibiotic susceptibility (eg, MIC) is of paramount importance to the selection/design of the optimal antibiotic regimen. Lastly, the importance of meaningful and continuous antimicrobial stewardship in combating the rate of pathogen resistance cannot be overemphasized.

Community-Acquired Pneumonia

Tables 107-8 and 107-9 provide evidence-based guidelines for the treatment of CAP in adults[4] and children,[5] respectively. The bacterial causes are relatively constant, even across geographic areas and patient populations. Unfortunately, pathogen resistance to standard antimicrobials is increasing (eg, penicillin-resistant pneumococci), which necessitates careful attention by the clinician to local and regional bacterial susceptibility patterns.[104] Thus, whenever possible, initial therapy should be based on presumed antibacterial susceptibility and consist of older, less-expensive agents, with newer and more expensive antibiotics reserved for unresponsive illness or special circumstances. Indiscriminate use of recently introduced agents increases healthcare costs and, in some instances (eg, widespread use of fluoroquinolones), induces resistance among a significant percentage of community-acquired organisms.[4] The rapidly evolving epidemiology of bacterial resistance, including the increasing emergence of penicillin-resistant *S. pneumoniae* in many areas of the United States and Europe, forces the clinician to be vigilant and knowledgeable about antibiotic sensitivity patterns in each community.

TABLE 107-10 Antibiotic Doses for Treatment of Bacterial Pneumonia

			Daily Antibiotic Dose[a]	
Antibiotic Class	**Antibiotic**	**Brand Name**	**Pediatric**	**Adult (Total Dose/Day)**
Penicillin	Ampicillin ± sulbactam	Unasyn®	150-200 mg/kg/day	6-12 g
	Amoxicillin ± clavulanate[b]	Augmentin®	45-100 mg/kg/day	0.75-1 g
	Piperacillin/tazobactam	Zosyn®	200-300 mg/kg/day	12-18 g
	Penicillin		100,000-250,000 units/kg/day	12-18 million units
Extended-spectrum cephalosporins	Ceftriaxone	Rocephin®	50-75 mg/kg/day	1-2 g
	Cefotaxime	Claforan®	150 mg/kg/day	2-12 g
	Ceftazidime	Fortaz®/Tazicef®	90-150 mg/kg/day	4-6 g
	Cefepime	Maxipime®	100-150 mg/kg/day	2-6 g
Macrolide/azalide	Clarithromycin	Biaxin®	15 mg/kg/day	0.5-1 g
	Erythromycin	Ery-Tab®	30-50 mg/kg/day	1-2 g
	Azithromycin	Zithromax®	10 mg/kg × 1 day (× 2 days if parenteral), and then 5 mg/kg days 2-5	500 mg × 1 day (× 2 days if parenteral), and then 250 mg days 2-5
Fluoroquinolones[c]	Moxifloxacin	Avelox®	–	400 mg
	Gemifloxacin	Factive®	–	320 mg
	Levofloxacin	Levaquin®	8-20 mg/kg/day	750 mg
	Ciprofloxacin	Cipro®	30 mg/kg/day	1.2 g
Tetracycline[d]	Doxycycline	Monodox®/Doxy 100™	2-5 mg/kg/day	100-200 mg
	Tetracycline HCl		25-50 mg/kg/day	1-2 g
Aminoglycosides	Gentamicin		7.5-10 mg/kg/day	7.5 mg/kg
	Tobramycin		7.5-10 mg/kg/day	7.5 mg/kg
Carbapenems	Imipenem	Primaxin®	60-100 mg/kg/day	2-4 g
	Meropenem	Merrem®	30-60 mg/kg/day	1-3 g
Other	Vancomycin		45-60 mg/kg/day	2-3 g
	Linezolid	Zyvox®	20-30 mg/kg/day	1.2 g
	Clindamycin	Cleocin®	30-40 mg/kg/day	1.8 g

[a]Doses can be increased for more severe disease and may require modification for patients with organ dysfunction.

[b]Higher-dose amoxicillin and amoxicillin/clavulanate (eg, 90 mg/kg/day) are used for penicillin-resistant *S. pneumoniae*.

[c]Fluoroquinolones have been avoided for pediatric patients because of the potential for cartilage damage; however, they have been used for MDR bacterial infection safely and effectively in infants and children (see text).

[d]Tetracyclines are rarely used in pediatric patients, particularly in those younger than 8 years because of tetracycline-induced permanent tooth discoloration.

Interestingly, the European National Institute for Health and Care Excellence pneumonia guidelines recommend point of care C reactive protein tests to assist in determining if antibiotics should be prescribed to patients with lower respiratory tract infections when pneumonia has not been diagnosed clinically.[71] Indiscriminate use of antimicrobials for treatment of pneumonia has contributed to the problem of antimicrobial resistance, underscoring the need for defining the optimal antibiotic regimen for each patient.

9 Evidence-based empirical therapy differs among outpatients, hospitalized patients, and hospitalized patients admitted to an intensive care unit (see Tables 107-8 and 107-9).[4,5] Antimicrobial therapy should be initiated for hospitalized patients with acute pneumonia within 8 hours of admission because an increase in mortality has been demonstrated when therapy was delayed beyond 8 hours of admission.

Hospital-Acquired Pneumonia

10 Antibiotic selection within the hospital environment demands greater care because of constant changes in antibiotic resistance patterns in vitro and in vivo. Ironically, some β-lactam antibiotics, which were developed to treat MDR hospital-acquired organisms, can themselves induce broad-spectrum bacterial β-lactamases and thereby lead to even greater problems with resistance.[99] These facts underscore the importance of regularly documenting the epidemiology of pathogens and infectious diseases within a specific practice or institution and tailoring empiric antibiotic therapy based on local antibiograms.[6] As a result, an antimicrobial agent for a specific infectious disease favored in one practice site may not be the most desirable selection in another site despite similarities in size and patient profile. Strict and careful control and, possibly, rotation of empirical antibiotics in the hospital environment may help to limit the emergence of resistant organisms. Newer antibiotics developed for treatment of resistant, hospital-acquired pathogens are costly; therefore, their use must be moderated to some extent in an era where capitated hospital costs and mandated budget cuts will not tolerate careless antibiotic use. Broad-spectrum antibiotics are more appropriate choices for patients with risk factors for MDR pathogens or if HAP develops after at least 5 days of hospitalization (see Table 107-8 for recommended antimicrobial therapy).[6] For most patients, a 7 day course of antibiotics is appropriate.[6]

Ventilator-Associated Pneumonia

The approach to treating VAP is similar to antibiotic selection in HAP (see Table 107-8). Patients should be carefully evaluated to determine whether they are at risk for MDR pathogens as this is essential in selecting appropriate empirical antibiotic therapy.[6] Risk factors for MDR VAP include septic shock, ARDS, acute renal replacement therapy, IV antibiotic use within the previous 90 days and/or being hospitalized at least 5 days prior to VAP.[6] It is also important to identify patients with VAP early since delays in initiating appropriate antibiotic therapy are associated with increased mortality. Current guidelines support shorter antibiotic courses (7 days versus 8-15 days) for VAP even for gram negative bacilli infections since mortality and clinical cure rates were not significantly affected with shorter courses.[6] Aerosolized antibiotic delivery has been considered for more targeted therapy; but is currently only recommended if patients are not responding to IV antibiotic therapy.[6,106] Inhaled plus systemic aminoglycosides or colistin can be used if the identified pathogen is only sensitive to one of those antibiotics.[6]

Atypical Pneumonia

Pneumonia caused by atypical pathogens may be more difficult to treat with antibiotics than "typical" pathogens. It is debatable whether empirical treatment for hospitalized patients with CAP should include antibiotic coverage of atypical pathogens; however, for patients requiring ICU admission, combination therapy including coverage for atypical pathogens has been associated with improved mortality.[107] There does not appear to be any benefit in terms of survival or clinical efficacy to providing atypical coverage for all outpatients unless they have risk factors for a poor outcome (eg, history of CHD, lung or liver disease, immunosuppression, DM, or malignancy) (see Table 107-8 for a summary of the evidence-based guidelines on management).[107]

For *Legionella* pneumonia, azithromycin and levofloxacin are recommended although other respiratory fluoroquinolones, tetracyclines, or macrolides could be utilized but may result in more side effects.[84] Double antibiotic coverage is not recommended if one of these agents is used, even in severe pneumonia, due to limited evidence of improved efficacy.[84] *Mycoplasma* pneumonia is difficult to treat similar to the other atypical pathogens due to the organism's lack of a cell wall, limiting the use of certain antibiotics, and because it is found on epithelial cells in the respiratory tract instead of inside the cells.[66] Macrolides and tetracyclines are generally effective against *Mycoplasma*; however, macrolide-resistant strains have been emerging over the past decade.[85] *Chlamydophila* organisms are sensitive to macrolides, doxycycline, and fluoroquinolones. Symptoms, such as cough and malaise, may be present for months following antibiotic therapy.[66] The management of tuberculosis is further discussed in Chapter 112.

For viral causes of pneumonia, antivirals such as oseltamivir and occasionally amantadine can be used, depending on viral susceptibility.[91] Treatment for H5N1 and H1N1 is primarily supportive; patients with H5N1 generally require aggressive oxygen therapy and intensive monitoring, while the majority of those with H1N1 are treated as outpatients. Both viruses are resistant to amantadine; therefore, the neuraminidase inhibitors oseltamivir and zanamivir are recommended if antivirals are administered. Treatment of SARS involves primarily supportive care and procedures to prevent transmission to others. Owing to the uncertainty associated with the diagnosis of SARS, empirical therapy with broad-spectrum antibiotics should be used including fluoroquinolones or macrolides/azalides. Although evidence for its efficacy is limited, oral ribavirin also has been used to treat patients with noninfluenza respiratory viral infections.[108] High dose systemic corticosteroids are not routinely recommended in severe viral respiratory infections due the risk of avascular osteonecrosis and prolonged viral shedding.[91]

Prevention

Prevention of some cases of pneumonia is possible through the use of vaccines and medications against selected infectious agents. Polyvalent polysaccharide vaccines are available for two of the leading causes of bacterial pneumonia, *S. pneumoniae* and *H. influenzae* type b. Children should be vaccinated against *S. pneumoniae*, *H. influenzae* type b, pertussis, and influenza while caregivers for infants less than 6 months should also be vaccinated against influenza and pertussis. Immune prophylaxis for RSV is only recommended for high-risk infants during RSV season. To minimize the risk of developing VAP, healthcare providers should seek to minimize colonization of the aerodigestive tract, prevent aspiration (head raised 45 degree), and limit the length of mechanical ventilation of patients.[75] In addition, evidence-based guidelines for preventing HCAP have been published (Table 107-11) (see Chapter 109 for a full discussion of influenza postexposure prophylaxis and Chapter 125 for vaccines.)[109]

TABLE 107-11 Evidenced-Based Guidelines for Preventing Healthcare-Associated Pneumonia

Recommendation	Recommendation Grade[a]
For nebulizers, use aerosolized medications in single-dose vials. If multidose medication vials are used, follow manufacturers' instructions for handling, storing, and dispensing the medications	1B
Pneumococcal vaccination is recommended for patients at high risk for severe pneumococcal infections	1A
Unless contraindicated, administer a macrolide to any person who has had close contact with persons having pertussis	1B
In acute care settings, offer vaccine to inpatients and outpatients at high risk for complications from influenza beginning in September and throughout the influenza season	1A
Unless contraindicated, provide prophylactic treatment to all patients without influenza illness in the involved unit with amantadine, rimantadine, or oseltamivir for a minimum of 2 weeks or until approximately 1 week after the end of the outbreak	1A
Unless contraindicated, patients with influenza should receive amantadine, rimantadine, oseltamivir, or zanamivir within 48 hours of the onset of symptoms	1A

[a]Grade 1A, strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies; grade 1B, strongly recommended for implementation and supported by certain clinical or epidemiologic studies and by strong theoretical rationale.

EVALUATION OF THERAPEUTIC OUTCOMES

After therapy has been instituted, appropriate clinical parameters should be monitored to ensure the efficacy and safety of the therapeutic regimen. For patients with bacterial infections of the upper or lower respiratory tract, the time to resolution of initial presenting symptoms and the lack of appearance of new associated symptomatology are important to determine. For patients with CAP or pneumonia from any source of mild to moderate clinical severity, the time to resolution of cough, decreasing sputum production, and fever as well as other constitutional symptoms of malaise, nausea, vomiting, and lethargy, should be noted. If the patient requires supplemental oxygen therapy, the amount and need should be assessed regularly. A gradual and persistent improvement in the resolution of these symptoms and therapies should be observed. Initial resolution of infection should be observed within the first 2 days of therapy and progression to complete resolution within 5 to 7 days (usually no more than 10 days).

For patients with HAP, substantial underlying diseases, or both, additional parameters can be followed, including the magnitude and character of the peripheral blood WBC count, chest radiograph, and blood gas determinations. Similar to patients with less severe disease, some resolution of symptoms should be observed within 2 days of instituting antibiotic therapy. If no resolution of symptoms is observed within 2 days of starting seemingly appropriate antibiotic therapy or if the patient's clinical status is deteriorating, the appropriateness of initial antibiotic therapy should be critically reassessed. The patient should be evaluated carefully for deterioration of underlying concurrent disease(s). Additionally, the caregiver should consider the possibility of changing the initial antibiotic therapy to expand antimicrobial coverage not included in the original regimen

(eg, *Mycoplasma*, *Legionella*, and anaerobes). Furthermore, the need for antifungal therapy (eg, triazoles, echinocandins) should be considered. Some resolution of symptoms should be observed within 2 days of starting proper antibiotic therapy, with complete resolution expected within 10 to 14 days.

ABBREVIATIONS

AECB	acute exacerbation of chronic bronchitis
AUC	area under the concentration curve
BAL	bronchoalveolar lavage
CAP	community-acquired pneumonia
Cmax	maximum concentration
COPD	chronic obstructive pulmonary disease
FEV_1	forced expiratory volume in the first second of expiration
GOLD	Global Initiative for Chronic Obstructive Lung Disease
HAP	hospital-acquired pneumonia
HIV	human immunodeficiency virus
LABA	long-acting β-receptor agonist
LAMA	long-acting muscarinic antagonist
MDR	multidrug resistant
MIC	minimum inhibitory concentration
MRSA	methicillin-resistant *Staphylococcus aureus*
NAC	*N*-acetyl cysteine
PCR	polymerase chain reaction
PDE4	phosphodiesterase 4
PK-PD	pharmacokinetic–pharmacodynamic
RSV	respiratory syncytial virus
SARS	severe acute respiratory syndrome
SARS-CoV	severe acute respiratory syndrome coronavirus
VAP	ventilator-associated pneumonia
WBC	white blood cell

Upper Respiratory Tract Infections

108

Christopher Frei and Bradi Frei

KEY CONCEPTS

1. Many upper respiratory tract infections will resolve spontaneously without pharmacologic therapy.
2. The most common bacterial causes are *Streptococcus pneumoniae* (acute otitis media and acute rhinosinusitis) and group A β-hemolytic *Streptococcus* (acute pharyngitis).
3. Vaccination against influenza and pneumococcus may decrease the risk of acute otitis media.
4. Because upper respiratory tract infections are so common, antibiotics used to treat them serve as catalysts for the emergence and spread of antibiotic resistance, thereby making prudent antibiotic use critically important.
5. When antibiotics are prescribed, the empirical medications of choice are amoxicillin or amoxicillin-clavulanate for acute otitis media, amoxicillin-clavulanate for acute rhinosinusitis, and amoxicillin or penicillin for acute pharyngitis.
6. For acute otitis media, high-dose amoxicillin (80-90 mg/kg/day in two divided doses) is recommended.

More patients present to physicians' offices and emergency departments for upper respiratory tract infections than any other infectious disease.[1,2] Otitis media, rhinosinusitis, and pharyngitis are the three most common upper respiratory tract infections. Because they are so common, community and emergency health care workers must be familiar with the diagnosis, assessment, and management of patients with these infections. Furthermore, antibiotics used for the treatment of upper respiratory tract infections serve as catalysts for the emergence and spread of antibiotic resistance, thereby making prudent antibiotic use critically important.

ACUTE OTITIS MEDIA

The term *otitis media* comes from the Latin *oto-* for "ear," *itis* for "inflammation," and *medi-* for "middle"; otitis media, then, is an inflammation of the middle ear. There are three subtypes of otitis media: acute otitis media, otitis media with effusion, and chronic otitis media. Acute otitis media is the subtype with the greatest role for antibiotics and will be discussed in detail.

Epidemiology

Otitis media is one of the leading reasons for physicians' office visits and emergency department visits in the United States, accounting for more than 16 million clinic and emergency department visits annually.[1,2] There are more than 709 million cases of otitis media worldwide each year; half of these cases occur in children under 5 years of age.[3] Many patients with otitis media will receive a prescription, and the costs associated with managing otitis media are $2.3 billion annually in the United States.[4]

Etiology

When comprehensive and sensitive microbiologic methods have been used in patients with a certain diagnosis of acute otitis media, bacteria have been found in more than 90% of cases; with standard diagnostic and microbiologic testing, bacteria have been found in approximately 70% of cases.[5]

Common bacterial pathogens include *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis*.[6] The microbial etiology has changed as a result of the introduction and widespread use of the pneumococcal conjugate vaccines. Specifically, the proportion of *S. pneumoniae* cases has declined, and the proportion of *H. influenzae* cases has risen.[7] Today, these two pathogens occur in approximately equal proportions.[5]

S. pneumoniae, *H. influenzae*, and *M. catarrhalis* can all possess resistance to β-lactams. *S. pneumoniae* develops resistance through alteration of penicillin-binding proteins, whereas *H. influenzae* and *M. catarrhalis* produce β-lactamases. Up to 40% of *S. pneumoniae* isolates in the United States are penicillin nonsusceptible, and up to half of these have high-level penicillin resistance.[8] Approximately 30% to 40% of *H. influenzae* and greater than 90% of *M. catarrhalis* isolates from the upper respiratory tract produce β-lactamases.[9]

Pathophysiology

Acute otitis media usually follows a viral upper respiratory tract infection that impairs the mucociliary apparatus and causes Eustachian tube dysfunction in the middle ear.[6] The middle ear is the space behind the tympanic membrane, or eardrum. A noninfected ear has a thin, clear tympanic membrane. In otitis media, this space becomes blocked with fluid, resulting in a bulging and erythematous tympanic membrane. Bacteria that colonize the nasopharynx enter the middle ear and are not cleared properly by the mucociliary system. The bacteria proliferate and cause infection. Children tend to be more susceptible to otitis media than adults because the anatomy of their Eustachian tube is shorter and more horizontal, facilitating bacterial entry into the middle ear.

Clinical Presentation

Patients or caregivers frequently characterize acute otitis media as having an acute onset of otalgia (ear pain). For parents of young children, irritability and tugging on the ear are often the first clues that a child has acute otitis media.

The American Academy of Pediatrics (AAP) guidelines have stringent diagnostic criteria to ensure accurate diagnosis. Children should be diagnosed with acute otitis media if they have middle ear effusion *and* either (1) moderate to severe bulging of the tympanic membrane *or* new onset otorrhea not due to acute otitis externa or (2) mild bulging of the tympanic membrane *and* onset of ear pain within the last 48 hours or intense erythema of the tympanic membrane. Middle ear effusion should be identified based on pneumatic otoscopy and/or tympanometry.[5]

CLINICAL PRESENTATION Acute Otitis Media

General

- Cases of acute otitis media often follow viral upper respiratory tract infections. Nonverbal children with ear pain might hold, rub, or tug their ear. Very young children might cry, be irritable, and have difficulty sleeping.

Signs and Symptoms

- Bulging of the tympanic membrane
- Otorrhea
- Otalgia (considered to be moderate or severe if pain lasts at least 48 hours)
- Fever (considered to be severe if temperature is 39°C [102.2°F] or higher)

Compiled from references 5 and 6.

The diagnoses of acute otitis media and otitis media with effusion are easily confused, and careful attention to history, signs, and symptoms is important. Otitis media with effusion is characterized by fluid in the middle ear without signs and symptoms of acute ear infection, such as pain and a bulging eardrum.[6,7]

TREATMENT

Desired Outcomes

6 Treatment goals include pain management and prudent antibiotic use. These will be discussed in detail, but, first, it is important to consider primary prevention of acute otitis media through the use of bacterial and viral vaccines.

3 Clinicians should recommend pneumococcal conjugate vaccine and annual influenza vaccine to all children according the Advisory Committee on Immunization Practices (ACIP) schedule from the United States Centers for Disease Control and Prevention.[5] A systematic review demonstrated that the seven-valent pneumococcal conjugate vaccine (PCV7) reduced the occurrence of acute otitis media episodes by 6% to 7% when the vaccine was administered during infancy.[10] Finally, because acute otitis media cases often follow influenza cases, influenza vaccination should be considered as a possible means to prevent acute otitis media.

General Approach to Treatment

The first step is to differentiate acute otitis media from otitis media with effusion or chronic otitis media, as the latter two types do not benefit substantially from antibiotic therapy. If the child has acute otitis media, then consider if the disease severity warrants antibiotic therapy. Recognize that amoxicillin is the mainstay of therapy and that penicillin resistance can be overcome, in many cases, with higher doses of amoxicillin. Address the child's pain as described below. The therapeutic strategy should be changed if complications develop or if symptoms fail to resolve within 3 days.

Nonpharmacologic Therapy

Children with acute otitis media should be assessed for pain. Those with pain should be offered treatment to reduce pain regardless of the decision to administer antibiotics.[5] This is largely because antibiotics do not reduce pain in the first 24 hours. Furthermore, some children may experience some pain up to 3 to 7 days even after antibiotics are started. Choice of pain treatment depends on possible benefits and risks to the individual patient. Acetaminophen and ibruprofen are mainstays of treatment, are effective analgesics for mild to moderate pain, and are readily available. Eardrops with a local anesthetic may offer additional, but brief, benefit over acetaminophen in patients at least 5 years of age.[5]

Pharmacologic Therapy

National clinical practice guidelines for appropriate diagnosis and management of acute otitis media were updated in 2013, by the AAP.[5] These guidelines are focused on children 6 months to 12 years of age with uncomplicated cases and without underlying conditions that may alter the natural course of the disease.

The decision to administer antibiotics depends on patient age, symptom severity, laterality, and joint decision-making with parents/caregivers. Children 6 months to 12 years of age, with moderate to severe ear pain or temperature of 39°C (102.2°F) or higher should receive antibiotics. Children 6 to 23 months of age, with nonsevere bilateral acute otitis media should also receive antibiotics. Children 6 to 23 months, with nonsevere unilateral acute otitis media, and children 24 months to 12 years of age, with nonsevere acute otitis media, may receive *initial antibiotics* or *initial observation*. Initial observation should be based on joint decision-making with parents/caregivers, and must include a plan to initiate antibiotics if the child's symptoms worsen or decline within 48 to 72 hours of symptom onset.[5] The central principle is to administer antibiotics quickly when the diagnosis is certain, but to withhold antibiotics, at least initially, when the diagnosis is uncertain.

4 Antibiotic therapy for upper respiratory diseases must be balanced with possible increases in adverse drug events and increased antibiotic pressure. Systematic reviews and randomized controlled trials suggest a moderate benefit of antibiotics for the treatment of acute otitis media, particularly in patients with severe symptoms.[7,11-14] On the other hand, rates of adverse effects, such as diarrhea and diaper rash, are more than double in children who received antibiotics for acute otitis media.[13,14]

5 If antibiotics are to be administered, then amoxicillin should be given to most children.[5] Exceptions include: children who have received amoxicillin in the last 30 days, have concurrent purulent conjunctivitis, or have a history of recurrent infection unresponsive to amoxicillin. These patients should receive amoxicillin-clavulanate instead of amoxicillin. Patients with otitis conjunctivitis syndrome are more likely to be infected with nontypeable *H. influenzae*, hence the need for a β-lactamase inhibitor.[5] Clinicians should reassess the plan if the child's symptoms worsen or decline within 48 to 72 hours of symptom onset.[5] Table 108-1 lists antibiotic recommendations for acute otitis media.

High-dose amoxicillin (80-90 mg/kg/day in two divided doses) is recommended for most patients. Amoxicillin has the best pharmacodynamic profile against drug-resistant *S. pneumoniae* of all available oral antibiotics. In addition, amoxicillin has a long record of safety, possesses a narrow spectrum of activity, is inexpensive, and is more palatable than other options. Higher middle ear fluid concentrations of amoxicillin, as a result of higher dosing, overcome most drug-resistant *S. pneumoniae*.[5] Its excellent efficacy against *S. pneumoniae* outweighs the issue of β-lactamase-producing

TABLE 108-1 Antibiotics and Doses for Acute Otitis Media

Antibiotic	Brand Name	Dose	Comments[a]
Initial Diagnosis			
Amoxicillin	Amoxil®	80-90 mg/kg/day orally divided twice daily	First-line
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally of amoxicillin plus 6.4 mg/kg/day orally of clavulanate, divided twice daily	First-line if certain criteria are present[b]
Cefdinir, cefuroxime, cefpodoxime	Omnicef®, Ceftin®, Vantin®	cefdinir (14 mg/kg/day orally in 1-2 doses) cefuroxime (30 mg/kg/day orally in 2 divided doses) cefpodoxime (10 mg/kg/day orally in 2 divided doses)	Second-line or nonsevere penicillin allergy
Ceftriaxone (1-3 days)	Rocephin®	50 mg/kg/day IM or IV for 3 days	Second-line or nonsevere penicillin allergy
Failure at 48-72 Hours			
Amoxicillin-clavulanate[b]	Augmentin®	90 mg/kg/day orally of amoxicillin plus 6.4 mg/kg/day orally of clavulanate, divided twice daily	First-line
Ceftriaxone (1-3 days)	Rocephin®	50 mg/kg/day IM or IV for 3 days	First-line or nonsevere penicillin allergy
Clindamycin	Cleocin®	30-40 mg/kg/day orally in 3 divided doses plus third-generation cephalosporin	Second-line or nonsevere penicillin allergy

[a]If a patient has received amoxicillin in the last 30 days, has concurrent purulent conjunctivitis, or has a history of recurrent infection unresponsive to amoxicillin.

[b]Amoxicillin-clavulanate 90:6.4 or 14:1 ratio is available in the United States; 7:1 ratio is available in Canada (use amoxicillin 45 mg/kg for one dose, amoxicillin 45 mg/kg with clavulanate 6.4 mg/kg for second dose).

IM, intramuscular; IV, intravenous; po, orally.

Data from reference 5.

H. influenzae and *M. catarrhalis*, against which amoxicillin may not be effective. This is because both *H. influenzae* and *M. catarrhalis* are more likely than *S. pneumoniae* to lead to a spontaneous resolution of the infection.

If a patient has received amoxicillin in the last 30 days, has concurrent purulent conjunctivitis, or has a history of recurrent infection unresponsive to amoxicillin, then they should receive high-dose amoxicillin-clavulanate (90 mg/kg/day of amoxicillin, with 6.4 mg/kg/day of clavulanate, in two divided doses) instead of amoxicillin. Amoxicillin-clavulanate has activity against β-lactamase-producing *H. influenzae* and *M. catarrhalis* as well as drug-resistant *S. pneumoniae*.[5] Other antibiotic choices include cefdinir, cefuroxime, cefpodoxime, and intramuscular or intravenous ceftriaxone.[5] Second-generation cephalosporins, though β-lactamase stable, are expensive, have an increased incidence of side effects, and may increase selective pressure for resistant bacteria. Furthermore, most cephalosporins do not achieve adequate middle ear fluid concentrations against drug-resistant *S. pneumoniae* for the desired duration of the dosing interval. Use of trimethoprim-sulfamethoxazole and erythromycin-sulfisoxazole is discouraged because of high rates of resistance. Intramuscular ceftriaxone is the only antibiotic, other than amoxicillin, that achieves middle ear fluid concentrations above the minimal inhibitory concentration (MIC) for greater than 40% of the dosing interval. Although single doses of ceftriaxone have been used, daily doses for 3 days are recommended to optimize clinical outcomes.[5] Ceftriaxone is more expensive than amoxicillin and the intramuscular injections are painful. Patients with a penicillin allergy can be treated with several alternative antibiotics, including a cephalosporin in cases absent severe or type 1 penicillin allergy, or clindamycin. Notably, clindamycin lacks efficacy against *H. influenzae*, whereas macrolides lack efficacy against both *H. influenzae* and *S. pneumoniae*; therefore, macrolides are not recommended. Finally, tympanocentesis can also be considered for treatment failure or persistent acute otitis media. It has a therapeutic effect of relieving pain and pressure and can be used to collect fluid to identify the causative agent.

There is ongoing debate regarding the optimal duration of therapy for acute otitis media. Traditional recommendations call for 10 days of antibiotic therapy; however, some experts have speculated that patients can be treated for as little as 5 to 7 days. Unfortunately, the data to support the shorter courses are inconclusive, with some studies demonstrating similar outcomes and others demonstrating worse outcomes with short-course therapy.[7] Short-course treatment is not recommended in children younger than 2 years of age. In children at least 6 years of age who have mild to moderate acute otitis media, a 5- to 7-day course may be used.[5]

Clinical **Controversy...**

The 2013 AAP guidelines for acute otitis media recommend an *initial observation* approach prior to administering antibiotics in selected patients.[5] This is because many cases of acute otitis media will resolve without antibiotics, and the guideline authors believe that delayed therapy might serve as a mechanism to reduce antibiotic overuse. A systematic review supports this view, maintaining that antibiotics had only a slight benefit on pain after the first day and only a modest effect on the number of children with tympanic perforations, contralateral otitis episodes, and abnormal tympanometry findings.[12] However, others believe that the modest benefit seen in these systematic reviews is because as many as half of the included patients did not have acute otitis media.[15,16] A placebo-controlled trial, with precise diagnostic criteria, *did* find that antibiotics reduced the time to resolution of middle ear effusion and normal otoscopy findings in children with otitis media.[11] This debate will continue, but there seems to be general agreement that precise diagnostics are key.[5] Unfortunately, there is also debate as to whether such diagnostic approaches are possible in the general clinical setting.[15,17]

Recurrent acute otitis media is defined as at least 3 episodes in 6 months or 4 episodes in 1 year, with 1 episode in the preceding 6 months. Recurrent episodes are of concern because children younger than 3 years of age are at high risk for hearing loss and language and learning disabilities. Clinicians should not prescribe antibiotics as prophylaxis against recurrent episodes, but they may offer tympanostomy tubes (T tubes).[5]

Personalized Pharmacotherapy

Procalcitonin increases in response to bacterial infection and declines as the infection resolves. Clinicians are starting to use procalcitonin blood levels to decide when to initiate and discontinue antibiotics in patients with acute upper respiratory infections (URIs).[18] A Cochrane systematic review of 14 trials with 4,221 participants found that procalcitonin protocols significantly reduced antibiotic consumption without negatively impacting patient survival or treatment failure.[19] The finding was driven by lower prescription rates in primary care and shorter durations of antibiotic therapy in emergency departments and intensive care units.[19] Despite the enthusiasm for this approach, there are still several aspects of procalcitonin monitoring that need to be resolved, including the timing of levels, the procalcitonin cutoff values for different clinical decision points, and the cost-effectiveness of this technology.[20]

Evaluation of Therapeutic Outcomes

Patients with acute otitis media should be reassessed after 48 to 72 hours. By this time, there should be clinical improvement in the signs and symptoms of infection, including pain, fever, and erythema/bulging of the tympanic membrane. If the patient has not responded and antibiotics were withheld initially, they should be instituted now. If the patient initially received an antibiotic, then the antibiotic should be changed (Table 108-1). Most children will become asymptomatic at 7 days.

Early reevaluation of the eardrum when signs and symptoms are improving can be misleading because effusions persist. Over a period of 1 week, changes in the eardrum normalize, and the pus becomes serous fluid. Air-fluid levels are apparent behind the eardrum, at which point the stage is now referred to as *otitis media with effusion*. This does not represent ongoing infection, nor are additional antibiotics required.[5]

Immediate reevaluation is appropriate if hearing loss results from persistent middle ear effusions following infection. Complications of otitis media are infrequent but include mastoiditis, bacteremia, meningitis, and auditory sequelae with the potential for speech and language impairment.[5]

ACUTE BACTERIAL RHINOSINUSITIS

Sinusitis is an inflammation and/or infection of the paranasal sinuses, or membrane-lined air spaces, around the nose.[21] The term *rhinosinusitis* is now preferred because sinusitis typically also involves the nasal mucosa.[21] Even though the majority of rhinosinusitis infections are viral in origin, antibiotics are frequently prescribed. It is thus important to differentiate between viral and bacterial rhinosinusitis to avoid antibiotic overuse.

Clinical practice guidelines for acute bacterial rhinosinusitis were published in 2012.[21] Several of the recommendations in these guidelines differ substantially from prior guidelines.

Epidemiology

1 Nearly 30 million cases of rhinosinusitis are diagnosed annually in the United States.[22] Acute bacterial rhinosinusitis is overdiagnosed; thus, antibiotics are overprescribed. Most rhinosinusitis infections have a viral etiology, and yet, antibiotics are frequently prescribed. Adults with rhinosinusitis miss an average of 6 workdays/y with these infections.[23] Patients with rhinosinusitis are significantly more likely to use the emergency room, spend more than $500/y on medical care, and see a medical specialist.[23]

Etiology

2 Acute bacterial rhinosinusitis is caused, most often, by the same bacteria implicated in acute otitis media: *S. pneumoniae* and *H. influenzae*. These organisms are responsible for approximately 50% to 70% of bacterial causes of acute bacterial rhinosinusitis in both adults and children.[21] *M. catarrhalis* is also sometimes implicated in adults and children (approximately 8%-16%).[21] *Streptococcus pyogenes*, *Staphylococcus aureus*, gram-negative bacilli, and anaerobes are associated less frequently with acute bacterial rhinosinusitis.[21] Issues of bacterial resistance are similar to those found with acute otitis media.

Pathophysiology

Similar to acute otitis media, acute bacterial rhinosinusitis is often preceded by a viral respiratory tract infection that causes mucosal inflammation. This can lead to obstruction of the sinus ostia—the pathways that drain the sinuses.[6] Mucosal secretions become trapped, local defenses are impaired, and bacteria from adjacent surfaces begin to proliferate. The maxillary and ethmoid sinuses are most frequently involved.[6] The pathogenesis of chronic rhinosinusitis has not been well studied. Whether it is caused by more persistent pathogens or a subtle defect in the host's immune function, some patients develop chronic symptoms after their acute infection.

Clinical Presentation

The greatest barrier to efficient use of antibiotics in acute bacterial rhinosinusitis is the lack of a simple and accurate diagnostic test. The gold standard for diagnosis is sinus puncture with recovery of bacteria in high density (10^4 colony-forming units/mL [10^7 cfu/L]

CLINICAL PRESENTATION — Acute Bacterial Rhinosinusitis

General

- There are three clinical presentations that are most consistent with acute bacterial versus viral rhinosinusitis:
- Onset with *persistent* signs or symptoms compatible with acute rhinosinusitis, lasting for ≥ 10 days without any evidence of clinical improvement
- Onset with *severe* signs or symptoms of high fever (≥39°C [102.2°F]) and purulent nasal discharge or facial pain lasting for at least 3 to 4 consecutive days at the beginning of illness
- Onset with *worsening* signs or symptoms characterized by new-onset fever, headache, or increase in nasal discharge following a typical viral URI that lasted 5 to 6 days and were initially improving ("double sickening")

Signs and Symptoms

- Purulent anterior nasal discharge, purulent or discolored posterior nasal discharge, nasal congestion or obstruction, facial congestion or fullness, facial pain or pressure, fever, headache, ear pain/pressure/fullness, halitosis, dental pain, cough, and fatigue

Data from reference 21.

or greater)[21]; however, sinus puncture is invasive and costly, and can be painful, so it is not routinely done. Sinus radiography can help, but it is not routinely recommended. Because there is no simple and accurate office-based test for acute bacterial rhinosinusitis, clinicians rely on clinical findings to make the diagnosis.

TREATMENT

Desired Outcomes

The goals of treatment for acute bacterial rhinosinusitis are to reduce signs and symptoms, achieve and maintain patency of the ostia, limit antibiotic treatment to those who may benefit, eradicate the bacterial infection with appropriate antibiotic therapy, minimize the duration of illness, prevent complications, and prevent progression from acute disease to chronic disease.

General Approach to Treatment

4 The first step is to delineate viral and bacterial rhinosinusitis. This is based on disease duration, initial severity of illness, and worsening symptomatology. Viral rhinosinusitis typically improves in 7 to 10 days; therefore, a diagnosis of acute bacterial rhinosinusitis requires persistent symptoms (10 days or greater) or a worsening of symptoms after 5 to 6 days. Acute bacterial rhinosinusitis may also be suspected if the patient has severe symptoms at the beginning of his/her illness. Amoxicillin-clavulanate is now recommended as the first-line antibiotic therapy for patients with acute bacterial rhinosinusitis.[21] Adjuvant, nonantibiotic therapies have a limited role.

The next step is to decide if the patient needs to be referred to a specialist. Potential reasons for referral include mental status changes, visual disturbances, immunosuppressive illness, nosocomial infections, anatomic defects causing obstruction and possibly requiring surgery, unusually severe symptoms, multiple recurrent episodes (3-4/y), unilateral findings, significant coexisting illnesses, risk factors for unusual or resistant pathogens, and history of antibiotic failure. The specialist may perform computed tomography to assess the severity and extent of disease and identify the underlying causes.

Nonpharmacologic Therapy

Several nonprescription therapies are used in the management of *nonbacterial rhinosinusitis* for symptomatic relief. These include nasal decongestant sprays that reduce inflammation by vasoconstriction. Use should be limited to no more than 3 days to prevent the development of tolerance and/or rebound congestion. Oral decongestants may also aid in nasal/sinus patency. Irrigation of the nasal cavity with saline and steam inhalation may be used to increase mucosal moisture, and mucolytics (eg, guaifenesin) may be used to decrease the viscosity of nasal secretions.

In contrast, if a patient is suspected of having *acute bacterial rhinosinusitis*, then decongestants and antihistamines are not recommended.[21] These can dry mucosa and disturb clearance of mucosal secretions. Other therapies are recommended to be used as adjuncts to antibiotics for patients with acute bacterial rhinosinusitis. Intranasal saline irrigation with either physiologic or hypertonic saline is recommended for adults,[21] but the evidence from a Cochrane review is unimpressive.[24] Intranasal corticosteroids are now recommended for patients with a history of allergic rhinitis.[25]

Pharmacologic Therapy

Several prestigious groups have published statements and clinical practice guidelines for the management of patients with acute bacterial rhinosinusitis, including the Academy of Pediatrics, the Sinus and Allergy Health Partnership, the American Academy of Otolaryngology—Head and Neck Surgery, the Agency for Healthcare Research and Quality, and the Joint Task Force on Practice Parameters, representing the American Academy of Allergy, Asthma, and Immunology, the American College of Allergy, Asthma, and Immunology, and the Joint Council of Allergy, Asthma, and Immunology. The Infectious Diseases Society of America (IDSA) published their clinical practice guideline in 2012;[21] these guidelines are the primary source for many of the statements in this chapter.

5 Amoxicillin-clavulanate is now the first-line treatment for acute bacterial rhinosinusitis in children and adults (Tables 108-2 and 108-3).[21] In contrast, prior guidelines, including the ones published by the Canadian government in 2011,[26] list amoxicillin as the first-line treatment option due to its safety, narrow spectrum of activity, good tolerability, and favorable cost. A randomized controlled trial questioned the value of amoxicillin in nonsevere cases of acute bacterial rhinosinusitis.[27] The IDSA guidelines support the choice of amoxicillin-clavulanate based on (a) the emergence of *H. influenzae* as a more common cause of upper respiratory tract infections in children than in the past[7,28] and (b) the high prevalence of β-lactam-producing respiratory pathogens in acute bacterial rhinosinusitis (particularly *H. influenzae* and *M. catarrhalis*). Recall that approximately 30% to 40% of *H. influenzae* and greater than 90% of *M. catarrhalis* isolates from the upper respiratory tract produce β-lactamases.[9] The advantage of using amoxicillin-clavulanate, as compared with amoxicillin, is a greater spectrum of coverage. The disadvantages are increased cost, greater risk of adverse effects including diarrhea, and an added risk of hypersensitivity to the clavulanate component.[21] No other antibiotics are recommended as first-line for initial empirical therapy.

High-dose amoxicillin-clavulanate is recommended as second-line for initial empirical therapy in children and adults; doxycycline is also second-line for adults but should be avoided in children.[21] High-dose amoxicillin-clavulanate is preferred in the following situations: (a) geographic regions with high endemic rates (10% or greater) of invasive penicillin-nonsusceptible *S. pneumoniae*, (b) severe infection, (c) attendance at daycare, (d) age less than 2 or greater than 65 years, (e) recent hospitalization, (f) antibiotic use within the last month, and (g) immunocompromised persons.[21] Severe infections are those with "evidence of systemic toxicity with fever of 39°C (102.2°F) or higher, and threat of suppurative complications."[21]

Clinical **Controversy...**

The IDSA guidelines support the use of intranasal corticosteroids for patients with acute bacterial rhinosinusitis, especially those who also have a history of allergic rhinitis; however, the guidelines are silent regarding the use of oral corticosteroids.[21] A Cochrane systematic review identified four randomized controlled trials with a total of 1,008 adult participants with acute bacterial rhinosinusitis.[29] All participants received oral antibiotics and either oral corticosteroids (prednisone 24-80 mg daily or betamethasone 1 mg daily) or a control treatment (placebo in three trials, nonsteroidal antiinflammatory drugs in one trial). All four trials observed faster resolution or improvement in symptoms among the patients who received oral corticosteroids. These studies did not report any information regarding the long-term effects of oral corticosteroids, such as relapse and recurrence of acute bacterial rhinosinusitis. This systematic review supports the use of oral corticosteroids as adjuvant therapy to antibiotics for the treatment of acute bacterial rhinosinusitis.

If a child has a β-lactam allergy, he/she may receive levofloxacin monotherapy or clindamycin plus cefixime or cefpodoxime combination therapy.[21] Adults may receive doxycycline, levofloxacin, or

TABLE 108-2 Antibiotics and Doses for Acute Bacterial Rhinosinusitis in Children

Antibiotic	Brand Name	Dose	Comments
Initial Empirical Therapy			
Amoxicillin-clavulanate	Augmentin®	45 mg/kg/day orally twice daily	First-line
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally twice daily	Second-line
***β*-Lactam Allergy**			
Clindamycin plus cefixime or cefpodoxime	Cleocin®, Suprax®, Vantin®	Clindamycin (30-40 mg/kg/day orally three times daily) plus cefixime (8 mg/kg/day orally twice daily) or cefpodoxime (10 mg/kg/day orally twice daily)	Non-type 1 allergy
Levofloxacin	Levaquin®	10-20 mg/kg/day orally every 12-24 hours	Type 1 allergy
Risk for Antibiotic Resistance or Failed Initial Therapy			
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally twice daily	
Clindamycin plus cefixime or cefpodoxime	Cleocin®, Suprax®, Vantin®	Clindamycin (30-40 mg/kg/day orally three times daily) plus cefixime (8 mg/kg/day orally twice daily) or cefpodoxime (10 mg/kg/day orally twice daily)	
Levofloxacin	Levaquin®	10-20 mg/kg/day orally every 12-24 hours	
Severe Infection Requiring Hospitalization			
Ampicillin-sulbactam	Unasyn®	200-400 mg/kg/day IV every 6 hours	
Ceftriaxone	Rocephin®	50 mg/kg/day IV every 12 hours	
Cefotaxime	Claforan®	100-200 mg/kg/day IV every 6 hours	
Levofloxacin	Levaquin®	10-20 mg/kg/day IV every 12-24 hours	

Data from reference 21.

moxifloxacin monotherapy.[21] The guidelines also provide several options for patients at risk for antibiotic resistance, who failed initial therapy, or who have a severe infection requiring hospitalization (Tables 108-2 and 108-3).[21] Notably, cephalosporins are no longer recommended as monotherapy due to variable rates of resistance against *S. pneumoniae*.[21] Macrolides are no longer recommended because of high rates of *S. pneumoniae* resistance.[21] Trimethoprim-sulfamethoxazole has not been recommended for some time due to resistance among *S. pneumoniae* and *H. influenzae*.[21]

The duration of therapy for the treatment of acute bacterial rhinosinusitis is not well established. Most trials have used 10- to 14-day antibiotic courses for uncomplicated rhinosinusitis, and the guidelines support this treatment duration in children.[21] For adults, the recommended duration is only 5 to 7 days.[21]

Personalized Pharmacotherapy

There is limited evidence to suggest that people with certain genetic polymorphisms may be at greater risk for chronic rhinosinusitis[30]; however, no such link has been identified for acute bacterial rhinosinusitis. Furthermore, patient genetics are not currently used to guide selection of antibiotic therapy for this condition. It is important to consider patient weight and renal function when selecting

TABLE 108-3 Antibiotics and Doses for Acute Bacterial Rhinosinusitis in Adults

Antibiotic	Brand Name	Dose	Comments
Initial Empirical Therapy			
Amoxicillin-clavulanate	Augmentin®	500 mg/125 mg orally three times daily, or 875 mg/125 mg orally twice daily	First-line
Amoxicillin-clavulanate	Augmentin®	2,000 mg/125 mg orally twice daily	Second-line
Doxycycline		100 mg orally twice daily or 200 mg orally once daily	Second-line
***β*-Lactam Allergy**			
Doxycycline		100 mg orally twice daily or 200 mg orally once daily	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Risk for Antibiotic Resistance or Failed Initial Therapy			
Amoxicillin-clavulanate	Augmentin®	2,000 mg/125 mg orally twice daily	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Severe Infection Requiring Hospitalization			
Ampicillin-sulbactam	Unasyn®	1.5-3 g IV every 6 hours	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Ceftriaxone	Rocephin®	1-2 g IV every 12-24 hours	
Cefotaxime	Claforan®	2 g IV every 4-6 hours	

Data from reference 21.

antibiotic therapy for acute bacterial rhinosinusitis. Notice that all of the antibiotics recommended for children are dosed according to patient weight. Furthermore, most of the recommended antibiotics are excreted through the kidneys and should be adjusted for renal function as described in the package labeling.

Evaluation of Therapeutic Outcomes

If symptoms persist or worsen after 48 to 72 hours of appropriate antibiotic therapy, then the patient should be reevaluated and alternative antibiotics should be considered.[21] Patients who do not respond to first- or second-line therapies should be referred to a specialist and worked up more aggressively, potentially with direct sinus aspiration or contrast-enhanced computed tomography.[21]

ACUTE PHARYNGITIS

1 2 Pharyngitis is an acute infection of the oropharynx or nasopharynx.[31] It is responsible for 1% to 2% of all outpatient visits.[32] Although viral causes are most common, group A β-hemolytic *Streptococcus* (GABHS; also known as *S. pyogenes*), is the primary bacterial cause;[31] pharyngitis due to GABHS is commonly known as "strep throat."

Clinical practice guidelines for GABHS were published in 2012.[31] Several of the recommendations in these guidelines differ substantially from prior guidelines.

Epidemiology

Acute pharyngitis accounts for approximately 2 million emergency department and outpatient department visits/y,[2] at a cost of up to $539 million for children alone.[31] Although viral causes are most common, GABHS is the primary bacterial cause and is associated with rare but severe sequelae if not treated appropriately.[31] Suppurative and nonsuppurative complications include acute rheumatic fever, acute glomerulonephritis, reactive arthritis, peritonsillar abscess, retropharyngeal abscess, cervical lymphadenitis, mastoiditis, otitis media, rhinosinusitis, and necrotizing fasciitis.

Although all age groups are susceptible, epidemiologic data demonstrate certain groups are at higher risk. Children 5 to 15 years of age are most susceptible; parents of school-age children and those who work with children are also at increased risk. Pharyngitis in a child younger than 3 years of age is rarely caused by GABHS.[31]

Seasonal outbreaks occur, and the incidence of GABHS is highest in winter and early spring.[31] The incubation period is 2 to 5 days, and the illness often occurs in clusters.[31] Spread occurs via direct contact (usually from hands) with droplets of saliva or nasal secretions, and transmission is thus worse in institutions, schools, families, and crowded areas.[31] Untreated, patients with streptococcal pharyngitis are infectious during the acute illness and for another week thereafter. Effective antibiotic therapy reduces the infectious period to about 24 hours.

Acute rheumatic fever is rarely seen in developed countries. In the United States, acute rheumatic fever secondary to GABHS infection was a cause of concern in the 1950s and was the major reason for penicillin therapy, but the annual incidence of this disease today is extremely rare (1 case or more per 1 million population); however, some risk does remain. Outbreaks have been reported in the United States as recently as the late 1980s and early 1990s. Furthermore, acute rheumatic fever is widespread in developing countries.

Etiology

1 Viruses cause the majority of acute pharyngitis cases. Specific etiologies include rhinovirus (20%), coronavirus (5%), adenovirus (5%), herpes simplex virus (4%), influenza virus (2%), parainfluenza virus (2%), and Epstein–Barr virus (1%).[31,32]

4 A bacterial etiology is far less likely. Of all the bacterial causes, GABHS is the most common (10%-30% of persons of all ages with pharyngitis) and is the only commonly occurring form of acute pharyngitis for which antibiotic therapy is indicated.[31] In the pediatric population, GABHS causes 15% to 30% of pharyngitis cases. In adults, GABHS is responsible for 5% to 15% of all symptomatic episodes of pharyngitis.[31]

Other, less common causes of acute pharyngitis, are groups C and G *Streptococcus*, *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *Mycoplasma pneumoniae*, *Arcanobacterium haemolyticum*, *Yersinia enterocolitica*, and *Chlamydia pneumoniae*.[31] Treatment options for these organisms are not addressed in this chapter.

Pathophysiology

The mechanism by which GABHS causes pharyngitis is not well defined. Asymptomatic pharyngeal carriers of the organism may have an alteration in host immunity (eg, a breach in the pharyngeal mucosa) and the bacteria of the oropharynx may migrate to cause an infection. Pathogenic factors associated with the organism itself may also play a role. These include pyrogenic toxins, hemolysins, streptokinase, and proteinase.

Clinical Presentation

Sore throat is the most common symptom of pharyngitis. Accurate differentiation of GABHS from pharyngitis caused by other agents is important for treatment decisions; however, this can be difficult even for experienced clinicians. Therefore, microbiologic testing is recommended for symptomatic patients unless they have symptoms suggestive of viral etiology or are younger than 3 years of age.[31]

In previous guidelines, clinical scoring systems, such as the Centor criteria or modifications of the Centor criteria, have been advocated for clinical diagnosis in adults as a way to overcome the lack of sensitivity and specificity of clinician judgment and to avoid laboratory testing of all patients; however, guidelines from Infectious Disease Society of America and the American Heart Association suggest testing be done in all patients with signs and symptoms of streptococcal pharyngitis.[31] Only those with a positive test for GABHS require antibiotic treatment.[31,33] Laboratory tests should not be performed unless the patient has symptoms consistent with GABHS pharyngitis. This is because a positive test does not necessarily indicate disease. A positive test may simply indicate that the patient is a carrier for GABHS and is not actively infected.

Approximately 20% of children are carriers; the prevalence is lower among adults.[31] There are several options to test for GABHS. A throat swab can be sent for culture or used for the RADT. Cultures are the gold standard, but they require 24 to 48 hours for results. The RADT is more practical in that it provides results quickly, it can be performed at the bedside, and it is less expensive than culture. If RADT is positive, it does not require a follow-up throat culture.[31] If RADT yields negative test results, it is generally recommended to follow up with a throat culture to confirm the results for children and adolescents, but not necessary in adults.[31] Delaying therapy while awaiting culture results does not affect the risk of complications (although some argue that symptomatic benefit is postponed, and contagion remains), and patients must be educated as to the value of waiting, given the low false-negative rate of RADT.[33]

TREATMENT

Desired Outcomes

The goals of treatment for pharyngitis are to improve clinical signs and symptoms, minimize adverse drug reactions, prevent transmission to close contacts, and prevent acute rheumatic fever and

suppurative complications, such as peritonsillar abscess, cervical lymphadenitis, and mastoiditis.[31]

General Approach to Treatment

Once the diagnosis of GABHS pharyngitis has been made, the clinician must decide appropriate supportive care, when to initiate antibiotic therapy, the appropriate antibiotic, and the duration of therapy. The selection of appropriate antibiotic therapy will involve careful consideration of cost, safety, efficacy, potential for regimen adherence, and bacterial resistance rates. Clinicians should be aware of local resistance patterns, which may differ from the national patterns.

4 Antibiotic overuse has been well documented.[31,32] Antibiotics are prescribed for 60% of patients who visit their provider with a complaint of "sore throat."[34,35] This rate is well above the incidence of GABHS pharyngitis. Antibiotic therapy should be reserved for those patients with clinical and epidemiologic features of GABHS pharyngitis, preferably with a positive laboratory test. Empirical therapy is not recommended unless there is a high index of suspicion based on clinical or epidemiologic data and laboratory results are pending. However, it is important to discontinue empirical antibiotics if laboratory results are negative.

Nonpharmacologic Therapy

Supportive care should be offered to all patients with acute pharyngitis. Little evidence is available for nonpharmacologic therapy for pharyngitis. However, pharmacologic supportive care interventions include antipyretic medications, analgesics, and nonprescription lozenges and sprays containing menthol and topical anesthetics for temporary relief of pain.[31] There are limited data for use of corticosteroids to reduce the symptoms of GABHS pharyngitis, and given the risk of adverse effects, their use is not recommended.[31] Because pain is often the primary reason for visiting a physician, emphasis on analgesics such as acetaminophen and nonsteroidal antiinflammatory drugs to aid in pain relief is strongly recommended.

Pharmacologic Therapy

The clinical practice guidelines published by the IDSA in 2012 are the primary source for many of the recommendations in this chapter.[31] Tables 108-4 and 108-5 outline dosing for acute GABHS pharyngitis and chronic carriers of GABHS.

5 For over 30 years, GABHS isolated in the United States have been susceptible to penicillin, with no reported cases of GABHS resistance to penicillin.[31] Because penicillin and amoxicillin have a narrow spectrum of activity and are readily available, safe, and inexpensive, they are considered to be the treatments of choice.[31,33] In a controlled study that demonstrated that antibiotic therapy prevents rheumatic fever following GABHS pharyngitis was done with procaine penicillin, which was later replaced with benzathine penicillin.[33] Penicillin given by other routes is assumed to be equally efficacious. The ability of other antibiotics to eradicate GABHS has led to extrapolation that these antibiotics will also prevent rheumatic fever.[33]

Amoxicillin may be preferable for children with GABHS pharyngitis because the suspension is more palatable than penicillin.[31] Gastrointestinal (GI) adverse effects and rash are more common with amoxicillin. A once-daily, extended-release formulation of amoxicillin has been approved for treatment of GABHS pharyngitis in adults and children aged 12 years and older.[31]

If patients are unable to take oral medications, intramuscular benzathine penicillin can be given, although it is painful.[31] In penicillin-allergic patients, azithromycin, clarithromycin, clindamycin, or a first-generation cephalosporin such as cephalexin can be used if the reaction is non–immunoglobulin E (IgE)-mediated.[31,33] Newer macrolides, such as azithromycin and clarithromycin, are equally effective as erythromycin and cause fewer GI adverse effects; therefore, these newer macrolides are preferred to erythromycin. GABHS resistance to macrolides is low (5%-8%) in the United States, but is higher in some other areas of the world.[31]

In previous pharyngitis guidelines, clindamycin was only an alternative to erythromycin-resistant strains; however, it is now considered an acceptable alternative for penicillin-allergic patients due to the low GABHS resistance rate of 1%.[31,33] Tonsillectomy is not recommended because a Cochrane review found that its impact on "sore throat" due to pharyngitis is unpredictable.[36]

GABHS resistance rates to tetracyclines are high. Sulfonamides and trimethoprim-sulfamethoxazole have poor eradication rates for GABHS; therefore, use of these antibiotics is no longer recommended.[31] Fluoroquinolones are not recommended due to poor activity of the older agents. The newer fluoroquinolones have activity against GABHS, but are expensive and have a broad spectrum of activity.[31,33]

CLINICAL PRESENTATION — Group A Streptococcal Pharyngitis

General

- A sore throat of sudden onset that is mostly self-limited
- Fever and constitutional symptoms resolving in about 3 to 5 days
- Clinical signs and symptoms are similar for viral causes and nonstreptococcal bacterial causes

Signs and Symptoms of GABHS Pharyngitis

- Sore throat
- Pain on swallowing
- Fever
- Headache, nausea, vomiting, and abdominal pain (especially in children)
- Erythema/inflammation of the tonsils and pharynx with or without patchy exudates
- Enlarged, tender lymph nodes
- Red swollen uvula, petechiae on the soft palate, and a scarlatiniform rash

Signs Suggestive of Viral Origin for Pharyngitis

- Conjunctivitis
- Coryza
- Cough

Laboratory Tests

- Throat swab and culture
- Rapid antigen-detection test (RADT)

Data from reference 31.

TABLE 108-4 Antibiotics and Doses for Group A β-Hemolytic Streptococcal Pharyngitis

Antibiotic	Brand Name	Dose	Duration	Rating
Preferred Antibiotics				
Penicillin V	Pen-V®	Children: 250 mg twice daily or three times daily orally Adult: 250 mg four times daily or 500 mg twice daily orally	10 days	IB
Penicillin G benzathine	Bicillin L-A®	< 27 kg: 0.6 million units; 27 kg or greater: 1.2 million units intramuscularly	One dose	IB
Amoxicillin[a]	Amoxil®	50 mg/kg once daily (maximum 1,000 mg); 25 mg/kg (maximum 500 mg) twice daily	10 days	IB
Penicillin Allergy				
Cephalexin	Keflex®	20 mg/kg/dose orally twice daily (maximum 500 mg/dose)	10 days	IB
Cefadroxil	Duricef®	30 mg/kg orally once daily (maximum 1 g)	10 days	IB
Clindamycin	Cleocin®	7 mg/kg/dose orally thrice daily (maximum 300 mg/dose)	10 days	IIaB
Azithromycin[b]	Zithromax®	12 mg/kg orally once daily (maximum 500 mg) for one day, then 6mg/kg orally once daily (maximum 250 mg) for four days	5 days	IIaB
Clarithromycin[b]	Biaxin®	15 mg/kg orally per day divided in two doses (maximum 250 mg twice daily)	10 days	IIaB

These guidelines provide a systematic weighting of the strength of the recommendation (Class I, conditions for which there is evidence and/or general agreement that a given procedure or treatment is beneficial, useful, and effective; Class II, conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment; Class IIa, weight of evidence/opinion is in favor of usefulness/efficacy; Class IIb, usefulness/efficacy is less well established by evidence/opinion; Class III, conditions for which there is evidence and/or general agreement that a procedure/treatment is not useful/effective and in some cases may be harmful) and quality of evidence (A, data derived from multiple randomized clinical trials or meta-analyses; B, data derived from a single randomized trial or nonrandomized studies; C, only consensus opinion of experts, cases studies, or standard of care).

[a]Standard formulation, not extended release.

[b]Resistance of group A β-hemolytic *Streptococcus* (GABHS) to these agents may vary and local susceptibilities should be considered with these agents.

Data from reference 31.

The ideal time to start antibiotics has not been established. The immediate start of antibiotics does not affect the risk of developing rheumatic fever, and no evidence suggests that it reduces recurrent infection.[33] Clinical guidelines recommend withholding antibiotics unless the patient has a positive laboratory result.[31,33]

The impact of appropriate antibiotic therapy is limited to decreasing the duration of signs and symptoms. It can decrease the severity of pharyngitis symptoms and communicability of the disease after 24 hours of antibiotic therapy.[37] The duration of therapy for GABHS pharyngitis is 10 days, except for benzathine penicillin and azithromycin, to maximize bacterial eradication.[31] A Cochrane review, published in 2012, examined short course therapy and concluded that 3 to 6 days of oral antibiotics had comparable efficacy to oral penicillin for 10 days.[38] Although some clinicians have proposed shorter courses of treatment for pharyngitis, confounding factors from these studies, such as the lack of strict entry criteria or differentiation between new and failed infections, limit the widespread application of short antibiotic courses at this time.[31]

Approximately 33% of household contacts of a person with acute GABHS pharyngitis harbor GABHS in their upper respiratory tracts.[31] Routine testing and/or treating of asymptomatic household contacts of an index patient is not recommended.[31] GABHS carriers do not need antimicrobial therapy due to very low risk of spreading GABHS pharyngitis or developing suppurative or nonsuppurative complications.[31] If tested, it is not necessary to treat these asymptomatic carriers. It is difficult to ascertain the cause of symptomatic pharyngitis in carriers of GABHS if they do develop symptoms. Providers should pay close attention to the symptoms to help differentiate viral versus bacteriologic cause of pharyngitis because laboratory tests will be positive in these patients.[31]

TABLE 108-5 Antibiotics and Doses for Eradication of Group A β-Hemolytic Streptococcal Pharyngitis in Chronic Carriers

Antibiotic	Brand Name	Dose
Clindamycin	Cleocin®	20-30 mg/kg/day orally in three divided doses (maximum 300 mg/dose)
Amoxicillin-clavulanate	Augmentin®	40 mg/kg/day orally in three divided doses (maximum 2,000 mg/day of amoxicillin)
Penicillin V and rifampin	Pen-V®, Rifadin®	Penicillin V: 50 mg/kg/day orally in four doses for 10 days (maximum 2,000 mg/day); *and* rifampin: 20 mg/kg/day orally in one dose for the last 4 days of treatment (maximum 600 mg/day)
Penicillin G benzathine and rifampin	Bicillin L-A®, Rifadin®	Penicillin G benzathine: < 27 kg—0.6 million units; 27 kg or greater—1.2 million units intramuscularly; *and* rifampin: 20 mg/kg/day orally in two doses during last 4 days of treatment with penicillin (maximum 600 mg/day)

Data from reference 31.

Clinical **Controversy...**

The ISDA pharyngitis guidelines recommend a 10-day course of appropriate antibiotics to achieve maximal rates of pharyngeal eradication of GABHS.[31] However, there has been increased interest in shorter courses of treatment to help improve adherence. Three antibiotics have been approved for 5-day course of therapy for GABHS pharyngitis, but these agents are not recommended as first-line therapy. The clinical trials for shorter course of antibiotic therapy tend to have less strict entry criteria, no assessment of adherence to therapy, and do not report details of outcomes, such as treatment failure or new infection. A Cochrane Review showed comparable efficacy for 3- to 6-day courses of therapy as compared to a 10-day course of oral penicillin.[38] The feasibility of shorter course therapy becoming a first-line recommendation needs to be determined in additional studies.

When acute GABHS pharyngitis occurs in a carrier, a treatment course of appropriate antibiotics is recommended.[31,33] In the treatment of recurring episodes of culture-positive GABHS pharyngitis, there are limited data to support a particular antibiotic regimen. Several alternative antibiotics are preferred over penicillin or amoxicillin with GABHS carriers and recurrent pharyngitis. Amoxicillin-clavulanate, clindamycin, penicillin/rifampin combination, and benzathine penicillin G/rifampin combination may be considered for recurrent episodes of pharyngitis to maximize bacterial eradication in potential carriers and to counter copathogens that produce β-lactamases.[31] Table 108-5 outlines dosing for eradication of GABHS in chronic carriers and those who experience symptomatic episodes.

Patients with documented histories of rheumatic fever (including cases manifested solely by Sydenham's chorea) and those with definite evidence of rheumatic heart disease should receive continuous prophylaxis initiated as soon as the patient is diagnosed and the initial infection has been treated. The duration of secondary prophylaxis is individualized based on patient risk of recurrence of rheumatic fever and/or rheumatic heart disease. Intramuscular benzathine penicillin G every 4 weeks is the recommended regimen for secondary prevention in the United States in most circumstances.[33] Additional options for secondary prophylaxis include oral penicillin V and sulfadiazine. Medication adherence is critical for successful secondary prevention with oral antibiotics. Sulfadiazine is an effective antibiotic for the prevention of infection and is appropriate if the patient is penicillin-allergic. Sulfonamides are not appropriate for treatment of GABHS pharyngitis because they are not effective for eradication of GABHS. If individuals are allergic to penicillin and sulfadiazine, a macrolide or azalide is recommended; however, this recommendation is based on expert opinion rather than clinical trial data.[33]

Personalized Pharmacotherapy

Currently, there are no pharmacogenetic or genomic factors involved in the diagnosis or treatment of GABHS pharyngitis. Factors that should be considered when personalizing therapy for a patient include allergy status, prior antibiotic use, and adherence. Those with a history of antibiotic use for acne may be at higher risk for resistant strains of GABHS. Short-course antibiotics or penicillin G benzathine may be considered in patients with a history of nonadherence.

Evaluation of Therapeutic Outcomes

Most pharyngitis cases are self-limited; however, antibiotics hasten resolution when given early for proven cases of GABHS pharyngitis.[31] Generally, fever and other symptoms resolve within 3 to 4 days of onset without antibiotics; however, symptoms will improve 0.5 to 2.5 days earlier with antibiotic therapy.[31] Follow-up testing is generally not necessary for index cases or asymptomatic contacts;[31] however, throat cultures 2 to 7 days after completion of antibiotics are warranted for patients who remain symptomatic or when symptoms recur despite completion of treatment.[33]

Influenza

Jessica C. Njoku

KEY CONCEPTS

1. Influenza is a viral illness associated with high mortality and high hospitalization rates among persons older than 65 years of age. The aging of the population is contributing to an increased disease burden in the United States.
2. Seasonal influenza epidemics are the result of viral antigenic drift, which is why the influenza vaccine is changed on an yearly basis. Antigenic drift forms the foundation of the recommendation for annual influenza vaccination.
3. The acquisition of a new hemagglutinin and/or neuraminidase by the influenza virus is called *antigenic shift*, which results in a novel influenza virus that has the potential to cause a pandemic.
4. The primary route of influenza transmission is person-to-person via inhalation of respiratory droplets, and transmission can occur for as long as the infected person is shedding virus from the respiratory tract.
5. Clinical diagnosis of influenza is difficult. Classic signs and symptoms include abrupt onset of fever, muscle pain, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms usually resolve within 1 week of presentation.
6. In the United States, the primary mechanism of influenza prevention is annual vaccination. Vaccination not only prevents influenza illness and influenza-related hospitalizations and deaths but may also decrease healthcare resource use and the overall cost to society.
7. The inactivated influenza vaccine (IIV) and the live-attenuated influenza vaccine (LAIV) are commercially available for prevention of seasonal influenza. Both vaccines contain influenza A subtypes H3N2 and H1N1, and influenza B virus, which are initially grown in hens' eggs.
8. Antiviral drugs for prophylaxis of influenza should be considered adjuncts to vaccine and are not replacements for annual vaccination.
9. The sooner antiviral drugs are started after the onset of illness, within 48 hours of symptom onset, the more effective they are.
10. Oseltamivir, zanamivir, and peramivir are neuraminidase inhibitors that have activity against both influenza A and influenza B viruses. Although the adamantanes inherently have activity against influenza A H1N1 viruses, they are no longer used clinically due to overwhelming viral resistance.

Influenza causes significant morbidity and mortality, particularly among young children and the elderly. Seasonal influenza epidemics result in 25 to 50 million influenza cases, approximately 200,000 hospitalizations, and more than 30,000 deaths each year in the United States.[1] Globally, influenza causes nearly 500,000 deaths each year. More people die of influenza than of any other vaccine-preventable illness. Significant societal consequences associated with influenza include visits to physicians' offices and emergency departments and days lost from school and/or work. The societal costs associated with influenza are more than $40 billion in the United States[1] and $16 billion in those older than or equal to 50 years alone.[2]

Vaccination is the primary mechanism of influenza prevention in the United States. The antiviral armamentarium for treatment and prophylaxis of influenza is limited, which further emphasizes the importance of prevention with vaccination and appropriate use of infection control measures during outbreaks. Research toward the development of novel antivirals and vaccines is needed for effective control of seasonal epidemics and for pandemic preparedness.

ETIOLOGY AND EPIDEMIOLOGY

Influenza infection can occur at any time during the year with the highest rates of influenza-associated illness during the winter months. The highest rate of infection occurs in children, but the highest rates of severe illness, hospitalization, and death occur among those older than age 65 years, young children (younger than 2 years old), and those who have underlying medical conditions, including pregnancy and cardiopulmonary disorders, that increase their risk of complications from influenza. 1 The seasonal influenza epidemics from 2012 to 2015 resulted in an average annual laboratory confirmed influenza-associated hospitalization rate of 48.1 per 100,000 person-years.[3] In 2012 to 2013 influenza season alone, the rate of influenza associated hospitalization was 202 (95% confidence interval, 143-260) per 100,000 person-years.[4] Influenza-associated hospitalization rates were four times higher among children aged 0 to 4 years compared with among those aged 5 to 17 years.[3] Similarly, influenza-associated hospitalization rates were 17 times higher, and 6 times higher, among persons older than or equal to 65 years compared with among those aged 18 to 49 years, and 50 to 64 years, respectively.[3] During the 2009 pandemic influenza H1N1pdm09 outbreak, an estimated 137,414 hospital discharges were attributed to influenza.[5] Influenza-related deaths is three times higher in high-risk individuals. From 1997 to 2009, influenza A/H3N2 accounted for 71% of influenza-related mortality, while influenza B was attributed with the most deaths (51%-95%).[7] Approximately 90% of seasonal influenza-related deaths occur in those older than age 65 years, with about 70% of deaths occuring among those older than or equal to 75 years.[6] In 2012 to 2013 influenza season, the rate of influenza associated death was 54.6 (95% confidence interval, 36.2-73.0) per 100,000 person-years among those age 65 years or older, compared to a rate of 1.1, less than18 years or 1.7, 18 to 64 years old.[4] Thus, the aging of the population is contributing to an increased disease burden. Deaths associated with influenza often result from secondary bacterial pneumonia, primary viral pneumonia, and/or exacerbation of underlying comorbidities.[7]

Influenza Viruses A, B, and C

Influenza virus types A, B, and C are members of the Orthomyxoviridae family and affect many species, including humans, pigs, horses, and birds. Influenza A and B viruses are the two types that cause disease in humans. Influenza A viruses are responsible for the regular, seasonal epidemics of the flu, whereas influenza B viruses are typically associated with sporadic outbreaks, particularly among residents of long-term care facilities. Influenza A viruses are further categorized into different subtypes based on changes in two surface antigens—hemagglutinin and neuraminidase (NA). Influenza B viruses are not categorized into subtypes.

Hemagglutinin allows the influenza virus to enter host cells by attaching to sialic acid receptors and is the major antigen to which antibodies are directed on exposure.[8] NA allows the release of new viral particles from host cells by catalyzing the cleavage of linkages to sialic acid.[8]

Sixteen hemagglutinin subtypes (H1-H16) and nine NA subtypes (N1-N9) of influenza A have been isolated from birds. However, the only influenza A subtypes that have circulated among humans since the 1918 pandemic (see Antigenic Drift and Antigenic Shift in the following sections) are H1 to H3 and N1 and N2.[8] The primary subtypes of influenza A that have been circulating among humans for the past three decades are H3N2 and H1N1.

Antigenic Drift and Antigenic Shift

2 Immunity to influenza virus occurs as a result of the development of antibody directed at the surface antigens, particularly hemagglutinin. However, immunity to one influenza subtype does not offer protection against other subtypes or types of influenza. Moreover, immunity to one antigenic variant of a subtype of influenza may not confer protection against other antigenic variants. Antigenic variants are created by point mutations in the surface antigens of a particular subtype, resulting in small changes in the hemagglutinin and/or NA molecules, which is called *antigenic drift*. Antigenic drift is the basis for seasonal epidemics of influenza, the reason for changes in the annual influenza vaccine, and the rationale behind the recommendation for annual vaccination.

Immunity to one subtype of influenza does not confer protection against other subtypes or types. 3 Antigenic shift occurs when the influenza virus acquires a new hemagglutinin and/or NA via genetic reassortment rather than point mutations.[4] Most likely, the genetic reassortment occurs when an animal that supports the growth of multiple subtypes of influenza, such as a pig, is concurrently infected with two subtypes of the influenza virus. Conversely, antigenic shift may occur directly from avian strains that have gained competency in the human host. Antigenic shift results in the emergence of a novel influenza virus and carries the potential of causing a pandemic. However, novelty alone is insufficient to cause an influenza pandemic; the virus must be able to replicate in humans, spread person-to-person, and affect a susceptible population.[8]

Spanish Influenza of 1918

The influenza pandemic of 1918 was the most significant infectious disease outbreak known to humans, causing approximately 40 to 50 million deaths in a year, with more than 500,000 deaths occurring in the United States.[9,10] The pandemic occurred almost concurrently in Europe, Asia, and North America.[9]

The 1918 pandemic was caused by a particularly virulent influenza A H1N1 virus, which was entirely of avian origin.[10,11] In contrast to the other pandemics of the 20th century, the 1918 pandemic resulted in an unusual mortality pattern. The mortality peaked for those younger than 4 years of age, those between the ages of 25 and 35 years, and those older than 65 years of age, which resulted in a W-shaped mortality curve, as opposed to the U- or J-shaped curve typically associated with influenza.[10,12] Over half of the deaths occurred in persons aged 20 to 40 years. The death toll associated with this pandemic culminated in an almost 10-year drop in the life expectancy of the population at the time.[10]

Asian Influenza of 1957

The Asian flu pandemic began when a new H2 subtype of influenza A surfaced in Hunan province in China in 1957.[10] The virus appeared to have formed from coinfection with an avian H2N2 virus and a human H1N1 virus in a common host, possibly a pig or a human.[11] The H2N2 virus quickly spread to Japan, South America, the United States, New Zealand, and Europe, resulting in approximately 4 million deaths worldwide, with 70,000 deaths occurring in the United States.[10] Unlike the Spanish flu of 1918, the mortality curve for the Asian flu pandemic was U- or J-shaped, with infants and elderly being most affected.[12]

Hong Kong Influenza of 1968

The H2N2 virus of the Asian flu circulated in the human population until 1968, when a new H3 subtype emerged in China and Hong Kong[12] following genetic reassortment with the H2N2 virus.[10,11] The H3N2 virus quickly spread to the United States and later to Europe. This pandemic caused more than 30,000 deaths in the United States and approximately 2 million deaths worldwide.[10,12] The lower morbidity and mortality associated with the Hong Kong flu may be explained by previous exposure of the population to the N2 subtype, and the availability of antibiotics for the management of secondary bacterial pneumonia. Similar to the Asian flu of 1957, the mortality curve for the Hong Kong flu pandemic was U- or J-shaped, primarily affecting infants and elderly.[12]

Avian Influenza

Influenza viruses are in circulation in southern China during all months of the year.[4] Given this fact and the close proximity of dense populations of people, pigs, and wild and domestic birds, this area proves ideal for the development of new influenza viruses via genetic reassortment (antigenic shift), as demonstrated by the pandemics of 1957 and 1968 and, most recently, the emergence of what is known as avian influenza.[8]

The first report of human infection with the avian H5N1 virus occurred in 1997 in Hong Kong in a 3-year-old who had a direct link with chickens and later died.[13] This was followed by 18 confirmed cases and 6 deaths.[14] The virus reemerged in 2003 as an antigenically and genetically different virus that has spread widely through wild and domestic bird populations in Asia, Africa, and Europe as well as infecting humans in 16 countries: Azerbaijan, Bangladesh, Cambodia, Canada, China, Djibouti, Egypt, Indonesia, Iraq, Lao People's Democratic Republic, Myanmar, Nigeria, Pakistan, Thailand, Turkey, and Vietnam.[12,15] From 2003 to September 10, 2015, a total of 844 cases and 449 deaths caused by H5N1 infection have been reported.[15,16] The current overall case fatality is 53%.

The novel avian influenza H7N9 virus infection was first reported in humans in March 2013, in China.[17] Since the outbreak, only one case of influenza H7N9 has been reported outside of China, and this occurred in Canada in February 2015. Avian influenza A(H7N9) is a subtype of influenza viruses that have been detected in birds in the past, but no previous infection had been documented in animals or people until recently. Other emerging avian H7 virus subtypes with documented infections in humans are H7N3 in Canada, 2004; H7N2 in New York, 2003, and H7N7 in Netherlands, 2003.[18] Majority of avian H7N9 human infection cases have been among those with recent exposure to live poultry or potentially contaminated environments, especially markets where live birds are sold.[17,18] Presently, the virus does not appear to transmit easily from person to person, and sustained human-to-human transmission has

not been reported. Nevertheless, the disease is of concern because patients become severely ill. As of July 16, 2015, a total of 677 cases and 275 deaths caused by H7N9 virus infection have been reported.[16,17] The current overall case fatality is 41%.

In May 2013, the first case of novel avian influenza H6N1 human infection, was reported in Taiwan,[18] and since May 2014, four laboratory-confirmed human case of avian influenza A(H5N6) virus infection were reported to World Health Organization (WHO) from China.[16] To date no evidence of human-to-human transmission of the viruses has been documented. Other influenza A(H5) subtypes, such as influenza A(H5N2), A(H5N3), and A(H5N8), continue to be detected in birds in West Africa, Asia, Europe, and North America.[16] Although influenza A(H5N2), A(H5N3), and A(H5N8) viruses might have the potential to cause disease in humans, so far no human cases of infection have been reported.[16] Other novel avian influenza strains emerging in 1999 (H9N2), with two cases of human infections, and in 2013 (H10N8), with three cases of infections, all in China, continue to be of concern.[18]

The spread of avian influenza viruses from person to person has been reported very rarely, and has been limited, inefficient, and unsustained.[18,19] The precise mode of transmission is unknown, but most cases have occurred as a result of contact with poultry, contaminated environment, and prolonged person-to-person contact.[15-18] Cases of transmission via aerosolization have not been reported.[20] Clinical presentation includes high fever and influenza-like illness, and watery diarrhea without blood may occur up to 1 week prior to respiratory symptoms.[21] Almost all patients have clinically apparent pneumonia. Progression to death, most commonly as a consequence of respiratory failure, occurs a mean of 9 to 10 days after the onset of illness.[15-17,20] The NA inhibitors, oseltamivir, zanamivir, and peramivir, have activity against the avian influenza viruses, although higher doses may be needed. Oseltamivir resistance has been detected in several patients infected with the H5N1 virus who were treated with oseltamivir.[20] Amantadine and rimantadine are ineffective against avian influenza viruses. An inactivated monovalent[22] and an adjuvanted monovalent[23] influenza virus vaccine, against H5N1 is available for vaccination of persons 18 to 64 years of age at increased risk of exposure to the H5N1 influenza virus. The recommended dose is two 1-mL injections given intramuscularly 28 days apart (range, 21 to -35 days) if non-adjuvanted vaccine,[22] or two 0.5-mL injections given 21 days apart if adjuvanted vaccine is used.[23] The vaccines are supplied in a 5-mL multi-dose vial, with ~50 mcg thimerosal per dose in the non-adjuvanted vaccine[22], and 5 mcg thimerosal per dose in the adjuvanted vaccine[23], added as a preservative. The monovalent adjuvanted vaccine is supplied in two separate vials, a vial of H5N1 antigen and a vial of AS03 adjuvant, that must be combined before use, for the final volume per vial that provides 10 doses at 0.5 ml per dose.[23] At the present time, the vaccines are being stockpiled for use if H5N1 begins transmitting easily from person to person. Individuals at high risk, for example, those who work with poultry and H5N1 poultry outbreak responders, are encouraged to receive annual seasonal influenza vaccine to minimize the risk of coinfection with human and avian influenza A viruses.

The potential for avian viruses H5N1 and H7N9 to cause a pandemic is of concern as it could spread more quickly than pandemics of the past because of the mobility of people in today's world. International travel has increased 73% since 1990, with 763 million people crossing international borders in 2004.[21] In 2012 alone, international tourist travels worldwide was projected at 1 billion, which was a 48% increase since 2000.[24] In 2009, the US residents made over 61 million travels outside the country, which was a 5% increase since 1999.[24] A severe pandemic, like that of 1918, could cause more than 9 million hospitalizations and more than 1.9 million deaths, whereas a moderate pandemic, like those of 1957 and 1968, could result in more than 800,000 hospitalizations and more than 200,000 deaths in the United States alone.[12,24]

Swine Influenza of 2009

An outbreak of a novel influenza A H1N1 (formerly swine origin influenza virus [SOIV]) was initially detected in Mexico in March 2009 and subsequently in the United States in April 2009 in California and Texas.[25,26] The virus then spread throughout North America, Europe, Asia, and subsequently worldwide, prompting the WHO on June 11, 2009 to declare phase 6, indicating widespread human infection, for the influenza pandemic.[26] Since 1998, triple reassortant swine influenza A (H1) viruses, containing genes from swine, avian, and human lineages, have circulated among swine in the United States.[25,27]

However, the novel influenza A H1N1 virus is unique in that although much of the genome is similar to the triple reassortant swine viruses previously seen in the United States, the genes encoding for NA and matrix (M) proteins are most similar to those circulating in the Eurasian swine population. This particular genetic combination has not been seen before.[25] The virus, now formally known as influenza A(H1N1) pdm09, has since become the predominant influenza A H1N1 in circulation, effectively replacing traditional seasonal influenza A (H1N1).

Several characteristics of the novel influenza A H1N1 outbreak differ from those of a typical seasonal influenza outbreak. Symptomatology associated with the novel influenza include fever (94%), cough (92%), sore throat (66%), diarrhea (25%), and vomiting (25%).[25,26] An estimated 43 to 89 million cases of 2009 H1N1 occurred between April 2009 and April 2010 with a median 274,000 hospitalizations. Globally, 18,500 laboratory-confirmed H1N1-related deaths were reported; however, this may represent an underestimation of true disease burden.[28] The majority of the cases occurred in otherwise healthy children and young adults younger than 65 years of age including pregnant women, with the highest incidence reported among those aged 18 to 64 years.[28] Contrary to seasonal influenza where about 60% of hospitalizations and 90% of deaths occur in people older than or equal to 65 years, approximately 90% and 87% of 2009 H1N1-related hospitalizations and deaths, respectively, occurred in people younger than 65 years. However, like seasonal influenza, people with underlying health conditions had greater risk of hospitalizations and death. Among those who were deceased due to novel H1N1 infection, the median age was ~40 years and 59% of deaths (respiratory and cardiovascular) occurred in Southeast Asia and Africa.[28]

Variant Influenza A (H3N2v), 2012

H3N2v is a non-human influenza virus that normally circulates in pigs and that has infected humans.[29] In August 2011, the US Centers for Disease Control and Prevention (CDC) reported the first case of an influenza infection due to influenza A H3N2 variant virus (H3N2v).[29] Since then, 345 cases have been documented from 13 states in the United States resulting in 20 hospitalizations and 1 death.[30] Human infections with H3N2v have been limited to the United States. The H3N2v is considered a variant virus because it is different from influenza A viruses circulating among humans. Infections due to variant influenza viruses, for example, A(H1N1)v, A(H3N2)v, and A(H1N2)v of swine origin, have been documented in the past.[29] The H3N2v virus contains genes from avian, swine, and human viruses and the M gene from the 2009 H1N1 pandemic virus (A[H1N1]pdm09).[29] The virus was originally detected in pigs in 2010 but human infection was first documented in July 2011. The virus appears to spread more readily from pigs to people than other variant viruses, but has limited person-to-person transmission. The main risk factor for infection with the virus based on evaluation of available cases is exposure to pigs, mostly in fair settings.[29] Since the virus is related to human flu viruses from the 1990s, most adults have some immunity against it.[29] Hence, most cases to date have occurred in children, who have little immunity against this virus.

The symptoms and severity of H3N2v have mostly been mild and similar to those of seasonal influenza (fever, cough, sore throat, body aches, etc.), but like seasonal influenza, serious illness with H3N2v infection is possible.[29] Vaccination remains key to preventing H3N2v infection. Additionally, the CDC has encouraged people at high risk of influenza complications to stay away from swine barns at fairs.[29,30] People who are at high risk of serious complications from influenza, including H3N2v virus infection, are: children younger than 5 years, people older than or equal to 65 years, pregnant women, and people with certain chronic medical conditions (asthma, diabetes, heart disease, immunocompromised, and neurologic or neurodevelopmental conditions). The treatment of H3N2v virus infection is similar to that of seasonal influenza. NA inhibitors are the mainstay of treatment. The adamantanes should not be used due to high resistance.[29]

PATHOGENESIS

4 The route of influenza transmission is person-to-person via inhalation of respiratory droplets, which can occur when an infected person coughs or sneezes.[31] Transmission may also occur if a person touches an object contaminated with respiratory secretions and then touches his or her mucus membranes. The incubation period for influenza ranges between 1 and 7 days, with an average incubation

CLINICAL PRESENTATION

Diagnosis of Influenza

General

- The clinical diagnosis of influenza can be difficult because the presentation is similar to a number of other respiratory illnesses. The sensitivity of clinical diagnosis ranges from 40% for children to 70% for adults and largely depends on the relative prevalence of influenza and other respiratory viruses circulating in a community.[34]
- The clinical course and outcome are affected by age, immunocompetence, viral characteristics, smoking, comorbidities, pregnancy, and the degree of preexisting immunity.
- Complications of influenza may include exacerbation of underlying comorbidities, primary viral pneumonia, secondary bacterial pneumonia or other respiratory illnesses (eg, sinusitis, bronchitis, otitis), encephalopathy, transverse myelitis, myositis, myocarditis, pericarditis, and Reye's syndrome.

Signs and Symptons

- 5 Classic signs and symptoms of influenza include rapid onset of fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis.
- Nausea, vomiting, and otitis media are also commonly reported in children.[35]
- Signs and symptoms typically resolve in approximately 3 to 7 days, although cough and malaise may persist for more than 2 weeks.
- Primary viral pneumonia, occurring predominantly in pregnant women and in those with underlying cardiovascular disease, usually begins with fever and dry cough, which changes to a productive cough of bloody sputum. This rapidly progresses to dyspnea, hypoxemia, and cyanosis with radiologic evidence of bilateral interstitial infiltrates.[34]
- Secondary bacterial pneumonia is usually seen in individuals with underlying pulmonary disorders and presents during the early stages of defervescence from the influenza infection. These patients usually present with fever, productive cough, and radiologic evidence of consolidation.[34]

Laboratory Tests

- Complete blood count and chemistry panels should be obtained to assess the overall status of the patient.
- The gold standard for diagnosis of influenza are reverse-transcription polymerase chain reaction (RT-PCR) or viral culture, which can provide information on the specific strain and subtype. Viral culture has a high sensitivity but can take as long as a week to develop, limiting the clinical relevance of the results.
- Tests such as the antigen-based rapid influenza diagnostic tests ([RIDTs], also known as point-of-care [POC] tests), direct (DFA) or indirect (IFA) fluorescence antibody tests, and the RT-PCR assay may be used for rapid detection of virus.[36]

Other Diagnostic Tests

- Cultures of potential sites of infection should be obtained if coinfection, superinfection, or secondary infection is suspected.
- Chest radiograph should be obtained if pneumonia is suspected.

Rapid Tests

- RIDTs have allowed for prompt diagnosis and initiation of antiviral therapy and decreased inappropriate use of antibiotics. RIDTs use enzyme immunoassay (EIA) technology to provide results within 1 hour of specimen collection. Appropriate specimens for collection, in decreasing order of sensitivity, are nasopharyngeal aspirates, nasopharyngeal swabs/washes, and oropharyngeal swabs.[36] RIDTs allow for differentiation of influenza viruses A and B, with sensitivity and specificity ranging from 50% to 70% and 85% to 99%, respectively.[36,37] In general, the use of RIDTs is contraindicated in those who have had symptoms for longer than 3 days, and results may be confounded following recent immunization with live-attenuated influenza vaccine (LAIV).[36]
- DFA testing requires more technical expertise and infrastructure than RIDTs. The advantages of DFA are increased sensitivity over RIDTs and simultaneous detection of other respiratory viruses, such as respiratory syncytial virus and adenovirus.[36] DFA provides results between 1 and 4 hours after specimen collection.
- RT-PCR assay is a nucleic acid amplification test and is the most sensitive, specific, and versatile diagnostic test for influenza.[36] RT-PCR is a gold standard diagnostic test and can determine the type, subtype, and strain of influenza. Results are provided within 1 to 6 hours of specimen collection.

of 2 days.[31] Transmission can occur for as long as the infected person is shedding virus from the respiratory tract. Adults are considered infectious within 1 day before until 7 days after onset of illness. Children, especially younger children, might potentially be infectious for longer periods (more than 10 days).[29,32] Viral shedding can persist for weeks to months in severely immunocompromised people.

The pathogenesis of influenza in humans is not well understood. The severity of the infection is determined by the balance between viral replication and the host immune response.[8] Severe illness is likely a result of both a lack of ability of host defense mechanisms to inhibit viral replication and an overproduction of cytokines leading to tissue damage in the host.[33]

PREVENTION

The best means to decrease the morbidity and mortality associated with influenza is to prevent infection through vaccination.[31,32] Appropriate infection control measures, such as hand hygiene, basic respiratory etiquette (eg, cover your cough, throw tissues away), and contact avoidance, are also important in preventing the spread of influenza. Additionally, chemoprophylaxis is useful in certain situations.

Vaccination

6 The primary means of influenza prevention used in the United States is annual vaccination. Vaccination can help prevent hospitalization and death among those at high risk, decrease influenza-like illness, decrease visits to physicians' offices and emergency rooms, decrease otitis media in children, and prevent school and/or work absenteeism. Annual vaccination is recommended for all persons aged 6 months or older and caregivers (eg, parents, teachers, babysitters, nannies) of children younger than 6 months. Vaccination is also recommended for those who live with and/or care for people who are at high risk, including household contacts and healthcare workers.

The ideal time for all influenza vaccination is during October or November to allow for the development and maintenance of immunity during the peak of the influenza season.[31,32] Table 109-1 lists the vaccination coverage rates and goals for various patient populations.

7 The two vaccine types currently available for prevention of seasonal influenza are the inactivated influenza vaccine (IIV), and the LAIV. IIV is available as trivalent (IIV3) and quadrivalent (IIV4) formulations, while LAIV is a quadrivalent formulation. Both vaccines contain two influenza A subtypes (H3N2 and H1N1) and influenza B virus; the specific strains included in the vaccine each year change based on antigenic drift. The viruses used for both vaccines are initially grown in embryonated hens' eggs, which explain the precautionary measures for vaccination of persons with a severe allergic reaction to eggs.[31] Of the two vaccines produced using nonegg based technologies, recombinant trivalent vaccine [RIV3 (Flublok®)] and cell-culture quadrivalent vaccine [ccIIV4 (Flucelvax Quadrivalent®)], only Flublok® is considered egg-free. Flucelvax® contains an estimated maximum of 5x10-8 mcg/0.5 mL dose of total egg protein ovalbumin. The Advisory Committee on Immunization Practices (ACIP) has made the following recommendations regarding the vaccinations of persons with reports of egg allergy: (a) Vaccination with any age appropriate IIV or RIV3 vaccine, for persons with a history of egg allergy that involves only hives. (b) Persons with severe allergic reactions (i.e. symptoms other than hives), such as angioedema, respiratory distress, light-headedness, or recurrent emesis or required epinephrine after an egg exposure may be immunized with any licensed IIV or RIV3 that is appropriate for age and health status. Vaccine should be administered in an inpatient or outpatient medical setting (including but not necessarily limited to hospitals, clinics, health departments, and physician offices), under the supervision of a health care provider who is able to recognize and manage severe allergic conditions. (c) Severe allergic reaction to influenza vaccine is a contraindication to receiving future vaccinations. (d) Vaccine providers should consider observing all patients for 15 minutes after vaccination to decrease the risk for injury should a patient experiences syncope.[31] The CDC encourages individuals to use the Vaccine Adverse Event Reporting System to aide in collecting and analyzing adverse events following influenza vaccinations.[31]

TABLE 109-1 Influenza Vaccination Rates and Goals by Patient Population[32,42]

Patient Population	Vaccination Coverage (%)	Vaccination Coverage National Goal (2013)
Children aged 6 months-7 years	47[a]	70%
Persons aged 18 or greater	38[a]	70%
Nursing home residents	62[b]	90%
Pregnant women	27[c]	80%
Healthcare workers	56[a]	90%

[c]2008-2009 data.

Trivalent and Quadrivalent Influenza Vaccine

7 Intramuscular IIV is FDA approved for use in people older than 6 months of age, regardless of their immune status. Of note, several commercial products are available and are approved for different age groups (Table 109-2). The intradermal IIV4, Fluzone Intradermal®, is approved by FDA for use in adults 18 to 64 years of age and is another vaccination option for people in this age group. IIV is made with killed viruses, meaning it cannot cause signs and symptoms of influenza-like illness (Table 109-3). Age and immune status can affect the efficacy of IIV as can the similarity of the vaccine to the viruses in circulation. Afluria® brand of IIV3 vaccine is contraindicated in patients with hypersensitivity to neomycin or polymyxin. Afluria® is also not recommended first line in children 6 months to 8 years, due to reports of high febrile episodes following administration.[31]

In children between 6 and 24 months of age, a 2-year randomized study of intramuscular IIV3 exhibited 89% seroconversion and efficacy of 66% in year 1 and 7% in year 2 versus culture-confirmed influenza.[38] In children between 1 and 15 years of age, the efficacy of IIV3 was 91.4% and 77.3% against culture-confirmed influenza A H1N1 and H3N2, respectively. Two doses of IIV are important for children under the age of 9 years, supporting the rationale for the recommendation of a booster dose of IIV at least 1 month after the initial dose in children between 6 months and less than 9 years of age if no previous vaccination (see Table 109-2).[31] Booster dose is also recommended for children 2 years to 8 years at least 6 weeks after the initial dose if no previous vaccination.

IIV is also effective in adult populations under and older than the age of 65 years. A double-blind, randomized controlled trial evaluating intramuscular IIV3 in healthy adults younger than the age of 65 years demonstrated an efficacy of 50% against serologically confirmed influenza during a season in which the vaccine and the circulating viruses were not well matched and an efficacy of 86% during a season in which the vaccine and the circulating viruses were well matched.[39] Vaccination of those younger than 65 years old during seasons when the virus and vaccine are well matched results in decreased work absenteeism and healthcare resource use.[38,39]

Intradermal IIV4 in adults 18 to 64 years of age provides immune response similar to the IIV3 intradermal injection for matched strains.[40] However, for both B strains intradermal IIV4, provides immune response superior to intradermal IIV3 without the corresponding B strain. Both vaccines were similar in their safety profile. In clinical trials, Fluzone® intradermal was noninferior to Fluzone® intramuscular in eliciting immune response as

TABLE 109-2 Approved Influenza Vaccines for Different Age Groups—United States, 2016-2017 Season[31,32]

Vaccine	Trade Name	Manufacturer	Dose/Presentation	Thimerosal Mercury Content (mcg Hg/0.5 mL dose)	Age Group	Number of Doses
Inactivated						
IIV3	Fluvirin	Seqirus Vaccines	0.5-mL prefilled syringe 5-mL multi-dose vial	≤1 25	≥4 years ≥4 years	1 or 2[a] 1 or 2[a]
IIV3	Afluria	Seqirus	0.5-mL prefilled syringe 5-mL multidose vial	0 24.5	≥9 years ≥9 years via needle/ syringe or 18-64 years via jet injector	1 1
ccIIV4	Quadrivalent	Seqirus Vaccines	0.5-mL prefilled syringe	0	≥4 years	1
RIV3	Flublok	Protein Sciences	0.5-ml single dose vial	0	≥18 years	1
IIV3 High Dose	Fluzone HD	Sanofi Pasteur	0.5-mL prefilled syringe	0	≥65 years	1
aIIV3	Fluad	Seqirus	0.5 mL single dose prefilled syringe	0	≥65 years	1
IIV4	Quadrivalent	ID Biomedical Corporation	5-mL multidose vial	<25	≥3 years	1
IIV4	Fluarix Quadrivalent	GlaxoSmithKline	0.5-mL prefilled syringe	0	≥3 years	1
IIV4	Fluzone Quadrivalent	Sanofi Pasteur	0.25-mL prefilled syringe 0.5-mL prefilled syringe 0.5-mL single-dose vial 5-mL multi-dose vial	0 0 0 25	≥6-35 months ≥36 months ≥36 months ≥6 months	1 or 2[a] 1 or 2[a] 1 or 2[a] 1 or 2[a]
IIV4 intradermal	Fluzone Intradermal Quadrivalent	Sanofi Pasteur	0.1-mL prefilled microinjection system	0	18-64 years	1[b]
LAIV	FluMist Quadrivalent[c]	MedImmune	0.2-mL sprayer	0	2-49 years	1 or 2[d]

LAIV, live-attenuated influenza vaccine; IIV3, trivalent influenza vaccine; IIV4, quadrivalent influenza vaccine; ccIIV3, cell culture-based trivalent influenza vaccine; RIV3, recombinant trivalent influenza vaccine; aIIV3, adjuvanted inactivated influenza vaccine, trivalent, standard dose.

[a]Two doses administered at least 1 month apart are recommended for children aged 6 months to less than 9 years who are receiving influenza vaccine for the first time or received one dose in first year of vaccination during the previous influenza season.

[b]*Given intradermally.* A 0.1-mL dose contains 9 mcg of each vaccine antigen (27 mcg total).

[c]ACIP recommends that FLumist (LAIV4) not be used during the 2016-2017 season.

[d]Two doses administered 4 weeks apart are recommended for children aged 2 to less than 9 years who are receiving influenza vaccine for the first time.

measured by hemagglutination inhibition antibody geometric mean titers (GMTs).[41] The rate of seroconversion was similar between the two vaccines against influenza strains A (H1N1 and H3N2), but not for strain B. The most common adverse reactions were injection site related, which were transient (resolving in 3-7 days), and include erythema (greater than 75%), swelling (greater than 50%), induration (greater than 50%), pain (greater than 50%), and pruritus (greater than 40%). Compared with the intramuscular vaccine, Fluzone® intradermal contains 40% less antigen (Table 109-2).

Adults older than the age of 65 years benefit from influenza vaccination, including prevention of complications, decreased risk of influenza-related hospitalization, and death. However, people in this population may not generate a strong antibody response to the vaccine and may remain susceptible to infection. In patients older than the age of 60 years who do not reside in a long-term care facility, IIV efficacy was 58% against influenza illness.[42] Although the efficacy against influenza illness for those living in long-term care facilities is between 30% and 40%, the vaccine is 50% to 60% effective in preventing influenza-related hospitalization or pneumonia and 80% effective in preventing influenza-related death.[42]

TABLE 109-3 Comparison of Inactivated Influenza Vaccine (IIV) and Live-Attenuated Influenza Vaccine (LAIV)

Characteristic	IIV (IIV3/IIV4)	LAIV
Age groups approved for use	>6 months	2-49 years
Immune status requirements	Immunocompetent or immunocompromised	Immunocompetent
Viral properties	Inactivated (killed) influenza A (H3N2), A (H1N1), and B viruses	Live-attenuated influenza A (H3N2), A (H1N1), and B viruses
Route of administration	Intramuscular/Intradermal	Intranasal
Immune system response	High serum IgG antibody response	Lower IgG response and high serum IgA mucosal response

The most frequent adverse effect associated with IIV is soreness at the injection site that lasts for less than 48 hours. IIV may cause fever and malaise in those who have not previously been exposed to the viral antigens in the vaccine.[31,42] Allergic-type reactions (hives, systemic anaphylaxis) rarely occur after influenza vaccination and are likely a result of a reaction to residual egg protein in the vaccine.

The 1976 swine influenza vaccine was linked to a rise in the incidence of Guillain-Barré syndrome (GBS), and this has propagated the belief that IIV may cause GBS.[42] However, there is insufficient evidence to establish causality. Although several studies have failed to establish a relationship between influenza vaccination and increased frequency of GBS, two studies have demonstrated a small but significant increase in GBS following influenza vaccination.[43,44] Therefore, vaccination should be avoided in persons who are not at high risk for influenza complications and who have experienced GBS within 6 weeks of receiving a previous influenza vaccine.[31,42] The potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the risks of GBS, and vaccination is recommended for all groups previously discussed.

The multidose vials and a few of the single-dose preparations of intramuscular IIV contain trace to small amounts of a preservative,

thimerosal, which is a mercury-containing compound (see Table 109-2). Some individuals are concerned about thimerosal exposure, particularly among children, because of the unfounded belief that thimerosal exposure is linked to the development of autism. No scientifically persuasive evidence exists to suggest harm from thimerosal exposure from a vaccine. Conversely, accumulating evidence reports the lack of harm from such exposure.[45-47] Thus, similar to GBS, the potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the theoretical risk associated with thimerosal exposure, and vaccination is recommended for all groups previously discussed. However, to maximize the public health benefit and placate concerned individuals, thimerosal-free vaccine is available (see Table 109-2).

Live-Attenuated Influenza Vaccine

7 LAIV is made with live, attenuated viruses and is approved for intranasal administration in healthy people between 2 and 49 years of age (see Table 109-3). Advantages of LAIV include its ease of administration, intranasal rather than intramuscular administration, and the potential induction of broad mucosal and systemic immune response.[31] The mucosal response occurs at the site of viral entry and may prevent infection before viral replication occurs. LAIV is more expensive than IIV and is approved for use in a more limited population. Originally licensed as a trivalent vaccine, in February 2012, the FDA approved FluMist® Quadrivalent vaccine for influenza prevention in people aged 2 to 49 years.[48] FluMist® Quadrivalent vaccine contains four strains of the influenza viruses, two influenza A strains and two influenza B strains. The inclusion of a second B strain in the vaccine is thought to increase the likelihood of adequate protection against circulating influenza B strains.

Studies of FluMist® trivalent, in addition to three new clinical trials with the quadrivalent vaccine in 4,000 children (2-17 years) and adults (18-49 years) in the United States, provide supporting evidence on the efficacy and safety of FluMist® Quadrivalent.[48-50] The studies show that immune responses were similar between FluMist® Quadrivalent and FluMist® trivalent. LAIV recipients aged 2 to 5 years had 52.5% and 54.4% fewer cases of influenza illness against matched and mismatched strains, respectively, as compared with IIV3 recipients.[49]

Although LAIV is FDA approved for adults younger than the age of 49 years, LAIV is effective in healthy adults between 18 and 64 years old.[50] Vaccination reduced the number of severe febrile illnesses by 18.8% and febrile upper respiratory tract illnesses by 23.6%.[50] Additionally, vaccination led to fewer days of illness, fewer days lost from work, fewer visits to healthcare providers, and decreased use of prescription antibiotics and nonprescription medications.[50]

Adverse reactions of LAIV are similar among those receiving FluMist® Quadrivalent and FluMist® trivalent. The adverse effects typically associated with LAIV administration include runny nose, congestion, sore throat, and headache. Because LAIV contains live, attenuated viruses, viral shedding may occur for several days following vaccination with LAIV, although this should not be equated with person-to-person transmission.[31] Additionally, because LAIV contains live, attenuated viruses, which carry a theoretical infection risk, LAIV should not be given to immunosuppressed patients or given by healthcare workers who are severely immunocompromised. Moreover, for the reasons discussed in IIV above, LAIV should not be administered to persons with a history of GBS or hypersensitivity to eggs. Although the quadrivalent vaccine has replaced the trivalent vaccine since 2012, for 2016-2017 influenza season vaccination, the ACIP has recommended against the use of LAIV due to low effectiveness against influenza A(H1N1)pdm09 in the United States in the past 2 influenza seasons. (Table 109-2).

Clinical **Controversy...**

LAIV is not recommended in several populations, including people older than 50 years and pregnant women, largely because the vaccine has not been studied extensively in these populations. However, many clinicians believe the use of LAIV in these populations is acceptable.

Postexposure Prophylaxis

8 Antiviral drugs available for prophylaxis of influenza should be considered adjuncts but are not replacements for annual vaccination. Historically, the adamantanes and NA inhibitors are two classes of antiviral drugs available for influenza prophylaxis and treatment. However, the adamantanes are no longer recommended for prophylaxis or treatment in the United States (because of widespread resistance among influenza viruses) until susceptibility is reestablished among influenza A virus.[51-54] Therefore, the NA inhibitors oseltamivir, zanamivir, and peramivir are the only drugs available for the treatment of influenza infection.[52] Peramivir is not approved for chemoprophylaxis, however, oseltamivir and zanamivir, are effective prophylactic agents against influenza in terms of preventing laboratory-confirmed influenza when used for seasonal prophylaxis (67% and 85% effective for zanamivir and oseltamivir, respectively) and preventing influenza illness among persons exposed to a household contact who was diagnosed with influenza (79%-81% and 68%-89% effective for zanamivir and oseltamivir, respectively).[52,53] Additionally, oseltamivir was 92% effective against influenza and also reduced associated complications when used as seasonal prophylaxis among immunized, institutionalized, elderly patients.[55] Both of these agents remain active against all influenza viruses, including influenza A H3N2v (Tables 109-4 and 109-5). Oseltamivir is FDA approved for the treatment of influenza in individuals 14 days and older, and for chemoprophylaxis in individuals 1 year and older. However, the CDC, the American Academy of Pediatrics (AAP), and the Pediatric Infectious Diseases Society (PIDS) provide an expanded recommendation for treatment in those less than 14 days, and chemoprophylaxis in those 3 months and older.[32,52,54] Table 109-6 gives dosing recommendations.

In those patients who did not receive the influenza vaccination and are receiving an antiviral drug for prevention of disease during the influenza season, the medication should optimally be taken for the entire duration of influenza activity in the community. The use of prophylaxis requires clinical judgment and depends on a variety of

TABLE 109-4 Antiviral Susceptibilities of Circulating Viruses

	Oseltamivir	Zanamivir	Peramivir	Adamantanes
Variant influenza A (H3N2), 2015	Susceptible	Susceptible	Susceptible	Resistant
Novel influenza A (H1N1)	Susceptible[a]	Susceptible	Susceptible[a]	Resistant
Seasonal A (H3N2)	Susceptible	Susceptible	Susceptible	Resistant
Influenza B	Susceptible	Susceptible	Susceptible	Resistant
Avian influenza (H5N1)	Susceptible	Susceptible	Susceptible	Variable

[a]Small number of isolates shown to be resistant to oseltamivir and peramivir.

TABLE 109-5 Interim Recommendations for the Selection of Antiviral Treatment Based on Confirmed Influenza Subtypes[32,52]

Laboratory Test	Preferred[a]	Alternative
Not performed or negative, but influenza suspected clinically[a]	Oseltamivir or zanamivir or peramivir	None
Positive variant H3N2v	Oseltamivir or zanamivir or peramivir	None
Positive novel H1N1	Oseltamivir or zanamivir or peramivir	None
Positive A (H3N2), or B	Oseltamivir or zanamivir or peramivir	None
Positive A + B	Oseltamivir or zanamivir or peramivir	None

[a]Viral surveillance data might help guide antiviral choices if oseltamivir resistance becomes more prevalent.

factors, but prophylaxis for seasonal influenza should be considered during influenza season for the following groups of patients after exposure to an infectious source:[52]

1. Persons at high risk of serious illness and/or complications who are exposed to an infectious person and cannot be vaccinated.
2. Persons at high risk of serious illness and/or complications who are vaccinated but exposed to an infectious person during the first two weeks following vaccination. The development of sufficient antibody titers after vaccination takes approximately 2 weeks.
3. Persons with severe immune deficiency or who may have an inadequate response to vaccination (eg, advanced human immunodeficiency virus [HIV] disease, persons receiving immunosuppressive medications), after exposure to an infectious person.
4. Long-term care facility residents, regardless of vaccination status, when an outbreak has occurred in the institution.

LAIV should not be administered until 48 hours after influenza antiviral therapy has stopped, and influenza antiviral drugs should not be administered for 2 weeks after the administration of LAIV because the antiviral drugs inhibit influenza virus replication.[31,48] No contraindication exists for concomitant use of IIV and influenza antiviral drugs.

Pregnant Women and Immunocompromised Hosts

Pregnant women and immunocompromised hosts are special populations at increased risk of influenza complications and are also populations in whom careful consideration must be given in regard to prevention strategies.

Pregnant women, regardless of trimester, should receive annual influenza vaccination with IIV but not with LAIV.[31,52] No studies have demonstrated an increased incidence of adverse effects in mothers or their infants related or potentially related to IIV, but no such data exist for LAIV.[31] Influenza vaccination of pregnant women reduced hospitalization of their infants by 92% during the first 6 months of life.[56] IIV is also safe for breast-feeding mothers. No data exist for LAIV and breast-feeding, but caution is warranted because of the potential for viral shedding.[31]

TABLE 109-6 Recommended Daily Dosage of Influenza Antiviral Medications for Treatment and Prophylaxis—United States[32,52,54]

Drug	Adult Treatment	Adult Prophylaxis[a]	Pediatric Treatment[b]	Pediatric Prophylaxis[c]
Oseltamivir	75-mg capsule twice daily for 5 days	75-mg capsule daily	<1 year: 3 mg/kg/dose twice daily 9-11 months[d]: 3.5 mg/kg/dose twice daily ≥1 year ≤15 kg: 30 mg twice daily 16-23 kg: 45 mg twice daily 23-40 kg: 60 mg twice daily >40 kg: 75 mg twice daily Duration: All for 5 days	3-8 months, 3 mg/kg/dose daily Not recommended if <3 months 9-11 months, 3.5 mg/kg/dose daily ≥1 year ≤15 kg: 30 mg daily 16-23 kg: 45 mg daily 23-40 kg: 60 mg daily >40 kg: 75 mg daily Duration: All for 10 days
Zanamivir	2 inhalations twice daily × 5 days	2 inhalations daily	2 inhalations twice daily × 5 days for ≥7 years old	2 inhalations daily for ≥5 years old for 10 days
Peramivir[e]	600 mg via intravenous infusion for 15-30 minutes once	None	None	None
Rimantadine[f]	200 mg/day in one to two doses × 7 days	200 mg/day in one to two doses	1-9 years old or <40 kg: 6.6 mg/kg/day divided twice daily (maximum 150 mg/day) ≥10 years old: 200 mg/day in one to two doses Treat 5-7 days	1-9 years old: 5 mg/kg daily (maximum 150 mg/day) ≥10 years old: 200 mg/day in one to two doses
Amantadine[f]	200 mg/day in one to two doses until 24-48 hours after symptom resolution	Same as treatment doses	>12 years old: same as adult 1-9 years old: 5 mg/kg/day in one to two doses; maximum 150 mg/day ≥10-12 years old: 100 mg orally twice daily	Same as treatment doses

[a]If influenza vaccine is administered, prophylaxis can generally be stopped 14 days after vaccination for noninstitutionalized persons. When prophylaxis is being administered following an exposure, prophylaxis should be continued for 10 days after the last exposure. In persons at high risk for complications from influenza for whom vaccination is contraindicated or expected to be ineffective, chemoprophylaxis should be continued for the duration that influenza viruses are circulating in the community during influenza season.

[b]Oseltamivir dosing for preterm infants—<38 weeks, 1 mg/kg/dose every 12 h; 38-40 weeks, 1.5mg/kg/dose every 12; >40 weeks, 3mg/kg/dose every 12 hours.[32]

[c]Alternate dosing by IDSA/PIDS (2011) is: 3-8 months—3 mg/kg/dose daily; 9-23 months—3.5 mg/kg/dose daily.[54]

[d]Unlabeled dosing.[54]

[e]Only approved for use in adults ≥18 years. Adjust dose if CrCl <50 mL/min (<0.83 mL/s)

[f]*Note:* Although amantadine and rimantadine have been used historically for the treatment and prophylaxis of influenza A viruses, due to high resistance, the CDC no longer recommends the use of these agents for the treatment and/or prophylaxis of influenza.

Immunocompromised hosts should receive annual influenza vaccination with IIV but not with LAIV. IIV was 100% effective against laboratory-confirmed influenza in HIV-positive patients with no significant effect on viral load or CD4 cell count.[57] However, antibody titers may not be as high as in immunocompetent individuals and are not improved with a second dose of vaccine.[58] Similarly, antibody titers may not be as high in solid-organ transplant patients as in immunocompetent persons, but, conversely, antibody titers were increased significantly after a second dose of IIV in adult liver transplant patients.[59] Although this suggests a potential benefit from a two-dose regimen, such a regimen is not currently recommended for solid-organ transplant recipients. Likewise, immune responses in patients receiving chemotherapy for either solid or hematologic tumors are lower (fourfold rise, 17%-52%) than in those who had completed chemotherapy (50%-83%) and healthy patients (67%-100%).[60] Data are currently limited in this arena for the intradermal IIV. In a study of intradermal IIV3 involving immunocompromised patients compared with healthy controls, humoral responses (GMTs and protection rates [PRs]) were significantly better among healthy controls than those among immunocompromised patients.[61] This is not surprising given an already attenuated immune system. But it was also noted that compared with the standard intramuscular IIV, GMTs and PRs were similar within all tested groups. Immune response to vaccine may be less than desired in immunocompromised patients.[31]

Large clinical trials evaluating the use of influenza antivirals for prophylaxis are lacking in immunocompromised hosts. Viral shedding occurs for prolonged periods in this population and may promote the development of antiviral resistance, which has been documented with oseltamivir in immunocompromised patients.[62-64]

TREATMENT

When prevention efforts fail or are not used, clinicians must turn to the agents available for treatment of influenza. Currently, the antiviral treatment options are limited, particularly in the face of resistance to the adamantanes and oseltamivir.

Goals of Therapy

The four primary goals of therapy of influenza are to control symptoms, prevent complications, decrease work and/or school absenteeism, and prevent the spread of infection.

General Approach to Treatment

In the era of pandemic preparedness and increasing resistance, early and definitive diagnosis of influenza is crucial. 9 The currently available antiviral drugs are most effective if started within 48 hours of the onset of illness. Moreover, the sooner the antiviral drugs are started after the onset of illness, the more effective they are. Antiviral drugs shorten the duration of illness and provide symptom control. Adjunct agents, such as acetaminophen for fever or an antihistamine for rhinitis, may be used concomitantly with the antiviral drugs.

Nonpharmacologic Therapy

Patients suffering from influenza should get adequate sleep and maintain a low level of activity. They should stay home from work and/or school in order to rest and prevent the spread of infection. Appropriate fluid intake should be maintained. Cough/throat lozenges, warm tea, or soup may help with symptom control (cough, sore throat).

Pharmacologic Therapy

The NA inhibitors, oseltamivir, zanamivir, and peramivir are the only antiviral drugs available for the treatment and prophylaxis of influenza.[52] Peramivir is the only intravenous formulation commercially available. The adamantanes (amantadine and rimantadine) are no longer recommended due to high resistance among influenza viruses. A limited discussion of adamantanes can be found in the following section, but the focus will be on oseltamivir, zanamivir, and peramivir.

Adamantanes

The adamantanes (amantadine and rimantadine) block the M2 ion channel, which is specific to influenza A viruses, and inhibit viral uncoating. Historically, the adamantanes were used for the treatment of seasonal influenza A H1N1, as they do not have activity against influenza A H3N2 or influenza B viruses. The novel influenza A H1N1 that emerged during the 2009 to 2010 influenza season, which has now replaced seasonal influenza A H1N1 as the predominant seasonal virus, was found to be discriminatorily resistant to the adamantanes. Data from the 2014 to 2015 influenza season showed that more than 99% of influenza A H3N2 and H1N1pdm09 were resistant to adamantanes.[51,52] As a result, the CDC only recommends the use of NA inhibitors for the treatment and prophylaxis of influenza A, until susceptibility of adamantanes is reestablished among influenza A viruses. Resistance to adamantanes is often conferred by a single-point mutation, and this is problematic because it results in cross-resistance to the entire class.[53]

Neuraminidase Inhibitors

10 Oseltamivir, zanamivir, and peramivir are NA inhibitors that have activity against both influenza A and influenza B viruses.[52,53] Without NA, release of the virus from infected cells is impaired, and, thus, viral replication is decreased. When administered within 48 hours of the onset of illness, NA inhibitors may reduce the duration of illness by approximately 1 day versus placebo.[53] In a pivotal trial, oseltamivir reduced the time to return to normal health in adults by 1.9 days and the time to return to normal activity by 2.8 days.[65] These reductions have a significant effect on not only the quality of life for the patient but also the societal costs associated with influenza. 9 Of note, the benefits of treatment are highly dependent on the timing of the initiation of treatment, with the ideal initiation period being within 12 hours of illness onset.[66] However, select observational studies have reported a lower risk for severe outcomes with oral oseltamivir started 4 and 5 days after onset of illness in critically ill patients with suspected or confirmed influenza.[67,68]

Oseltamivir treatment in adults and adolescents with documented influenza illness resulted in a 26.7% reduction in overall antibiotic use, a 55% reduction in lower respiratory tract complications (bronchitis, pneumonia), and a 59% reduction in hospitalizations.[69] Zanamivir treatment in adults and adolescents with influenza-like illness resulted in a 28% reduction in antibiotic use and a 40% reduction in lower respiratory tract complications.[70] The data in these studies largely come from healthy individuals rather than those at highest risk for complications associated with influenza. The impact of appropriate treatment in high-risk populations may be even greater than that which has been documented to date.

Oseltamivir is approved for treatment in those 14 days and older, zanamivir for treatment in those older than the age of 7 years, and peramivir for those 18 years and older.[51] The recommended doses vary by agent and age (see Table 109-6). The recommended duration of treatment for both oseltamivir and zanamivir is 5 days, and one dose for one day for peramivir.

The FDA approved single dose peramivir injection (Rapivab®) for intravenous use for the treatment of acute uncomplicated influenza in people 18 years and older.[71] Peramivir is as effective as oseltamivir, without severe adverse events.[72] Therefore, peramivir is an effective option in patients who are unable to tolerate or absorb oral or enterically-administered oseltamivir due to gastric stasis, malabsorption, or gastrointestinal bleeding. Based on an observational study, the 14-day, 28-day, and 56-day survival rates of 31 patients

with severe H1N1pdm09 infection treated with peramivir were 77%, 67%, and 59%, respectively.[73] Peramivir shortened duration of influenza symptoms in outpatient adults with uncomplicated influenza by about 1 day, with a corresponding reduction in median time to resumption of usual activities to about 1.5 days.[74] Studies exploring the use of peramivir beyond 1 day have not shown a benefit. A randomized trial of influenza treatment in hospitalized patients younger than 6 years, with intravenous peramivir at a dosage of 600 mg once daily (10 mg/kg once daily in children) for five days plus standard of care compared with placebo plus standard did not demonstrate a clinical benefit.[75]

Neuropsychiatric complications consisting of delirium, seizures, hallucinations, and self-injury in pediatric patients (mostly from Japan) have been reported following treatment with oseltamivir, and peramivir.[66,76] Since influenza itself can be associated with neuropsychiatric manifestations, a causal relationship between oseltamivir or peramivir and neuropsychiatric effects has not been delineated.[42] However, the labels for oseltamivir and peramivir have been updated to include neuropsychiatric events as a precaution, and their occurrence with use of these agents should not be ignored.

Influenza resistance to the NA inhibitors has been documented but cross-resistance between the NA inhibitors has not been reported.[51-53] Antiviral resistance remains relatively low. During the 2014 to 2015 influenza season, 98.4% of the tested 2009 H1N1 viruses were susceptible to oseltamivir and peramivir, and 100% of the 2009 H1N1 viruses tested were susceptible to zanamivir; 100% of influenza A (H3N2) tested were susceptible to both oseltamivir and zanamivir; and 100% of influenza B viruses tested were susceptible to both oseltamivir and zanamivir.[52,77] Antiviral susceptibility testing of circulating viruses confirmed that seasonal influenza A H3N2 and variant influenza H3N2 maintain susceptibility to oseltamivir, peramivir, and zanamivir.[30,51] The burden of surveillance rests on clinicians to identify local patterns of influenza circulation to guide antiviral therapy.

Clinical **Controversy...**

Some clinicians debate the cost–benefit of the use of diagnostic tests for influenza as well as treatment of influenza in otherwise healthy individuals who are likely to experience resolution without treatment. This controversy is compounded by the fact that the diagnostic tests and the benefits associated with treatment of influenza are highest early in the disease process and many patients present after this time period.

Special Populations

Inadequate data exist regarding the use of antiinfluenza medications in special populations, such as immunocompromised hosts. Furthermore, limited data exist regarding use of influenza antivirals during pregnancy. The adamantanes are embryotoxic and teratogenic in rats, and limited case reports of adverse fetal outcomes following amantadine use in humans have been published. Oseltamivir and zanamivir have been used but lack solid safety clinical data in pregnant women. Pregnancy should not be considered a contraindication to oseltamivir or zanamivir use. Oseltamivir is preferred for the treatment of pregnant women because of its systemic activity; however, the drug of choice for chemoprophylaxis is not yet defined. Zanamivir may be preferred because of its limited systemic absorption, but respiratory complications need to be considered, especially in women with underlying respiratory diseases. Both the adamantanes and the NA inhibitors are excreted in breast milk and should be avoided by mothers who are breast-feeding their infants. More studies are needed in these populations who are at high risk for serious disease and complications from influenza.

Clinical **Controversy...**

Some debate exists regarding the benefit of antiviral administration more than 48 hours after onset. While clinicians agree that the most benefit is achieved the earlier the medications are started, some data suggest benefit even beyond 48 hours after onset, albeit more limited.

PANDEMIC PREPAREDNESS

This chapter is not meant to provide an exhaustive review of the biology of influenza or pandemic preparedness. This topic is rapidly changing and interested readers are referred to the following websites: *www.flu.gov*, *www.who.int/influenza/human_animal_interface/en/*, and *www.cdc.gov/h1n1flu*.

A vital component of pandemic preparedness is forethought—plans must be established for how to effectively triage large numbers of ill patients, prioritize and/or ration vaccine and antivirals, and communicate with the public through mass media during a period of severe labor shortage (a result of stress and illness among healthcare workers) and supply shortfall (a result of societal and economic disruption).

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored daily for resolution of signs and symptoms associated with influenza, such as fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms will typically resolve within approximately 1 week. If the patient continues to exhibit signs and symptoms of illness beyond 10 days or a worsening of symptoms after 7 days, a physician visit is warranted as this may be an indication of a secondary bacterial infection. Ideally, antiviral therapy should not be started until influenza is confirmed via the laboratory. However, therapy should be initiated within 48 hours of illness onset, emphasizing the need for rapid diagnosis. Repeat diagnostic tests to demonstrate clearance of the virus are not necessary.

Skin and Soft-Tissue Infections

110

Douglas N. Fish

KEY CONCEPTS

1. Folliculitis, furuncles (boils), and carbuncles begin around hair follicles and are caused most often by *Staphylococcus aureus*. Folliculitis and small furuncles are generally treated with warm, moist heat to promote drainage; larger furuncles and carbuncles require incision and drainage. Purulent, moderately severe infections (eg, with fever or other systemic signs of infection) have a higher suspicion for community-associated methicillin-resistant *S. aureus* (MRSA) and empiric treatment should include trimethoprim–sulfamethoxazole or a tetracycline such as doxycycline.
2. Erysipelas, a superficial skin infection with extensive lymphatic involvement, is caused by *Streptococcus pyogenes*. The treatment of choice is penicillin, administered orally or parenterally, depending on the severity of the infection.
3. Impetigo is a superficial skin infection that occurs most commonly in children. It is characterized by fluid-filled vesicles that develop rapidly into pus-filled blisters that rupture to form golden-yellow crusts. Effective therapy includes penicillinase-resistant penicillins (dicloxacillin), first-generation cephalosporins (cephalexin), and topical mupirocin or retapamulin. *S. aureus* is the primary cause of impetigo, with infections caused by MRSA emerging in recent years.
4. Lymphangitis, an infection of the subcutaneous lymphatic channels, is generally caused by *S. pyogenes*. Acute lymphangitis is characterized by the rapid development of fine, red, linear streaks extending from the initial infection site toward the regional lymph nodes, which are usually enlarged and tender. Penicillin is the drug of choice.
5. Cellulitis is an infection of the epidermis, dermis, and superficial fascia most commonly caused by *S. pyogenes* and *S. aureus*. Lesions generally are hot, painful, and erythematous, with nonelevated, poorly defined margins. Oral trimethoprim–sulfamethoxazole, doxycycline, or minocycline is used for initial treatment of suspected MRSA in patients with purulent, moderately severe cellulitis (ie, lesion with purulent drainage or exudate, or nondrainable abscess plus systemic signs of infection). Treatment of nonpurulent cellulitis generally consists of penicillin VK, a penicillinase-resistant penicillin (dicloxacillin), first-generation cephalosporin (cephalexin), or clindamycin for 5 days, with the option of adding coverage for MRSA in certain patients. More severe infections in hospitalized and/or immunocompromised patients should receive empiric therapy with parenteral agents active against streptococci (nonpurulent infections) or both streptococci and MRSA (purulent infections).
6. Necrotizing fasciitis is a rare but life-threatening infection of subcutaneous tissue that results in progressive destruction of superficial fascia and subcutaneous fat. Early and aggressive surgical debridement is an essential part of therapy for treatment of necrotizing fasciitis. Mixed infections are treated with broad-spectrum regimens that cover streptococci, gram-negative aerobes, and anaerobes. Infections caused by *S. pyogenes* or *Clostridium* species should be treated with the combination of penicillin and clindamycin.
7. Diabetic foot infections are managed with a comprehensive treatment approach that includes both proper wound care and antimicrobial therapy. Potential pathogens include staphylococci, streptococci, aerobic gram-negative bacilli, and obligate anaerobes. Antimicrobial regimens for diabetic foot infections are based on severity of the infection, expected treatment setting, and risk factors for infection with more resistant pathogens such as MRSA and *Pseudomonas aeruginosa*. Outpatient therapy with oral antimicrobials should be used whenever possible for less severe infections, while more severe infections initially require IV therapy.
8. Prevention is the single most important aspect in the management of pressure sores. After a sore develops, successful local care includes a comprehensive approach consisting of relief of pressure, proper cleaning (debridement), disinfection, and appropriate antimicrobial therapy if an infection is present. Good wound care is crucial to successful management.
9. All bite wounds (either animal or human) should be irrigated thoroughly with large volumes of sterile normal saline, and the injured area should be immobilized and elevated. Depending on the severity of the bite wound, amoxicillin–clavulanic acid or ampicillin–sulbactam is often used for treatment of animal bites because of their coverage of *Pasteurella* species, streptococci, *S. aureus*, and anaerobes typically present in the oral flora of dogs and cats.
10. Antimicrobial prophylaxis (early preemptive therapy) of animal bites is not recommended routinely; however, patients at high risk of infection (eg, immunocompromised, moderate to severe bite injuries especially to the hands and face, penetration of the periosteum or joint capsule) should be given prophylactic antimicrobial therapy for 3 to 5 days. Infected bite wounds should be treated for 7 to 14 days with oral or IV antibiotics having activity against *Eikenella corrodens*, streptococci, *S. aureus*, and β-lactamase–producing anaerobes.

Skin and soft-tissue infections (SSTIs) may involve any or all layers of the skin (epidermis, dermis, subcutaneous fat), fascia, and muscle. They may also spread far from the initial site of infection and lead to more severe complications, such as endocarditis, gram-negative sepsis, or streptococcal glomerulonephritis. Sometimes the treatment of SSTIs may necessitate both medical and surgical management. This chapter presents details of the pathogenesis and management of some of the most common infections involving the skin and soft tissues, ranging in severity from superficial to life-threatening.

EPIDEMIOLOGY

Bacterial infections of the skin can be classified as primary or secondary (Table 110-1).[1-3] Primary bacterial infections usually involve areas of previously healthy skin and are caused by a single pathogen. In contrast, secondary infections occur in areas of previously damaged skin and are frequently polymicrobic. SSTIs are also classified as complicated or uncomplicated. Complicated infections are those that involve deeper skin structures (eg, fascia, muscle layers), require significant surgical intervention, or occur in patients with compromised immune function (eg, diabetes mellitus, human immunodeficiency virus [HIV] infection).[4] Other categories that are crucial for successful treatment are the differentiation of necrotizing versus nonnecrotizing, as well as purulent versus nonpurulent, SSTIs.[4–7]

SSTIs are among the most common infections seen in community and hospital settings.[8,9] However, most infections are believed to be mild and are treated in an outpatient setting, making it difficult to accurately quantify community-acquired SSTIs. SSTIs were diagnosed in 0.8% of physician office visits between 1993 and 2005; this corresponded to approximately 82 million diagnoses of SSTI, being more common among those 70 years of age and older.[3] Emergency room visits for SSTIs have increased dramatically in recent years, attributed primarily to an increase in community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) cellulitis and abscesses.[10,11] A study of emergency department visit rates between 1997 and 2007 found a 3.1-fold increase (11% per year) for abscess SSTIs, with only a minimal increase in nonabscess SSTIs.[11] According to an Agency for Healthcare Research and Quality report, in 2009 SSTIs were responsible for nearly 600,000 hospitalizations and represented 2% of all admissions in males and 1.2% in females.[9] While the exact incidence of SSTIs is unknown, the frequency of infections caused by drug-resistant gram-positive cocci has been increasing.[4–7] The high incidence of healthcare-associated MRSA (HA-MRSA) has been a major concern for many years and the emergence of CA-MRSA is even more problematic.[5–7,12–18] CA-MRSA are characteristically isolated from patients lacking typical risk factors (eg, prior hospitalization, long-term care facility) and are often susceptible to non–β-lactam antibiotics such as trimethoprim–sulfamethoxazole, doxycycline, and clindamycin.[1,12,13,15,17-19] They also differ genetically from HA-MRSA with methicillin resistance carried on the type IV or type V staphylococcal chromosomal cassette *mec* (SCC*mec*) element of the *mecA* gene.[1,12,18] CA-MRSA strains often harbor genes for Panton-Valentine leukocidin (PVL), a cytotoxin responsible for leukocyte destruction and tissue necrosis. In contrast, HA-MRSA strains usually lack genes for PVL and are associated with SCC*mec* alleles I to III.[1,12,15,18] While the incidence of HA-MRSA has declined in recent years,[20] the incidence of CA-MRSA has dramatically increased; nearly half (46%) of all culture-positive SSTIs are caused by MRSA.[4–7,8,19] Clinicians should suspect CA-MRSA in geographic areas with a high prevalence of these strains, or in recurrent or persistent infections that are not responding to appropriate β-lactam therapy. In addition to the emergence of CA-MRSA, treatment choices for SSTIs have been further complicated by the increased incidence of macrolide-resistant strains of *S. aureus* and *Streptococcus pyogenes*.[15,19,21] Data from the Minnesota Department of Health found erythromycin susceptibility among CA-MRSA strains decreased from 45% to 13% during the years 2000 to 2005.[19] There is concern about the use of clindamycin for CA-MRSA infections due to the risk of inducible clindamycin resistance in *S. aureus* strains that are erythromycin-resistant, but clindamycin-susceptible.[18,19] A double-disk test (D-zone test) is recommended to identify erythromycin-resistant strains with inducible clindamycin resistance if treatment with clindamycin is desired.[6,7,12] A positive D-zone test, indicating the presence of inducible resistance conferred by the *erm* gene, suggests the possibility of the emergence of clindamycin resistance during therapy.[12]

TABLE 110-1 Bacterial Classification of Important Skin and Soft-Tissue Infections [1–3]

Primary Infections	
Erysipelas	Group A streptococci (*Streptococcus pyogenes*)
Impetigo	*Staphylococcus aureus* (including methicillin-resistant strains), group A streptococci
Lymphangitis	Group A streptococci; occasionally *S. aureus*
Cellulitis	Group A streptococci, *S. aureus* (potentially including methicillin-resistant strains); occasionally other gram-positive cocci, gram-negative bacilli, and/or anaerobes
Necrotizing fasciitis	
Type I	Anaerobes (*Bacteroides* spp., *Peptostreptococcus* spp.) and facultative bacteria (streptococci, Enterobacteriaceae)
Type II	Group A streptococci
Type III	*Clostridium perfringens*
Secondary Infections	
Diabetic foot infections	*S. aureus*, streptococci, Enterobacteriaceae, *Bacteroides* spp., *Peptostreptococcus* spp., *Pseudomonas aeruginosa*
Pressure sores	*S. aureus* including methicillin-resistant strains, streptococci, Enterobacteriaceae, *Bacteroides* spp., *Peptostreptococcus* spp., *P. aeruginosa*
Bite wounds	
Animal	*Pasteurella* spp., *S. aureus*, streptococci, *Bacteroides* spp.
Human	*Eikenella corrodens*, *S. aureus*, streptococci, *Corynebacterium* spp., *Bacteroides* spp., *Peptostreptococcus* spp.
Burn wounds	*P. aeruginosa*, Enterobacteriaceae, *S. aureus*, streptococci

ETIOLOGY

The majority of SSTIs are caused by gram-positive organisms present on the skin surface.[7,22] Gram-positive bacteria (coagulase-negative staphylococci, diphtheroids) are the predominant flora of the skin, with gram-negative organisms being relatively uncommon (Table 110-2).[1–3] *S. aureus*, as well as a variety of gram-negative

TABLE 110-2 Predominant Microorganisms of Normal Skin [1–3]

Bacteria
Gram-positive
Coagulase-negative staphylococci
Micrococci (*Micrococcus luteus*)
Corynebacterium species (diphtheroids)
Propionibacterium species
Gram-negative
Acinetobacter species
Fungi
Malassezia species
Candida species

bacteria, including *Acinetobacter* species, can be found in moist intertriginous areas (eg, axilla, groin, and toe webs) of the body.[1,2,23] Approximately 30% to 35% of healthy individuals are reported to be colonized with *S. aureus* on the skin or in the anterior nares.[1,3] Colonization, whether transient or permanent, provides a nidus for infection should the integrity of the epidermis be compromised.[1,2,10]

S. aureus and *S. pyogenes* account for the majority of community-acquired SSTIs.[1,10,22] Data from large surveillance studies showed *S. aureus* to be the most common cause of SSTIs in hospitalized patients, with often 30%-40% of these being caused by MRSA.[3,8,9] Other common nosocomial pathogens included *Pseudomonas aeruginosa* (11%), enterococci (9%), and *Escherichia coli* (7%).[3,8,9]

PATHOPHYSIOLOGY

The skin serves as a barrier between humans and their environment, therefore functioning as a primary defense mechanism against infections. The skin and subcutaneous tissues normally are extremely resistant to infection but may become susceptible under certain conditions. Even when high concentrations of bacteria are applied topically or injected into the soft tissue, resulting infections are rare.[1–3,24,25] Although the human skin supports an abundant and diverse microbiome of bacteria and fungi,[1,2] several host factors act together to confer protection against skin infections. Continuous renewal of the epidermal layer results in the shedding of keratocytes, as well as skin bacteria.[2] In addition, sebaceous secretions are hydrolyzed to form free fatty acids that strongly inhibit the growth of many bacteria and fungi. A normal commensal skin microbiome itself serves a protective function by not allowing space or environmental conditions favorable to colonization with more pathogenic strains.[1,2] Conditions that may predispose a patient to the development of skin infections include (a) high concentrations of bacteria (more than 10^5 microorganisms), (b) excessive moisture of the skin, (c) inadequate blood supply, (d) availability of bacterial nutrients, and (e) damage to the corneal layer allowing for bacterial penetration.[2,3,24,25]

The best defense against SSTI is intact skin.[2,24] The majority of SSTIs result from the disruption of normal host defenses by processes such as skin puncture, abrasion, or underlying diseases (eg, diabetes).[1,2,24,26] The nature and severity of the infection depend on both the type of microorganism present and the site of inoculation.

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

1 Folliculitis is inflammation of the hair follicle and is caused by physical injury, chemical irritation, or infection. Infection occurring at the base of the eyelid is referred to as a stye. While folliculitis is a superficial infection with pus present only in the epidermis,[10,22] furuncles and carbuncles occur when a follicular infection extends from around the hair shaft to involve deeper areas (subcutaneous tissue) of the skin.[26] A furuncle, commonly known as a *boil*, is a walled-off mass of purulent material arising from a hair follicle.[10] The lesions are called *carbuncles* when adjacent furuncles coalesce to form a single inflamed area.[10] This aggregate of infected hair follicles forms deep masses that generally open and drain through multiple sinus tracts.[12,26] *S. aureus* is the most common cause of folliculitis, furuncles, and carbuncles.[12,26] Inadequate chlorine levels in whirlpools, hot tubs, and swimming pools have been responsible for outbreaks of folliculitis caused by *P. aeruginosa*.[1,26] Outbreaks of furunculosis caused by *S. aureus* and CA-MRSA have been reported in settings involving close contact (eg, families, prisons), especially when skin injury was common (such as with sports).[12,26] In addition, some individuals experience repeated episodes of furunculosis.[22] A major predisposing factor in recurrent infection is the presence of *S. aureus* in the anterior nares.[15,22,26]

TREATMENT
Folliculitis, Furuncles, and Carbuncles

Desired Outcomes

The goals of treatment include relieving discomfort, preventing further spread of the infection, and preventing recurrence. Controlling recurrent furunculosis is key due to the difficulty in treating chronic furunculosis.[22] Treatments should be effective and inexpensive and have minimal adverse effects.

CLINICAL PRESENTATION

Folliculitis

- Clustering, pruritic papules localized to hair follicles.
- Generally develop in areas subject to friction and perspiration.
- Papules are generally 5 mm or less in diameter and erythematous.
- Papules evolve into pustules that generally spontaneously rupture in several days.
- Systemic signs (fever, malaise) are uncommon.

Furuncles

- Inflammatory, draining nodule involving a hair follicle.
- Generally develop in areas subject to friction and perspiration.
- Lesions are discrete, whether occurring as singular or multiple nodules.
- Lesion starts as a firm, tender, red nodule that becomes painful and fluctuant.
- Lesions often drain spontaneously.
- Lesions caused by CA-MRSA often have necrotic centers characteristic of "spider bites."
- Systemic signs are uncommon.

Carbuncles

- Formed when adjacent furuncles coalesce to form a single inflamed area.
- Form broad, swollen, erythematous, deep, and painful follicular masses.
- Commonly develop on the back of the neck and are more likely to occur in patients with diabetes.
- Commonly associated with systemic signs (fever, chills, malaise).
- Bacteremia with secondary spread to other tissues is common.

Treatment

Table 110-3 summarizes evidence-based treatment recommendations from clinical guidelines for SSTIs.[3,5,6,15,27-29] Treatment of folliculitis generally requires only local measures, such as warm moist compresses or topical therapy (eg, clindamycin, erythromycin, mupirocin, or benzoyl peroxide).[3,26] Topical agents generally are applied two to four times daily for 7 days. Small furuncles generally can be treated with moist heat, which promotes localization and drainage of pus.[3,26] Large and/or multiple furuncles and carbuncles require incision and drainage.[3,4,12,15,28] Systemic antibiotics are usually not necessary unless accompanied by fever or extensive cellulitis.[4,15] Treatment of more severe infections (eg, accompanied by systemic signs of infection) should include oral trimethoprim–sulfamethoxazole or a tetracycline (either doxycycline or minocycline) for 5 to 10 days due to a higher suspicion for MRSA (refer to Table 110-4 for adult and pediatric doses).[4,6,15,22,28] For individuals with nasal colonization, application of mupirocin ointment twice daily in the anterior nares for the first 5 days of each month decreases recurrent furunculosis by almost half.[15,22] Daily chlorhexidine washes and daily washing of personal items such as towels, bedding, and clothes may also be recommended.[15]

Evaluation of Therapeutic Outcomes

Many follicular infections resolve spontaneously without medical or surgical intervention. Lesions should be incised if they do not respond to a few days of moist heat and nonprescription topical agents. Following drainage, most lesions begin to heal within several days without antimicrobial therapy. Any patient who is unresponsive to several days of systemic antibiotic therapy or suffers recurrent infection should have a culture and sensitivity test performed to guide continued antibiotic selection.

ERYSIPELAS

2 Erysipelas is a distinct form of cellulitis involving the more superficial layers of the skin and cutaneous lymphatics.[5,12,22,30] The intense red color and burning pain associated with this skin infection led to the common name of "St. Anthony's fire." The infection is almost always caused by β-hemolytic streptococci, with the organisms gaining access via small breaks in the skin. Group A streptococci (*S. pyogenes*) are responsible for most infections.[3,15,22] Infections are more common in infants, young children, the elderly, and patients with nephrotic syndrome.[3,6] Erysipelas also commonly occurs in areas of preexisting lymphatic obstruction or edema.[3,12] Diagnosis is made on the basis of the characteristic lesion.

TREATMENT
Erysipelas

Desired Outcomes

The goal of treatment of erysipelas is rapid eradication of the infection, thereby providing relief of symptoms (pain, tenderness, fever).[30] Preventing recurrent infection is also important, as recurrence is a primary complication, occurring in approximately 20% of patients.[22,30] Treatments should be effective and inexpensive and have minimal adverse effects.

Treatment

Mild to moderate cases of erysipelas are treated with intramuscular procaine penicillin G or penicillin VK for 7 to 10 days (see Table 110-4).[3,22] Recommended doses and monitoring parameters for selected antibiotics are given in Tables 110-5 and 110-6. Penicillin-allergic patients can be treated with clindamycin. For more serious infections, the patient should be hospitalized and aqueous penicillin G administered IV.[3,22] Marked improvement usually is seen within 48 hours, and the patient often may be switched to oral penicillin to complete the course of therapy. Although one study has shown that the median time for cure, IV antibiotics, and hospital stay was reduced in patients receiving prednisolone in addition to antibiotics, further studies are needed before corticosteroids can be recommended for routine use.[3,15,31]

Evaluation of Therapeutic Outcomes

Erysipelas generally responds quickly to appropriate antimicrobial therapy. Temperature and white blood cell count should return to normal within 48 to 72 hours. Erythema, edema, and pain also should resolve gradually.

IMPETIGO

3 Impetigo is a superficial skin infection that is seen most commonly in children.[6,22,33] The infection is generally classified as bullous or nonbullous based on clinical presentation.[10,33] Impetigo is most common during hot, humid weather, which facilitates microbial colonization of the skin.[3,6,22,33] Minor trauma, such as scratches or insect bites, allows entry of organisms into the superficial layers of skin, and infection ensues.[3,22,26,33] Impetigo is highly communicable and readily spreads through close contact, especially among siblings and children in daycare centers and schools.[3,22,33]

CLINICAL PRESENTATION
Erysipelas

General

- Lower extremities are the most common sites.

Symptoms

- Flu-like symptoms (fever, chills, malaise) common prior to the appearance of the lesion.
- Infected area described as painful or as a burning pain.

Signs

- Lesion is intensely erythematous and edematous, often with lymphatic streaking.
- Lesion has raised border, which is sharply demarcated from uninfected skin.
- Temperature is often mildly elevated.

Laboratory Tests

- Causative organism usually cannot be cultured from the surface skin.
- Needle aspiration or punch biopsies occasionally identify organism.
- Cultures considered for more severe cases (eg, atypical clinical findings such as fluid-filled blisters).

Other Diagnostic Tests

- A complete blood count is often performed because leukocytosis is common.
- C-reactive protein is also generally elevated.

TABLE 110-3 Evidence-Based Recommendations for Treatment of Skin and Soft-Tissue Infections[3,5,6,15,27-29]

Recommendations	Recommendation Grade[a]
Folliculitis, Furuncles, Carbuncles	
Gram stain and culture of pus from carbuncles and abscesses are recommended, but treatment without cultures is reasonable in most patients	Strong, moderate
Carbuncles, abscesses and large furuncles of mild severity should be treated with incision and drainage	Strong, high
Administration of antibiotics with activity against *Staphylococcus aureus* as an adjunct to incision and drainage should be based on presence or absence of systemic signs of infection	Strong, low
Antibiotics with activity against MRSA are recommended for patients with carbuncles or abscesses of higher severity who have failed initial antibiotic therapy, have severe systemic signs of infection, or are immunocompromised	Strong, low
Erysipelas	
Most infections are caused by *Streptococcus pyogenes*. Penicillin (oral or IV depending on clinical severity) is the drug of choice	A-I
If *S. aureus* is suspected, a penicillinase-resistant penicillin or first-generation cephalosporin should be used	A-I
Impetigo	
Gram stain and culture of pus or exudates should be obtained to help identify causative pathogens	Strong, moderate
Bullous and nonbullous impetigo should be treated with either mupirocin or retapamulin for 5 days	Strong, high
Impetigo should be treated with oral antibiotics active against S. aureus unless cultures show streptococci alone. Dicloxacillin or cephalexin is recommended for 7 days. Doxycycline, clindamycin, or sulfamethoxazole-trimethoprim should be used when MRSA is suspected or confirmed	Strong, moderate
Cellulitis	
Cultures of blood or cutaneous aspirates, biopsies or swabs are not routinely recommended	Strong, moderate
Blood cultures are recommended, and cultures of cutaneous aspirates, biopsies, or swabs should be considered, in patients receiving chemotherapy for malignancies, neutropenia, severe cell-mediated immunodeficiency, immersion injuries, or animal bites	Strong, moderate (blood) Weak, moderate (other cultures)
Typical cases of mild nonpurulent cellulitis should be treated with antibiotics active against streptococci	Strong, moderate
Systemic antibiotics are recommended for moderate nonpurulent cellulitis with systemic signs of infection. Use of antibiotics active against methicillin-susceptible *S. aureus* could be considered	Weak, low
Patients with severe nonpurulent cellulitis associated with penetrating trauma, MRSA infection in another location, MRSA nasal colonization, injection drug use, or systemic signs of infection should be treated with vancomycin or other antibiotics active against both MRSA and streptococci	Strong, moderate
Broad-spectrum antibiotic therapy with vancomycin plus either piperacillin–tazobactam, imipenem, or meropenem may be considered for empiric treatment of severe nonpurulent cellulitis in severely immunocompromised patients	Weak, moderate (need for broad-spectrum therapy) Strong, moderate (recommended broad-spectrum antibiotic regimen if used)
A treatment duration of 5 days is recommended for cellulitis, but may be extended if lack of clinical response within that time	Strong, high
Elevation of the affected area and treatment of predisposing factors are recommended for cellulitis	Strong, moderate
Systemic corticosteroids for 7 days can be considered for adjunctive treatment of cellulitis in nondiabetic patients	Weak, moderate
Patients with mild nonpurulent cellulitis who do not have systemic signs of infection, altered mental status, or hemodynamic instability should be treated as outpatients	Strong, moderate
Hospitalization is recommended for patients with moderate to severe nonpurulent cellulitis who have failed outpatient therapy, have poor adherence to therapy, are immunocompromised, or in whom there is a concern for deeper or necrotizing infection	Strong, moderate
Empiric antibiotics for outpatients with purulent cellulitis should provide activity against community-associated MRSA; coverage of β-hemolytic streptococci is likely not required. Mild–moderate infections can generally be treated with oral agents (dicloxacillin, cephalexin, clindamycin) unless resistance is high in the community	A-II
Recommended antibiotics for empiric coverage of MRSA in outpatients include orally administered trimethoprim–sulfamethoxazole, doxycycline, minocycline, clindamycin, and linezolid	A-II for all listed options
If coverage of both β-hemolytic streptococci and community-associated MRSA is desired, empiric antibiotic regimens for outpatient therapy include orally administered clindamycin alone; linezolid alone; or trimethoprim–sulfamethoxazole, doxycycline, or minocycline in combination with amoxicillin	A-II for all listed options
Hospitalized patients with complicated or purulent cellulitis should receive IV antibiotics with activity against MRSA pending culture data. Antibiotic options include vancomycin, linezolid, daptomycin, telavancin, and clindamycin	A-I for all except clindamycin; clindamycin A-III
In the treatment of *S. aureus* infections, trough serum vancomycin concentrations should always be maintained >10 mg/L (>7 µmol/L) to avoid development of resistance	B-III
Necrotizing Fasciitis	
Patients with severe nonpurulent cellulitis characterized by aggressive infection and associated with signs of systemic toxicity, necrotizing fasciitis, or gas gangrene should have prompt surgical consultation	Strong, low

(*continued*)

TABLE 110-3 Evidence-Based Recommendations for Treatment of Skin and Soft-Tissue Infections[3,5,6,15,27-29] (*Continued*)

Recommendations	Recommendation Grade[a]
Early and aggressive surgical debridement of all necrotic tissue is essential	A-III
Necrotizing fasciitis should be empirically treated with broad-spectrum antibiotics such as vancomycin or linezolid plus piperacillin–tazobactam or a carbapenem, or vancomycin or linezolid plus ceftriaxone and metronidazole	Strong, low
Necrotizing fasciitis caused by *S. pyogenes* should be treated with the combination of clindamycin and penicillin	Strong, low
In the treatment of necrotizing fasciitis caused by methicillin-resistant *S. aureus* infections, trough serum vancomycin concentrations of 15-20 mg/L (10-14 μmol/L) are recommended	B-II
Clostridial gas gangrene (myonecrosis) should be treated with clindamycin and penicillin	B-III
Diabetic Foot Infections	
Clinically uninfected wounds should not be treated with antibiotics	A-III
Empiric antibiotic regimens should be selected based on severity of infection and likely pathogens	A-III
Antibiotic therapy should target only aerobic gram-positive cocci in patients with mild to moderate infection who have not received antibiotics within the previous month	C-III
Broad-spectrum empiric antibiotic therapy should be initiated in most patients with severe infections, until culture and susceptibility data are available	A-III
Empiric antibiotics directed against *Pseudomonas aeruginosa* are usually unnecessary except in patients with specific risk factors for infection with this pathogen: patient has been soaking feet, patient has failed previous antibiotic therapy with nonpseudomonal agents, or clinically severe infection	A-III
Empiric antibiotics directed against MRSA should be considered in patients with specific risk factors, including: prior history of infection or colonization with MRSA, high local prevalence of MRSA (eg, ≥50% for mild infections, ≥30% for severe infection), or clinically severe infection	C-III
Oral agents with high bioavailability may be used in the treatment of most mild, and many moderate, infections	A-II
Parenteral therapy is initially preferred for all severe, and some moderate, infections. After initial response, step-down therapy to oral agents can be considered	C-III
Definitive therapy should be based on results of appropriately collected cultures and sensitivities, as well as clinical response to empiric antimicrobial agents	A-III
Appropriate wound care, in addition to appropriate antimicrobial therapy, is often necessary for healing of infected wounds	A-III
Antibiotic therapy should only be continued until resolution of signs/symptoms of infection, but not necessarily until the wound is fully healed. The duration of therapy should initially be 1-2 weeks for mild infections and 2-3 weeks for moderate to severe infection	C-III
Animal Bites	
Preemptive early antibiotics should be administered for 3-5 days in patients with any of the following: immunocompromised; asplenic; advanced liver disease; preexisting or resultant edema of the bitten area; moderate to severe bite-related injuries, especially to the hands or face; or bite injuries that have penetrated the periosteum or joint capsule	Strong, low
Amoxicillin–clavulanic acid or other antibiotics active against both aerobic and anaerobic bacteria should be used for treatment of infected animal bites	Strong, moderate
Serious infections requiring IV antimicrobial therapy can be treated with a β-lactam/β-lactamase inhibitor combination or second-generation cephalosporin with activity against anaerobes (eg, cefoxitin)	B-II
Penicillinase-resistant penicillins, first-generation cephalosporins, macrolides, and clindamycin should not be used for treatment of infected wounds because of their poor activity against *Pasteurella multocida*	D-III
Human Bites	
Antimicrobial therapy should provide coverage against *Eikenella corrodens*, *S. aureus*, and β-lactamase–producing anaerobes	B-III

[a]Cited evidence-based guidelines utilize different systems for grading the strengths of recommendation and quality of the associated evidence. Qualitative (descriptive) recommendations are from reference 16; letter- and roman numeral-based recommendations are from the other cited guidelines. Readers are advised to consult the original documents for full explanations of the grading systems and definitions used in individual guidelines.

Strength of recommendation: A, good evidence for use; B, moderate evidence for use; C, poor evidence for use, optional; D, moderate evidence to support not using; E, good evidence to support not using. *Quality of evidence*: I, evidence from ≥1 properly randomized controlled trials; II, evidence from ≥1 well-designed clinical trials without randomization, case–control analytic studies, multiple time series, or dramatic results from uncontrolled experiments; III, evidence from expert opinion, clinical experience, descriptive studies, or reports of expert committees.

Qualitative (descriptive) recommendations: *Strong, high*: strong recommendation, high-quality evidence from well-performed randomized controlled trials (RCTs) or exceptionally strong evidence from unbiased observational studies; *Strong, moderate*: strong recommendation, moderate quality evidence from RCTs with important limitations or exceptionally strong evidence from unbiased observational studies; *Strong, low*: strong recommendation, low-quality evidence for at least 1 critical outcome from observational studies, RCTs with serious flaws, or indirect evidence; *Weak, moderate*: weak recommendation, moderate quality evidence from RCTs with important limitations or exceptionally strong evidence from unbiased observational studies; *Weak, low*: weak recommendation, low-quality evidence for at least one critical outcome from observational studies, RCTs with serious flaws, or indirect evidence.

TABLE 110-4 Recommended Oral Drugs for Outpatient Treatment of Mild–Moderate Skin and Soft-Tissue Infections

Infection	Adults	Children
Folliculitis	None; warm saline compresses usually sufficient	
Furuncles and carbuncles	Trimethoprim–sulfamethoxazole[a,b] Doxycycline[a,b] Minocycline[a,b]	Trimethoprim–sulfamethoxazole[a,b] Clindamycin[a,b]
Erysipelas	Procaine penicillin G Penicillin VK Clindamycin[a] Erythromycin[a]	Penicillin VK Clindamycin[a] Erythromycin[a]
Impetigo	Mupirocin ointment[a] Retapamulin ointment[a] Dicloxacillin Cephalexin Trimethoprim–sulfamethoxazole[a,b] Clindamycin[a,b] Doxycycline[a,b]	Mupirocin ointment[a] Retapamulin ointment[a] Dicloxacillin Cephalexin Trimethoprim–sulfamethoxazole[a,b] Clindamycin[a,b]
Lymphangitis	Initial IV therapy, followed by penicillin VK Clindamycin[a]	Initial IV therapy, followed by penicillin VK Clindamycin[a]
Diabetic foot infections	Dicloxacillin Clindamycin Cephalexin Amoxicillin–clavulanate Levofloxacin ± metronidazole or clindamycin[a,c] Ciprofloxacin ± metronidazole or clindamycin[a,c] Moxifloxacin	
Bite wounds (animal or human)	Amoxicillin–clavulanate Doxycycline[a] Moxifloxacin[a] Trimethoprim–sulfamethoxazole + metronidazole or clindamycin[a] Levofloxacin or ciprofloxacin + metronidazole or clindamycin[a] Cefuroxime axetil + metronidazole or clindamycin Dicloxacillin + penicillin VK	Amoxicillin–clavulanate Trimethoprim–sulfamethoxazole + metronidazole or clindamycin[a] Cefuroxime axetil + metronidazole or clindamycin Dicloxacillin + penicillin VK

[a]May be used in patients with penicillin allergy.

[b]Recommended if CA-MRSA is suspected.

[c]Fluoroquinolone alone may be suitable for mild infections, while addition of drugs with antianaerobic activity may be recommended for more severe infections.

TABLE 110-5 Drug Dosing Table[a]

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Oral Agents					
Amoxicillin–clavulanate	Augmentin®	875/125 mg orally two times daily	875/125 mg orally two times daily	Pediatric: 40 mg/kg (of the amoxicillin component) orally in two divided doses	
Cefaclor	Ceclor®	500 mg orally every 8 hours	500 mg orally every 8 hours	Pediatric: 20-40 mg/kg/day (not to exceed 1 g) orally in three divided doses	
Cefadroxil	Duricef®	500 mg orally every 12 hours	250-500 mg orally every 12 hours	Pediatric: 30 mg/kg orally in two divided doses	
Cefuroxime axetil	Ceftin®	500 mg orally every 12 hours	250-500 mg orally every 12 hours	Pediatric: 20-30 mg/kg orally in two divided doses	
Cephalexin	Keflex®	250-500 mg orally every 6 hours	250-500 mg orally every 6 hours	Pediatric: 25-50 mg/kg orally in four divided doses	
Ciprofloxacin	Cipro®	500 mg orally every 12 hours	500-750 mg orally every 12 hours		
Clindamycin	Cleocin®	300-600 mg orally every 6-8 hours	300-600 mg orally every 6-8 hours	Pediatric: 10-30 mg/kg/day orally in three to four divided doses[4]	May be used for oral treatment of MRSA infection
Dicloxacillin	Dynapen®	250-500 mg orally every 6 hours	250-500 mg orally every 6 hours	Pediatric: 25-50 mg/kg orally in four divided doses	
Doxycycline	Vibramycin®	100-200 mg orally every 12 hours	100-200 mg orally every 12 hours		May be used for oral treatment of MRSA infection

(*continued*)

TABLE 110-5 Drug Dosing Table[a] (*Continued*)

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Erythromycin	E-Mycin® Erythrocin®	250-500 mg orally every 6 hours	250-500 mg orally every 6 hours	Pediatric: 30-50 mg/kg orally in four divided doses[a]	
Levofloxacin	Levaquin®	500-750 mg orally once daily	500-750 mg orally once daily		
Linezolid	Zyvox®	600 mg orally every 12 hours	600 mg orally every 12 hours	Pediatric: 20-30 mg/kg/day orally in two to three divided doses	For oral treatment of MRSA infection
Metronidazole	Flagyl®	250-500 mg orally every 8 hours	250-500 mg orally every 8 hours	Pediatric: 30 mg/kg orally in three to four divided doses	
Moxifloxacin	Avelox®	400 mg orally once daily	400 mg orally once daily		
Mupirocin ointment	Bactroban®	Apply to affected areas every 8 hours	Apply to affected areas every 8 hours	Pediatric: apply to affected areas every 8 hours	
Penicillin VK	Veetids® Pen-V®	250-500 mg orally every 6 hours	250-500 mg orally every 6 hours	Pediatric: 25,000-90,000 units/kg orally in four divided doses	
Retapamulin ointment	Altabax®	Apply to affected area every 12 hours	Apply to affected area every 12 hours	Pediatric: apply to affected area every 12 hours	
Tedizolid	Sivextro®	200 mg orally once daily	200 mg orally once daily		For oral treatment of MRSA infection
Trimethoprim–sulfamethoxazole	Bactrim® Septra® Cotrimoxazole®	160/800 mg orally every 12 hours	160/800 mg orally every 12 hours	Pediatric: 4-6 mg/kg (of the trimethoprim component) orally every 12 hours	Up to double the usual dose may be considered for oral treatment of MRSA infection
Parenteral Agents					
Ampicillin	Omnipen® Polycillin® Principen®	2 g IV every 6 hours	1-2 g IV every 4-6 hours	Pediatric: 200-300 mg/kg/day IV in four to six divided doses	
Aztreonam	Azactam®	1 g IV every 6 hours	1 g IV every 6 hours	Pediatric: 100-150 mg/kg/day IV in four divided doses	
Cefazolin	Ancef® Kefzol®	1 g IV every 8 hours	1 g IV every 6-8 hours	Pediatric: 75 mg/kg/day IV in three divided doses	
Cefepime	Maxipime®	2 g IV every 12 hours	1-2 g IV every 12 hours	Pediatric: 100 mg/kg/day IV in two divided doses	
Cefotaxime	Claforan®	2 g IV every 6 hours	1-2 g IV every 6 hours	150-200 mg/kg/day in three to four divided doses	
Cefoxitin	Mefoxin®	1-2 g IV every 6 hours	1-2 g IV every 6 hours	Pediatric: 30-40 mg/kg/day IV in four divided doses	
Ceftazidime	Fortaz®	2 g IV every 8 hours	1-2 g IV every 8 hours	Pediatric: 150 mg/kg/day IV in three divided doses	
Ceftaroline	Teflaro®	600 mg IV every 12 hours	600 mg IV every 12 hours		For MRSA infection
Ceftriaxone	Rocephin®	1 g IV once daily	1 g IV once daily		
Cefuroxime	Zinacef®	1.5 g IV every 8 hours	0.75-1.5 g IV every 8 hours	Pediatric: 150 mg/kg/day IV in three divided doses	
Ciprofloxacin	Cipro®	400 mg IV every 8-12 hours	400 mg IV every 8-12 hours		
Clindamycin	Cleocin®	300-600 mg IV every 6-8 hours	300-600 mg IV every 6-8 hours; 600-900 mg IV every 6-8 hours for necrotizing fasciitis	Pediatric: 30-50 mg/kg/day IV in three to four divided doses	

(*continued*)

TABLE 110-5 Drug Dosing Table[a] (*Continued*)

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Dalbavancin	Dalvance®	1,000 mg IV once on Day 1 of therapy	500 mg IV once on Day 8 of therapy		For MRSA infection
Daptomycin	Cubicin®	4 mg/kg IV once daily	4 mg/kg IV once daily		For MRSA infection
Doripenem	Doribax®	500 mg IV every 8 hours	500 mg IV every 8 hours		
Ertapenem	Invanz®	1 g IV once daily	1 g IV once daily	Pediatric: 30 mg/kg/day IV in one to two divided doses	
Gentamicin	Garamycin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours. Alternative: 5-7 mg/kg IV once daily	Traditional dosing: guided by measured serum concentrations	Pediatric: 5-7 mg/kg/day IV in three divided doses; doses guided by serum concentrations	
Imipenem–cilastatin	Primaxin®	500 mg IV every 6 hours	250-500 mg IV every 6-8 hours	Pediatric: 40-80 mg/kg/day IV in four divided doses	
Levofloxacin	Levaquin®	750 mg IV once daily	500-750 mg IV once daily		
Linezolid	Zyvox®	600 mg IV every 12 hours	600 mg IV every 12 hours	Pediatric: 20-30 mg/kg/day IV in two to three divided doses	For MRSA infection
Meropenem	Merrem®	1 g IV every 8 hours	1 g IV every 8 hours	Pediatric: 60 mg/kg/day IV in three divided doses	
Metronidazole	Flagyl®	500 mg IV every 8 hours	500 mg IV every 8 hours	Pediatric: 30-50 mg/kg/day IV in three divided doses	
Moxifloxacin	Avelox®	400 mg IV once daily	400 mg IV once daily		
Nafcillin	Nafcil®	2 g IV every 6 hours	1-2 g IV every 4-6 hour	Pediatric: 100-200 mg/kg/day IV in four to six equally divided doses	
Oritavancin	Orbactiv®	1,200 mg IV once	(no additional doses)		For MRSA infection
Penicillin G	Pfizerpen® Bicillin® Wycillin®	1-2 million units IV every 4-6 hours	1-2 million units IV every 4-6 hours	Pediatric: 100,000-200,000 units/kg/day IV in four divided doses[a]	
Piperacillin–tazobactam	Zosyn®	4.5 g IV every 6 hours	3.375-4.5 g IV every 6 hours	Pediatric: 250-350 mg/kg/day IV in three to four divided doses	
Procaine penicillin G	Bicillin C-R®	600,000 units IM every 12 hours	600,000-1.2 million units IM every 12 hours	Pediatric: 25,000-50,000 units/kg (maximum 1.2 million units) IM once daily	
Tedizolid	Sivextro®	200 mg IV once daily	200 mg IV once daily		For MRSA infection
Telavancin	Vibativ®	10 mg/kg IV once daily	10 mg/kg IV once daily		For MRSA infection
Tigecycline	Tigacil®	100 mg IV once, and then 50 mg IV every 12 hours	100 mg IV once, and then 50 mg IV every 12 hours		
Tobramycin	Nebcin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours. Alternative: 5-7 mg/kg IV once daily	Traditional dosing: guided by measured serum concentrations	Pediatric: 5-7 mg/kg/day IV in three divided doses; doses guided by serum concentrations	
Vancomycin	Vancocin®	30-40 mg/kg/day IV in two divided doses	Dosing guided by serum concentrations to achieve trough of 15-20 mg/L	Pediatric: 40-60 mg/kg/day IV in three to four divided doses; doses guided by serum concentrations	For MRSA infection

IM, intramuscularly; MRSA, methicillin-resistant *S. aureus*.

[a]Dosing guidelines in patients with normal renal function.

TABLE 110-6 Drug Monitoring

Drug	Adverse Reaction	Monitoring Parameters	Comments
Aminoglycosides (tobramycin, gentamicin)	Nephrotoxicity	Serum creatinine, urine output, serum concentrations	Extended-interval ("once-daily") dosing potentially associated with less renal toxicity, similar efficacy to traditional dosing. Goal trough concentration <1 mcg/mL (mg/L; <2 μmol/L) during extended-interval dosing
Daptomycin	Myopathy	Serum creatine phosphokinase	Most creatinine phosphokinase elevations will be asymptomatic; risk of myopathy may be increased with concomitant use of HMG-coA reductase inhibitors
Imipenem–cilastatin	CNS toxicities, seizures	Serum creatinine, mental status, CNS function	Increased incidence with higher dose, failure to adjust dose/interval for reduced renal function. Increased risk compared with meropenem or doripenem
Linezolid	Myelosuppression, thrombocytopenia, optic/peripheral neuropathy, serotonin syndrome	CBC, vision changes, serum lactate, heart rate, blood pressure, temperature, myoclonus	Myelosuppression and neuropathy more common with prolonged use. Weak MAO inhibitor, serotonin syndrome possible with other serotonergic drugs such as SSRIs and SNRIs
Nafcillin	Interstitial nephritis	Serum creatinine, urine output	Reversible, requires switch to alternative β-lactam
Vancomycin	Nephrotoxicity, infusion reactions	Serum creatinine, urine output, blood pressure, heart rate, serum concentrations	Dose adjustment required for renal dysfunction. Pretreatment and slow infusion may decrease incidence of infusion reaction. Goal trough concentration 15-20 mcg/mL (mg/L; 10-14 μmol/L) for serious infections, including necrotizing fasciitis

CBC, complete blood count; MAO, monoamine oxidase; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

Although historically caused by *S. pyogenes*, *S. aureus* has emerged as a principle cause of impetigo (either alone or in combination with *S. pyogenes*).[22,33] The bullous form is caused by strains of *S. aureus* capable of producing exfoliative toxins.[22,33] The bullous form most frequently affects neonates,[34] and accounts for approximately 30% of all cases of impetigo.[3,33] Similar to other SSTIs, impetigo has been reported to be increasingly due to MRSA.[22,33]

TREATMENT
Impetigo

Desired Outcomes

The goals of treatment include relieving discomfort, improving the cosmetic appearance of lesions, preventing further spread of the infection, and preventing recurrence. Preventing transmission to others is also important.[22,33] Treatments should be effective and inexpensive and have minimal adverse effects.[33]

Treatment

Although impetigo may resolve spontaneously, antimicrobial treatment is indicated to relieve symptoms, prevent formation of new lesions, and prevent complications such as cellulitis. A review of interventions for impetigo by the Cochrane Collaboration found that topical mupirocin and oral antibiotics (except penicillin and erythromycin) were equally effective for the treatment of impetigo;[34] topical mupirocin ointment or retapamulin ointment for 5 days are now recommended as first-line treatment of mild cases of impetigo not involving multiple lesions or the face.[15,22,33] Penicillinase-resistant penicillins (such as dicloxacillin) are preferred for treatment because of the increased incidence of infections caused by *S. aureus*.[15,22,33] First-generation cephalosporins (eg, cephalexin) are

CLINICAL PRESENTATION
Impetigo

General

- Exposed skin, especially the face, is the most common site.

Symptoms

- Pruritus is common.
- Systemic signs and symptoms of infection are minimal.
- Weakness, fever, and diarrhea occasionally seen with bullous form.

Signs

Nonbullous:

- Lesions start as small, fluid-filled vesicles.
- Vesicles rapidly develop into pustules that rupture readily.
- Purulent discharge dries to form characteristic golden yellow crusts.

Bullous:

- Lesions start as vesicles that rapidly progress into bullae containing clear yellow fluid.
- Bullae soon rupture, forming thin, light brown crusts.
- Regional lymph nodes may be enlarged.

Laboratory Tests

- Cultures should be collected.
- Crusted tops of lesions should be raised to obtain purulent material at the base for culture.
- Open, draining pustules should not be cultured as they may be colonized with skin flora.

Other Diagnostic Tests

- Complete blood count often performed as leukocytosis is common.

also commonly used.[15,22,33] Penicillin, administered as a single intramuscular dose of benzathine penicillin G or as oral penicillin VK, is effective for infections known to be caused by *S. pyogenes*. Penicillin-allergic patients, or those known to be infected with MRSA, can be treated with clindamycin, doxycycline, or trimethoprim–sulfamethoxazole. The duration of therapy is 7 days.[15] With proper treatment, healing of skin lesions generally is rapid and occurs without residual scarring. Removal of crusts by soaking in soap and warm water also may be helpful in providing symptomatic relief.[3,22,33]

Evaluation of Therapeutic Outcomes

Clinical response should be seen within 5-7 days of initiating antimicrobial therapy for impetigo. Treatment failures could be a result of noncompliance or antimicrobial resistance. A followup culture of exudates should be collected for culture and sensitivity, with treatment modified accordingly.

LYMPHANGITIS

4 Acute lymphangitis is an inflammation involving the subcutaneous lymphatic channels. Lymphangitis usually occurs secondary to puncture wounds, infected blisters, or other skin lesions. Most infections are caused by *S. pyogenes*.[35]

TREATMENT
Lymphangitis

Desired Outcomes

The goal of treatment of lymphangitis is rapid eradication of the infection, thereby providing relief of symptoms (pain, tenderness, fever). Prevention of systemic complications is also an important goal as thrombophlebitis and abscess formation are possible. Treatments should be effective and inexpensive and have minimal adverse effects.

Treatment

Penicillin is the antibiotic of choice. Because these infections are potentially serious and rapidly progressive, initial treatment should be with IV penicillin G 1 to 2 million units every 4 to 6 hours. Parenteral treatment should be continued for 48 to 72 hours, followed by oral penicillin VK for a total of 10 days.[35] Nondrug therapy includes immobilization and elevation of the affected extremity and warm-water soaks every 2 to 4 hours.[35] For penicillin-allergic patients, clindamycin may be used.

Evaluation of Therapeutic Outcomes

Lymphangitis usually responds rapidly to appropriate therapy; signs and symptoms often are decreased markedly or absent within 24 hours of starting antibiotics.

CELLULITIS

5 Cellulitis is an acute infectious process that initially affects the epidermis and dermis and may spread subsequently within the superficial fascia.[10] Cellulitis is considered a serious disease because of the propensity of the infection to spread through lymphatic tissue and to the bloodstream. *S. pyogenes* and *S. aureus* are the most frequent bacterial causes.[5,7,12,21,26] However, many bacteria have been implicated in various types of cellulitis (Table 110-1). Approximately 4 million patients were hospitalized for cellulitis between 1998 and 2006, representing 10% of all infection-related admissions.[8,9,36] The rising incidence of infections caused by methicillin-resistant *S. aureus* (MRSA) is a major concern in both the community and hospital settings.[13-18]

Injection drug users are predisposed to several infectious complications, including abscess formation and cellulitis at the site of injection.[15] These SSTIs are often polymicrobic in nature and are believed to originate from the skin and/or oropharynx, as well as from contaminated needles, syringes, and diluents.[15] *S. aureus*, including MRSA, is the most common pathogen isolated from injection drug users.[15,6,37] Anaerobic bacteria, especially oropharyngeal

CLINICAL PRESENTATION — Lymphangitis

General

- Lymphadenitis (acute or chronic inflammation of the lymph nodes) may occur when microorganisms reach the lymph nodes.

Symptoms

- Systemic signs and symptoms (ie, fever, chills, malaise, and headache) often develop rapidly before any sign of infection is evident at the initial site of inoculation, or after the initial lesion has subsided.
- Systemic signs and symptoms often are more profound than would be expected based on examination of the cutaneous lesion.

Signs

- Peripheral lesion associated with proximal red linear streaks directed toward the regional lymph nodes is diagnostic of acute lymphangitis.
- Lymph nodes usually are enlarged and tender.
- Peripheral edema of the involved extremity often is present.
- Thrombophlebitis and acute lymphangitis in the lower extremities may be confused because both are associated with red linear streaking and tender areas; however, in thrombophlebitis, no portal of entry is identifiable.

Laboratory Tests

- Cultures of the affected lesions often yield negative results.
- Pathogens often identified by Gram stain of the initial lesion if done early in the course of the disease.

Other Diagnostic Tests

- Complete blood count often performed as leukocytosis is common.

CLINICAL PRESENTATION Cellulitis

General

- Usually a history of an antecedent wound from minor trauma, abrasion, ulcer, or surgery.

Symptoms

- Patients often experience fever, chills, or malaise and complain that the affected area feels hot and painful.
- Systemic findings such as hypotension, dehydration, and altered mental status are common.

Signs

- Characterized by erythema and edema of the skin.
- Lesions are nonelevated and have poorly defined margins.
- Affected areas generally are warm to touch.
- Inflammation generally is present with little or no necrosis or suppuration of soft tissue.
- Lesions may be associated with purulent drainage, exudates, and/or abscesses.
- Tender lymphadenopathy associated with lymphatic involvement is common.

Laboratory Tests

- Cultures should be collected when possible.
- Gram stain of fluid obtained by injection and aspiration of 0.5 mL of saline (using a small 22-gauge needle) into the advancing edge of the lesion may aid the microbiologic diagnosis but often yields negative results.
- Diagnosis usually is made on clinical grounds rather than by culture.

Other Diagnostic Tests

- Complete blood count often performed as leukocytosis is common.
- Blood cultures often useful because bacteremia may be present in up to 30% of cases.

anaerobes, are also found commonly, particularly in polymicrobic infections.[15] Outbreaks caused by *Clostridium* species have also been reported in injection drug users.[15]

Acute cellulitis with mixed aerobic and anaerobic pathogens may occur in diabetics, following traumatic injuries, at sites of surgical incisions to the abdomen or perineum, or where host defenses have been otherwise compromised (vascular insufficiency).[6,10,26] In older patients, cellulitis of the lower extremities also may be complicated by thrombophlebitis. Other complications of cellulitis include local abscess, osteomyelitis, and septic arthritis.[15,38]

TREATMENT Cellulitis

Desired Outcomes

The goals of therapy of acute bacterial cellulitis are rapid eradication of the infection and prevention of further complications. Effective treatment of cellulitis includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Drug and Nondrug Management of Cellulitis

Local care of cellulitis includes elevation and immobilization of the involved area to decrease swelling.[5,15,38] Cool sterile saline dressings may decrease pain and can be followed later with moist heat to aid in localization of the cellulitis. Surgical intervention (incision and drainage) as a mode of therapy is rarely indicated in the treatment of uncomplicated cellulitis, but may play an important role in management of more severe or complicated cases. Antimicrobial therapy is directed against the type of bacteria either documented or suspected to be present based on the clinical presentation. Particular attention must be paid to patients with risk factors for more atypical or resistant bacterial pathogens when selecting antibiotics for treatment of cellulitis. Such organisms include particularly MRSA, but also aerobic gram-negative bacteria and anaerobes.

Because staphylococcal and streptococcal cellulitis are indistinguishable clinically,[21,38] and because of concern regarding appropriate recognition and treatment of MRSA infections, guidelines from the Infectious Diseases Society of America provide detailed recommendations for empiric antibiotic therapy of cellulitis.[15,28] Antibiotic selection for treatment of cellulitis is chiefly determined by clinical findings such as appearance of the infected lesion and presence of more severe systemic illness. Cellulitis may be broadly classified as either purulent or nonpurulent for purposes of determining likely pathogens and appropriate empiric antibiotic therapy. Purulent cellulitis is defined as infection associated with purulent drainage or exudate in the absence of a simple drainable abscess; the presence of abscesses are also often associated with purulent cellulitis but by definition that is not the only clinical feature.[15,28] Incision and drainage of any abscesses and good wound care are the primary therapies for mild purulent infections when no systemic findings of infection are present. Systemic antibiotic therapy is often unnecessary in such cases.[15,28] Antibiotic therapy is recommended along with incision and drainage in patients with more complicated abscesses and/or moderately severe purulent cellulitis including the following: those with systemic signs of infection; multiple sites of infection; rapidly progressive infection in the presence of associated cellulitis; complicating factors such as extremes of age, comorbidities, or immunosuppression; abscesses in areas that are difficult to drain, such as hands, face, and genitalia; or lack of response to previous drainage alone.[15,28,38,40-43] Such patients are usually treated as outpatients using orally administered antibiotics with activity against MRSA; infection due to streptococci is less likely in this situation and specific coverage is not required.[28,44-46] Oral agents recommended for moderate purulent cellulitis include trimethoprim–sulfamethoxazole and doxycycline (Fig. 110-1).[15] Oral linezolid is also recommended in such cases but is significantly more expensive and apparently no more efficacious than other treatment options.[28] Tedizolid, a newer oxazolidinone, is also indicated for the treatment of complicated SSTI but the relative advantages or role of tedizolid compared to linezolid have not been well established.[15]

Severe purulent cellulitis is defined as purulent infections occurring in patients who have failed incision and drainage plus oral antibiotic therapy, patients with systemic signs of infection (defined

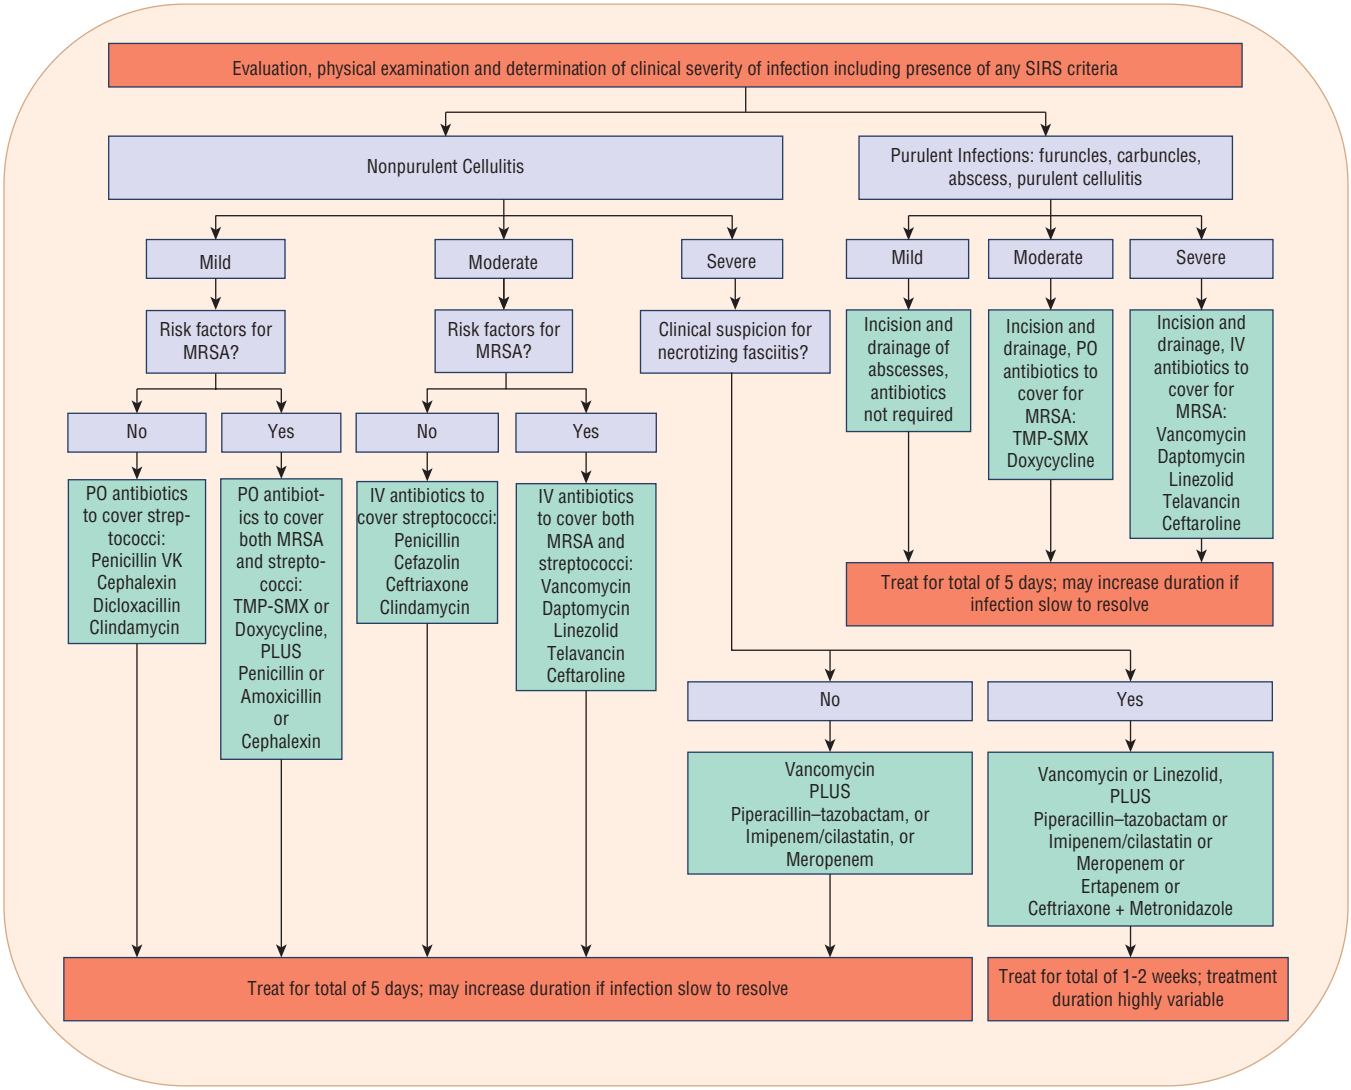

FIGURE 110-1 Recommended treatment algorithm for initial empiric management of selected purulent and nonpurulent skin and soft tissue infections. (GNR, aerobic gram-negative rods; GPC, aerobic gram-positive cocci; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; PO, oral; SIRS, systemic inflammatory response syndrome; TMP-SMX, trimethoprim–sulfamethoxazole.)

as temperature more than 38°C, heart rate more than 90 beats/minute, respiratory rate more than 24 breaths/minute, or white blood cell count more than 12,000 or less than 400 cells/μL[less than 12×10^9/L or $<0.4 \times 10^9$/L]), or immunocompromised patients. Appropriate clinical specimens for culture and susceptibility testing should be collected whenever possible in such patients.[5,15,28,38] Patients with severe purulent cellulitis should be hospitalized for empiric treatment with parenteral antibiotics having activity against MRSA. Vancomycin, daptomycin, linezolid, televancin, and ceftaroline are all acceptable treatment options with comparable efficacy in adults (Fig. 110-1).[3,15,28,47] In children, vancomycin, linezolid, or clindamycin is the preferred treatment option.[15]

Linezolid, tedizolid, daptomycin, ceftaroline, and telavancin all exhibit excellent activity against resistant gram-positive pathogens.[40-43,47] However, significantly higher cost compared with vancomycin, as well as lack of demonstrated advantages in efficacy, makes them most appropriate for the treatment of complicated or refractory infections, or those documented as caused by multidrug-resistant pathogens, rather than as initial therapy. The availability of orally administered linezolid and tidezolid may provide cost-effective "step-down" options as alternatives to prolonged treatment with parenteral agents for many patients with more complicated infections and/or those patients who require initial hospitalization.[44]

Carbapenems (ie, imipenem, meropenem, ertapenem, and doripenem) and the β-lactam–β-lactamase inhibitor combination antibiotics (ampicillin–sulbactam, ticarcillin–clavulanate, and piperacillin–tazobactam) appear to be equivalent to standard therapies in adults.[3,5,15,38] However, the greater cost of these agents without increased efficacy compared with other reliable regimens, particularly given the increasing problem of MRSA, makes them less desirable for empiric therapy except in serious polymicrobic infections.[5,15,38]

Clinical **Controversy...**

The appropriate roles of dalbavancin and oritavancin, two newer drugs indicated for the treatment of complicated SSTI and with good activity against MRSA, are not well defined at this time. Dalbavancin exhibits a terminal elimination half-life of approximately 14 days and is administered as only two doses given one week apart, while oritavancin has a half-life of approximately 10 days and is administered as a single one-time dose. The ability to provide an entire course of therapy with only one or two doses is attractive in terms of convenience, negating any drug adherence concerns with

oral therapy, and potentially saving hospitalization costs with administration of effective therapy in the emergency department or even outpatient physician offices. However, the drugs are expensive compared to other treatment options and there are concerns related to potential lack of patient follow-up for monitoring of their infection. The most appropriate roles of these drugs in the routine management of cellulitis and other complicated SSTIs have yet to be determined.

Nonpurulent cellulitis ("typical cellulitis") is defined as cellulitis without purulent drainage or exudate and no associated abscess. The role of MRSA in these types of infection is not clear, so empiric therapy of nonpurulent cellulitis is directed primarily against Group A β-hemolytic streptococci.[48] Recommended empiric therapy of mild nonpurulent cellulitis (ie, no focus of purulence or systemic signs of infection) consists of an orally administered β-lactam such as penicillin VK, cephalexin or dicloxacillin (Fig. 110-1).[15,28,38] Oral cephalosporins, such as cefadroxil, cefaclor, cefprozil, cefpodoxime proxetil, and cefdinir, are also effective in the treatment of cellulitis but are more expensive.[15,38] Oral clindamycin may be used in penicillin-allergic patients.[15,28,38] Alternatively, a first-generation cephalosporin may be used cautiously for patients without a history of immediate or anaphylactic reactions to penicillin. Patients with moderately severe nonpurulent cellulitis (ie, systemic evidence of infection) or poor adherence to oral therapy should be hospitalized and treated with parenteral antibiotics directed against Group A streptococci. Recommended agents include penicillin VK, ceftriaxone, cefazolin, and clindamycin.[15,48] Hospitalization and treatment with parenteral antibiotics are also recommended for patients with severe nonpurulent cellulitis as indicated by the presence of systemic findings of infection (as previously defined for purulent cellulitis), failure of previous oral antibiotic therapy, immunocompromised states, or presence of clinical signs of deeper infection such as bullae, skin sloughing, hypotension, or organ dysfunction.[15] Empiric antibiotics for severe nonpurulent cellulitis should provide a broad spectrum of activity against MRSA and streptococci, as well as gram-negative and anaerobic bacteria. Recommended regimens include vancomycin plus piperacillin–tazobactam, and vancomycin plus imipenem-cilastatin or meropenem.

Empiric treatment of MRSA should be considered for patients with either moderate or severe nonpurulent cellulitis that is associated with penetrating trauma, evidence of MRSA infection at another site or nasal colonization with MRSA, injection drug use, or in patients meeting SIRS criteria (fever, tachycardia, tachypnea, or leukocytosis or leukopenia as previously defined).[15,28] Recommended drugs for the coverage of MRSA in this setting are the same as those for purulent cellulitis. Clindamycin has reasonably good activity against β-hemolytic streptococci, but the activities of trimethoprim–sulfamethoxazole and the tetracyclines against this organism are not well defined.[28] Therefore, if empiric coverage of both MRSA and β-hemolytic streptococci is desired for patients with nonpurulent cellulitis, they should receive clindamycin alone or amoxicillin in combination with trimethoprim–sulfamethoxazole, doxycycline, or minocycline.[28] Hospitalized patients with nonpurulent cellulitis who are not initially treated for MRSA should have their antibiotic changed to an agent with activity against MRSA if there is unsatisfactory clinical response.[28] Although often used for treatment of uncomplicated outpatient cellulitis, fluoroquinolones (eg, levofloxacin, moxifloxacin) are not recommended for routine use due to their unnecessarily broad spectrum of activity, concerns for resistance, and higher cost compared with other preferred options.

Clinical **Controversy...**

The administration of systemic corticosteroids (eg, prednisone 40 mg daily for 7 days) has been recommended as a potential option for adjunctive treatment of cellulitis in nondiabetic patients. Since patients who are immunocompromised are at increased risk of severe SSTI and also potentially resistant pathogens such as MRSA, the notion of administering immunosuppressant agents such as corticosteroids to patients with cellulitis seems counterintuitive and even potentially harmful. However, a randomized, double-blind, placebo-controlled trial found that administration of oral corticosteroids plus antibiotics was associated with favorable outcomes including more rapid resolution of the infection without increased risk of relapse or recurrence.[32] Additional studies are needed to define the optimal role of corticosteroids in the treatment of cellulitis.

Patients in whom specific pathogens have been identified by culture should have empiric antibiotics narrowed according to susceptibility test results. If documented to be a mild cellulitis secondary to streptococci, oral penicillin VK or intramuscular procaine penicillin G may be administered. Since *S. aureus* susceptibilities are more variable, treatment of documented staphylococcal infections will depend on test results for specific isolates. The usual duration of therapy for outpatient treatment of cellulitis, either purulent or nonpurulent, is 5 days; a longer duration should be considered if the infection has not sufficiently improved within that time.[3,15,38] A 7 to 14 day course of antibiotics has been recommended for cellulitis in hospitalized patients, but shorter courses (5 to 7 days) are often as effective as longer courses and should be used whenever possible.[15] In all cases, duration of therapy should be individualized based on patient response.[15,28]

For cellulitis caused by gram-negative bacilli or a mixture of microorganisms, immediate antimicrobial chemotherapy, as determined by Gram stain, is essential. Surgical debridement of necrotic tissue and drainage also may be appropriate. Gram-negative cellulitis may be treated appropriately with an aminoglycoside (such as gentamicin or tobramycin), or a first- or second-generation cephalosporin (eg, cephalexin, cefaclor, or cefuroxime). Ceftriaxone, ceftazidime, and the fluoroquinolones are also effective in the treatment of cellulitis caused by both gram-negative and gram-positive bacteria.[3,5,15,38] If gram-positive aerobic bacteria are also present on Gram stain, an additional agent such as penicillin G or a penicillinase-resistant penicillin may need to be added to provide coverage against staphylococci or streptococci as appropriate.[28] Addition of an agent active against MRSA (eg, vancomycin) may need to be considered for severe, complicated infections in hospitalized patients.[3,5,15,28,38] Ceftaroline is potentially advantageous in this setting since it has activity against MRSA and streptococci as well as gram-negative aerobic bacteria.

Because some polymicrobic infections may also involve anaerobic bacteria, antibiotic therapy may need to be broadened to include agents with good activity against these organisms. Many different treatment regimens are possible depending on the bacteriology of the lesion (Fig. 110-1). Orally administered antibiotics, as monotherapy or in combination regimens, may be appropriately used in the treatment of mild to moderate infections in outpatients. Monotherapy or combination regimens of IV antibiotics may be necessary for more severe infections in hospitalized patients. Therapy should be 5 to 7 days in duration, with longer durations potentially needed in patients who do not respond to therapy in that time.[3,15,38]

Because gram-negative and mixed aerobic–anaerobic cellulitis can progress quickly to serious tissue invasion, therapeutic

intervention should be immediate.[3,15,38] If treated early, a rapid response can be seen. Unfortunately, because these infections often occur in patients with compromised immune defenses, they may still progress, even with therapeutic intervention. If the infectious process is secondary to a systemic cause (eg, diabetes), the treatment course often is prolonged and may be associated with high morbidity and mortality.[3,15,38]

Infections in injection drug users generally are treated similarly to those in other types of patients.[3,15,38] It is important that blood cultures be obtained in these cases because 25% to 35% of patients may be bacteremic.[3,15] Also, patients should be assessed for the presence of abscesses; incision, drainage, and culture of these lesions are of extreme importance.[15] Initial antimicrobial therapy while awaiting culture results of abscesses should include broad coverage for gram-negative and anaerobic organisms, in addition to MRSA and streptococci.[3,15,38]

Evaluation of Therapeutic Outcomes

If treated promptly with appropriate antibiotics, the majority of patients with cellulitis are cured rapidly. Culture and sensitivity results should be evaluated carefully for both the adequacy of culture material and the presence of resistant organisms. Additional high-quality samples for culture may be needed for microbiologic analysis. Failure to respond to therapy also may be indicative of an underlying local or systemic problem or a misdiagnosis.

NECROTIZING SOFT-TISSUE INFECTIONS

Necrotizing soft-tissue infections consist of a group of extremely severe infections, associated with high morbidity and mortality, that require early and aggressive surgical debridement in addition to appropriate antibiotics and intensive supportive care.[4,7,49-52] Different terms have been used to classify necrotizing infections based on factors such as predisposing conditions, onset of symptoms, pain, skin appearance, etiologic agent, gas production, muscle involvement, and systemic toxicity.[5,26,50] However, while many types of necrotizing soft-tissue infections have been designated as unique infectious processes, they all share similar pathophysiologies, clinical features, and treatment approaches.[49-52] The major clinical entities of necrotizing infections are *necrotizing fasciitis* and *clostridial myonecrosis* (gas gangrene).[49-51]

6 Necrotizing fasciitis is a rare but severe infection of the subcutaneous tissue that may be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat.[3,5,12,50,51] Type I necrotizing fasciitis is the most common and accounts for approximately 80% of necrotizing soft-tissue infections.[50,51] It generally occurs after trauma or surgery and involves a mixture of anaerobes (*Bacteroides*, *Peptostreptococcus*) and facultative bacteria (streptococci and Enterobacteriaceae) that act synergistically to cause destruction of fat and fascia.[7,50] Type I necrotizing fasciitis is also reported more commonly among injection drug users.[49-52] In type I infections, the skin may be spared, and the speed at which the infection spreads (3 to 5 days) is somewhat slower than that in type II.[26] Necrotizing fasciitis affecting the male genitalia is termed *Fournier gangrene*.[50] Type II necrotizing fasciitis is caused by virulent strains of *S. pyogenes* and is commonly referred to as *streptococcal gangrene*.[7,50] This type of infection has often been called "flesh-eating bacteria" by the lay press. Unlike previous reports of streptococcal gangrene that affected older individuals with underlying diseases, recent reports have occurred primarily in young, previously healthy adults following some type of minor trauma. It differs from type I infections in its clinical presentation. Type II infections have rapidly extending necrosis (ie, 24 to 72 hours) of subcutaneous tissues and skin, gangrene, severe local pain, and systemic toxicity.[26,49-52] They are also highly associated with an early onset of shock and organ failure and are present in approximately half the cases of streptococcal toxic shock-like syndrome.[26,49,50] Of note, MRSA is increasingly reported in type II infections, either as a single organism or in combination with streptococci.[9,50,51] Clinicians should consider MRSA in areas that are endemic for MRSA or if patients have risk factors for these organisms.

Clostridial myonecrosis (type III necrotizing fasciitis) is a necrotizing infection that involves the skeletal muscle.[9,50] Type III infections account for less than 5% of necrotizing infections.[50] Gas production and muscle necrosis are prominent features of this infection, which readily explains why this infection is commonly referred to as *gas gangrene*.[49-51] The infection advances rapidly, often over a matter of a few hours.[49-51] Most infections occur after surgery or trauma, with *Clostridium perfringens* identified as the most common etiologic agent.[50]

TREATMENT
Necrotizing Soft-Tissue Infections

Desired Outcomes

The goals of therapy of acute bacterial cellulitis are rapid eradication of the infection, prevention of further complications, and reduction in mortality. Effective treatment of necrotizing soft-tissue infections includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Management of Necrotizing Infections

Immediate and aggressive surgical debridement of all necrotic tissues is essential in all patients with suspected or confirmed necrotizing fasciitis.[9,15,49-53] Initial surgical debridement performed greater than 14 hours after the diagnosis of necrotizing infection was independently associated with increased patient mortality, including a 34-fold increased risk of death in patients with septic shock.[53] Patients often require further surgical intervention following initial debridement to ensure that all necrotic tissue has been removed.[15,49-53] Type I necrotizing fasciitis must be empirically treated with broad-spectrum antibiotics that include coverage against streptococci, Enterobacteriaceae, and anaerobes. Piperacillin–tazobactam plus vancomycin is specifically recommended as appropriate empiric therapy of necrotizing fasciitis, although a number of antibiotic regimens are also appropriate to successfully treat necrotizing soft-tissue infections (see Fig. 110-1). These antibiotic regimens are generally similar to regimens used for polymicrobic cellulitis.[3,49-52] Antibiotic therapy can be modified after Gram stain and culture reports are available.

If a diagnosis of either type II (streptococcal) or type III (clostridial) necrotizing fasciitis is established, broad-spectrum empiric therapy should be replaced with the combination of penicillin plus clindamycin.[15,49-51] Although *S. pyogenes* remains susceptible to penicillin, the combination with clindamycin is more effective.[49,51] Several factors have been postulated to explain the greater efficacy of clindamycin, including the mechanism of action (inhibition of protein synthesis) that may cause decreased production of bacterial exotoxins.[49-52] In addition, clindamycin has immunomodulatory properties that may account for the higher efficacy.[49,51] Clindamycin is also effective against strains of MRSA.[50] Hyperbaric oxygen is potentially beneficial for clostridial myonecrosis, but its use is not currently recommended due to lack of clear evidence of improved patient outcomes.[15,49-52] Likewise, the use of intravenous immunoglobulin (IVIG) has not yet been proven beneficial in the treatment of necrotizing streptococcal infections and its use is not routinely recommended.[15]

Evaluation of Therapeutic Outcomes

Because of the high mortality associated with necrotizing infections, rapid and complete debridement of all devitalized and necrotic tissue is essential. Surgical debridement, coupled with appropriate

CLINICAL PRESENTATION Necrotizing Infections

General

- Most frequently involve the abdomen, perineum, and lower extremities.
- Predisposing factors such as diabetes mellitus, local trauma or infection, or recent surgery often present.
- Rapid diagnosis is critical due to the aggressive nature and high associated mortality (20% to 50%).

Symptoms

- Systemic symptoms generally are marked (eg, fever, chills, and leukocytosis) and may include shock and organ failure, especially in patients with type II infections.
- Pain in the affected area and systemic toxicity are characteristically more pronounced than with cellulitis.

Signs

- May be difficult to differentiate between necrotizing fasciitis and cellulitis early in infection.
- Affected area is initially hot, swollen, and erythematous without sharply demarcated margins.
- Affected area is often shiny, exquisitely tender, and painful.
- Diffuse swelling of the area is followed by the appearance of bullae filled with clear fluid.
- Rapidly progressive infection with the frequent development of a maroon or violaceous color of the skin after several days.
- Infection may rapidly evolve into a frank cutaneous gangrene, sometimes with myonecrosis.

Laboratory Tests

- Tissue samples should be obtained for histologic examination, and culture and susceptibility testing.
- Clostridial myonecrosis shows little inflammation on histologic examination.

Other Diagnostic Tests

- Surgical exploration is the best and most rapid diagnosis of necrotizing infections; computed tomography and magnetic resonance imaging may also be helpful.
- Blood samples should be collected for complete blood count and chemistry profile, as well as for bacterial culture.
- Laboratory tests that may aid in the diagnosis of necrotizing infections (LRINEC score) include C-reactive protein, white blood cell count, hemoglobin, sodium, creatinine, and glucose.

antimicrobial therapy and supportive measures for management of shock and organ failure, should stabilize the patient. Vital signs and laboratory tests should be monitored carefully for signs of resolution of the infection. Change in antimicrobial therapy or additional surgical debridement may be needed in patients who do not show signs of improvement.

DIABETIC FOOT INFECTIONS

Three major types of foot infections are seen in diabetic patients: deep abscesses, cellulitis of the dorsum, and mal perforans ulcers.[54,55] Most deep abscesses involve the central plantar space (arch) and are caused by minor penetrating trauma or by an extension of infection of a nail or web space of the toes. Infections of the dorsal area generally arise from infections in the toes that are related to routine care of the nails, nail beds, and calluses of the toes. Mal perforans ulcer is a chronic ulcer of the sole of the foot. The ulcer develops on thickened, hardened calluses over the first or fifth metatarsal. Mal perforans ulcers are associated with neuropathic changes, which are responsible for the misalignment of the weight-bearing bones of the foot.[54,55] Osteomyelitis is one of the most serious complications of diabetic foot infection (DFI) and may occur in 30% to 40% of infections.[27,54]

Epidemiology

DFI is among the most common complications of diabetes, accounting for as many as 20% of all hospitalizations in diabetic patients at an annual cost of $200 to $350 million.[27,54,56] Approximately 15% of diabetic patients experience significant soft-tissue infection during their lifetime.[56] Approximately 71,000 lower-extremity amputations, often sequelae of uncontrolled infection, are performed each year on diabetic patients; this represents up to 70% of all nontraumatic amputations in the United States.[27,54,56] Approximately 20% of diabetics will undergo additional surgery or amputation of a second limb within 12 months of the initial amputation.[27,54]

Etiology

Mild cases of DFI are often monomicrobial. However, more severe infections are typically polymicrobic; up to 60% of hospitalized patients have polymicrobial infections (Table 110-7).[27,54,55,57-62] Wide ranges in the frequency of various bacteria in DFI reflect differences in culture techniques as well as variation among different types and severity of infections. Staphylococci and streptococci are the most common pathogens, although gram-negative bacilli and/or anaerobes occur in up to 50% of cases.[27,57-62] Although *P. aeruginosa* is an important pathogen in DFI, it is usually reported to occur in <10% of wounds and is most commonly associated with more severe infections.[27,58] Obligate anaerobes are also more commonly associated with severe infections in patients with chronic foot ischemia.[27,57,58] MRSA is increasingly important in DFI and has been reported in 10% to 30% of infected wounds.[27,58,59,62-64] The presence of MRSA in DFI has been associated with increased risk of treatment failure and worse patient outcomes, but these findings have not been consistent among studies and the clinical relevance of MRSA in this setting is still unclear.[27,55,63]

Identifying causative pathogens from cultures of diabetic wounds is often difficult. The chronic nature of DFI means that these wounds are often heavily colonized by organisms not playing a role in the infection. Superficial swab cultures are not as reliable as culture specimens obtained from deep tissues via biopsy, tissue scraping (curettage), or needle aspiration of drainage or abscess fluid.[59,62] Therefore, cultures and sensitivity tests should be done with specimens obtained from a deep culture of the wound base whenever possible. Before the wound is cultured, it should be scrubbed vigorously with saline-moistened sterile gauze to remove any overlying necrotic debris and further debrided as necessary.[27,59] Bone cultures should also be performed when there is diagnostic uncertainty regarding the presence of osteomyelitis or when therapeutic decisions are dependent on knowing the exact etiology of infection.[27,59]

TABLE 110-7 Bacterial Isolates from Foot Infections in Diabetic Patients[27,54,55,57-63,65]

Organisms	Percentage of Lsolates
Aerobes	63-100
Gram-positive	24-100
Staphylococcus aureus (all)	10-80
S. aureus (MRSA)	1-37
Streptococcus spp.	3-37
Enterococcus spp.	2-25
Coagulase-negative staphylococci	6-10
Other gram-positive aerobes	0-19
Gram-negative	16-73
Proteus spp.	3-7
Enterobacter spp.	1-9
Escherichia coli	3-10
Klebsiella spp.	1-6
Pseudomonas aeruginosa	1-48
Other gram-negative bacilli	3-13
Anaerobes	1-40
Peptostreptococcus spp.	4-28
Bacteroides fragilis group	2-9
Other *Bacteroides* spp.	3-6
Clostridium spp.	0-2
Other anaerobes	7-19

Pathophysiology

Three key factors are involved in the development of diabetic foot problems: neuropathy, angiopathy and ischemia, and immunologic defects. Any of these disorders can occur in isolation; however, they frequently occur together.[56]

Neuropathic changes to the autonomic nervous system as a consequence of diabetes may affect the motor nerve supply of small intrinsic muscles of the foot, resulting in muscular imbalance, abnormal stresses on tissues and bone, and repetitive injuries.[54,56] Diminished sensory perception causes an absence of pain and unawareness of minor injuries and ulceration. The sympathetic nerve supply may be damaged, resulting in an absence of sweating that may lead to dry cracked skin and secondary infection.[27,54,56]

Atherosclerosis is more common, appears at a younger age, and progresses more rapidly in the diabetic than in the nondiabetic. Diabetics may have problems with both small vessels (microangiopathy) and large vessels (macroangiopathy) that can result in varying degrees of ischemia, ultimately leading to skin breakdown and infection.

Diabetic patients typically have normal humoral immunity, normal levels of immunoglobulins, and normal antibody responses. Patients with diabetes, however, have impaired phagocytosis and intracellular microbicidal function as compared with nondiabetics; this may be related to angiopathy and low tissue levels of oxygen.[27,54,56] These defects in cell-mediated immunity make patients with diabetes more susceptible to certain types of infection and impair the patients' ability to heal wounds adequately.[54-56]

TREATMENT
Diabetic Foot Infections

Desired Outcomes

7 The goals of therapy in the management of DFI include the following: (a) successfully treat infected wounds by using effective nondrug and antibiotic therapy; (b) prevent additional infectious complications; (c) preserve as much normal limb function as possible; (d) avoid unnecessary use of antimicrobials that contribute to increased resistance; and (e) minimize toxicities and cost while increasing patient quality of life.

MANAGEMENT

Up to 90% of infections can be treated successfully with a comprehensive treatment approach that includes both wound care and antimicrobial therapy.[27,55,59,60] After carefully assessing the extent of the lesion and obtaining necessary cultures, necrotic tissue must be thoroughly debrided, with wound drainage and amputation as required. Wounds must be kept clean and dressings changed frequently (two to three times daily). Because of the relationship

CLINICAL PRESENTATION
Diabetic Foot Infections

General

- Infections are often much more extensive than they appear initially.

Symptoms

- Patients with peripheral neuropathy often do not experience pain; simple complaints of swelling or edema are common.

Signs

- Clinical signs of infection may not be present secondary to angiopathy and neuropathy.
- Lesions vary in size and clinical features (eg, erythema, edema, warmth, presence of pus, draining sinuses, pain, and tenderness).
- Foul-smelling odor suggests the presence of anaerobic organisms.
- Temperature may be mildly elevated or normal.

Laboratory Tests

- Specimens for culture and sensitivities should be collected.
- Deep-tissue samples obtained during surgical debridement are most useful for culture and susceptibility testing.
- Wounds must be cultured for both aerobic and anaerobic organisms.

Other Diagnostic Tests

- Possible presence of osteomyelitis also must be assessed via radiograph, bone scan, or both, as appropriate.

between hyperglycemia and immune system defects, glycemic control must be maximized to ensure optimal wound healing. In addition, the patient's activities should be restricted initially to bed-rest for leg elevation and control of edema, if present. Adequate pressure relief from a foot wound (ie, off-loading) is crucial to the healing process.[27,56,59] Finally, appropriate antimicrobials must be initiated.[27,55,56,59,60] However, the optimal antimicrobial therapy for DFI has yet to be defined. Empiric therapy that is totally comprehensive in its coverage of all possible pathogens does not seem to be necessary unless the infection is life- or limb-threatening, assuming that adequate wound care is also being performed.[27,55,59,60] This is particularly true regarding MRSA, *P. aeruginosa*, and anaerobes; the perceived need for empiric coverage of these organisms often leads to use of excessively broad-spectrum drug regimens. Several studies have shown good antimicrobial treatment efficacy despite the fact that the regimens did not have consistently good activity against these particular organisms.[27,59,61-63,65]

Proper selection of empiric antibiotics for DFI begins with thorough patient assessment and classification of the severity of the infection. Specific drug regimens, route of administration, and duration of therapy are all then largely dependent on the severity of infection. Although a number of classification systems are available, the most recent DFI treatment guidelines use those summarized in Table 110-8.[27,59] Wounds with no local signs of infection often do not require antibiotic therapy, and the majority of mild, uncomplicated infections can be managed successfully on an outpatient basis with highly bioavailable oral antimicrobials and good wound care (Tables 110-8 and 110-9).[37,55,61,62] Antibiotics for treatment of mild infections should be largely limited to those with activity against skin flora such as streptococci and methicillin-susceptible *S. aureus* (MSSA), except in those patients with risk factors for infection with other types of pathogens (Fig. 110-2).[27,59] Patients with specific risk factors for MRSA (Table 110-9) should empirically receive trimethoprim–sulfamethoxazole or doxycycline orally, while those who have received antibiotics within the past month should also receive empiric antibiotics that provide activity against gram-negative bacilli. Oral antimicrobials should be used cautiously in DFI complicated by osteomyelitis, extensive ulceration, areas of necrosis, or a combination of these. The use of topical antimicrobials, including medical-grade honey, has been advocated for the treatment of DFI in an attempt to minimize the cost of therapy and systemic antibiotic exposure leading to adverse effects and resistance. Although the most recent guidelines allow for consideration of topical therapy in mild infection in selected patients, use of topical agents is quite controversial and not routinely recommended.[27,55,59,66,67]

Appropriate initial therapy for patients with moderate to severe infection is also dependent on the presence of specific risk factors that increase the likelihood of infection with more resistant pathogens such as *P. aeruginosa* and MRSA (Table 110-9).[27,59] Many moderate infections can be successfully treated with orally administered antibiotics that provide activity against MSSA, streptococci, and gram-negative aerobic bacilli; coverage of obligate anaerobes may also be considered in patients with chronic or previously treated wounds (Fig. 110-3).[27,59] The addition of orally administered agents with activity against MRSA is recommended in patients with moderate or severe infection and specific risk factors for MRSA; such patients may also be considered for hospitalization and initial treatment with parenteral antibiotics in order to ensure adequate antibiotics for potentially more complex infections.[27,59] Patients with more extensive or chronically unhealed wounds, even though assessed as moderate in severity, may also be more appropriately treated initially with parenteral antibiotics in the hospital setting.[27,59]

All patients with severe DFI should be hospitalized initially and treated with broad-spectrum IV antibiotics (Table 110-9 and Fig. 110-3).[27,59] Severe infection is considered a risk factor for *P. aeruginosa*, so most patients with severe DFI will be initially started on antipseudomonal antibiotics.[27,59] Many patients will also be initially started on antibiotics that provide activity against MRSA due to risk-versus-benefit considerations, but assessment of risk factors in individual patients should still be performed in order to minimize the use of excessively broad-spectrum antibiotics when possible.

Clinical **Controversy...**

The decision whether or not to provide empiric coverage for MRSA and/or *P. aeruginosa* in the empiric treatment of diabetic foot infections remains controversial. Although proposed risk factors and treatment recommendations are provided in recent guidelines, these recommendations are somewhat broad due to lack of definitive data defining patients at high risk for infection with these pathogens. The nonspecific nature of the current recommendations may potentially lead to use of unnecessarily broad-spectrum antibiotic therapy in order to cover patients who are not actually at risk for infection with such drug-resistant pathogens. Additional studies defining specific patient risk factors are needed in order to more specifically and accurately guide empiric antibiotic management of diabetic foot infections.

TABLE 110-8 Classifications and Treatment Strategies for Diabetic Foot Infections of Varying Severity[27]

Clinical Signs/Symptoms of Infection	Infection Severity	Treatment Setting
None	Uninfected	Outpatient management; nonantibiotic wound management only
Local infection present (≥2 of the following): local swelling or induration, erythema, local tenderness or pain, local warmth, purulent discharge		
Local infection involving only skin and subcutaneous tissue, without involvement of deeper tissues or SIRS criteria present; if erythema is present, must be >0.5 and ≤2 cm around ulcer	Mild	Outpatient management; topical or oral antibiotics
Local infection with erythema >2 cm around ulcer, or involving structures deeper than skin and subcutaneous tissue (eg, abscess, osteomyelitis, septic arthritis, fasciitis); no SIRS criteria present	Moderate	Outpatient (or initial inpatient) management; oral (or initial parenteral) antibiotics
Local infection with ≥2 SIRS criteria: • Temperature >38°C or <36°C (>100.4°F or <96.8°F) • HR >90 • RR >20 • WBC >12,000 or <4,000, or >10% bands (>12 x 10^9/L or <4 x 10^9/L, or ≥0.10 bands)	Severe	Inpatient, followed by outpatient, management; initial parenteral antibiotics, followed by switch to oral when possible

TABLE 110-9 Suggested Antibiotic Regimens for Empiric Treatment of Diabetic Foot Infections[27]

Severity of Infection	Probable Pathogens	Drug(s)[a]	Duration of Therapy
Mild	*Staphylococcus aureus* (MSSA) *Streptococcus* spp. *S. aureus* (MRSA) • Patients with history of MRSA infection or colonization in past year • Prevalence of MRSA ≥50% in local geographic area • Recent hospitalization	Amoxicillin–clavulanate Cephalexin Dicloxacillin Clindamycin Levofloxacin Moxifloxacin[b]	1-2 weeks; may increase up to 4 weeks if infection slow to resolve
Moderate to severe (initially oral or IV antibiotics for moderately severe infections, IV antibiotics for severe infections)	MSSA *Streptococcus* spp. Enterobacteriaceae Obligate anaerobes	Ampicillin/Sulbactam Cefoxitin Ceftriaxone Imipenem/cilastatin Ertapenem Levofloxacin Moxifloxacin Tigecycline Levofloxacin or ciprofloxacin + clindamycin	Moderately severe infection: 1-3 weeks; severe infection: 2-4 weeks
	MRSA • Patients with history of MRSA infection or colonization in past year • Prevalence of MRSA ≥30% in local geographic area • Recent hospitalization • Infection severe enough that not empirically covering MRSA poses unacceptable risk of treatment failure	Add to one of the above regimens: • Vancomycin • Linezolid • Daptomycin	
	Pseudomonas aeruginosa • Patient has been soaking feet • Patient has previously failed therapy with nonpseudomonal antibiotic regimen • Severe infection	Piperacillin/tazobactam	
	Mixed infections potentially including all of the above	Cefepime, ceftazidime, or aztreonam + metronidazole or clindamycin + vancomycin[c] *Or* piperacillin–tazobactam or imipenem–cilastatin or meropenem[b] + vancomycin[c]	

MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-susceptible *S. aureus*.

[a]Agents not shown in any particular order of preference.

[b]Not specifically recommended in IDSA guidelines but may be appropriate treatment option.

[c]Linezolid or daptomycin may be used in place of vancomycin.

Guidelines for management of DFI include options for both monotherapy and combination regimens (Table 110-9).[27] Monotherapy, along with appropriate medical or surgical management, or both, is often effective in treating DFI, including those in which osteomyelitis is present.[27,55,60,61] Monotherapy is particularly attractive because of the potential advantages of convenience, cost, and avoidance of toxicities. Microbiologic and clinical cure rates ranging from 60% to 90% may be expected from any of these agents.[61] Selection of a specific regimen is determined by patient-specific factors including allergies, renal function, history of previous antibiotic use, and cost. In penicillin-allergic patients, metronidazole or clindamycin plus a fluoroquinolone, aztreonam, or possibly a third- or fourth-generation cephalosporin is appropriate.[27,55,60] Vancomycin also is used frequently in severe infections because of its excellent activity against gram-positive pathogens. Linezolid, daptomycin, and tigecycline are specifically recommended alternatives for the treatment of this pathogen.[27,55,59,60] Tigecycline may be particularly useful in this setting because of its activity against gram-negative aerobes and anaerobic bacteria, thus allowing it to be used as monotherapy for the treatment of mixed infections in patients where coverage of *P. aeruginosa* is not of great concern. Ceftaroline fosamil has in vitro activity that is suitable for DFI but has not been studied for this indication and its role is not yet defined. Because many patients already have some degree of diabetic nephropathy that may place them at higher risk of nephrotoxicity, strong recommendations have been made against the use of aminoglycoside antibiotics unless no alternative agents are available.[27,55] When an aminoglycoside is used, care must be taken to avoid further compromising renal function. All antibiotic regimens should be adjusted as necessary for renal dysfunction.

Duration of therapy for DFI depends on the severity of the infection, ranging from 1 to 2 weeks for mild infections up to 2 to 4 weeks or more for severe infections.[27,55] In the cases of underlying osteomyelitis, treatment should continue for 6 to 12 weeks.[27,55,60] After healing of the infection has occurred, a well-designed program for the prevention of further infections should be instituted. The use of adjunctive agents such as colony-stimulating factors, growth factors, and hyperbaric oxygen for either prevention or treatment of DFIs is controversial and not widely recommended.[27]

Evaluation of Therapeutic Outcomes

Therapy should be reevaluated carefully after 48 to 72 hours to assess favorable response. Change in therapy (or route of administration, if oral) should be considered if clinical improvement is not observed at this time. For optimal results, drug therapy should be appropriately modified according to information from deep-tissue culture and the clinical condition of the patient. Infections in diabetic patients often require extended courses of therapy because of impaired host immunity and poor wound healing.

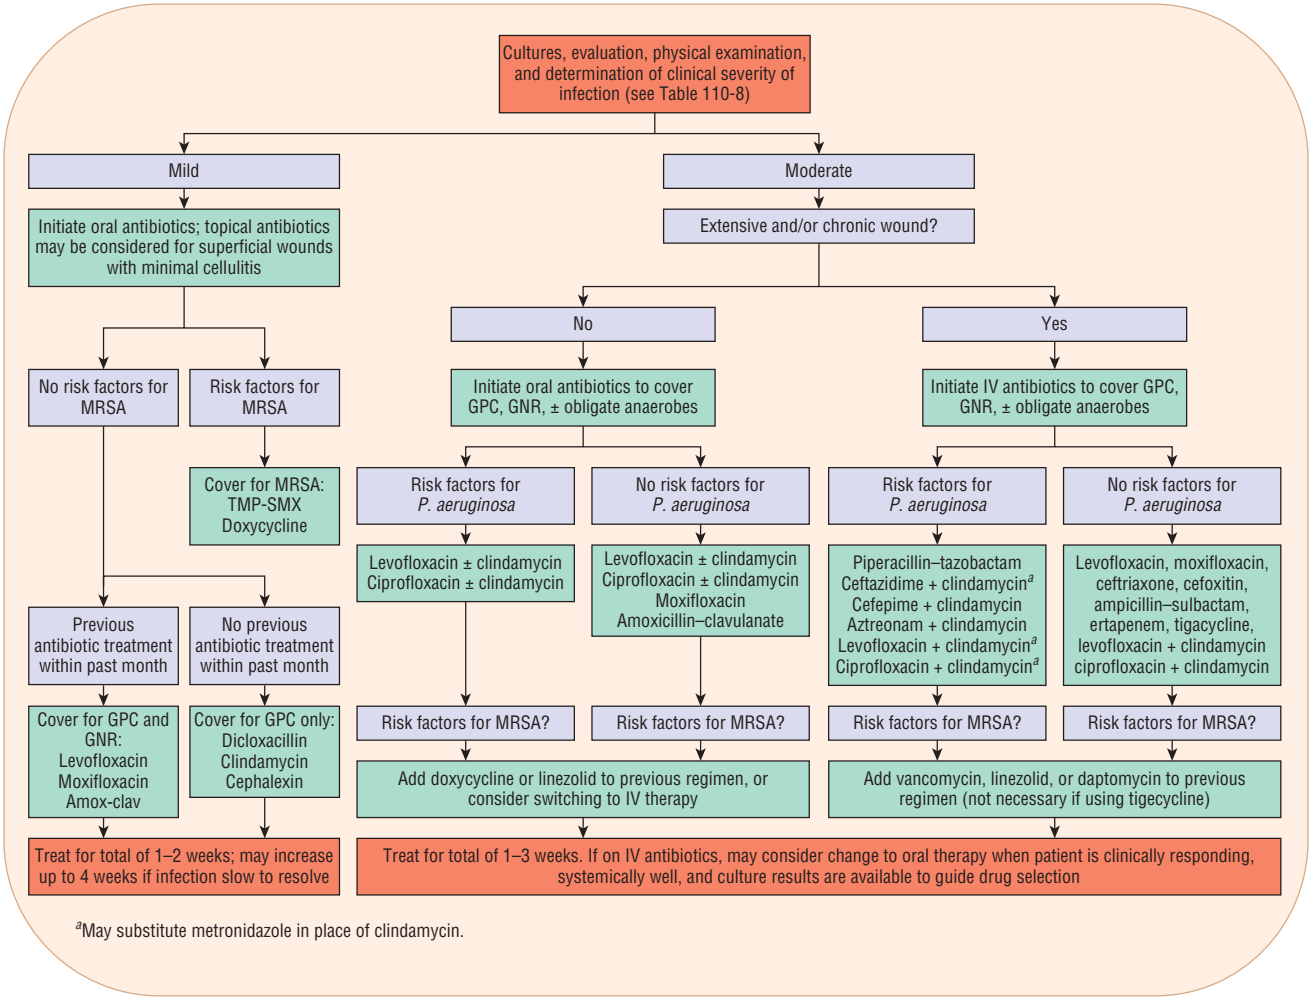

FIGURE 110-2 Recommended treatment algorithm for initial empiric management of mild to moderate diabetic foot infections. (GNR, aerobic gram-negative rods; GPC, aerobic gram-positive cocci; MRSA, methicillin-resistant *Staphylococcus aureus*; TMP-SMX, trimethoprim–sulfamethoxazole.)

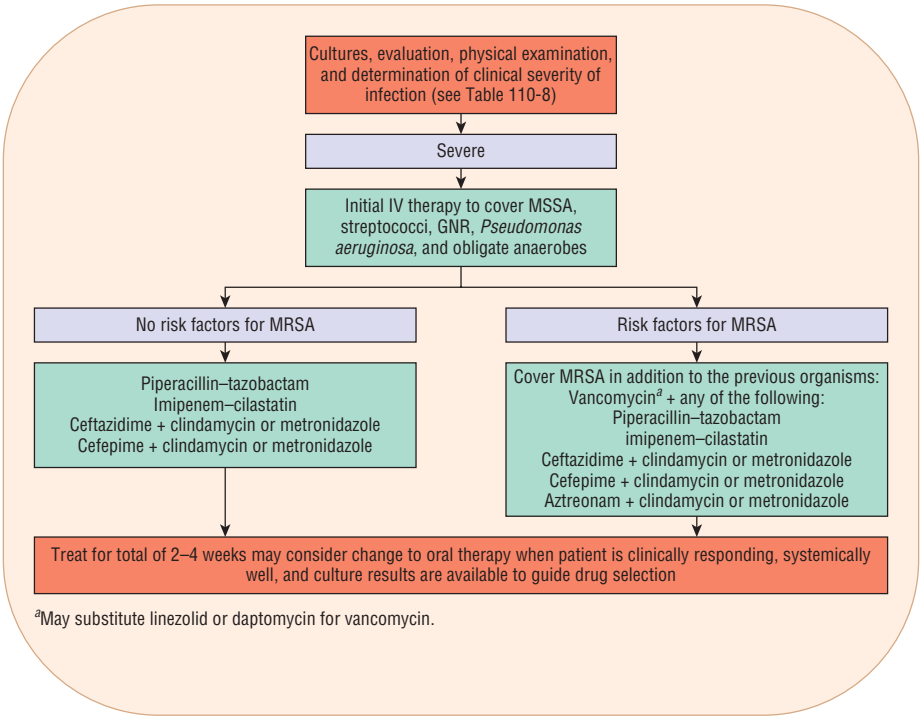

FIGURE 110-3 Recommended treatment algorithm for initial empiric management of severe diabetic foot infections. (GNR, aerobic gram-negative rods; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *S. aureus*.)

PRESSURE SORES

The terms *decubitus ulcer*, *bed sore*, and *pressure sore* are used interchangeably.[68,69] The decubitus ulcer and the bed sore are types of pressure sores. The term *decubitus ulcer* is derived from the Latin word *decumbere*, meaning "lying down." Pressure sores, however, can develop regardless of a patient's position.

Numerous systems for classification of pressure sores have been described. The 2007 recommendations of the National Pressure Ulcer Advisory Panel are shown in Table 110-10 and illustrate the various stages of progression through which a pressure sore may pass.[70]

Complications of pressure sores are common and may be life-threatening. Infection is one of the most serious and most frequently encountered complications of pressure ulcers.[69] Although most pressure sore wounds are heavily colonized, the majority of these eventually heal.[71-73] When true infection is present, however, there is bacterial invasion of previously healthy tissue. Without treatment, an initial small, localized area of ulceration can rapidly progress to large ulcers within days. The visible ulcer is just a small portion of the actual wound[74]; up to 70% of the total wound is below the skin. A pressure-gradient phenomenon is created by which the wound takes on a conical nature; the smallest point is at the skin surface, and the largest portion of the defect is at the base of the ulcer (Fig. 110-4).

Epidemiology

Pressure sores are most common among chronically debilitated persons, the elderly (70% involve persons greater than 70 years of age), and persons with serious spinal cord injury.[25,69,74,75] Generally, patients who are at risk for pressure sores are elderly or chronically ill young patients who are immobilized, in either bed or a wheelchair, and who may have altered mental status and/or incontinence.[69,74,75]

Etiology

Similar to DFIs, a large variety of aerobic gram-positive and gram-negative organisms, as well as anaerobes, frequently are isolated from wound cultures.[25] Most pressure sores are colonized with microorganisms, making assessment for infection a clinical challenge.[25,71] Curettage of the ulcer base after debridement provides more reliable culture information than does needle aspiration.[71-73] Biopsy specimens give the most reliable data but may not be practical to obtain. Deep-tissue cultures from different sites may give different results. Cultures collected from pressure ulcers reveal polymicrobial growth. A culture collected by swab is likely to identify surface bacteria colonizing the wound rather than to diagnose the infection.[71]

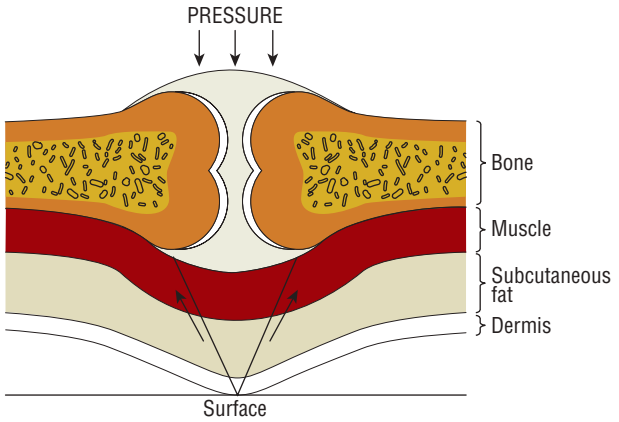

FIGURE 110-4 Distribution of forces involved with sore formation in a conical fashion.

Pathophysiology

Many factors apparently predispose patients to the formation of pressure sores: paralysis, paresis, immobilization, malnutrition, anemia, infection, and advanced age. Factors thought to be most critical to their formation are pressure, shearing forces, friction, and moisture[25,76]; however, there is still debate as to the exact pathophysiology of pressure sore formation.[76]

Pressure is the essential element in the formation of pressure sores.[25,69,74,76] The areas of highest pressure are generated most often over the bony prominences.[25,68,69,71,75,76] Both the degree of pressure and the length of time that the pressure is applied are important.[69,76]

Shearing occurs when two surfaces move in opposite directions.[25,76] This situation can occur when the head of a bed is raised, causing the upper torso to slide downward, transmitting pressure to the sacrum and other areas. This effect results in occlusion or distortion of vessels, leading to compromise of the dermis. At the same time, sitting and gravity create shearing forces; the posterior sacral skin area can become fixed secondary to friction with the bed. The effects of friction and shearing forces combine, resulting in transmission of force to the deep portion of the superficial fascia and leading to further damage of soft-tissue structures.[25,71,76]

Compounding the problems of shearing and friction forces are the macerating effects of excessive moisture in the local environment, resulting from incontinence and perspiration. This factor is of critical importance because when combined with the other forces, it increases the risk of pressure sore formation fivefold.[25,72,76]

TABLE 110-10 Pressure Sore Classification

Suspected deep-tissue injury	Area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. Area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared with adjacent tissue
Stage 1	Pressure sore is generally reversible, is limited to the epidermis, and resembles an abrasion. Intact skin with nonblanchable redness of a localized area, usually over a bony prominence. The area may be painful, firm, soft, warmer or cooler as compared with adjacent tissue
Stage 2	A stage 2 sore also may be reversible; partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed. May also present as an intact or open/ruptured serum-filled blister, or as a shiny or dry shallow ulcer
Stage 3[a]	Full thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscles are not exposed. May include undermining and tunneling. Depth of the ulcer varies by anatomical location; may range from shallow to extremely deep over areas of significant adiposity
Stage 4[a]	Full thickness tissue loss with exposed bone, tendon, or muscle; can extend into muscle and/or supporting structures (eg, fascia, tendon, or joint capsule) making osteomyelitis possible. Often includes undermining and tunneling; depth of the ulcer varies by anatomical location
Unstageable[a]	Full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed. True depth, and therefore stage, cannot be determined

[a]Stage 3, stage 4, and unstageable lesions are unlikely to resolve on their own and often require surgical intervention.

Data from reference 70.

CLINICAL PRESENTATION Pressure Sores

General

- Most pressure sores are in the pelvic region and lower extremities; see Fig. 110-5.
- Most common sites: sacral and coccygeal areas, ischial tuberosities, and greater trochanter.

Symptoms

- Patients commonly have other medical problems that may mask signs and symptoms of infection.
- Pain may be present with or without infection; continuous pain may indicate infection.

Signs

- A dark red color on the surface of a pressure sore may indicate local infection.
- Surrounding erythema, swelling, and heat are commonly present with infection.
- Purulent discharge, foul odor, and systemic signs (eg, fever and leukocytosis) of infection may be present.

Laboratory Tests

- Cultures should be collected from either a biopsy or fluid obtained by needle aspiration.

Other Diagnostic Tests

- Complete blood count often performed for assessment of potential infection.
- Consider magnetic resonance imaging if suspicious of underlying osteomyelitis.

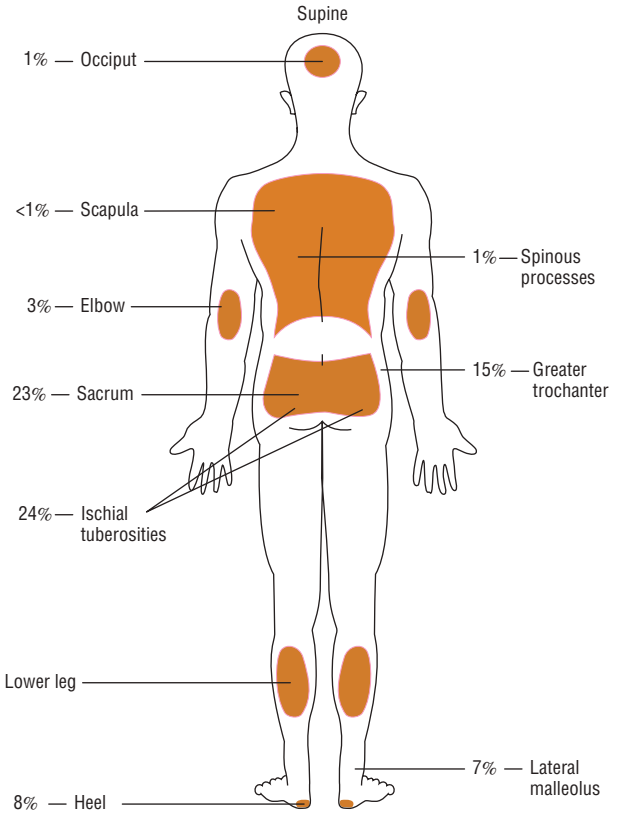

FIGURE 110-5 Supine view of areas where pressure sore formation tends to occur.

TREATMENT Pressure Sores

Desired Outcomes

The primary goal for pressure sores is prevention. Once a pressure sore has developed, the goals of therapy are prevention of complications (ie, infections), preventing sores from growing larger, and preventing the development of sores in other locations.[74] Eradication of infection should include good wound care and topical therapies, and avoidance of broad-spectrum antimicrobials unless guided by results from appropriately collected cultures or in patients with bacteremia, sepsis, cellulitis, or osteomyelitis.

Drug and Nondrug Management

8 Prevention is the single most important aspect in the management of pressure sores. Skin surveillance and frequent repositioning (ie, pressure reduction) are key in preventing pressure sores.[69,74] Prevention is far easier and less costly than the intensive care necessary for the healing and eventual closure of pressure sores. Of primary importance, then, is the ability to identify patients who are at high risk so that preventive measures may be instituted. Relief of pressure through proper positioning, and periodic repositioning, is probably the single most important factor in preventing pressure sore formation. Relief for a period of only 5 minutes once every 2 hours is believed to give protection against pressure sore formation.[69,71-74] Repositioning seated patients every 15 to 60 minutes is also recommended.[25,74] Pressure relief devices such as mattresses or overlays filled with air, water, gel, or foam are helpful in preventing pressure sores.[77] Cushions and ankle or heel protectors should also be encouraged.[69,71] Skin care and prevention of soilage are also important, with the intent being to keep the surface relatively free of moisture. Patients with problems of incontinence should be cleaned frequently, and efforts should be made to keep the involved areas dry.[68]

The medical approach to the treatment of pressure sores depends on the stage of the disease. Medical management generally is indicated for lesions that are of moderate size and relatively shallow depth (stage 1 or 2 lesions) and are not located over a bony prominence. Depending on their location and severity, from 30% to 80% of these ulcers will heal without an operation. Surgical intervention is almost always necessary for ulcers that extend through superficial layers or into bone (stage 3, stage 4, and unstageable lesions).[70]

The goal of therapy is to clean and decontaminate the ulcer in order to permit formation of healthy granulation tissue that promotes wound healing or prepares the wound for an operative procedure. The main factors to be considered for successful topical therapy (local care) are (a) relief of pressure, (b) debridement of necrotic tissue as needed, (c) wound cleansing, (d) dressing selection, and (e) prevention, diagnosis, and treatment of infection.[25,69,71,74,75]

Relief of pressure is important once a pressure sore has developed. The same repositioning methods and pressure-reducing devices used for preventive care also apply to treatment.[25,69]

The goals of debridement and cleansing measures are removal of devitalized tissue and reduction of bacterial contamination, which

can slow granulation time and impede healing.[25,69] Debridement can be accomplished by surgical, mechanical, or chemical means.[25,69] Surgical debridement rapidly removes necrotic material from the wound and is recommended for urgent situations (eg, cellulitis and sepsis).[71-73] Mechanical debridement generally involves wet-to-dry dressing changes. Saline-soaked gauze is applied to the wound; after drying, the gauze is removed and with it any adherent necrotic tissue. Other effective mechanical therapies include hydrotherapy (use of the whirlpool [Hubbard tank] to remove necrotic tissue and debris), wound irrigation, and dextranomers (beads placed in the wound to absorb exudate and bacteria).[25,69] Chemical debridement includes enzymatic and autolytic agents. Enzymatic debridement involves application of topical debriding agents to remove devitalized tissue. This method is recommended for patients who cannot tolerate surgery or are in a long-term care or home setting.[25,69] Autolytic debridement involves the use of synthetic dressings that allow devitalized tissue to self-digest via enzymes present in wound fluids. Autolytic debridement is contraindicated in the treatment of infected pressure sores.[25]

Pressure sore wounds should be cleaned with normal saline.[69] No cleansing solution or technique has demonstrated greater efficacy on healing.[77] Cleansing agents that are cytotoxic, such as povidone–iodine, iodophor, sodium hypochlorite solution, hydrogen peroxide, and acetic acid, should be avoided.[69,72,73] Many of these agents destroy granulation tissue and impair healing. Many different types of dressings are available for pressure sores.[25] Wound dressing materials should keep the wound moist, allow free exchange of air, act as a physical barrier to bacteria, and prevent physical damage.[25,69] Controlled studies of the various types of wound dressings have shown no significant differences in healing outcomes.[68] Occlusive dressings (hydrocolloid, such as DuoDERM™ or Tegaderm™) and transparent dressings (eg, 3M Tegaderm™) are not recommended for infected wounds.[25,69] If occlusive dressings are used, any infection should be controlled or the dressing frequency increased.

A 2-week trial of topical antibiotics (silver sulfadiazine or triple antibiotic) may be considered for a clean ulcer that is not healing or is producing a moderate amount of exudate despite appropriate care.[72] Systemic treatment of pressure ulcers is generally for infections associated with bacteremia, sepsis, cellulitis, or osteomyelitis.[72,73] Empiric therapy for infected pressure sores or associated infectious complications should cover MRSA, anaerobes, enterococci, and more resistant gram-negative bacteria such as *Pseudomonas* (see Table 110-5).[69] Thereafter, antibiotics should be guided by results from appropriately collected cultures.

Other nonpharmacologic approaches to shorten the healing time have included the use of hyperbaric oxygenation, hydrotherapy, high-frequency/high-intensity sound waves, and electrotherapy.[72,73,77] Electrical stimulation is the only adjunctive therapy that is proven effective.[72,73] Various comorbid conditions (diabetes mellitus, smoking, peripheral vascular disease, malnutrition) may impair wound healing. Eliminating or optimizing these factors is recommended, although studies have not demonstrated benefit.[25,69,74-76]

Evaluation of Therapeutic Outcomes

With appropriate wound care and antimicrobial therapy, infected pressure sores can heal. A reduction in erythema, warmth, pain, and other signs and symptoms should be seen in 48 to 72 hours.

ANIMAL AND HUMAN BITE WOUNDS

Approximately half the population in the United States will be bitten by either an animal or another human sometime during their lifetimes.[78,79] Animal bites (typically from dogs or cats) are common causes of injury, particularly to children, and are associated with significant risk of infection without prompt attention to appropriate management. Likewise, human bite wounds are often deceptively severe and frequently require aggressive management to reduce the risk of infectious complications. If left untreated, soft-tissue infection and osteomyelitis may occur, possibly requiring extensive debridement or amputation.

Epidemiology

Dog bites account for approximately 60% of all animal bite wounds requiring medical attention.[78] The Centers for Disease Control and Prevention reports that nearly 350,000 individuals seek emergency room attention for dog bites annually.[79] The rate of dog bite–related injuries is highest in children aged 5 to 9 years. Most dog bites are to the extremities,[78] but the majority of bites to children less than 5 years of age are to the face and neck.[79] Cat bites are the second most common cause of bite wounds in the United States, accounting for up to 20% of all animal bites.[78] Cat bites occur most commonly on the upper extremities and face, with most injuries reported in women and the elderly.[78,80] Human bites are the third most frequent type of bites requiring medical attention.

Infection rates after dog and cat bites are estimated at 20% overall. However, infection may occur in up to 30% to 80% of serious cat bites, a rate more than double those seen with dog bites.[80] Also, bite wounds to the hands become infected in 30% to 40% of cases.[78] Patients at greatest risk of acquiring animal bite–related infection have had a puncture wound (usually to the hand), have not sought medical attention within 8 hours of the injury, and are older than 50 years of age.[78,80]

Infected human bites can occur as bites from the teeth or from blows to the mouth (clenched-fist injuries). Bites by others can occur to any part of the body, but most often involve the hands. Infectious complications occur in 10% to 50% of patients with human bites.[80]

Etiology

Infections in bite wounds are caused predominantly by mouth flora from the animal or human biter, and from the victim's own skin flora (Table 110-11).[78,80-84] Most infections are polymicrobial, with a median of three to nine bacterial isolates per culture.[78,80-84] *Pasteurella* is the most frequent isolate from both dog and cat bites. *Pasteurella multocida* is part of the normal oral flora of up to 90% of cats; dog bites more commonly involve *P. canis* (approximately 26% of infections).[80,82] Tularemia (*Pasteurella tularensis*) and cat scratch disease (*Bartonella henselae*) have also been transmitted by cat bites, while rabies is associated with dog bites, particularly in developing countries.[82,83,85] Human bite wounds are notable for potential involvement of *Eikenella corrodens* in approximately 30% of infections.

Pathophysiology

The potential for infection from an animal bite is great owing to the pressure that can be exerted during the bite and the vast number of potential pathogens that make up the normal oral flora.[78,80-83] Cats' teeth are slender and extremely sharp. Their teeth easily penetrate into bones and joints, resulting in a higher incidence of septic arthritis and osteomyelitis.[78,80-83] Although a dog's teeth may not be as sharp, they can exert a pressure of 200 to 450 lb/in^2 (~1,400 to 3,100 kPa) and therefore result in a serious crush injury with much devitalized tissue.[78,80-83] In addition, the polymicrobic (aerobic and anaerobic) nature of animal bites provides a synergistic relationship, thus making an infection harder to eradicate.[81]

Human bites generally are more serious and more prone to infection than animal bites, particularly clenched-fist injuries.[81] While the force of a punch may sever a tendon or nerve or break a bone, it most often causes a breach in the capsule of the metacarpophalangeal joint, leading to direct inoculation of bacteria into the joint or bone.[81,83] When the hand is relaxed, the tendons carry bacteria into deeper spaces of the hand, resulting in more extensive infection.[81,83]

TABLE 110-11 Bacterial Isolates from Infections in Animal and Human Bite Wounds [78,80-83]

	Percentage of Isolates	
Organisms	**Dog and Cat**	**Human**
Aerobes	74-90	44
Pasteurella spp.	50-75	—
Streptococcus spp.	46-50	52-84

Peptostreptococcus spp.	8-16	22
Veillonella spp.	2	24
Mixed aerobic and anaerobic	50-75	40-66

TREATMENT

Desired Outcomes

The goals of therapy of bite wounds, whether caused by animals or humans, are twofold: to provide effective prophylaxis against infection, when appropriate, and to achieve rapid eradication of established infection and prevent further complications. Effective treatment of bite wounds includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Management of Bite Wounds

9 Bite wounds should be irrigated thoroughly with a copious volume of sterile water or saline, and the wound washed vigorously with soap or povidone–iodine in order to reduce the bacterial count in the wound.[80,83] Surgical debridement and immobilization of the affected area is often required in dog and human bites associated with more extensive tissue injury. Clinical failures due to edema have occurred despite appropriate antibiotic therapy.[78] Therefore, it is important to stress to patients that the affected area should be elevated for several days or until edema has resolved. In the case of animal bites, an immunization history of the animal should be obtained. It is also important for the patient's tetanus immune status to be determined. Because transmission of viruses (HIV, herpes, hepatitis B and C) is a possibility with human bites, information about the biter is important. Although the possibility of acquiring HIV through saliva alone is believed to be unlikely, the presence of virus-containing blood in the saliva makes disease transmission possible.[86,87] Bite victims exposed to blood-tainted saliva may be offered antiretroviral chemoprophylaxis, but each case should be individually assessed based on the potential for significant exposure and potential risks and benefits of antiretroviral therapy.[86,87]

Patients with clenched-fist injuries should be seen by a specialist in hand care to evaluate for penetration into the synovium, joint capsule, and bone.[15,81] Primary closure for human bites generally is not recommended. Tetanus toxoid and antitoxin may be indicated.

10 All patients with human bite injuries should receive prophylactic antibiotic therapy ("early preemptive therapy") for 3 to 5 days due to high infection risk (Table 110-4).[83,84,87] Prophylactic antimicrobial agents should be given as soon as possible to all patients, regardless of the appearance of the wound, unless it can be documented that the wound does not involve hands, feet, or joints and penetrates no deeper than the epidermis.[15,72,83]

The role of prophylactic antimicrobial therapy for early, noninfected animal bite wounds remains controversial.[15,78,80,81,83] Recommendations from the Infectious Diseases Society of America suggest that prophylactic or early preemptive therapy seems to provide only marginal benefit for most patients in the absence of specific factors that increase the risk of infection.[15] The decision to administer prophylactic antibiotics is therefore based on an assessment of wound severity and host immune competence. Specifically, prophylaxis is more strongly recommended in patients with the following factors associated with increased risk for infection: immunocompromised; asplenic; advanced liver disease; preexisting or resultant edema of the affected area; moderate to severe bite-related injuries, especially to the hands or face; or bite injuries that have penetrated the periosteum or joint capsule.[15] A 3- to 5-day course of prophylactic antibiotics is recommended when such therapy is considered to be appropriate.[15,80,81,83]

Empiric antibiotics for the treatment of established infection of bite wounds should be directed at a variety of aerobic and anaerobic flora (Table 110-4). Amoxicillin–clavulanic acid is most commonly recommended for oral outpatient therapy due to excellent activity against all likely pathogens, including *Pasteurella* and *Eikenella*.[15,78,80,81,83] Alternative oral agents include moxifloxacin or doxycycline alone, or trimethoprim–sulfamethoxazole, levofloxacin, ciprofloxacin, or a second- or third-generation cephalosporin in combination with metronidazole or clindamycin to provide activity against oropharyngeal anaerobes. Although the combination of penicillin VK plus dicloxacillin has been recommended traditionally for the treatment of bite wounds, its use has become less common in favor of other alternatives. Failure to provide adequate initial treatment of bite wounds results in treatment failures and increased need for hospitalization for parenteral antibiotics.[15,78,80-83]

Hospitalization for minor wounds is unnecessary if surgical repair of vital structures has not been performed. Patients with clenched-fist or other serious bite injuries and severe resultant infection may be considered for IV antibiotics. Treatment options for patients requiring IV therapy include β-lactam–β-lactamase inhibitor combinations (ampicillin–sulbactam, piperacillin–tazobactam), second-generation cephalosporins with antianaerobic activity (eg, cefoxitin), and ertapenem.[15,83] The combination of doxycycline or a fluoroquinolone with metronidazole or clindamycin may be used in patients with severe β-lactam allergies. The length of antimicrobial therapy depends on the severity of the injury/infection. However, therapy should generally be continued from 7 to 14 days.[15,78,87-91]

Tetanus does not occur commonly after dog bites; however, it is possible. If the immunization history of a patient with anything other than a clean, minor wound is unknown, or if the last known vaccination was longer than 10 years ago, tetanus–diphtheria (TD) toxoids should be administered.[88,89] Both TD toxoids and tetanus immune globulin should be administered to patients who have never been immunized.[83,90]

CLINICAL PRESENTATION — Bite Wounds

General

Animal bites:

- Only general wound care is required for most patients with dog bites who present early (<12 hours) after injury; infection is more likely in patients presenting late (≥12 hours) after injury.

Human bites:

- Most patients with clenched-fist injuries present for medical care after infection is already established.

Symptoms

- Patients often seek medical care for infection-related complaints (ie, pain, purulent discharge, and swelling) at the site of the injury.
- Wounds often have a purulent discharge, and decreased range of motion may be present.

Signs

- Erythema, swelling, and clear or purulent discharge at site of infected wound.

Animal bites:

- If *P. multocida* is present, a rapidly progressing cellulitis is observed within 24 to 48 hours of initial injury.
- Fever is uncommon.
- Adenopathy or lymphangitis is uncommon.

Human bites:

- Lymphadenopathy is common.
- In clenched-fist injuries, edema may limit the ability of tendons to glide in their sheaths, thereby limiting a joint's range of motion.

Laboratory Tests

- Samples for bacterial cultures (aerobic and anaerobic) should be obtained from infected wounds.
- Wounds seen <8 hours or more than 24 hours after injury that show no signs of infection may not need to be cultured.
- White blood counts should be monitored for resolution of infection if initially elevated.

Other Diagnostic Tests

- Radiographic evaluation should be performed if damage to a bone or joint is suspected.

Because the rabies virus can be transmitted via saliva, rabies may be a potential complication of a bite. When the symptoms of rabies develop after a bite, the prognosis for survival is poor. Roughly 3% of rabies cases documented in animals were in dogs (the most frequent vectors are skunks, raccoons, and bats).[85,91] In the United States, recommendations for postexposure prophylaxis after a dog bite depend on the health of the dog. If the animal is healthy and able to be observed for a 10-day period, active prophylaxis is only required if the dog develops signs of rabies.[78,80,85] If the dog is known or suspected to be rabid, postexposure procedures should be initiated; current treatment guidelines should be consulted for appropriate management recommendations.[85,91] Outside of the United States, locally applicable guidelines such as those from the World Health Organization should be consulted.[92]

Evaluation of Therapeutic Outcomes

Evaluation of treatment for either animal or human bites should follow the same general guidelines. Bite victims treated on an outpatient basis with oral antimicrobials should be followed up within 24 hours by either phone or office visit.[15] Hospitalization or change to IV therapy should be considered if the infection has progressed. For hospitalized patients with no improvement in signs and symptoms following 24 hours of appropriate therapy, surgical debridement may be needed. Physical therapy may be needed to improve complications such as residual joint stiffness and loss of function, particularly after human bites involving clenched-fist injuries.

PERSONALIZED PHARMACOTHERAPY

Desired treatment outcomes for the various types of SSTIs described in this chapter are achieved through close monitoring and frequent patient assessment, including judicious evaluation of antimicrobial therapies. SSTIs are challenging in that cultures are often not performed due to the unavailability of easily obtained culturable specimens and the low yield of common culturing techniques. Empiric antibiotic selection based on most likely pathogens is an effective strategy in less severe infections such as erysipelas, impetigo, and furuncles. However, treatment of more severe infections such as cellulitis, DFI, and necrotizing fasciitis should be individualized based on properly obtained culture specimens and documented pathogens and susceptibilities whenever possible. Aggressive antimicrobial use must be balanced against unnecessary administration of drugs that may lead to increased antimicrobial resistance, adverse effects, and cost. Proper evaluation of an individual patient's severity of infection and risk of complications allows for selection of appropriate antimicrobials for the treatment of infection and selection of appropriate treatment settings (eg, inpatient vs outpatient), both of which may allow for the most cost-effective therapy.

Infective Endocarditis

Angie Veverka, Brian L. Odle, and Jeffrey A. Kyle

KEY CONCEPTS

1. Infective endocarditis usually occurs in adult patients with specific risk factors (eg, IV drug abuse, heart failure, valvular disease, and healthcare exposure) and those with implanted cardiac material (eg, prosthetic heart valves).
2. Three groups of organisms cause a majority of infective endocarditis cases: streptococci, staphylococci, and enterococci.
3. The clinical presentation of infective endocarditis is highly variable and nonspecific, although a fever and murmur are usually present. Classic peripheral manifestations (eg, Osler's nodes) may or may not occur.
4. The diagnosis of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The two major diagnostic criteria are bacteremia and echocardiographic changes (eg, valvular vegetation).
5. Treatment of infective endocarditis involves isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, bactericidal antibiotics for an extended period.
6. Surgical replacement of the infected heart valve is an important adjunct to endocarditis treatment in certain situations (eg, patients with acute heart failure).
7. β-Lactam antibiotics, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively.
8. Aminoglycoside antibiotics are essential to obtain a synergistic bactericidal effect in the treatment of enterococcal endocarditis. Adjunctive aminoglycosides also may decrease the emergence of resistant organisms (eg, prosthetic valve endocarditis caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (eg, some streptococcal and staphylococcal infections).
9. Vancomycin is reserved for patients with immediate β-lactam allergies and the treatment of resistant organisms.
10. Antimicrobial prophylaxis is used to prevent infective endocarditis for patients who are at the highest risk (such as persons with prosthetic heart valves) before a bacteremia-causing procedure (eg, dental extraction).

Endocarditis is an inflammation of the endocardium, the membrane lining the chambers of the heart and covering the cusps of the heart valves.[1,2] More commonly, *endocarditis* refers to infection of the heart valves by various microorganisms. Although it typically affects native valves, it also may involve nonvalvular areas or implanted material (eg, prosthetic heart valves, cardiac defibrillators, pacemakers, and catheters). Bacteria primarily cause endocarditis, but fungi and other atypical microorganisms can lead to the disease; hence, the more encompassing term *infective endocarditis* is preferred.[1,3]

Endocarditis is often referred to as *acute* or *subacute* depending on the pace and severity of the clinical presentation. The acute, fulminating form is associated with high fevers and systemic toxicity. Virulent bacteria, such as *Staphylococcus aureus*, frequently cause this syndrome, and if untreated, death may occur within days to weeks. On the other hand, subacute infective endocarditis is more indolent, is caused by less invasive organisms, such as viridans streptococci, and usually occurs in preexisting valvular heart disease. Although infective endocarditis is often referred to as acute or subacute, it is best classified based on the etiologic organism, the anatomic site of infection, and pathogenic risk factors.[1,4,5] Infection may also occur following surgical insertion of a prosthetic heart valve, resulting in prosthetic valve endocarditis (PVE), or insertion of a cardiac implantable electronic device, resulting in cardiac device infective endocarditis (CDIE).[6,7]

EPIDEMIOLOGY AND ETIOLOGY

Infective endocarditis is an uncommon, but not rare, infection. Population-based studies have reported annual incidence rates of 2 to 15 cases per 100,000 person-years.[8,9] In the United States, the infection is listed as the primary or secondary diagnosis of 34,000 hospital discharges.[10] The mean male-to-female ratio is approximately 2:1.[11] As the population ages and as valve replacement surgery becomes more common, the mean age of patients with infective endocarditis increases. Most cases occur in individuals older than 50 years of age, and it is less common in children.[11-14] PVE and CDIE account for 20% and 6.4% of cases of infective endocarditis, respectively.[5,11,15] Those with a history of IV drug abuse (IVDA) are also at high risk. Of note, the incidence of healthcare-associated infective endocarditis is rising, especially in the elderly population.[11,12] Other conditions associated with a higher incidence of infective endocarditis include diabetes, long-term hemodialysis, and poor dental hygiene.[5,13]

1 Most persons with infective endocarditis have risk factors, such as preexisting cardiac valvular abnormalities. Many types of structural heart disease result in turbulent blood flow that increases the risk for infective endocarditis. A predisposing risk factor, however, may be absent in up to 25% of cases. Some of the more important risk factors include:[4,5,7,11,13,16]

1. Presence of a prosthetic valve (highest risk)
2. Previous endocarditis (highest risk)
3. Healthcare-related exposure (high risk)
4. Congenital heart disease (CHD)
5. Chronic IV access
6. Diabetes mellitus

TABLE 111-1 Etiologic Organisms in Infective Endocarditis[a]

Agent	Percentage of Cases
Staphylococci	30-70
Coagulase positive	20-68
Coagulase negative	3-26
Streptococci	9-38
Viridans streptococci	10-28
Other streptococci	3-14
Enterococci	5-18
Gram-negative aerobic bacilli	1.5-13
Fungi	1-9
Miscellaneous bacteria	<5
Mixed infections	1-2
"Culture negative"	<5-17

[a]Values encompass community-acquired, healthcare-associated, native valve, and prosthetic valve infective endocarditis.

Data from references 3, 11, and 16.

7. Acquired valvular dysfunction (eg, rheumatic heart disease)
8. Cardiac implantable device
9. Chronic heart failure
10. Mitral valve prolapse with regurgitation
11. IVDA

Rheumatic heart disease was a prevalent risk factor for infective endocarditis, but the incidence of this disease continues to decline. The risk of infective endocarditis in persons with mitral valve prolapse and regurgitation is small; however, because the condition is prevalent, it is an important contributor to the overall number of infective endocarditis cases.[5,11] PVE occurs in 1% to 3% of patients undergoing valve replacement surgery in the first postoperative year.[11,17]

2 Nearly every organism causing human disease may cause infective endocarditis, but three groups of organisms result in a majority of cases: streptococci, staphylococci, and enterococci (Table 111-1).[3-5,11,16] The incidence of staphylococci, particularly *S. aureus*, continues to increase primarily due to healthcare exposure, and case series have documented that staphylococci have surpassed viridans streptococci as the leading cause of infective endocarditis.[4,11,16] In general, streptococci cause infective endocarditis in patients with community-acquired disease and underlying cardiac abnormalities, such as mitral valve prolapse or rheumatic heart disease. Staphylococci (*S. aureus* and coagulase-negative staphylococci) are the most common cause of PVE within the first year after valve surgery, and *S. aureus* is common in those with a history of IVDA. Although polymicrobial infective endocarditis is uncommon, it is encountered most often in association with IVDA.[11,16] Enterococcal endocarditis tends to follow genitourinary manipulations or obstetric procedures.[17] There are many exceptions to the preceding generalizations; thus, isolation of the causative pathogen and determination of its antimicrobial susceptibilities offer the best chance for successful therapy.

The mitral and aortic valves are affected most commonly in cases involving a single valve. Subacute endocarditis tends to involve the mitral valve, whereas acute disease often involves the aortic valve. Up to 35% of cases involve concomitant infections of both the aortic and the mitral valves. Infection of the tricuspid valve is less common, with a majority of these cases occurring in patients with a history of IVDA. It is rare for the pulmonary valve to be infected.[11,16,17]

Pathophysiology

The development of infective endocarditis via hematogenous spread, the most common route, requires the sequential occurrence of several factors. These components are complex and not fully elucidated.[2,18,19]

1. *The endothelial surface of the heart is damaged.* This injury occurs with turbulent blood flow associated with the valvular lesions previously described.
2. *Platelet and fibrin deposition occurs on the abnormal epithelial surface.* These platelet-fibrin deposits are referred to as *nonbacterial thrombotic endocarditis*.
3. *Bacteremia gives organisms access to and results in colonization of the endocardial surface.* Bacteremia is the result of trauma to a mucosal surface with a high concentration of resident bacteria such as the oral cavity and GI tract. Transient bacteremia commonly follow certain dental, GI, urologic, and gynecologic procedures. Staphylococci, viridans streptococci, and enterococci are most likely to adhere to nonbacterial thrombotic endocarditis, probably because of production of specific adherence factors such as dextran by some oral streptococci and glycocalyx for staphylococci. Gram-negative bacteria rarely adhere to heart valves and are uncommon causes of infective endocarditis.
4. *After colonization of the endothelial surface, a "vegetation" of fibrin, platelets, and bacteria forms.* The protective cover of fibrin and platelets allows unimpeded bacterial growth to concentrations as high as 10^9 to 10^{10} organisms per gram of tissue.

The pathogenesis of early PVE or CDIE differs from infective endocarditis acquired by the hematogenous route because surgery may directly inoculate prosthetic material with bacteria from the patient's skin or operating room personnel. In the case of early PVE, a recently placed nonendothelialized valve is more susceptible to bacterial colonization than are native valves. Bacteria also may colonize the new valve from contaminated bypass pumps, cannulas, and pacemakers or from a nosocomial bacteremia subsequent to an intravascular catheter.[7,16,17] The mechanism of bacterial colonization and pathogenesis in late PVE is similar to native valve endocarditis (NVE).[17]

The vegetations seen in infective endocarditis may be single or multiple and vary in size from a few millimeters to centimeters. Bacteria within the vegetation grow slowly and are protected from antibiotics and host defenses. The adverse effects of infective endocarditis and the resulting lesions can be far-reaching and include: (a) local perivalvular damage, (b) embolization of septic fragments with potential hematogenous seeding of remote sites, and (c) formation of antibody complexes.[17,19]

Formation of vegetations may destroy valvular tissue, and continued destruction can lead to acute heart failure via perforation of the valve leaflet, rupture of the chordae tendineae or papillary muscle, or, for patients with PVE, valve dehiscence. Occasionally, valvular stenosis may occur. Abscesses can develop in the valve ring or in myocardial tissue itself. Even with resolution of the process, fibrosis of tissue with some residual dysfunction is possible.

Vegetations may be friable, and fragments may be released downstream. These infected particles, termed *septic emboli*, can result in organ abscess or infarction. Septic emboli from right-sided endocarditis commonly lodge in the lungs, causing pulmonary abscesses. Emboli from left-sided vegetations commonly affect organs with high blood flow such as the kidneys, spleen, and brain.[4,17,19]

Circulating immune complexes consisting of antigen, antibody, and complement may deposit in organs, producing local inflammation, and damage (eg, glomerulonephritis in the kidneys). Other potential pathologic changes that result from immune-complex deposition or septic emboli include the development of "mycotic" aneurysms (although the aneurysm is usually bacterial in origin, not fungal), cerebral infarction, splenic infarction and abscess, and

skin manifestations such as petechiae, Osler's nodes, and Janeway's lesions.[1,17,19]

CLINICAL PRESENTATION

3 The clinical presentation of infective endocarditis is highly variable and nonspecific. Fever is the most common finding and is often accompanied by other vague symptoms (Table 111-2). Fever may be relatively low grade, particularly in subacute cases. Heart murmurs are found in a majority of patients, most often preexisting, with some documented as new or changing. Infective endocarditis usually begins insidiously and worsens gradually. Patients may present with nonspecific findings such as fever, chills, weakness, dyspnea, night sweats, weight loss, or malaise. In contrast, patients with acute disease, such as those with a history of IVDA and *S. aureus* infective endocarditis, may appear with classic signs of sepsis.

Splenomegaly is a frequent finding for patients with prolonged endocarditis. Other important clinical signs especially prevalent in subacute illness may include the following peripheral manifestations ("stigmata") of endocarditis:[11,12,16,19]

1. Osler's nodes: Purplish or erythematous subcutaneous papules or nodules on the pads of the fingers and toes. These lesions are 2 to 15 mm in size and are painful and tender. These nodes are not specific for infective endocarditis and may be the result of embolism, immunologic phenomena, or both.
2. Janeway's lesions: Hemorrhagic, painless plaques on the palms of the hands or soles of the feet. These lesions are believed to be embolic in origin.
3. Splinter hemorrhages: Thin, linear hemorrhages found under the nail beds of the fingers or toes. These lesions are not specific for infective endocarditis and more commonly are the result of traumatic injuries. Distal lesions are more likely the result of trauma, whereas proximal lesions tend to be associated with infective endocarditis.
4. Petechiae: Small (usually 1-2 mm in diameter), erythematous, painless, hemorrhagic lesions. These lesions appear anywhere on the skin but more frequently on the anterior trunk, buccal mucosa and palate, and conjunctivae. Petechiae are nonblanching and resolve after a few days.
5. Clubbing of the fingers: Proliferative changes in the soft tissues about the terminal phalanges observed in long-standing endocarditis.
6. Roth's spots: Retinal infarct with central pallor and surrounding hemorrhage.
7. Emboli: Embolic phenomena occur in up to one third of cases and may result in significant complications. Left-sided endocarditis can result in renal artery emboli causing flank pain with hematuria, splenic artery emboli causing abdominal pain, and cerebral emboli, which may result in hemiplegia or alteration in mental status. Right-sided endocarditis may result in pulmonary emboli, causing pleuritic pain with hemoptysis.

TABLE 111-2 Clinical Presentation of Infective Endocarditis

General
The clinical presentation of infective endocarditis is highly variable and nonspecific
Symptoms
The patient may complain of fever, chills, weakness, dyspnea, night sweats, weight loss, and/or malaise
Signs
Fever is common, as is a heart murmur (sometimes new or changing). The patient may have embolic phenomenon, splenomegaly, or skin manifestations (eg, Osler's nodes, Janeway's lesions)
Laboratory tests
The patient's white blood cell count may be normal or only slightly elevated
Nonspecific findings include anemia (normocytic, normochromic), thrombocytopenia, an elevated erythrocyte sedimentation rate or C-reactive protein, and altered urinary analysis (proteinuria/microscopic hematuria)
The hallmark laboratory finding is continuous bacteremia; three sets of blood cultures should be collected over 24 hours
Other diagnostic tests
An electrocardiogram, chest radiograph, and echocardiogram are commonly performed. Echocardiography to determine the presence of valvular vegetations plays a key role in the diagnosis of infective endocarditis; it should be performed in all suspected cases

Patients with infective endocarditis typically have laboratory abnormalities; however, none of these changes is specific for the disease. Anemia (normocytic, normochromic), leukocytosis, and thrombocytopenia may be present. The white blood cell count is often normal or only slightly elevated, sometimes with a mild left shift. Acute bacterial endocarditis, however, may present with an elevated white blood cell count, consistent with a fulminant infection. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may be elevated in approximately 60% of patients. Often the urinary analysis is abnormal, with proteinuria and microscopic hematuria occurring in approximately 25% of individuals.[11,19]

The hallmark of infective endocarditis is a continuous bacteremia caused by bacteria shedding from the vegetation into the bloodstream; 90% to 95% of patients with infective endocarditis have positive blood cultures.[1,11,17] In most cases, three sets of blood cultures, each from separate venipuncture sites, should be collected promptly, with the first and last set drawn at least 1 hour apart. This allows expedient initiation of empiric antibiotic therapy and can help guide early decisions regarding other potential interventions. "Culture-negative" endocarditis describes a patient in whom a clinical diagnosis of infective endocarditis is likely but blood cultures do not yield a pathogen. This condition is often the consequence of previous antibiotic therapy, improperly collected blood cultures, or unusual organisms.[4] When blood cultures from patients suspected of having infective endocarditis show no growth after 48 to 72 hours, cultures should be held for up to a month to detect growth of fastidious organisms.[4]

An electrocardiogram, chest radiograph, and echocardiogram are performed for patients suspected of endocarditis. The electrocardiogram rarely shows important diagnostic findings but may reveal heart block, suggesting extension of the infection. The chest radiograph may provide more diagnostic information, especially in a patient with right-sided endocarditis. Septic pulmonary emboli may occur, leading to multiple lung foci. The echocardiogram is the most important test and should be performed for all patients suspected of this infection.

Echocardiography plays an important role in the diagnosis and management of infective endocarditis.[4,5] The chosen approach, transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE), depends on the clinical setting. The TEE technique is more sensitive for detecting vegetations (85%-90%) as compared with TTE (58%-75%), and TEE maintains good specificity (>90%).[1,5] In addition to helping in the diagnosis of infective endocarditis, the echocardiogram allows the physician to evaluate hemodynamic stability and the need for urgent surgical intervention; it also provides a rough estimate of the likelihood of embolism.[4,20] An initial TTE will be performed in most patients due to the rapidity (ie, fasting state unnecessary) and accessibility (ie, 24-hour service available in most institutions) of testing. This may be the only evaluation needed for children or adults in whom the clinical suspicion of infective endocarditis is relatively low.[4,21] An initial or follow-up TEE is recommended in high-risk patients such as those with many CHDs,

previous endocarditis, new murmur, heart failure, or other stigmata of endocarditis.[4,20,22] For those patients with suspected PVE or CDIE, TEE should be considered mandatory. The lack of vegetation on echocardiogram does not exclude infection even if the transesophageal approach is used. In these cases, there is an evolving role for advanced imaging modalities such as 3D TEE, ^{18}F-fluorodeoxyglucose positron emission tomography, single-photon emission computed tomography, and multidetector computed tomography.[4,5,20]

DIAGNOSIS

4 The signs and symptoms of infective endocarditis are not specific, and the diagnosis is often unclear. The identification of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The Duke diagnostic criteria include major and minor variables (Table 111-3).[23,24] Based on the number of major and minor criteria that are fulfilled, patients suspected of infective endocarditis are categorized into three separate groups: definite infective endocarditis, possible infective endocarditis, or infective endocarditis rejected.[24]

TABLE 111-3 Diagnosis of Infective Endocarditis According to the Modified Duke Criteria

Major Criteria
Blood culture positive for infective endocarditis
Typical microorganisms consistent with infective endocarditis from two separate blood cultures:
Viridans streptococci, *S. gallolyticus*, HACEK group, *S. aureus*; or
Community-acquired enterococci, in the absence of a primary focus; or
Microorganisms consistent with infective endocarditis from persistently positive blood cultures, defined as follows:
At least two positive cultures of blood samples drawn greater than 12 hours apart; or
All of three or a majority of four or more separate cultures of blood (with first and last sample drawn at least 1 hour apart)
Single positive blood culture for *Coxiella burnetii* or antiphase I immunoglobulin G antibody titer >1:800
Evidence of endocardial involvement
Echocardiogram positive for infective endocarditis (transesophageal echocardiography recommended for patients with prosthetic valves, rated at least "possible infective endocarditis" by clinical criteria, or complicated infective endocarditis [paravalvular abscess]; transthoracic echocardiography as first test for other patients), defined as follows:
Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets or on implanted material in the absence of an alternative anatomic explanation; or abscess; or
New partial dehiscence of prosthetic valve
New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)
Minor Criteria
Predisposition, predisposing heart condition, or injection drug use
Fever, temperature >38°C (100.4°F)
Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway's lesions
Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor
Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above or serologic evidence of active infection with organism consistent with infective endocarditis
Echocardiographic minor criteria eliminated

HACEK, *Haemophilus* species (*H. parainfluenzae, H. aphrophilus, H. paraphrophilus*), *Aggregatibacter* species, *Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*.

Note: Cases are defined clinically as *definite* if they fulfill two major criteria, one major criterion plus three minor criteria, or five minor criteria; cases are defined as *possible* if they fulfill one major and one minor criterion or three minor criteria. Cases are rejected if there is a firm alternate diagnosis explaining evidence of infective endocarditis; resolution of infective endocarditis syndrome with antibiotic therapy for <4 days; no pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for <4 days; or criteria for possible infective endocarditis are not met, as above.

Data from references 23 and 24.

The outcome for endocarditis is improved with rapid diagnosis, appropriate treatment (ie, antimicrobial therapy, surgery, or both), and prompt recognition of complications should they arise. Factors associated with increased mortality include: (a) heart failure, (b) increasing age, (c) endocarditis caused by resistant organisms, such as fungi or gram-negative bacteria, (d) left-sided endocarditis caused by *S. aureus*, (e) paravalvular complications, (f) healthcare-acquired infection, and (g) PVE.[4,5,11,16] The presence of heart failure has the greatest negative impact on the short-term prognosis.[4] For left-sided native valve infective endocarditis, mortality rates range from 15% to 45%; lower rates (4%-16%) occur with community-acquired disease that is most commonly caused by viridans streptococci. Higher rates (25%-45%) occur with healthcare-associated disease that is more commonly caused by enterococci and staphylococci.[25] Even higher rates of mortality are seen with unusually encountered organisms (eg, mortality > 80% for fungi).[4,5] The mortality rate for right-sided infective endocarditis associated with IVDA is generally low (eg, <10%).[4,25] For those who relapse after treatment for infective endocarditis, most will do so within the first 2 months after discontinuation of antimicrobials. Relapse rates for viridans streptococcus are generally low (2%), whereas relapse is more likely in those with enterococcal infection (8%-20%) and PVE (10%-15%).[17] After appropriate treatment and recovery, the risk of morbidity and mortality following infective endocarditis persists for years, although it gradually declines annually. Morbidity remains elevated because of a greater likelihood of recurrent infective endocarditis, heart failure, and embolism or, if a valve is replaced, the risk of anticoagulation, valve thrombosis, or additional valve surgery.[22]

TREATMENT

Desired Outcomes

The desired outcomes for treatment and prophylaxis of infective endocarditis are to:

1. Relieve the signs and symptoms of the disease
2. Decrease morbidity and mortality associated with the infection
3. Eradicate the causative organism with minimal drug exposure
4. Provide cost-effective antimicrobial therapy determined by the likely or identified pathogen, drug susceptibilities, hepatic and renal function, drug allergies, and anticipated drug toxicities
5. Prevent infective endocarditis from occurring or recurring in high-risk patients with appropriate prophylactic antimicrobials

General Approach to Treatment

Specific treatment recommendations from the American Heart Association (AHA) provide guidance for the management of infective endocarditis, and these were last updated in 2015.[4] Guidelines published by the European Society of Cardiology (ESC) remain consistent, for the most part, with the AHA guidelines.[5] Both now provide important recommendations for the combination of early diagnosis, early antibiotic therapy, and early surgery; but there are some subtle differences. For the first time, the ESC guidelines recommend that an "endocarditis team" is crucial for the management of infective endocarditis. The team should include cardiologists, cardiac surgeons, and specialists in infectious disease. The AHA guidelines place more emphasis on a team-based approach when assessing the timing and need for surgical intervention. The ESC guidelines also provide recommendations for specific situations, including infective endocarditis in the intensive care unit, in patients with cancer, and in patients with nonbacterial endocarditis.[5]

The AHA and ESC guidelines use an evidence-based scoring system where recommendations are given a classification as well as level of evidence. Class I recommendations are conditions for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective. Class II recommendations are conditions for which there is conflicting evidence, a divergence of opinion, or both about the usefulness/efficacy of a procedure or treatment (IIa implies that the weight of evidence/opinion is in favor of usefulness/efficacy, whereas IIb implies that usefulness/efficacy is less well established by evidence/opinion). Class III recommendations are conditions for which there is evidence, general agreement, or both that the procedure/treatment is not useful/effective and in some cases may be harmful. Level of evidence is listed as A (data derived from multiple randomized clinical trials), B (data derived from a single randomized trial or nonrandomized studies), and C (consensus opinion of experts).

5 The most important approach in the treatment of infective endocarditis is isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, and bactericidal antibiotics for an extended period.[1,4,5,6,19] Identification of susceptibilities is crucial given the escalating level of antibiotic resistance to commonly encountered pathogens. Treatment usually is started in the hospital, but for select patients it is often completed in the outpatient setting so long as defervescence has occurred and follow-up blood cultures show no growth.[26] Large doses of parenteral antimicrobials usually are necessary to achieve bactericidal concentrations within vegetations. An extended duration of therapy is required, even for susceptible pathogens, because microorganisms are enclosed within valvular vegetations and fibrin deposits. These barriers impair host defenses and protect microbes from phagocytic cells. In addition, high bacterial concentrations within vegetations may result in an inoculum effect that further resists killing (see Chapter 24 for additional discussion). Many bacteria are not actively dividing, further limiting the rate of bacterial death. For most patients, a minimum of 4 to 6 weeks of therapy is required.[4,5]

Nonpharmacologic Therapy

6 Surgery is an important adjunct in the management of both NVE and PVE and is now performed in up to 50% of patients.[27] In most surgical cases, valvectomy and valve replacement are performed to remove infected tissue and to restore hemodynamic function. Indications for surgery include heart failure, persistent bacteremia, persistent vegetation, an increase in vegetation size, or recurrent emboli despite prolonged antibiotic treatment, valve dysfunction, paravalvular extension (eg, abscess), or endocarditis caused by resistant organisms (eg, fungi or gram-negative bacteria).[4-6] More controversial is the appropriate timing of surgery as well as duration of antibiotic therapy post-surgery. Additionally, studies evaluating postsurgical outcomes and associated mortality are limited such that a specific risk prediction system has not been established.[28-32] Early surgery (eg, within 48 hours) may be appropriate in patients with severe heart failure and large vegetations, whereas patients with septic shock, advanced age, or neurologic complications of infective endocarditis may have more detrimental outcomes.[28,29,33,34] The multiple factors that need to be considered in evaluating the need for and timing of surgery is why a multidisciplinary management approach (ie, "endocarditis team") is critical.[4,5,19]

Clinical **Controversy...**

The role of surgery in the management of infective endocarditis is increasing; however, the duration of antibiotic therapy post-surgery is unclear and can depend on whether prosthetic material was inserted and if resected tissue is culture positive or culture negative.

Pharmacologic Therapy

7 β-Lactam antibiotics, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively. Tables 111-4 to 111-7 summarize these recommendations, which are discussed in more detail in the following sections. Tables 111-8 and 111-9 list drug dosing and monitoring recommendations for adult and pediatric patients. Because these guidelines focus on common causes of endocarditis, readers are referred to other references for more in-depth discussion of unusually encountered organisms.[4,5,35-38]

8 For some pathogens, such as enterococci, the use of synergistic antimicrobial combinations (including an aminoglycoside) is essential to obtain a bactericidal effect. Combination antibiotics also may decrease the emergence of resistant organisms during treatment (eg, PVE caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (eg, some streptococcal and staphylococcal infections). Occasionally, combination treatment will result in a shorter treatment course.

Streptococcal Endocarditis

Streptococci are a common cause of infective endocarditis, with most isolates being viridans group streptococci. Viridans group streptococci refers to a large number of different species, such as *Streptococcus sanguinis, Streptococcus oralis, Streptococcus salivarius, Streptococcus mutans*, and *Gemella morbillorum*.[4] These bacteria are common inhabitants of the human mouth and gingiva, and they are especially common causes of endocarditis involving native valves.[4,16,25] During dental surgery, and even when brushing the teeth, these organisms can cause a transient bacteremia. In susceptible individuals, this may result in infective endocarditis. Streptococcal endocarditis is usually subacute, and the response to medical treatment is very good. *Streptococcus gallolyticus* (formerly known as *Streptococcus bovis*) is not a viridans group streptococcus, but it is included in this treatment group because it is penicillin sensitive and requires the same treatment. *S. gallolyticus* is a nonenterococcal group D *Streptococcus* that resides in the GI tract. Infective endocarditis caused by this organism is often associated with a GI pathology, especially colon carcinoma. Endocarditis caused by *Streptococcus pneumoniae, Streptococcus pyogenes*, and group B, C, and G streptococci are uncommon, and their treatment is not well defined.[4,5]

Antimicrobial regimens for viridans group streptococci are well studied, and in uncomplicated cases, the cure rate is expected to be more than 95%.[4,5] Viridans group streptococci are penicillin susceptible, although some are more susceptible than others. Most are highly sensitive to penicillin G and have minimal inhibitory concentrations (MICs) of less than 0.12 mcg/mL (mg/L).[4] Approximately 10% to 20% are moderately susceptible (MIC 0.12-0.5 mcg/mL [mg/L]). This different in vitro susceptibility led to recommendations that the MIC be determined for all viridans streptococci and that the results be used to guide therapy. Some streptococci are deemed tolerant to the killing effects of penicillin, where the minimal bactericidal concentration (MBC) exceeds the MIC by 32 times. A tolerant organism is inhibited but not killed by an antibiotic normally considered bactericidal.[4] Bactericidal activity is required for successful treatment of infective endocarditis; therefore, infections with a tolerant organism may relapse after treatment. Despite some animal studies of endocarditis suggesting that tolerant strains do not respond as readily to β-lactam therapy as nontolerant ones, this phenomenon is primarily a laboratory finding with little clinical significance.[4] Treatment for tolerant strains is identical to that for nontolerant organisms, and measurement of the MBC is not recommended.[4]

An assortment of regimens can be used to treat uncomplicated NVE caused by fully susceptible viridans group streptococci (see Table 111-4). Two single-drug regimens consist of high-dose

TABLE 111-4 Treatment Options for Native Valve Endocarditis by Causative Organism

Agent[a]	Duration	Strength of Recommendation	Comments
Highly Penicillin-Susceptible (MIC ≤ 0.12 mcg/mL [mg/L]) Viridans Group Streptococci and *S. Gallolyticus*			
Aqueous crystalline penicillin G sodium[b]	4 weeks	IIaB	2-week regimens are not intended for the following patients: • Most patients >65 years of age • Children • Impairment of the eighth cranial nerve function • Renal function with a creatinine clearance <20 mL/min (<0.33 mL/s) • Known cardiac or extracardiac abscess • Infection with *Abiotrophia, Granulicatella*, or *Gemalla* species
Ceftriaxone	4 weeks	IIaB	
Aqueous crystalline penicillin G sodium[b] plus gentamicin	2 weeks	IIaB	
Ceftriaxone plus gentamicin	2 weeks	IIaB	
Vancomycin	4 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Viridans Group Streptococci and *S. Gallolyticus* Relatively Resistant to Penicillin (MIC >0.12 to ≤0.5 mcg/mL [mg/L])			
Aqueous crystalline penicillin G sodium[b] plus gentamicin	4 weeks 2 weeks	IIaB	
Ceftriaxone plus gentamicin	4 weeks 2 weeks	IIbC	
Vancomycin	4 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Oxacillin-Susceptible Staphylococci[c]			
Nafcillin or oxacillin	6 weeks	1C	
Cefazolin	6 weeks	1B	For use in patients with nonanaphylactoid-type penicillin allergies; patients with an unclear history of immediate-type hypersensitivity to penicillin should be considered for skin testing
Vancomycin	6 weeks	1B	For use in patients with anaphylactoid-type hypersensitivity to penicillin and/or cephalosporins
Daptomycin	6 weeks	IIaB	For use in patients with immediate-type hypersensitivity reactions to penicillin
Oxacillin-Resistant Staphylococci			
Vancomycin	6 weeks	1C	
Daptomycin	6 weeks	IIbB	

Please refer to Table 111-6 for treatment of NVE caused by enterococci.

[a]See Tables 111-8 and 111-9 for appropriate dosing, administration, and monitoring information.

[b]May use ampicillin in the event of a penicillin shortage.

[c]Regimens indicate treatment for left-sided endocarditis or complicated right-sided endocarditis; uncomplicated right-sided endocarditis may be treated for shorter durations and is described in the text.

Data from references 4 and 20.

parenteral penicillin G or ceftriaxone for 4 weeks. If short term, 2 week therapy is desired, the guidelines suggest either high-dose parenteral penicillin G or ceftriaxone in combination with an aminoglycoside.[4] When used in select patients, this combination is as effective as 4 weeks of penicillin alone. Although streptomycin was listed in previous guidelines, gentamicin is the preferred aminoglycoside because serum drug concentrations are obtained easily, clinicians are more familiar with its use, and the few strains of streptococci resistant to the effects of streptomycin-penicillin remain susceptible to gentamicin–penicillin. Other aminoglycosides are not recommended.

The decision of which regimen to use depends on the perceived risk versus benefit. For example, a 2-week course of gentamicin in an elderly patient with renal impairment may be associated with ototoxicity, worsening renal function, or both. Furthermore, the 2-week regimen is not recommended for patients with known extracardiac infection. On the other hand, a 4-week course of penicillin alone generally entails greater expense, especially if the patient remains in the hospital. Monotherapy with once-daily ceftriaxone offers ease of administration, facilitates home healthcare treatment, and may be cost-effective.[4,5,25]

The British Society for Antimicrobial Chemotherapy guidelines suggest that all of the following conditions be present to consider a 2-week treatment regimen for penicillin-sensitive streptococcal endocarditis:[35]

1. Penicillin-sensitive viridans streptococcus or *S. gallolyticus* (penicillin MIC <0.1 mcg/mL [mg/L])
2. No cardiovascular risk factors such as heart failure, aortic insufficiency, or conduction abnormalities
3. No evidence of thromboembolic disease
4. Native valve infection
5. No vegetation of greater than 5 mm diameter on echocardiogram
6. Low risk of nephrotoxicity
7. Not at risk for *Clostridium difficile*
8. Clinical response within 7 days (the temperature should return to normal, the patient should feel well, and the patient's appetite should return to normal)

9 When a patient has a history of an immediate-type hypersensitivity to penicillin, vancomycin should be chosen for infective endocarditis caused by viridans streptococci. When vancomycin is used, the addition of gentamicin is not recommended.[4] Most patients who report a penicillin allergy have a negative penicillin skin test and consequently are at low risk of anaphylaxis.[39] The published experience with penicillin is more extensive than with alternative regimens; consequently, a thorough allergy history must be obtained before a second-line therapy is administered.

For patients with complicated infections (eg, extracardiac foci) or when the streptococcus has an MIC of 0.12 to less than or equal to 0.5 mcg/mL (mg/L), combination therapy with an aminoglycoside for the first 2 weeks and penicillin (higher dose) or ceftriaxone is recommended, followed by penicillin or ceftriaxone alone for an

TABLE 111-5 Treatment Options for Prosthetic Valve Endocarditis (PVE) by Causative Organism

Agent[a]	Duration	Strength of Recommendation	Comments
Highly Penicillin-Susceptible (MIC ≤ 0.12 mcg/mL [mg/L]) Viridans Group Streptococci and *S. Galloyticus*			
Aqueous crystalline penicillin G sodium[b] with or without gentamicin	6 weeks 2 weeks	IIaB	Combination therapy with gentamicin has not demonstrated superior cure rates compared with monotherapy with a penicillin or cephalosporin and should be avoided in patients with CrCl <30 mL/min (<0.50 mL/s)
Ceftriaxone with or without gentamicin	6 weeks 2 weeks	IIaB	
Vancomycin	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Relatively Resistant or Fully Resistant (MIC > 0.12 mcg/mL [mg/L]) Viridans Group Streptococci and *S. Gallolyticus*			
Aqueous crystalline penicillin G sodium[b] plus gentamicin	6 weeks	IIaB	
Ceftriaxone plus gentamicin	6 weeks	IIaB	
Vancomycin[c]	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Oxacillin-Susceptible Staphylococci			
Nafcillin or oxacillin plus rifampin plus gentamicin	≥6 weeks ≥6 weeks 2 weeks	1B	Cefazolin may be substituted for nafcillin or oxacillin in patients with non-immediate-type hypersensitivity
Vancomycin plus rifampin plus gentamicin	≥6 weeks ≥6 weeks 2 weeks	1B	Recommended only for patients with anaphylactoid-type hypersensitivity to penicillin and/or cephalosporins
Oxacillin-Resistant Staphylococci			
Vancomycin plus rifampin plus gentamicin	≥6 weeks ≥6 weeks 2 weeks	1B	

Please refer to Table 111-6 for treatment of PVE caused by enterococci.

[a]See Tables 111-8 and 111-9 for appropriate dosing, administration, and monitoring information.

[b]May use ampicillin in the event of a penicillin shortage.

[c]The ESC 2015 guidelines recommend gentamicin (3 mg/kg/day) be administered with vancomycin for the initial 2 weeks of therapy in patients with relatively resistant strains to penicillin.

Data from references 4, 5, and 20.

TABLE 111-6 Treatment Options for Native or Prosthetic Valve Endocarditis Caused by Enterococci

Agent[a]	Duration[b]	Strength of Recommendation	Comments
Ampicillin-, Penicillin-, and Vancomycin-Susceptible Strains			
Ampicillin plus gentamicin	4-6 weeks	IIaB	Native valve plus symptoms present for <3 months: use 4-week regimen
Aqueous crystalline penicillin G sodium plus gentamicin	4-6 weeks	IIAB	Prosthetic valve or native valve plus symptoms present for >3 months: use 6-week regimen
Ampicillin plus ceftriaxone	6 weeks	IIaB	Recommended regimen if creatinine clearance is <50 mL/min (<0.83 mL/s; at baseline or due to therapy with a gentamicin-containing regimen)
Vancomycin plus gentamicin	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ampicillin
Gentamicin-Resistant Strains			
If susceptible, use streptomycin in place of gentamicin in the regimens listed above as long as creatinine clearance is >50 mL/min (>0.83 mL/s), cranial nerve VIII function is intact and there is laboratory capability for rapid streptomycin serum concentrations.			
Penicillin-Resistant Strains			
Ampicillin–sulbactam plus gentamicin (β-lactamase–producing strain)	6 weeks	IIbC	
Vancomycin plus gentamicin (intrinsic penicillin resistance[c])	6 weeks	IIbC	May also use in patients with β-lactamase–producing strains who have known intolerance to ampicillin–sulbactam
***Enterococcus Faecium* Strains Resistant to Penicillin, Aminoglycosides, and Vancomycin[d]**			
Linezolid	>6 weeks	IIbC	Antimicrobial cure rates may be <50%; bacteriologic cure may only be achieved with cardiac valve replacement
Daptomycin	>6 weeks	IIbC	

[a]See Tables 111-8 and 111-9 for appropriate dosing, administration, and monitoring information.

[b]All patients with prosthetic valves should be treated for at least 6 weeks.

[c]Infectious disease consult highly recommended.

[d]Patients should be managed by a multidisciplinary team that includes specialists in cardiology, cardiovascular surgery, infectious diseases, and clinical pharmacy.

Data from reference 4.

TABLE 111-7 Treatment Options for Culture-Negative Endocarditis and Endocarditis Caused by Gram-Negative Organisms[a]

Agent[b]	Duration[c]	Strength of Recommendation	Comments
HACEK[d] Microorganisms			
Ceftriaxone	4 weeks	IIaB	Other third- or fourth-generation cephalosporins may be used as an alternative
Ampicillin or Ampicillin–sulbactam	4 weeks	IIaB	Should only use if growth is adequate for in vitro susceptibility testing; otherwise, consider organism to be resistant
Ciprofloxacin	4 weeks	IIbC	Recommended for patients with known intolerance to cephalosporins or ampicillin; other fluoroquinolones may be used as an alternative
Culture-Negative Endocarditis, Native Valve[e]			
Vancomcyin plus cefepime	4-6 weeks	IIaC	Recommended when onset is acute (days); *S. aureus*, β-hemolytic streptococci, and aerobic gram-negative bacilli should be covered
Vancomycin plus ampicillin-sulbactam	4-6 weeks	IIaC	Recommended when onset is subacute (weeks); *S. aureus*, viridans group streptococci, HACEK, and enterococci should be covered
Culture-Negative Endocarditis, Early (<1 Year) Prosthetic Valve[e]			
Vancomycin plus cefepime plus rifampin plus gentamicin	6 weeks	IIaC	Staphylococci, enterococci, and aerobic gram-negative bacilli should be covered
Culture-Negative Endocarditis, Late (>1 Year) Prosthetic Valve[e]			
Vancomycin plus ceftriaxone	6 weeks	IIaC	Staphylococci, viridans group streptococci, and enterococci should be covered
Suspected *Bartonella*, Culture-Negative			
Ceftriaxone plus gentamicin with or without doxycycline	6 weeks 2 weeks 6 weeks	IIaB	
Culture-Positive *Bartonella*			
Doxycycline plus gentamicin	6 weeks 2 weeks	IIaB	Rifampin is recommended as an alternative in patient who cannot be given gentamicin

[a]Infectious disease consult highly recommended.

[b]See Tables 111-8 and 111-9 for appropriate dosing, administration, and monitoring.

[c]All patients with prosthetic valves should be treated for 6 weeks.

[d]*Haemophilus species* (*H. parainfluenzae, H. aphrophilus, and H. paraphrophilus*), *Aggregatibacter* species, *Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*.

[e]Duration of therapy for culture-negative endocarditis may be variable and should be based on clinical course and recommendations from infectious diseases consult.

Haemophilus parainfluenzae, *Haemophilus aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*.

Data from references 4 and 5.

additional 2 weeks (see Table 111-4).[4] Some viridans streptococci, previously referred to as nutritionally variant streptococci, have biologic characteristics that complicate diagnosis and treatment. *Abiotrophia defectiva* and *Granulicatella* species have nutritional deficiencies that hinder growth in routine culture media.[4] These organisms require special broth supplemented with pyridoxal hydrochloride or cysteine. For patients infected with nutritionally variant streptococci or when the *Streptococcus* has an MIC of more than 0.5 mcg/mL (mg/L), treatment should follow the enterococcal endocarditis treatment guidelines.[4]

The rationale for combination therapy of penicillin-susceptible viridans streptococci is that enhanced activity against these organisms usually is observed when cell-wall–active agents are combined with aminoglycosides in vitro.[40] Combined treatment results in quicker sterilization of vegetations in animal models of endocarditis and probably explains the high response rates observed for patients treated for a total of 2 weeks.[4,41] The combined treatment, however, is not superior to penicillin alone. Some authors question the need for combination therapy in relatively resistant streptococci, emphasizing that few human data suggest that patients with endocarditis caused by these organisms respond less well to penicillin alone.[40,42]

For patients with endocarditis of prosthetic valves or other prosthetic material caused by viridans group streptococci and *S. gallolyticus*, choices of treatment are similar to those without prosthetic material (eg, penicillin or ceftriaxone); however, treatment courses are extended to 6 weeks (see Table 111-5) for both the β-Lactam and the aminoglycoside. Whether extended-interval aminoglycoside dosing has a role in infective endocarditis continues to be debated. At this time, data support extended-interval dosing for the treatment of streptococcal infective endocarditis, and as compared with three-times-daily dosing this approach may have greater efficacy.[43,44] One study specifically evaluated the combination of ceftriaxone (2 g daily) with gentamicin (3 mg/kg daily) for 2 weeks compared with ceftriaxone (2 g daily) alone for 4 weeks for penicillin-sensitive streptococci. Both regimens were safe and effective with similar clinical cure rates at 3 months following treatment.[41]

Staphylococcal Endocarditis

Endocarditis caused by staphylococci has become more prevalent, mainly because of increased IVDA, more frequent use of peripheral and central venous catheters, and increased frequency of valve replacement surgery.[45,46] *S. aureus* is the most common organism causing infective endocarditis among those with IVDA and persons with venous catheters. Coagulase-negative staphylococci (usually *Staphylococcus epidermidis*) and *S. aureus* are prominent causes of PVE.

Staphylococcal endocarditis is not a homogeneous disease; appropriate management requires consideration of several questions: Is the organism methicillin resistant? Should combination therapy be used? Is the infection on a native or prosthetic valve? Does the patient have a history of IVDA? Is the infection on the left or right side of the heart? Another consideration in staphylococcal endocarditis is that some organisms may exhibit tolerance to antibiotics.

TABLE 111-8 Drug Dosing Table for Treatment of Infective Endocarditis[a]

Drug	Brand Name	Recommended Dose	Pediatric (Ped) Dose[b]	Additional Information
Ampicillin	NA	2 g IV every 4 hours	50 mg/kg every 4 hours or 75 mg/kg every 6 hours	24-hour total dose may be administered as a continuous infusion: 12 g IV every 24 hours
Ampicillin–sulbactam	Unasyn®	2 g IV every 4 hours	50 mg/kg every 4 hours or 75 mg/kg every 6 hours	
Aqueous crystalline penicillin G sodium	NA			24-hour total dose may be administered as a continuous infusion: 12-18 million units IV every 24 hours (Ped: 200,000 units/kg IV/24 hours)
• MIC <0.12 mcg/mL (mg/L) (native valve only)		3 million units IV every 4 hours or every 6 hours	50,000 units/kg IV every 6 hours	
• All other indications		4 million units IV every 4 hours or 6 million units IV every 6 hours	50,000 units/kg IV every 4 hours or 75,000 units/kg IV every 6 hours	24 million units IV every 24 hours (Ped: 300,000 units/kg IV every 24 hours)
Cefazolin	Ancef®	2 g IV every 8 hours	33 mg/kg IV every 8 hours	
Cefepime	Maxipime®	2 g IV every 8 hours	50 mg/kg IV every 8 hours	
Ceftriaxone sodium	Rocephin®	2 g IV or IM every 24 hours 2 g IV or IM every 12 hours (*E. faecalis only*)	100 mg/kg IV or IM every 24 hours	
Ciprofloxacin	Cipro®	400 mg IV every 12 hours or 500 mg po every 12 hours	20-30 mg/kg IV or po every 12 hours	Avoid use if possible in patients <18 years of age
Daptomycin	Cubicin®	≥8 mg/kg IV every 24 hours	6 mg/kg IV every 24 hours	Doses as high as 10-12 mg/kg IV every 24 hours have been used in adults with enterococcus resistant to penicillin, aminoglycosides and vancomycin; doses should be calculated using actual body weight
Doxycline	Vibramycin®	100 mg IV or po every 12 hours	1-2 mg/kg IV or po every 12 hours	
Gentamicin sulfate	NA	3 mg/kg IV or IM every 24 hours or 1 mg/kg IV or IM every 8 hours[c]	1 mg/kg IV or IM every 8 hours	Once-daily dosing is only recommended for treatment of streptococcal infections.
Linezolid	Zyvox®	600 mg IV or po every 12 hours	10 mg/kg IV every 8 hours	
Nafcillin or oxacillin	NA	2 g IV every 4 hours	50 mg/kg IV every 6 hours	
Rifampin	Rifadin®	300 mg IV or po every 8 hours	5-7 mg/kg IV or po every 8 hours	
Streptomycin	NA	7.5 mg/kg IV or IM every 12 hours		
Vancomycin	Vancocin®	15-20 mg/kg IV every 8 hours or every 12 hours	15 mg/kg IV every 6 hours	A loading dose of 25-30 mg/kg may be administered in adults; doses should be calculated using actual body weight; single doses should not exceed 2 g

[a]All doses assume normal renal function.

[b]Should not exceed adult dosage.

[c]Actual body weight should be used when the full aminoglycoside dose is administered once daily; when administered in three divided doses, use ideal body weight or adjusted body weight when actual body weight is >120% ideal body weight.

TABLE 111-9 Drug Monitoring of Select Agents

Drug	Major Adverse Drug Reactions	Monitoring Parameters	Comments
Daptomycin	Myopathy, rhabdomyolysis	Creatinine phosphokinase (CPK) at least weekly; monitor for signs and symptoms of muscle pain	More frequent monitoring may be warranted in patients with renal dysfunction or receiving concomitant therapy with HMG-CoA reductase inhibitors; discontinue if symptomatic and CPK >5 times the upper limit of normal (ULN) or if CPK ≥10 times ULN
Gentamicin	Nephrotoxicity, ototoxicity, neuromuscular blockade	When dosed three times daily: • Target peak serum concentrations of 3-4 mcg/mL (mg/L; 6.3-8.4 µmol/L) and trough serum concentrations of <1 mcg/mL (mg/L; <2.1 µmol/L)	Avoid concomitant use of other nephrotoxic agents such as diuretics, nonsteroidal antiinflammatory drugs, and radiocontrast media. Avoid rapid IV administration
Linezolid	Thrombocytopenia, optic, or peripheral neuropathy	Platelet counts at baseline and weekly, visual changes	More common with prolonged therapy (≥2 weeks for thrombocytopenia, >28 days for visual symptoms); avoid concomitant myelosuppressive agents
Rifampin	Hepatotoxicity	Baseline liver function tests, and then at least every 2-4 weeks during therapy	Avoid concomitant medications that cause hepatotoxicity; may cause red or orange discoloration of bodily secretions (urine, sweat, tears)
Vancomycin	Nephrotoxicity, red man syndrome	Target trough concentrations of 15-20 mcg/mL[a] (mg/L; 10-14 µmol/L)	Red man syndrome may be managed by prolonging the infusion time from 1 to 2 hours; administration of an antihistamine prior to loading or maintenance doses may also be considered

[a]Measuring peak serum vancomycin concentrations is no longer recommended.

Similar to streptococci, however, the concern for tolerance among staphylococci should not affect antibiotic selection.[4]

Any patient who develops staphylococcal bacteremia is at risk for endocarditis. Many investigators have attempted to develop criteria that identify the bacteremic patient likely to have infective endocarditis.[45] In the past, patients were considered to be at high risk for infective endocarditis if *S. aureus* bacteremia was community acquired versus hospital acquired; however, nosocomial *S. aureus* bacteremia is now considered as a major criterion for development of infective endocarditis.[23,24] The prevalence of infective endocarditis in patients with *S. aureus* bacteremia is approximately 25%, leading some authors to suggest that screening echocardiography be performed in all patients.[47] In hospitalized patients with *S. aureus* bacteremia and an identified focus of infection, such as a vascular catheter, the risk of concomitant infective endocarditis is low, and treatment of the bacteremia can be reduced to 2 weeks. This approach applies only if the patient does not have a prosthetic valve or additional clinical evidence for endocarditis.[48] Additionally, the following parameters predict higher risk of infective endocarditis for patients with *S. aureus* bacteremia: (a) the absence of a primary site of infection, (b) metastatic signs of infection, and (c) valvular vegetations detected by echocardiography.[24,47]

The recommended therapy for patients with left-sided, native valve infective endocarditis caused by methicillin-sensitive *S. aureus* (MSSA) is 6 weeks of nafcillin or oxacillin; a longer duration of therapy may be needed for complicated infections (ie, presence of perivalvular abscess or septic metastases). The AHA and ESC guidelines no longer recommend the addition of gentamicin because clinical benefit has not been demonstrated and there is an increase risk of toxicity (see Table 111-4). From in vitro studies, the combination of an aminoglycoside and penicillinase-resistant penicillin or vancomycin enhances the activity of these drugs for MSSA. In animal models of endocarditis, combinations of penicillin with an aminoglycoside eradicate organisms from vegetations more rapidly than penicillins alone.[5,40,49] In most human studies, the addition of an aminoglycoside to nafcillin hastens the resolution of fever and bacteremia, but it does not affect survival or relapse rates and can increase renal toxicity.[40,50,51] One small cohort study has demonstrated a decrease in recurrent bacteremia with combination therapy.[52]

If a patient has a mild, delayed allergy to penicillin, first-generation cephalosporins (such as cefazolin) are effective alternatives, but they should be avoided for patients with a history of immediate-type hypersensitivity reactions to penicillins (see Table 111-4). The potential for a true immediate-type allergy should be assessed carefully. A penicillin skin test should be conducted before giving antibiotic treatment to any patient with infective endocarditis caused by MSSA if there is a questionable penicillin allergy.[53] 9 For a patient with a positive skin test or a history of immediate hypersensitivity to penicillin, vancomycin is an option. Vancomycin, however, kills *S. aureus* slowly and is regarded as inferior to penicillinase-resistant penicillins for MSSA.[4] Alternatively, patients with immediate-type hypersensitivity reactions to penicillin can be considered for penicillin desensitization or daptomycin, a lipopeptide antibiotic approved for right sided infective endocarditis and *S. aureus* bacteremia.[4,5] Unfortunately, left-sided infective endocarditis caused by *S. aureus* continues to have a poor prognosis, with a mortality rate between 25% and 40%.[4] For reasons discussed in the following section, those with infective endocarditis associated with IVDA have a more favorable response to therapy.

During the past decade, staphylococci more commonly have become resistant to penicillinase-resistant penicillins (ie, methicillin-resistant *S. aureus* [MRSA]). 9 Although vancomycin is still the most commonly selected alternative in these cases (see Table 111-4), susceptibility reports with MIC more than 2 mcg/mL (mg/L) and reports of vancomycin-resistant *S. aureus* strains are increasing.[21] Success with daptomycin or linezolid has been demonstrated for these patients.[54-59] Based on available data, daptomycin (at a dose of 6 mg/kg/day) was approved by the FDA in 2006 for the treatment of *S. aureus* bacteremia associated with right-sided NVE and is now a recommended alternative.[21,55] Higher doses of daptomycin (8-10 mg/kg/day) have been used in clinical practice and may be preferred by some experts, although prospective, randomized clinical trials are lacking.[21,60-63] To date, linezolid has not been approved by the FDA for use in endocarditis as most available data are based on case reports, and there is concern regarding use of a bacteriostatic agent for this condition.[21,54] Furthermore, the FDA issued a warning for linezolid in 2007 following reports from one study that patients with catheter-related bacteremia treated with linezolid had an increased incidence of death due to gram-negative bacillary infections.[64] The presence or lack of a prosthetic heart valve in patients with a methicillin-resistant organism guides therapy and determines whether vancomycin should be used alone or, if a prosthetic valve is present, whether combination therapy is necessary (see Table 111-5).[4]

Clinical **Controversy...**

Use of daptomycin in clinical practice may extend beyond the FDA-indication of right-sided NVE. Selection as an alternative to vancomycin in patients with left-sided NVE (MRSA or MSSA) and in those with MSSA NVE and severe allergy to penicillins or cephalosporins may be observed (ie, in the setting of vancomycin failure or resistance). Furthermore, although the data for use of high-dose daptomycin (8-10 mg/kg/day) is limited, the favorable drug tolerability and the potential for decreased treatment-emergent resistance may compel some prescribers to opt for high-dose therapy in complicated cases.

Staphylococcus Endocarditis: IV Drug Abuser

Infective endocarditis in those with IVDA is frequently (60%-70%) caused by *S. aureus*, although other organisms may be common in certain geographic locations.[25] In this setting, the tricuspid valve is frequently infected, resulting in right-sided infective endocarditis. Most patients have no history of valve abnormalities, are usually otherwise healthy, and have a good response to medical treatment. Nonetheless, surgery may be required.

As previously mentioned, an uncomplicated, left-sided MSSA endocarditis may be treated sufficiently with 6 weeks of monotherapy with penicillinase-resistant penicillin.[4] However, the clinical response with right-sided MSSA endocarditis in the IVDA is usually excellent and may be treated effectively (clinical and microbiologic cure exceeding 85%) with a 2-week course of nafcillin, oxacillin or daptomycin.[4] Previous guidelines emphasized combination therapy with an aminoglycoside for the 2-week duration based on earlier studies.[65-67] The current recommendation for monotherapy is based on data showing that a 2-week regimen of a penicillinase-resistant penicillin alone, without the addition of an aminoglycoside, is as effective as combined therapy in MSSA tricuspid valve endocarditis.[68] Additionally, a post-hoc analysis comparing daptomycin monotherapy with combination treatment (daptomycin plus 4 days of gentamicin) showed no difference in success rates but higher rates of renal toxicity.[50] Selection of a 2-week duration of treatment may be appropriate as long as the following criteria are fulfilled:[5]

- Pathogen identified as MSSA
- Good response to treatment
- Absence of metastatic sites of infection or empyema
- Absence of cardiac and extracardiac complications

- Absence of associated prosthetic valve or left sided valve infection
- Vegetation size less than 20 mm
- Absence of severe immunosuppression (<200 CD4 cells/μL [$<0.200 \times 10^9$/L]) with or without acquired immune deficiency syndrome (AIDS)

Short, 2-week, courses of vancomycin in IVDAs are not recommended because of limited bactericidal activity, poor penetration into vegetations, and increased drug clearance in this population. The standard 6-week regimen should therefore be used. While vancomycin and daptomycin are both options for native valve MRSA infective endocarditis in IVDAs, daptomycin would be the drug of choice in cases where the vancomycin MIC is more than 1 mcg/mL (mg/L).[5]

An intriguing therapeutic approach for staphylococcal endocarditis in those with IVDA is oral treatment. One study indicated that short-course IV treatment (primarily nafcillin; mean: 16 days) followed by oral treatment (dicloxacillin or oxacillin; mean: 26 days) might be effective for tricuspid valve MSSA endocarditis.[69] The positive results of this trial can be explained by the relatively long duration of IV antibiotics (>2 weeks). Two other studies that predominantly used oral therapy (ciprofloxacin and rifampin) demonstrated efficacy (cure rates exceeding 90%) in addicts with uncomplicated right-sided endocarditis caused by MSSA.[70,71] At this time, concerns with resistance (eg, ciprofloxacin), patient adherence, and limited published data preclude routine use of oral antibacterial regimens for the treatment of infective endocarditis in IVDAs.[4]

Staphylococcal Endocarditis: Prosthetic Valves

Prosthetic valve endocarditis accounts for 10% to 30% of all infective endocarditis cases.[5,8] Staphylococcal, fungi, and gram-negative bacilli are the main causes of early PVE, while the microbiology of late PVE mirrors that of NVE. An episode of PVE occurring within 2 months of surgery strongly suggests that the cause is staphylococci implanted during the procedure. Yet the risk of staphylococcal endocarditis remains elevated for up to 12 months after valve replacement.[72] Because this type of infective endocarditis is typically a nosocomial infection, methicillin-resistant organisms are common, and vancomycin is the cornerstone of therapy. Combination antimicrobials are recommended because of the high morbidity and mortality associated with PVE and its refractoriness to therapy.[4,5,11,21] Although the addition of rifampin to a penicillinase-resistant penicillin or vancomycin does not result in predictable bacterial synergism, rifampin may have unique activity against staphylococcal infection that involves prosthetic material, where its addition results in a higher microbiologic cure rate.[4] Combination therapy also decreases the emergence of resistance to rifampin, which frequently occurs when it is used alone. For methicillin-resistant staphylococci (both MRSA and coagulase-negative staphylococci), vancomycin is recommended with rifampin for 6 weeks or more (see Table 111-5). An aminoglycoside is added for the first 2 weeks if the organism is aminoglycoside susceptible; traditional dosing should be used as once-daily regimens have not been adequately evaluated in PVE and are not recommended.[4]

For MSSA, penicillinase-resistant penicillin is administered in place of vancomycin. PVE responds poorly to medical treatment and has a higher mortality compared with NVE. Valve dehiscence and incompetence can result in acute heart failure, and surgery is often a component of treatment.[4,33]

The use of anticoagulation is controversial in PVE. In general, those who require anticoagulation for a prosthetic valve should continue the anticoagulant cautiously during endocarditis therapy, unless a contraindication to therapy exists. It is recommended to hold all anticoagulation for at least 2 weeks for patients with *S. aureus* PVE if a recent CNS embolic event has occurred.[4]

Enterococcal Endocarditis

Enterococci are normal inhabitants of the human GI tract and, occasionally, of the anterior urethra. These organisms are usually of low virulence but can become pathogens following healthcare intervention or in predisposed patients (most commonly elderly with comorbid conditions such as diabetes or need for hemodialysis).[25] Historically, enterococci were considered group D streptococci, but they have been reclassified into the genus *Enterococcus* (*E. faecalis* and *E. faecium*). *E. faecalis* is the most common clinical isolate (approximately 97%) of the two species. Enterococci are the third leading cause of infective endocarditis, but they are more resistant to therapy than staphylococci and streptococci.[73] Enterococci are noteworthy for the following reasons: (a) no single antibiotic is bactericidal, (b) MICs to penicillin are relatively high (1-25 mcg/mL [mg/L]), (c) intrinsic resistance occurs to all cephalosporins and relative resistance occurs to aminoglycosides (eg, "low-level" aminoglycoside resistance), (d) combinations of a cell-wall–active agent such as a penicillin or vancomycin and an aminoglycoside are necessary for killing, and (e) resistance to all available drugs is increasing.[4,74-76]

Monotherapy with penicillin for infective endocarditis caused by enterococci results in relapse rates of 50% to 80%. When used alone, penicillins are only bacteriostatic against enterococci, and thus combination therapy is always recommended for susceptible strains.[4,75] The killing of enterococci by the bactericidal combination of an aminoglycoside antibiotic and a penicillin is the best clinical example of antibiotic synergy. Because the aminoglycoside cannot penetrate the bacterial cell in the absence of the penicillin, enterococci usually will appear to be resistant to aminoglycosides by routine susceptibility testing (low-level resistance). However, in the presence of an agent that disrupts the cell wall such as penicillin, the aminoglycoside can gain entry, attach to bacterial ribosomes, and cause rapid cell death. An aminoglycoside–vancomycin combination is also synergistic against enterococci and is appropriate therapy for the penicillin-allergic patient.[4,75-77]

Enterococcal endocarditis ordinarily requires 4 to 6 weeks of ampicillin or high-dose penicillin G plus an aminoglycoside for cure (see Table 111-6). Recent literature suggests that ampicillin plus ceftriaxone is as effective as ampicillin plus gentamicin and should be considered as a treatment option.[4,5] Ampicillin has greater in vitro activity than penicillin G, although there are no clinical data to document differences in efficacy. A 6-week course is recommended for patients with symptoms lasting longer than 3 months and those with PVE. Streptomycin and gentamicin have similar efficacy, but gentamicin is preferred due to the inability to obtain streptomycin serum levels in most labs.[75] Because of resistance, other aminoglycosides, such as tobramycin and amikacin, cannot be substituted routinely. In the treatment of enterococcal endocarditis, relatively low serum concentrations of aminoglycosides appear adequate for successful therapy, such as a gentamicin peak concentration of approximately 3 to 4 mcg/mL (mg/L; 6.3-8.4 μmol/L).[4,75,77] Treatment of enterococcal endocarditis does not have the high success rate seen with infective endocarditis caused by viridans streptococci, presumably because the organism is more resistant to killing.

Although some data support the use of extended-interval aminoglycoside dosing for other types of endocarditis (ie, streptococci), the data are more vague regarding this strategy in enterococcal infective endocarditis.[78] Some studies suggest that extended-interval aminoglycoside dosing and short-interval (traditional) dosing are clinically equivalent, discordant studies imply otherwise.[79-83] Newer evidence suggests that extended-interval dosing is appropriate in the setting of non-high level aminoglycoside resistant (MIC < 500 mcg/mL [mg/L]) *E. faecalis* IE and this strategy has been adopted by the

new European Society of Cardiology Guidelines.[5,84,85] As such, the duration of therapy can be shortened from 4 to 6 weeks to 2 weeks. This recommendation differs from the current AHA guidelines, which continue to support traditional dosing.[4]

Resistance among enterococci to penicillins and aminoglycosides is increasing.[4] Enterococci that exhibit high-level resistance to streptomycin (MIC > 2,000 mcg/mL [mg/L]) are not synergistically killed by penicillin and streptomycin because the aminoglycoside either no longer binds to the ribosome or is inactivated by an aminoglycoside-modifying enzyme, streptomycin adenylase.[75] Because enterococci will appear resistant to aminoglycosides on routine susceptibility testing, the only way to distinguish high-level from low-level resistance is by performing special susceptibility tests using 500 to 2,000 mcg/mL (mg/L) of the aminoglycoside.[77] High-level streptomycin-resistant enterococci occur with a frequency approaching 60%, and high-level resistance to gentamicin is now found in 10% to 50% of isolates. Although most gentamicin-resistant enterococci are resistant to all aminoglycosides (including amikacin), 30% to 50% remain susceptible to streptomycin.[86] High-level gentamicin resistance is mediated by a bifunctional aminoglycoside-modifying enzyme, 6-acetyltransferase/2-phosphotransferase, and most strains also possess streptomycin adenylase. The incidence of high-level aminoglycoside resistance is increasing; however, data on appropriate therapy are sparse, and therapeutic options are few.[75,86,87]

In addition to isolates with high-level aminoglycoside resistance, β-lactamase–producing enterococci (especially *E. faecium*) have been reported. If these organisms are discovered, use of vancomycin or ampicillin–sulbactam in combination with gentamicin should be considered. Vancomycin-resistant enterococci are reported increasingly, primarily with *E. faecium*. Vancomycin resistance occurs when the bacterium replaces the normal vancomycin target with a peptidoglycan precursor that does not bind vancomycin.[76,87,88]

Treating multidrug-resistant enterococci is difficult, and data on appropriate therapy are sparse. Guidelines suggest either linezolid or daptomycin, although the latter agent has produced conflicting results.[89-95] Surgery and replacement of the infected cardiac valve may be the only cure.

HACEK Group

Fastidious gram-negative bacteria from the group of bacteria including *Haemophilus parainfluenzae, Haemophilus aphrophilus, Aggregatibacter* species*, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae* (HACEK group) account for 0.8% to 6% of infective endocarditis cases.[96] Frequently, these types of infective endocarditis present as subacute illnesses with large vegetations and emboli.[96,97] These oropharyngeal organisms typically are slow growing and should be considered as possible causes of "culture-negative" endocarditis.[97] With proper treatment, infectious endocarditis caused by HACEK organisms has a low mortality rate.[96] β-lactamase–producing organisms are occurring more often; hence, HACEK organisms should be considered resistant to ampicillin alone and should not be used unless in vitro susceptibility testing is adequate. Ceftriaxone, or an alternate third- or fourth-generation cephalosporin, is the preferred treatment in most cases. Ciprofloxacin may be considered as an option if an allergy to cephalosporins is present (see Table 111-7).[4,5] Treatment is usually for 4 weeks, but it should be extended to 6 weeks in PVE caused by one of these organisms.

Less Common Types of Infective Endocarditis

Atypical Microorganisms

Endocarditis caused by organisms, such as *Bartonella*; *Coxiella burnetii*; *Brucella, Candida*, and *Aspergillus* spp.; *Legionella*; and gram-negative bacilli (eg, *Pseudomonas*), is relatively uncommon. Medical therapy for infective endocarditis caused by these organisms is usually unsuccessful.[4,5] Consultation with an infectious disease expert is warranted when these microorganisms are identified.

In addition to *Pseudomonas* spp., other gram-negative bacilli that have been implicated include *Salmonella* spp., *Escherichia coli, Citrobacter* spp., *Klebsiella–Enterobacter* spp., *Serratia marcescens, Proteus* spp., and *Providencia* spp.[37] Generally, these infections have a poor prognosis, with mortality rates as high as 60% to 80%.[37] Cardiac surgery in concert with extended-course antibacterial therapy is recommended (class IIa; level of evidence: B) for most patients with gram-negative bacillary infective endocarditis. Readers are referred to the AHA guidelines for more extensive review of treatment regimens for infective endocarditis *due to Pseudomonas* spp. and unusual gram-negative bacteria.[4]

Fungi cause less than 2% of endocarditis cases; most patients with fungal endocarditis have undergone recent cardiovascular surgery, are IV drug abusers, have received prolonged treatment with indwelling central venous catheters, or are immunocompromised.[36,98] *Candida* spp. and *Aspergillus* spp. are the most commonly involved, and the mortality rate is high (>80%) for the following reasons: (a) large, bulky vegetations that often form, (b) systemic septic embolization that may occur, (c) the tendency of fungi to invade the myocardium, (d) poor penetration of vegetations by antifungals, (e) the low toxic-to-therapeutic ratio of agents such as amphotericin B, and (f) the lack of consistent fungicidal activity of available antifungal agents.[3,5,99] When fungal infective endocarditis is identified, a combined medical–surgical approach is warranted. Because these infections occur infrequently, scant clinical data are available to make solid treatment recommendations. Amphotericin B with or without flucytosine or an enchinocandin (high dose) is the recommended pharmacologic approach for *Candida* IE while voriconazole with the addition of amphotericin B or enchinocandin is suggested for those with Aspergillus IE.[5,37] Greater than 6 weeks of therapy is usually recommended; subsequent life-long suppressive therapy with an oral azole may be recommended for some.[4,5,37]

C. burnetii (Q fever) may be recovered from blood cultures, but infection is more likely to be identified via serologic tests. It is a common cause of infective endocarditis in certain areas of the world where goat, cattle, and sheep farming are widespread. The most favorable therapy for Q fever is unknown but may include doxycycline with hydroxychloroquine, trimethoprim–sulfamethoxazole, rifampin, or fluoroquinolones for at least 18 months.[100] *Brucella* are facultative intracellular gram-negative bacilli. Humans are infected by this organism after ingesting infected unpasteurized milk or undercooked meat, inhaling infectious aerosols, or contacting infected tissues. This type of infective endocarditis is more common in veterinarians and livestock handlers. Cure requires valve replacement and antimicrobial agents including doxycycline with streptomycin or gentamicin or doxycycline with trimethoprim–sulfamethoxazole or rifampin for an extended period (6 weeks to months).[101]

Culture-Negative Endocarditis

Sterile blood cultures are reported in up to 31% of patients with infective endocarditis if strict diagnostic criteria are used.[1,5] This type of infective endocarditis may occur as a result of unidentified subacute right-sided infective endocarditis, previous antibiotic therapy, slow-growing fastidious organisms, nonbacterial etiologies (eg, fungi), noninfective endocarditis, and improperly collected blood cultures. When blood cultures from patients suspected of infective endocarditis show no growth after 48 to 72 hours, cultures should be held for up to a month and special testing techniques (eg, serological analysis, polymerase chain reaction) pursued to detect fastidious or nonbacterial organisms.[4,36,97]

The AHA guidelines provide very general recommendations for culture-negative infective endocarditis (see Table 111-7) and suggest that therapy should be guided based on the individual patient's past medical history and epidemiological risks identified. Selection of treatment can be difficult, balancing the need to cover all likely organisms against potential toxic drug effects (eg, aminoglycosides). Antimicrobial selection should involve consultation with an infectious disease specialist. Irrespective of the chosen treatment, extended antimicrobial therapy is required. The empirical approaches for culture-negative infective endocarditis highlight the need for proper collection and monitoring of blood cultures and an extensive medication history.

PERSONALIZED PHARMACOTHERAPY

Infective endocarditis remains an uncommon disease, but the cost of treatment can be substantial. In the past, the long duration of hospitalization required to administer IV antimicrobials was the major expense. In select cases, abbreviated and/or outpatient, oral antimicrobial therapy may appreciably reduce the cost of care.

Shorter-course antimicrobial regimens are advocated when possible. For instance, in sensitive streptococcal endocarditis (MICs <0.12 mcg/mL [mg/L]), a 2-week regimen of high-dose parenteral penicillin G or ceftriaxone in combination with an aminoglycoside is as effective as 4 weeks of penicillin alone.[4] Uncomplicated right-sided MSSA endocarditis in the IV drug abuser may be treated with a 2-week course of nafcillin, oxacillin, or daptomycin.

The initiation of outpatient parenteral antibiotics should be considered early in the treatment of infective endocarditis, after the patient is stable clinically and responds favorably to initial antibiotics. Outpatient treatment is safe and cost-effective in select situations.[26,102,103] Patients considered for home therapy must be hemodynamically stable, compliant with therapy, have careful medical monitoring, understand the potential complications of the disease, and have immediate access to medical care. Advances in technology allow for the outpatient administration of complex antibiotic regimens that significantly reduce the cost of therapy. Simple regimens, such as single daily doses of ceftriaxone for streptococcal infective endocarditis, are particularly attractive. Although endocarditis is common in those with a history of IVDA and home healthcare would substantially reduce the cost of treatment, many clinicians are uncomfortable with outpatient IV therapy because central venous access is required. Sudden cardiac decompensation in an outpatient setting is also of concern.[4]

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of patients treated for infective endocarditis includes assessment of disease signs and symptoms, blood cultures, microbiologic tests, inflammatory markers, serum drug concentrations, and other tests that evaluate organ function.

Signs and Symptoms

Fever usually subsides within 1 week of initiating therapy.[17] Persistence of fever may indicate ineffective antimicrobial therapy, emboli, right-sided endocarditis, intravascular catheter infections, or drug reactions. For some patients, low-grade fever may persist even with appropriate antimicrobial therapy. With defervescence, the patient should begin to feel better, and other symptoms, such as lethargy or weakness, should subside. Echocardiography should be performed when antibiotic therapy has been completed to determine new baseline cardiac function (ie, ventricular size and function). A TTE is usually sufficient.

Blood Cultures

After initiation of appropriate therapy, blood cultures should be negative within a few days, although microbiologic response to vancomycin may be slower. If bacteria continue to be isolated from blood beyond the first few days of therapy, it may indicate that the antimicrobials are inactive against the pathogen or that the doses are not producing adequate concentrations at the site of infection. If this is the case, therapeutic adjustments should be made and blood cultures should be rechecked until negative. During the remainder of therapy, frequent blood cultures are not necessary but should be obtained if fever recurs.[4]

Microbiologic Tests

For all isolates from blood cultures, MICs should be determined; MBCs are no longer recommended.[4] The agent currently being used should be tested, as well as alternatives that may be required if intolerance, allergy, or resistance occurs. Occasionally, it is useful to determine whether synergy exists for antimicrobial combinations, although synergistic regimens usually can be predicted from the literature. Chapter 24 summarizes the methods for in vitro determinations of synergy.

Inflammatory Markers

Inflammatory markers are commonly used in infectious disease processes for diagnosing, monitoring of clinical outcomes, as well as assisting clinicians with evaluating the efficacy of antibiotic therapy. Currently only one inflammatory marker, rheumatoid factor (RF), is part of the modified Duke criteria for diagnosis. Other inflammatory markers, such as ESR, CRP, and procalcitonin (PCT), have all been investigated for evaluating the outcomes of patients with in endocarditis.[104] High PCT levels (eg, >0.5 ng/mL [mcg/L]) indicate the need for surgical intervention and correlate with poor outcomes (ie, death or serious infectious complications).[105,106] While these markers may be beneficial in assessing clinical outcomes, further evidence is needed to establish routine use for infective endocarditis.

Serum Drug Concentrations

Of the agents used commonly for infective endocarditis, measurement of serum drug concentrations is routinely available for aminoglycosides (except streptomycin) and vancomycin. Few data, however, support attaining any specific serum concentrations for patients with infective endocarditis. In general, serum concentrations of the antimicrobial should exceed the MIC of the organisms.

When aminoglycosides are administered for infective endocarditis caused by gram-positive cocci with a traditional three-times-daily regimen, peak serum concentrations are recommended to be on the low side of the traditional ranges (3-4 mcg/mL [mg/L; 6.3-8.4 µmol/L] for gentamicin). If extended-interval dosing is used, which is only recommended in streptococcal infective endocarditis, the most appropriate method of monitoring has not been determined. When vancomycin is administered, the primary goal is to ensure adequate trough concentrations, in this case 15 to 20 mcg/mL (mg/L; 10-14 µmol/L), are achieved.[107]

PREVENTION

10 Antimicrobial prophylaxis is used as an attempt to prevent infective endocarditis for patients who are at the highest risk.[6,5,18] The use of antimicrobials for this purpose requires consideration of (a) cardiac conditions associated with endocarditis, (b) procedures causing bacteremia, (c) organisms likely to cause endocarditis, and

(d) pharmacokinetics, spectrum, cost, adverse effects, and ease of administration of available antimicrobial agents. The objective of prophylaxis is to diminish the likelihood of infective endocarditis in high-risk individuals from procedures that result in bacteremia. Although there are no prospective, controlled human trials demonstrating that prophylaxis in high-risk individuals protects against the development of endocarditis during bacteremia-inducing procedures, animal studies suggest possible benefit.[18] However, other studies have questioned the benefit of antibiotic prophylaxis prior to invasive procedures.[108] Furthermore, many causes of infective endocarditis appear not to be secondary to an invasive procedure. Bacteremia as a consequence of daily activities may, in fact, be the major culprit, and the value of antibiotic prophylaxis before bacteremia-causing procedures has been questioned.[109] The literature lacks adequate evidence to prove the effectiveness or ineffectiveness of antibiotic prophylaxis, and the common practice of using antimicrobial therapy in this setting remains controversial.[110] The mechanism of a beneficial effect in humans is unclear, but antibiotics may decrease the number of bacteria at the surgical site, kill bacteria after they are introduced into the blood, and prevent adhesion of bacteria to the valve.

Clinical **Controversy...**

The common practice of administering antibiotics to high-risk individuals before a bacteremia-causing procedure is controversial. Despite limited data supporting this approach and the fact that 100% compliance with AHA preventative guidelines would have only a modest benefit, the use of single-dose antibiotics for the prevention of endocarditis remains a standard of care.

Regardless of the controversy about whether prophylactic antibiotics should be used, infective endocarditis prophylaxis is recommended in select situations, specifically dental procedures, in those with underlying high-risk cardiac conditions. The AHA released updated guidelines that better define who should and should not receive infective endocarditis prophylaxis.[18] The appropriateness of the new guidelines, however, has been called into question due to epidemiological studies showing an increase in the overall incidence of IE, especially due to *Streptococcus*.[8]

Key points of this report are that (a) only a small number of cases of infective endocarditis might be prevented with antibiotic prophylaxis for dental procedures, even if 100% effective; (b) infective endocarditis prophylaxis for dental procedures should be recommended only for patients with underlying cardiac conditions associated with the highest risk; (c) for those with high-risk underlying cardiac conditions, prophylaxis is recommended for all dental procedures involving manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa; (d) prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of infective endocarditis; and (e) administration of antibiotics solely to prevent endocarditis is not recommended for patients who undergo a genitourinary or GI tract procedure.

To determine whether a patient should receive prophylactic antibiotics, one needs to assess the patient's risk and whether he or she is undergoing a procedure resulting in bacteremia. When antibiotic prophylaxis is appropriate, a single 2 g dose of amoxicillin is recommended for adult patients at risk, given 30 to 60 minutes before undergoing procedures associated with bacteremia. Because the duration of antimicrobial prophylaxis appears to be relatively short, guidelines do not advocate a second oral dose of amoxicillin, which was recommended previously. Alternative prophylaxis regimens for patients allergic to penicillins or those unable to take oral medications are also provided. A summary of guideline recommendations is available in Table 111-10. Consultation of the full AHA guideline is suggested for more detailed information.[18]

TABLE 111-10 Prophylaxis of Infective Endocarditis

Highest Risk Cardiac Conditions	Presence of a prosthetic heart valve Prior diagnosis of infective endocarditis Cardiac transplantation with subsequent valvulopathy Congenital heart disease (CHD)[a]
Types of procedures	Any that require perforation of the oral mucosa or manipulation of the periapical region of the teeth of gingival tissue

Antimicrobial Options	Adult Doses[b]	Pediatric Doses[b] (mg/kg)
Oral amoxicillin	2 g	50
IM or IV ampicillin[c]	2 g	50
IM or IV cefazolin or ceftriaxone[c,d,e]	1 g	50
Oral cephalexin[d,e,f]	2 g	50
Oral clindamycin[e]	600 mg	20
Oral azithromycin or clarithromycin[e]	500 mg	15
IV or IM clindamycin[c,e]	600 mg	20

[a]Includes only the following: unrepaired cyanotic CHD, prophlyaxis within the first 6 months of implanting prosthetic material to repair a congenital heart defect, and repaired CHD with residual defects at or adjacent to prosthetic material.

[b]All one-time doses administered 30-60 minutes prior to initiation of the procedure.

[c]For patients unable to tolerate oral medication.

[d]Should be avoided in patients with immediate-type hypersensitivity reaction to penicillin or ampicillin (eg, anaphylaxis, urticaria, or angioedema).

[e]Option for patients with nonimmediate hypersensitivity reaction to penicillin or ampicillin.

[f]May substitute with an alternative first- or second-generation cephalosporin at an equivalent dose.

Data from reference 18.

ABBREVIATIONS

AHA	American Heart Association
CDIE	cardiac device infective endocarditis
CHD	congenital heart disease
CRP	C-reactive protein
ESC	European Society of Cardiology
ESR	erythrocyte sedimentation rate
HACEK	the group of bacteria including *Haemophilus parainfluenzae, Haemophilus aphrophilus, Aggregatibacter* species, *Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*
IE	infective endocarditis
IVDA	IV drug abuse
MBC	minimal bactericidal concentration
MIC	minimal inhibitory concentration
MRSA	methicillin-resistant *Staphylococcus aureus*
MSSA	methicillin-sensitive *Staphylococcus aureus*
NVE	native valve endocarditis
PCT	procalcitonin
PVE	prosthetic valve endocarditis
RF	rheumatoid factor
SBT	serum bactericidal titer
TEE	transesophageal echocardiography
TTE	transthoracic echocardiography

112 Tuberculosis

Rocsanna Namdar, Michael Lauzardo, and Charles A. Peloquin

KEY CONCEPTS

1. Tuberculosis (TB) is the most prevalent communicable infectious disease on earth; and it remains out of control in many developing nations. These nations require medical and financial assistance from developed nations in order to control the spread of TB globally.
2. In the United States, TB disproportionately affects the foreign born and other ethnic minorities, reflecting immigration patterns and greater ongoing transmission in these communities. Additional TB surveillance and preventive treatments are required within these communities.
3. TB is the leading cause of death in human immunodeficiency virus (HIV) infection worldwide. Coinfection with HIV and TB accelerates the progression of both diseases, thus requiring rapid diagnosis and treatment of both diseases.
4. Mycobacteria are slow-growing organisms; in the laboratory, they require special stains, special growth media, and long periods of incubation to isolate and identify.
5. TB can produce atypical signs and symptoms in infants, the elderly, and immunocompromised hosts, and it can progress rapidly in these patients.
6. Latent TB infection (LTBI) can lead to reactivation disease years after the primary infection occurred.
7. The patient suspected of having active TB disease must be isolated until the diagnosis is confirmed and the patient is no longer contagious. Often, isolation takes place in specialized "negative-pressure" hospital rooms to prevent the spread of TB.
8. Isoniazid and rifampin are the two most important drugs in the treatment of TB. Organisms resistant to both these drugs (multidrug-resistant TB [MDR-TB]) are much more difficult to treat.
9. Directly observed treatment (DOT) should be used whenever possible to reduce treatment failures and the selection of drug-resistant isolates.
10. To avoid the development of resistance, never add a single drug to a failing TB treatment regimen.

1 Tuberculosis (TB) remains a leading infectious killer globally. TB is caused by *Mycobacterium tuberculosis*, which can produce either a silent, latent infection or a progressive, active disease.[1] Left untreated or improperly treated, TB causes progressive tissue destruction and, eventually, death. Because of renewed public health efforts, TB rates in the United States continue to decline. In contrast, TB remains out of control in many developing countries and—one third of the world's population currently is infected.[1] Given increasing drug resistance, it is critical that a major effort be made to control TB before the most potent drugs are no longer effective.

TB rates generally have risen with increasing urbanization and overcrowding because it is easier for an airborne disease to spread when people are living in closer proximity to each other. Hence, TB became a significant pathogen in Europe during the Middle Ages and peaked during the Industrial Revolution, when it caused significant mortality in Europe and in the United States.[1] This dire threat led to the rise of public health departments and to procedures such as the isolation of infected patients. Thus, TB was directly responsible for many of the healthcare practices that are used today. Unfortunately, in developing nations, some of these practices are not widely available, and TB continues to rage unabated.

EPIDEMIOLOGY

Globally, approximately 2 billion people are infected by *M. tuberculosis*, and roughly 1.5 million people die from active TB each year despite the fact that it is curable.[1] In the United States, an estimated 9 million people are latently infected with *M. tuberculosis*, meaning that they are not currently sick but that they could fall ill with TB at any time.[2] In 2014, 9,412 new TB cases were reported in the United States, which is 2.2% lower than in 2013.[2] The annual incidence of TB in the United States declined by approximately 5% per year from 1953 to 1983.[2] In 1984, this decline slowed, and then the incidence of TB rose from 1988 reaching its peak in 1992 (**Fig. 112-1**). Since 1993, more effective infection control practices and treatment protocols have reduced TB rates significantly as mentioned above. Despite this good news, the eradication of TB from the United States remains difficult. One reason is that TB among immigrants to the United States from high incidence countries remains a problem.[1,2]

Risk Factors for Infection

The following section will discuss the risk factors for infection including location, race, ethnicity, and human immunodeficiency virus (HIV) coinfection. Risk factors and likelihood of progression from infection to disease will also be discussed.

Location and Place of Birth

California, Florida, New York, and Texas accounted for 51% of the TB cases reported nationally in 2014.[2] Within these states, TB is most prevalent in large urban areas and among those born outside the United States in high TB incidence countries.[2]

In 2014, the TB rate among foreign-born persons was 13.4 times that of US-born persons.[2] The percentage of foreign-born TB patients in the United States has increased annually, reaching 66.5% in 2014.[2] with a total of 6,181 TB cases reported among foreign-born persons. In 2014, 55.3% of foreign-born persons with TB originated from five countries: Mexico, the Philippines, Vietnam, India, and China.[2] Therefore, healthcare workers must consider TB when caring for patients from these countries who experience symptoms such as cough, fever, and weight loss. Furthermore, in 2013, foreign-born persons accounted for 90.6% of the multidrug-resistant (MDR) TB cases.

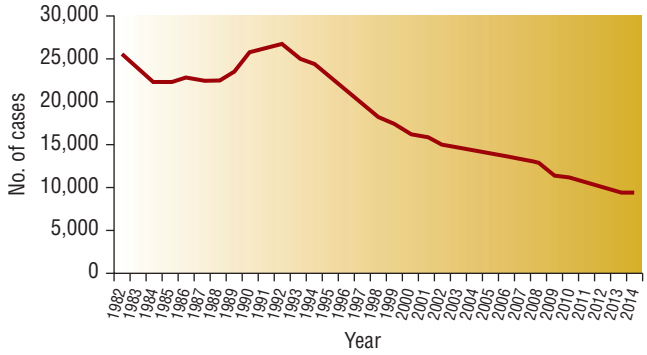

FIGURE 112-1 Reported cases of tuberculosis, United States, 1982-2011. *Updated as of June 5, 2015. *(Reproduced from Centers for Disease Control and Prevention. Reported Tuberculosis in the United States, 2014. Atlanta, GA: US Department of Health and Human Services, CDC, 2014, Available at: http://www.cdc.gov/tb/.)*

Close contacts of pulmonary TB patients such as family members, coworkers, or coresidents in places such as prisons, shelters, or nursing homes are the most likely to become infected. The more prolonged the contact, the greater is the risk, with infection rates as high as 30%.[2,3] TB patients frequently have limited access to healthcare, live in crowded conditions, or are homeless.[2,3] Many patients have histories of alcohol abuse or illicit drug use, and are coinfected with hepatitis B or HIV. These concurrent social and health problems make treating some TB patients particularly difficult.

Race, Ethnicity, Age

2 In the United States, TB disproportionately affects the foreign born and other ethnic minorities. In 2014, Asians had the largest percentage of total TB cases; however, the incidence rate among Asians decreased from 18.6 per 100,000 in 2013 to 17.9 in 2014.[2,4] TB rates among Hispanics remained relatively constant whereas rates decreased among blacks, whites, and Asians. In the American Indian/Alaska Native, Native Hawaiian or other Pacific Islander TB rates increased from 3.8 in 2013 to 4.3 in 2014.[2,4] Despite declines in the rates of TB among foreign and US-born individuals, the TB rate among foreign-born individuals was 13 times higher than among US-born individuals.[2,4] Among US-born group, non-Hispanic blacks were the ethnic group with the greatest number of TB cases and the largest disparity compared with US-born whites.[2,4]

TB is most common during adulthood primarily in the 25- to 44-year-age group and the 45- to 64-year-age group. In 2013, the case rates of TB declined from the previous years in all age groups except among children aged 14 years or younger, which remained the same from the previous year.[2]

Coinfection with Human Immunodeficiency Virus

3 In patients who have latent TB infection, HIV is the most important risk factor for progressing to active TB, especially among people between ages 25 and 44 years.[2,4,5] TB and HIV to act synergistically within patients and across populations, making each disease worse than it might otherwise be. In 2014, 6.3% of incident cases of TB in the United States were coinfected with HIV.[2,5] These numbers are estimates because laws and regulations in some states prohibit sharing HIV status of TB patients with the TB program. HIV coinfection may not increase the risk of acquiring *M. tuberculosis* infection, but it does increase the likelihood of progression to active disease.[1,5] There is evidence for higher mortality rates in HIV coinfected with MDR and extensively drug-resistant (XDR) TB.[5]

Risk Factors for Disease

Close contacts of pulmonary TB patients such as family members, coworkers, or coresidents in places such as prisons, shelters, or nursing homes are the most likely to become infected. The more prolonged the contact, the greater is the risk, with infection rates as high as 30%.[2-4] TB patients frequently have limited access to healthcare, live in crowded conditions, or are homeless.[2-4] Many patients have histories of alcohol abuse or illicit drug use, and are coinfected with hepatitis B or HIV. These concurrent social and health problems make treating some TB patients particularly difficult.

Once infected with *M. tuberculosis*, a person's lifetime risk of active TB is approximately 10%.[2-4] The greatest risk for active disease occurs during the first 2 years after infection. Children younger than 2 years and adults older than 65 years have two to five times greater risk for active disease compared with other age groups. Patients with underlying immune suppression (eg, renal failure, cancer, and immunosuppressive drug treatment) have 4 to 16 times greater risk than other patients.[2] Finally, HIV-infected patients with *M. tuberculosis* infection are 100 times more likely to develop active TB than normal hosts.[2-4] HIV-infected patients have an annual risk of active TB of approximately 10%, rather than a lifetime risk at that rate.[5] Therefore, all patients with HIV infection should be screened for tuberculous infection, and those known to be infected with *M. tuberculosis* should be tested for HIV infection.

ETIOLOGY

M. tuberculosis is a slender bacillus with a waxy outer layer.[2,6] It is 1 to 4 μm in length, and under the microscope, it is either straight or slightly curved in shape.[6] It does not stain well with Gram stain, so the Ziehl-Neelsen stain or the fluorochrome stain must be used instead.[6] After Ziehl-Neelsen staining with carbol-fuchsin, mycobacteria retain the red color despite acid–alcohol washes. Hence, they are called *acid-fast bacilli* (AFB).[6] On culture, *M. tuberculosis* grows slowly, doubling about every 20 hours. This is slow compared with gram-positive and gram-negative bacteria, which double about every 30 minutes.

Culture and Susceptibility Testing

All clinical specimens suspected of containing mycobacteria should be cultured. Culture is required for species identification and for drug susceptibility testing.

4 Direct susceptibility testing involves inoculating specialized media with organisms taken directly from a concentrated, smear-positive specimen.[1,6] This approach produces susceptibility results in 2 to 3 weeks. Indirect susceptibility testing involves inoculating the test media with organisms obtained from a pure culture of the organisms, which can take several more weeks. The most common agar method, known as the *proportion method*, uses the ratio of colony counts on drug-containing agar to that on drug-free agar.[1,6] In the United States, the critical proportion for resistance is 1%. That means that if a drug-containing plate shows 1% or more of the growth seen on a drug-free plate, some of the organisms from the specimen were resistant to that drug. Therefore, it is likely that many of the organisms in the patient also are resistant to that drug, and in general it should not be used to treat that patient.

The proportion method's limitations include many weeks to obtain results, drug degradation during the incubation, and a qualitative result (susceptible or resistant). The newer mycobacterial growth indicator tube (Becton Dickson, Sparks, MD) systems use liquid media and detect live mycobacteria in as few as 9 to 14 days.[6,7]

Rapid-identification tests are now available, but cost and care of equipment, remain an issue in many parts of the world. Nucleic acid amplifications tests use DNA probes to identify the presence of complementary ribosomal ribonucleic acid (rRNA) for several mycobacterial species.[6,7] DNA fingerprinting using restriction-fragment-length polymorphism analysis has been used to identify clusters of cases.[1,7,8] Amplification of the genetic material can be achieved through polymerase chain reaction (PCR), the amplified *M. tuberculosis* direct (MTD) test, and strand-displacement amplification.[7] Thin-layer chromatography, high-performance liquid

chromatography for mycolic acid identification, and gas chromatography for short-chain fatty acids (methyl esters) have been used to speciate mycobacterial isolates.[6-9] The Enhanced Amplified *Mycobacterium Tuberculosis* Direct Test (E-MTD) has been approved for use by the US Food and Drug Administration in AFB smear-positive and smear-negative specimen in patients with fewer than 7 days of antimycobacterial therapy and the Gene X-pert MTB/RIF assay in patients with fewer than 3 days of treatment. The Amplicor *Mycobacterium Tuberculosis* Test has been approved for smear-positive samples.[9-12]

The Hain test, a line-probe assay that diagnoses resistance to isoniazid and rifampin by detecting several gene mutations responsible for drug resistance, has also entered into limited clinical use in the United States. The Gene X-pert MTB/RIF test simultaneously identifies *M. tuberculosis* and rapidly determines if resistance to rifampin is present.[9,13] The test has excellent performance in both smear-positive and -negative patients, and high accuracy for determination of rifampicin resistance.[11] Colorimetric redox indicator and nitrate reduction assays for rapid detection of rifampicin and isoniazid resistance are both inexpensive and have rapid turnaround times of 1 week. Microscopic observation drug susceptibility assay is simple test using sputum samples to detect characteristic patterns of growth of *M. tuberculosis* and resistance patterns. Time to diagnosis is 7 days and drug susceptibilities are available at the time of diagnosis.[11] Most patients with microscopic observation drug susceptibility assays are diagnosed within 2 weeks and it is similarly efficient irrespective of bacterial burden.[12]

Other tests are designed to detect common genetic changes associated with drug resistance, such as changes in the *katG* gene associated with isoniazid resistance and the *rpoB* gene associated with rifampin resistance.[5,8,13] Probe assays do not eliminate the need for conventional culture and susceptibility testing; conventional drug susceptibility testing is needed to diagnose XDR TB. The decision to use nucleic acid amplification tests should be individualized.

Transmission

M. tuberculosis is transmitted from person to person by coughing or other activities that cause the organism to be aerosolized.[2,3] These particles, called *droplet nuclei*, contain one to three bacilli and are small enough (1-5 mm) to reach the alveolar surface. This produces "droplet nuclei" that are dispersed in the air. Each droplet nuclei contains one to three organisms. Approximately 30% of individuals who experience prolonged contact with an infectious TB patient will become infected.

A person with cavitary, pulmonary TB and a cough is considered very infectious and may infect greater than 30% of contacts until that person is treated effectively, although this percentage and the absolute number can vary significantly. A person with the uncommon laryngeal form of TB can spread organisms even when talking, so the transmission rates can be even higher.

PATHOPHYSIOLOGY

The following section will discuss the pathophysiology of primary infection, reactivation disease, and the influence of HIV on the pathogenesis of *M. tuberculosis* infections.

Immune Response

T-lymphocyte responses are essential to controlling *M. tuberculosis* infections.[2,3,14,15] In the mouse model, two different T-cell responses—the T-helper type 1 (TH_1) response and the T-helper type 2 (TH_2) response—have been described. The TH_1 response is the preferred response to TB, and the TH_2 response, including the potentially subversive influence of interleukin (IL) 4, is undesirable.[2,14,15] Some workers have argued that this dichotomy is clearer in the mouse model, and in many humans, the T-cell response may be classified as TH_0 (elements of both TH_1 and TH_2).[14] In either case, T lymphocytes activate macrophages that, in turn, engulf and kill mycobacteria. T lymphocytes also destroy immature macrophages that harbor *M. tuberculosis* but are unable to kill the invaders.[14,15] CD4+ cells are the primary T cells involved, with contributions by γ δ T cells and CD8+ T cells.[14] CD4+ T cells produce interferon-γ (INF-γ) and other cytokines, including IL-2 and IL-10, that coordinate the immune response to TB.[14] Because CD4+ cells are depleted in HIV-infected patients, these patients are unable to mount an adequate defense to TB.[14,15]

Although B-cell responses and antibody production can be demonstrated in TB-infected mammals, these humoral responses do not appear to contribute much to the control of TB within the host.[3,14] Tumor necrosis factor-α (TNF-α) and INF-γ are important cytokines involved in coordinating the host's cell-mediated response. Rheumatoid arthritis patients treated with TNF-α inhibitors (such as infliximab) have high rates of reactivation TB.[16] Therefore, patients known to be deficient in the activity of TNF-α or INF-γ should be screened for TB infection and offered appropriate treatment.

M. tuberculosis has several ways of evading or resisting the host immune response.[14,15] In particular, *M. tuberculosis* can inhibit the fusion of lysosomes to phagosomes inside macrophages. This prevents the destructive enzymes found in the lysosomes from getting to the bacilli captured in the phagosomes. This inhibition of destructive mechanisms allows time for *M. tuberculosis* to escape into the cytoplasm. Virulent *M. tuberculosis* is able to multiply in the macrophage cytoplasm, thus perpetuating their spread. Finally, lipoarabinomannan (LAM), the principal structural polysaccharide of the mycobacterial cell wall, inhibits the host immune response.[14,15] LAM induces immunosuppressive cytokines, thus blocking macrophage activation; additionally, LAM scavenges O_2, thus preventing attack by superoxide anions, hydrogen peroxide, singlet oxygen, and hydroxyl radicals.[14,15] These survival mechanisms make *M. tuberculosis* a particularly difficult organism to control. Any defects in the host immune system make it likely that *M. tuberculosis* will not be controlled and that active disease will ensue.

Primary Infection

Primary infection usually results from inhaling airborne particles that contain *M. tuberculosis*.[3,15] The progression to clinical disease depends on three factors: (a) the number of *M. tuberculosis* organisms inhaled (infecting dose), (b) the virulence of these organisms, and (c) the host's cell-mediated immune response.[3,15,17] At the alveolar surface, the bacilli that were delivered by the droplet nuclei are ingested by pulmonary macrophages. If these macrophages inhibit or kill the bacilli, infection is aborted.[15] If the macrophages cannot do this, the organisms continue to multiply. The macrophages eventually rupture, releasing many bacilli, and these mycobacteria are then phagocytized by other macrophages. This cycle continues over several weeks until the host is able to mount a more coordinated response.[15] During this early phase of infection, *M. tuberculosis* multiplies logarithmically.[15]

Some of the intracellular organisms are transported by the macrophages to regional lymph nodes in the hilar, mediastinal, and retroperitoneal areas. The cycle of phagocytosis and cell rupture continues. During lymph node involvement, the mycobacteria may be held in check. More frequently, *M. tuberculosis* spreads throughout the body through the bloodstream.[3,15] When this intravascular dissemination occurs, *M. tuberculosis* can infect any tissue or organ in the body. Most commonly, *M. tuberculosis* infects the posterior apical region of the lungs. This may be so because of the high oxygen content, and it may be because of a less vigorous immune response in this area.

After about 3 weeks of infection, T lymphocytes are presented with *M. tuberculosis* antigens. These T cells become activated and begin to secrete INF-γ and the other cytokines noted earlier.

The processes described in the Immune Response section above then begin to occur. First, T lymphocytes stimulate macrophages to become bactericidal.[15] Large numbers of activated microbicidal macrophages surround the solid caseous (cheese-like) tuberculous foci (the necrotic area of infection).[15] This process of creating activated microbicidal macrophages is known as *cell-mediated immunity* (CMI).[15]

At the same time that CMI occurs, delayed-type hypersensitivity (DTH) also develops through the activation and multiplication of T lymphocytes. DTH refers to the cytotoxic immune process that kills nonactivated immature macrophages that are permitting intracellular bacillary replication.[15] These immature macrophages are killed when the T lymphocytes initiate Fas-mediated apoptosis (programmed cell death).[15] The bacilli released from the immature macrophages then are killed by the activated macrophages.[15]

By this time (more than 3 weeks), in most recently infected individuals, macrophages have begun to form granulomas to contain the organisms. In a typical tuberculous granuloma, activated macrophages accumulate around a caseous lesion and prevent its further extension.[15] At this point, the infection is largely under control, and bacillary replication falls off dramatically. Depending on the inflammatory response, tissue necrosis and calcification of the infection site plus the regional lymph nodes may occur.

Over 1 to 3 months, activated lymphocytes reach an adequate number, and tissue hypersensitivity results. In practical terms, this is the reason why tests to diagnose latent TB infection, purified protein derivative (PPD) skin test, and the INF-γ release assays, take between 2 and 12 weeks to become positive. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis, although some residual bacilli have been found in various types of cells.[3,14]

Approximately 90% of infected patients have no further clinical manifestations. Most patients only show a positive skin test (70%), whereas some also have radiographic evidence of stable granulomas. This radiodense area on chest radiograph is called a *Ghon's complex*. Approximately 5% of patients (usually children, the elderly, and the immunocompromised) experience "progressive primary" disease that occurs before skin test conversion, which presents as a progressive pneumonia, usually in the lower lobes.[18] Disease frequently spreads, leading to meningitis and other severe forms of TB.[18] Because of this risk of severe disease, very young, elderly, and immunocompromised patients, including those with HIV, should be evaluated and treated for latent or active TB.

Reactivation Disease

6 Roughly 10% of infected patients develop reactivation disease at some point in their lives. Nearly half of these cases occur within 2 years of infection.[3,15] In the United States, most cases of TB are believed to result from reactivation. Reinfection is uncommon in the United States because of the low rate of exposure and because previously sensitized individuals possess some degree of immunity to reinfection.[3,15] Exceptions include patients coinfected with HIV who live in areas of higher exposure to *M. tuberculosis*.

The apices of the lungs are the most common sites for reactivation (85% of cases).[3] For reasons that are not entirely known (waning cellular immunity, loss of specific T-cell clones, blocking antibody), organisms within granulomas emerge and begin multiplying extracellularly.[15] The inflammatory response produces caseating granulomas, which eventually will liquefy and spread locally, leading to the formation of a hole (cavity) in the lungs.

The immune response contributes to the severity of the lung damage, and DTH allows for intracellular mycobacterial multiplication.[14,15] In addition, there is "innocent bystander" killing of host cells and locally thrombosed blood vessels.[15] The killing of mycobacteria, macrophages, and neutrophils that have entered the battle releases cytokines and lysozymes into the infectious foci. This toxic mixture can be too much for the surrounding alveoli and airway cells, causing regional necrosis and structural collapse.[3,15] These unstable foci liquefy, spreading the infection to neighboring areas of the lung, creating a cavity. Some of this necrotic material is coughed out, producing droplet nuclei. Bacterial counts in the cavities can be as high as 10^8 per milliliter (or 10^{11}/L) of cavitary fluid. Partial healing may result from fibrosis, but these lesions remain unstable and may continue to expand.[3,15] If left untreated, pulmonary TB continues to destroy the lungs, resulting in hypoxia, respiratory acidosis, and eventually death.

Extrapulmonary and Miliary Tuberculosis

Caseating granulomas at extrapulmonary sites can undergo liquefaction, releasing tubercle bacilli and causing symptomatic disease.[3] Extrapulmonary TB without concurrent pulmonary disease is uncommon in normal hosts but more common in HIV-infected patients. Because of these unusual presentations, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.[3] Lymphatic and pleural diseases are the most common forms of extrapulmonary TB, followed by bone, joint, genitourinary, meningeal, and other forms.[3] Occasionally, a massive inoculum of organisms enters the bloodstream, causing a widely disseminated form of the disease known as *miliary TB*. It is named for the millet seed appearance of the small granulomas seen on chest radiographs, and it can be rapidly fatal.[14] Miliary TB is a medical emergency requiring immediate treatment.

Influence of Human Immunodeficiency Virus Infection on Pathogenesis

3 HIV infection is the strongest single risk factor for progressing to active TB.[3,14] As CD4+ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them. In turn, the TB-fighting lymphocytes are depleted.[14] This vicious cycle puts HIV-infected patients at 100 times the risk of active TB compared with HIV-negative people.[19,20] In addition, the combination of HIV infection and certain social behaviors increases the risk of newly acquired TB. In select areas of the United States during the resurgence of TB during the early 1990s, up to 50% of new TB cases were the result of recent infection, particularly among HIV-infected individuals.[1,19,20]

As mycobacteria spread throughout the body, HIV replication accelerates in lymphocytes and macrophages. This leads to progression of HIV disease.[14,19,20] HIV-infected patients who are infected with TB deteriorate more rapidly unless they receive antimycobacterial chemotherapy.[19,20] Most clinicians now recommend integrated antiretroviral therapy (ART) beginning TB treatment first, and then beginning HIV treatment within 2 to 12 weeks.[21-23] However, the timing needs to be individualized based on degree of immunosuppression from HIV and the patient's tolerance of the treatment regimen. Immune reconstitution inflammatory syndrome or a paradoxical worsening of TB can occur, especially in patients with more severe immunosuppression; this appears to result from a reinvigorated inflammatory response to TB.[21-23] HIV-positive patients, should be screened for tuberculous infection or disease soon after they are shown to be HIV-positive.[21,22]

CLINICAL PRESENTATION

The classical presentation of TB is weight loss, fatigue, a productive cough, fever, and night sweats. The onset of TB may be gradual, and the diagnosis may not be considered until a chest radiograph is performed. Unfortunately, many patients do not seek medical attention until more dramatic symptoms, such as hemoptysis, occur. At this point, patients typically have large cavitary lesions in the lungs. These cavities are loaded with *M. tuberculosis*. Expectoration or

CLINICAL PRESENTATION Tuberculosis

Signs and Symptoms

- Patients typically present with cough weight loss, fatigue, fever, and night sweats.[3,14,15]
- Frank hemoptysis usually occurs late in the course of disease but may present earlier.

Physical Examination

- Dullness to chest percussion, rales, and increased vocal fremitus are observed frequently on auscultation but a normal lung examination is very common compared to the degree of radiological lung involvement.
- Patient is usually thin with evidence or recent weight loss.

Laboratory Tests

- Moderate elevations in the white blood cell (WBC) count with a lymphocyte predominance.
- High platelet count (thrombocytosis) and mild to moderate anemia are common.

Diagnostic Considerations

- Positive-sputum smear
- Fiber-optic bronchoscopy (if sputum tests are inconclusive and suspicion is high)

Chest Radiograph

- Patchy or nodular infiltrates in the apical areas of the upper lobes or the superior segment of the lower lobes.[3,14,15]
- Cavitation that may show air–fluid levels as the infection progresses.

swallowing of infected sputum may spread the disease to other areas of the body.[1,3,17] Physical examination is nonspecific but suggestive of progressive pulmonary disease.

Human Immunodeficiency Virus

5 Patients coinfected with HIV may have atypical presentations.[1,3,17] As their CD4+ counts decline, HIV-positive patients are less likely to have positive skin tests, cavitary lesions, or fever. Pulmonary radiographic findings may be minimal or absent. HIV-positive patients have a higher incidence of extrapulmonary TB and are more likely to present with progressive primary disease. Because their symptoms are not specific to TB, a thorough workup for TB is essential.[3,14,15]

Extrapulmonary

Extrapulmonary TB typically presents as a slowly progressive decline in organ function.[3,17] Patients may have low-grade fever and other constitutional symptoms. Patients with genitourinary TB may present with sterile pyuria and hematuria. Lymphadenitis often involves the cervical and supraclavicular nodes and may appear as a neck mass with spontaneous drainage. Tuberculous arthritis and osteomyelitis occur most commonly in the elderly and usually affect the lower spine and weight-bearing joints. TB of the spine is known as *Pott's disease*.[3] Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis. Involvement of the peritoneum, pericardium, larynx, and adrenal glands also occurs.[3,17]

The Elderly

5 TB in the elderly is easily confused with other respiratory diseases. Many clinical findings are muted or absent altogether. Compared with younger patients, TB in the elderly is far less likely to present with positive skin tests, fevers, night sweats, sputum production, or hemoptysis.[2,19,24] Weight loss may occur but is nonspecific. In contrast, mental status changes are twice as common in the elderly, and mortality is six times higher.[3,17] TB is a preventable cause of death in the elderly that should not be overlooked.

Children

5 TB in children, especially those younger than 12 years, may present as a typical bacterial pneumonia and is called *progressive primary TB*.[17,18] Clinical disease often begins 1 to 2 months after exposure and precedes skin-test positivity. Unlike adults, pulmonary TB in children often involves the lower and middle lobes.[17,18] Dissemination to the lymph nodes, GI and genitourinary tracts, bone marrow, and meninges is common. Because of delays in recruitment of cellular immunity, cavitary disease is infrequent, and the number of organisms present typically is smaller than in an adult. Because cavitary lesions are uncommon, children do not spread TB readily. However, TB can be rapidly fatal in a child, and it requires prompt chemotherapy.

DIAGNOSIS

The following section focuses on diagnostic testing for infection with *M. tuberculosis*. If active disease is suspected based on clinical presentation, additional diagnostic tests are also reviewed to confirm active disease.

Diagnostic Testing

The key to stopping the spread of TB is early identification of infected individuals.[3,17] Table 112-1 lists the populations most likely to benefit from testing (column 1 patients are at highest risk for TB, followed by those in column 2). Members of these high-risk groups should be tested for TB infection and educated about the disease.

The Mantoux test is a quantitative TB skin test that uses tuberculin PPD. The standard 5-tuberculin-unit PPD dose is placed intracutaneously on the volar aspect of the forearm with a 26- or 27-gauge needle.[3,17,24] This injection should produce a small, raised, blanched wheal. An experienced professional should read the test in 48 to 72 hours. The area of induration (the "bump") is the important end point, not the area of redness. Table 113-1 lists the criteria for interpretation.[3,17,24] The Centers for Disease Control and Prevention (CDC) does not recommend the routine use of anergy panels.[24-26] Aplisol and Tubersol 5-tuberculin-unit products are available commercially and are similar in sensitivity, specificity, and reactivity. It is important, however, to use one product and notify appropriate users when switching between products.[27,28]

The "booster effect" occurs for patients who do not respond to an initial skin test but show a positive reaction if retested about a

TABLE 112-1 Criteria for Tuberculin Positivity by Risk Group

Reaction 5 mm of Induration	Reaction ≥10 mm of Induration	Reaction ≥15 mm of Induration
HIV-positive persons	Recent immigrants (ie, within the last 5 years) from high-prevalence countries	Persons with no risk factors for TB
Recent contacts of TB case patients	Injection-drug users	
Fibrotic changes on chest radiograph consistent with prior TB	Residents and employees[a] of the following high-risk congregate settings: prisons and jails, nursing homes and other long-term care facilities for the elderly, hospitals and other healthcare facilities, residential facilities for patients with AIDS, homeless shelters	
Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of ≥15 mg/day of prednisone for 1 month or more)[b]	Mycobacteriology laboratory personnel Persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders (eg, leukemias and lymphomas), other specific malignancies (eg, carcinoma of the head or neck and lung), weight loss of ≥10% of ideal body weight, gastrectomy, jejunoileal bypass Children younger than 4 years or infants, children, and adolescents exposed to adults at high risk	

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; TB, tuberculosis.

[a]For persons who are otherwise at low risk and who are tested at the start of employment, a reaction of ≥15 mm induration is considered positive.

[b]Risk of TB for patients treated with corticosteroids increases with higher dose and longer duration.

Adapted from Screening for tuberculosis and tuberculosis infection in high-risk populations: Recommendations of the Advisory Council for the Elimination of Tuberculosis. MMWR Recomm Rep *1995;44(RR-11):19-34.*

week later or longer.[17,26] Patients with past *M. tuberculosis* infection and some patients with past immunization with bacillus Calmette-Guérin (BCG) vaccine or past infection with other mycobacteria may "boost" with a second skin test. Individuals who require periodic skin testing, such as healthcare workers, should receive a two-stage test initially.[17,26,29] Once they are shown to be skin-test negative, any positive skin test later shows recent infection, and this requires an evaluation to consider treatment.

The PPD skin test is an imperfect diagnostic tool. Up to 20% of patients with active TB are falsely skin-test negative, presumably because they may be immunocompromised.[14,26] False-positive results are more common in low-risk patients and those recently vaccinated with BCG. Despite BCG vaccination, one should not ignore a positive PPD result especially if the induration is more than 15 mm.[24] These patients require careful evaluation for active disease, and they may be offered preventive treatment because many come from areas where TB infection is common.

Interferon-γ release assays (IGRA) measure the release of INF-γ in blood in response to the TB antigens.[30] They may provide quick and specific results for identifying *M. tuberculosis*. IGRAs do not trigger a booster effect and are more specific for testing *M. tuberculosis* than the PPD. The QuantiFERON-TB Gold test (QFT-G) is an enzyme-linked immunosorbent assay (ELISA) and the T-SPOT.TB, is an enzyme-linked immunospot assay[30,31] Both tests can be used for diagnosing latent TB infection (LTBI) and TB disease caused by *M. tuberculosis*. However, these are tests desgined to diagnose LTBI and are not to be used to confirm or reject a diagnosis of active TB disease. For active TB, the IGRAs provide supporting evidence for the diagnosis but need to be interpreted in light of other evidence of active TB disease such as epidemiological risk factors and other studies. The antigenic proteins are absent from BCG vaccine strains and from most non-TB mycobacteria. Therefore, QFT-G does not trigger a booster effect and is more specific for testing of *M. tuberculosis* than the PPD. Although these tests can provide results to diagnose both latent infection and disease, they cannot differentiate between the two. Results are available within 24 hours, instead of the 2 to 3 days required for the traditional PPD skin test; and the patient does not have to return to the clinic as required by the PPD skin test. The CDC has approved the use of these tests in all circumstances in which the PPD is currently used. IGRAs may be preferred for testing in patients that are suspected not to return for follow up PPD reads or in patients who have received the BCG vaccine. The sensitivity for young children (younger than 5 years) and in immunocompromised patients has not clearly established.[30–34] The American Academy of Pediatrics recommends IGRAs in place of PPD skin test in immunocompetent children aged 5 years or older who have received BCG vaccination to confirm TB infection.[32] However, an increasing number of experts are using the IGRAs in children 2 years or older.

IGRAs perform similarly to the PPD in detecting TB in HIV-infected patients with LTBI. Both PPD and IGRA have suboptimal sensitivity for active TB especially in the severely immunocompromised.[30,35]

Culture and Staining

When active TB is suspected, attempts should be made to isolate *M. tuberculosis* from the site of infection.[3,17,26] Sputum collected in the morning usually has the highest yield.[3,17] Daily sputum collection over 3 consecutive days is recommended. Microscopic examination is the most rapid and inexpensive TB diagnostic tool. After staining, microscopic examination ("smear") detects about 8,000 to 10,000 organisms per milliliter (8×10^6/L to 10×10^6/L) of specimen, so a patient can be "smear-negative" but still grow *M. tuberculosis* on culture. Microscopic examination also cannot determine which of the more than 100 mycobacterial species is present or whether the organisms in the original samples were alive or dead.[1,6]

For patients unable to expectorate, sputum induction with aerosolized hypertonic saline may produce a diagnostic sample. Bronchoscopy, in older children, or aspiration of gastric fluid via a nasogastric tube, in children (5 years or younger), may be attempted for select patients.[17] For patients with suspected extrapulmonary TB, samples of draining fluid, biopsies of the infected site, or both may be attempted. Blood cultures are positive occasionally, especially in acquired immunodeficiency syndrome (AIDS) patients.[17,36]

TREATMENT

Drugs used in the treatment of active disease are divided into first-line and second-line agents. First-line agents should be the preferred options unless susceptibility results dictate otherwise. Treatment in special populations is also addressed.

Desired Outcome

The desired outcomes during the treatment of TB are:

1. Rapid identification of a new TB case.
2. Initiation of specific anti-TB treatment.
3. Eradicating *M. tuberculosis* infection.
4. Achievement of a noninfectious state in the patient, thus ending isolation.
5. Preventing the development of resistance.
6. Adherence to the treatment regimen by the patient.
7. Cure of the patient as quickly as possible (generally at least 6 months of treatment).

It is also important that patients with active disease are isolated to prevent spread of the disease and that appropriate samples for smears and cultures are collected. Secondary goals are identification of the index case that infected the patient, identification of all persons infected by both the index case and the new case of TB ("contact investigation"), and completion of appropriate treatments for those individuals.

General Approaches

Drug treatment is the cornerstone of TB management.[3,37] Monotherapy can be used only for infected patients who do not have active TB (latent infection, as shown by a positive skin test or positive IGRA). Once active disease is present, a minimum of two drugs, and generally three or four drugs, must be used simultaneously.[37] The duration of treatment depends on the condition of the host, extent of disease, presence of drug resistance, and tolerance of medications. The shortest duration of treatment generally is 6 months, and 18 to 24 months of treatment may be necessary for cases of MDR-TB.[37] Because the duration of treatment is so long and because many patients feel better after a few weeks of treatment, careful follow-up is required. Directly observed therapy (DOT) by a healthcare worker is a cost-effective way to ensure completion of treatment and is considered the standard of care.[37-39]

Principles for Treating Latent Infection and for Treating Disease

Asymptomatic patients with tuberculous infection have a bacillary load of about 10^3 organisms, compared with 10^{11} organisms in a patient with cavitary pulmonary TB.[3,7] As the number of organisms increases, the likelihood of naturally occurring drug-resistant mutants also increases. Naturally occurring resistant mutants are found at rates of 1 in 10^6 to 1 in 10^8 organisms for the anti-TB drugs.[3,7,37] When treating asymptomatic latent infection with isoniazid monotherapy, the risk of selecting out isoniazid-resistant organisms is low. The isoniazid mutation rate is about 1 in 10^6, but only about 10^3 organisms are present in the body. In contrast, the risk of selecting out isoniazid-resistant organisms is unacceptably high for patients with cavitary TB. One can prevent selection of these resistant mutants by adding more drugs because the rates for resistance mutations to multiple drugs are additive functions of the individual rates. For example, only 1 in 10^{13} organisms would be naturally resistant to both isoniazid (1 in 10^6) and rifampin (1 in 10^7).[3,7,37] It is unlikely that such rare organisms are present in a previously untreated patient.

Combination chemotherapy is required for treating active TB disease. The patient should receive at least two drugs to which the isolate is susceptible, and, generally, four drugs are given at the outset of treatment. Rifampin and isoniazid are the best drugs for preventing drug resistance, followed by ethambutol, streptomycin, and pyrazinamide.[3,7,37,40]

Three subpopulations of mycobacteria are proposed to exist within the body, and each appears to respond to certain drugs.[7,37] Most numerous are the extracellular, rapidly dividing bacteria, often found within cavities (about 10^7 to 10^9 organisms). These are killed most readily by isoniazid, followed by rifampin, streptomycin, and the other drugs. A second group resides within caseating granulomas (possibly 10^5 to 10^7 organisms). These organisms appear to be in a semidormant state, with occasional bursts of metabolic activity. Pyrazinamide, through its conversion within *M. tuberculosis* to pyrazinoic acid, appears most active against these organisms. Rifampin and isoniazid also may be active against this subpopulation. The third subset is the intracellular mycobacteria present within macrophages (10^4 to 10^6). Rifampin, isoniazid, and the quinolones appear to be most active against intracellular *M. tuberculosis*. While this appears to explain what happens during the treatment of TB, there is no practical way to quantitate these populations within a given patient.

Nonpharmacologic Therapy

7 Nonpharmacologic interventions aim to (a) prevent the spread of TB, (b) find where TB has already spread using contact investigation, and (c) replenish the weakened (consumptive) patient to a state of normal weight and well-being. The first two items are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB.

Workers in hospitals and other institutions must prevent the spread of TB within their facilities.[7,24,27] All such workers should learn and follow each institution's infection control guidelines. This includes using personal protective equipment, including properly fitted respirators, and closing doors to "negative-pressure" rooms. These hospital isolation rooms draw air in from surrounding areas rather than blowing air (and *M. tuberculosis*) into these surrounding areas. The air from the isolation room may be treated with ultraviolet lights and then vented safely outside. However, these isolation rooms work properly only if the door is closed.

Debilitated TB patients may require therapy for other medical problems, including substance abuse and HIV infection, and some may need nutritional support. Therefore, clinicians involved in substance abuse rehabilitation and nutritional support services should be familiar with the needs of TB patients. Surgery may be needed to remove destroyed lung tissue, space-occupying infected lesions (*tuberculomas*), and certain extrapulmonary lesions.[37] BCG is the only clinically relevant vaccine for TB in use today. Although it is one of the most commonly administered vaccines in history, it is of limited value, and cannot prevent infection by *M. tuberculosis*. BCG (discussed further) may prevent extreme forms of TB in infants.[37,41]

Pharmacologic Therapy

Treating Latent Infection

Isoniazid is the preferred drug for treating LTBI.[24,37] Generally, isoniazid alone is given for 9 months. The treatment of LTBI reduces a person's lifetime risk of active TB from approximately 10% to approximately 1%. Because TB is spread easily through the air, each case prevented also prevents a second wave of cases that each prevented case would have produced. The treatment of LTBI has is called *prophylaxis*. Table 112-2 lists the LTBI treatment options.

Because young children, the elderly, and HIV-positive patients are at greater risk of active disease once infected with *M. tuberculosis*, they require careful evaluation. Once active TB is ruled out, they should receive treatment for latent infection.[24,37]

The keys to successful treatment of LTBI are (a) infection by an isoniazid-susceptible isolate, (b) adherence to the regimen, and (c) no exogenous reinfection.[24] Isoniazid adult doses are usually 300 mg daily (5-10 mg/kg of body weight)[37] (see Table 112-2). Lower doses are less effective.[24,42,43] Isoniazid should be given on an empty stomach, and antacids should be avoided within 2 hours

TABLE 112-2 Recommended Drug Regimens for Treatment of LTBI in Adults

Drug	Interval and Duration	Comments	Rating[a] (Evidence)[b] HIV–	HIV+
Isoniazid	Daily for 9 months[b,c]	In HIV-infected patients, isoniazid may be administered concurrently with NRTIs, protease inhibitors, or NNRTIs	A (II)	A (II)
	Twice weekly for 9 months[b,c]	DOT must be used with twice-weekly dosing	B (II)	B (II)
Isoniazid	Daily for 6 months[c]	Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children	B (I)	C (I)
	Twice weekly for 6 months[c]	DOT must be used with twice-weekly dosing	B (II)	C (I)
Rifampin	Daily for 4 months	For persons who are contacts of patients with isoniazid-resistant, rifampin-susceptible TB who cannot tolerate pyrazinamide	B (II)	B (III)
Isoniazid and rifapentine	Once weekly for 3 months	DOT must be used with once-weekly dosing. Not recommended for the following: children <2 years old, HIV/AIDS patients taking antiretroviral treatment, isoniazid- or rifampin-resistant strains, pregnant women or women expecting to become pregnant within the 12-week regimen	B (II)	B (II)

AIDS, acquired immunodeficiency syndrome; DOT, directly observed therapy; HIV, human immunodeficiency virus; LTBI, latent tuberculosis infection; NNRTIs, non-nucleoside reverse transcriptase inhibitors; NRTIs, nucleoside reverse transcriptase inhibitors.

[a]Strength of recommendation: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given.

[b]Quality of evidence: I, randomized clinical trial data; II, data from clinical trials that are not randomized or were conducted in other populations; III, expert opinion.

[c]Recommended regimen for children younger than 18 years of age.

Adapted from Targeted tuberculin testing and treatment of latent tuberculosis infection. American Thoracic Society. MMWR Recomm Rep 2000;49(RR-6):31.

of dosing. Rifampin 600 mg daily for 4 months can be used when isoniazid resistance is suspected or when the patient cannot tolerate isoniazid.[24,37] There is a growing body of evidence that 4 months of rifampin may be a safer and more cost-effective alternative to 9 months of isoniazid. Four months of rifampin was significantly cheaper per patient completing treatment because of better completion and fewer adverse events.[44] The combination of pyrazinamide plus rifampin is no longer recommended because of higher than expected rates of hepatotoxicity. Rifabutin 300 mg daily might be substituted for rifampin for patients at high risk of drug interactions. When resistance to isoniazid and rifampin is suspected in the isolate causing infection, there are no randomized controlled trials to prove what regimen should be used to treat LTBI among contacts.[24,37] However, a course of 12-month regimen of a fluoroquinolone was effective in reducing the incidence of progression to active TB disease for MDR-TB contacts.[45] Regimens that *might* be effective include ethambutol plus levofloxacin, but data regarding efficacy are lacking.

In 2011, a randomized controlled trial compared 12 weeks of once-weekly isoniazid and rifapentine by DOT with daily self-administered isoniazid for 9 months.[46] This study, with over 8,000 participants, showed that the 12 weeks of weekly isoniazid and rifapentine given by DOT was not inferior in efficacy to 9 months of self-administered isoniazid, had a significantly higher completion rate (82% vs 69%), and was associated with fewer grade 3 or 4 adverse reactions (1.6% vs 3%).[46] Hypersensitivity reactions were more common with the isoniazid/rifapentine regimen and close clinical follow-up should be undertaken while experience is gained with this new regimen for LTBI therapy. The CDC now recommends the 12-week isoniazid/rifapentine regimen as an equal alternative to 9 months of daily isoniazid for treating LTBI in otherwise healthy patients aged older than or 12 years who have a predictive factor for greater likelihood of TB developing, which included recent exposure to contagious TB, conversion from negative to positive on an indirect test for infection (ie, IGRA or tuberculin skin test), and radiographic findings of healed pulmonary TB.[47] HIV-infected patients who are otherwise healthy and are not taking antiretroviral medications are also included in this category. However, precautions should be taken as HIV-infected patients are more likely to have extrapulmonary TB or pulmonary TB with normal findings on chest radiograph. For recent skin-test converters of all ages, the risk of active TB outweighs the risk for drug toxicity.[24,37] Pregnant women, alcoholics, and patients with poor diets who are treated with isoniazid should receive pyridoxine (vitamin B_6) 10 to 50 mg daily to reduce the incidence of central nervous system (CNS) effects or peripheral neuropathies. All patients who receive treatment of LTBI should be monitored monthly for adverse drug reactions and for possible progression to active TB.

Treating Active Disease

8 The CDC, American Thoracic Society (ATS), and the Infectious Diseases Society of America have published an algorithm for the treatment of TB (Fig. 112-2). The treatment of active TB requires the use of multiple drugs. There are two primary anti-TB drugs, isoniazid and rifampin, with the rest of the drugs having specific roles.[37,40] Isoniazid and rifampin should be used together whenever possible. Typically, *M. tuberculosis* is either very susceptible or very resistant to a given drug. Theoretically, minimal inhibitory concentration (MIC) results could be used to guide dosing in the treatment of moderately resistant *M. tuberculosis*, but this remains to be studied prospectively.[37,42]

Drug susceptibility testing should be done on the initial isolate for all patients with active TB. These data should guide the selection of drugs over the course of treatment.[12,37] However, some patients are unable to provide a suitable specimen for laboratory testing. If susceptibility data are not available for a given patient, the drug susceptibility data for the suspected source case or regional susceptibility data should be used.[12,37]

Drug resistance should be expected for patients presenting for the retreatment of TB. These patients require retesting of drug susceptibility using freshly collected specimens. It is imperative to learn what drugs the patient received and for how long the patient received them.[12,37] A treatment history, often called a "*drug-o-gram*," shows the start and stop dates of all antimycobacterial drugs on a horizontal bar graph.[37] A drug-o-gram should be constructed for all retreatment patients.

9 The standard TB treatment regimen is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, a total of 6 months of treatment.[37] If susceptibility to isoniazid, rifampin, and pyrazinamide is shown,

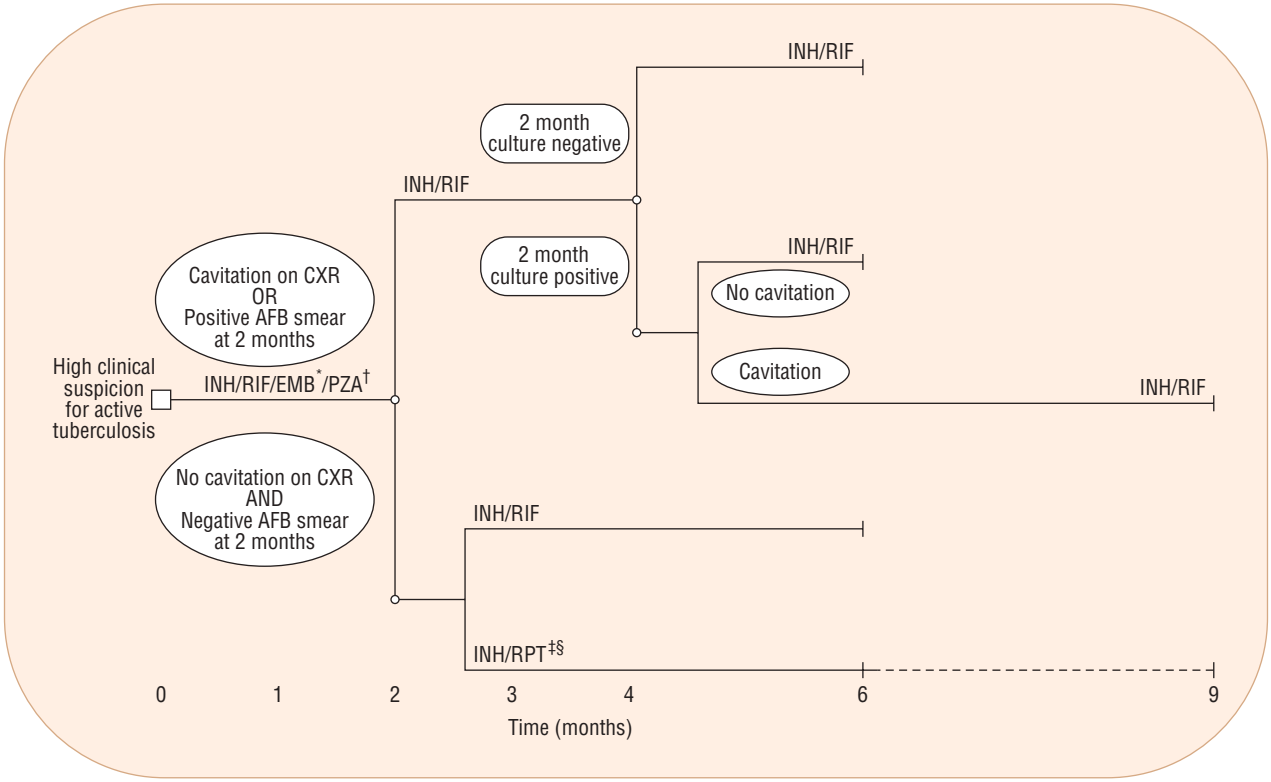

FIGURE 112-2 Treatment algorithm for tuberculosis (TB). Note: Patients in whom TB is proved or strongly suspected should have treatment initiated with isoniazid, rifampin, pyrazinamide, and ethambutol for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph or the acid-fast smear is positive at completion of 2 months of treatment, the continuation phase of treatment should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial chest radiograph and the culture at the time of completion of 2 months of therapy is positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the CD^+ cell count is <100/μL (<100 × 10^6/L), the continuation phase should consist of daily or three-times-weekly isoniazid and rifampin. In HIV-uninfected patients having no cavitation on chest radiograph and negative acid-fast smears at completion of 2 months of treatment, the continuation phase may consist of either once-weekly isoniazid and rifapentine, or daily or twice-weekly isoniazid and rifampin, to complete a total of 6 months (bottom). Patients receiving isoniazid and rifapentine, and whose 2-month cultures are positive, should have treatment extended by an additional 3 months (total of 9 months). (CXR, chest radiograph; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.) [a]EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. [b]PZA may be discontinued after it has been taken for 2 months (56 doses). [c]RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. [d] Therapy should be extended to 9 months if the 2-month culture is positive. *(Reproduced from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep 2003;52(RR-11):1-7.)*

ethambutol can be stopped at any time. Without pyrazinamide, a total of 9 months of isoniazid and rifampin treatment is required. Table 112-3 shows the recommended treatment regimens. When intermittent therapy is used, DOT is essential. Doses missed during an intermittent TB regimen decrease its efficacy and increase the relapse rate. Note that Table 112-3 shows recommendations that differ for HIV-negative and HIV-positive patients. HIV-positive patients should not receive highly intermittent regimens. In general, regimens given daily five times each week or three times weekly can be used for HIV-positive patients. Less frequent dosing is associated with higher failure and relapse rates and the selection of rifampin-resistant organisms.[37]

When a patient's sputum smears convert to a negative, the risk of the patient infecting others is greatly reduced, but it is not zero.[15,17,37] Such patients can be removed from respiratory isolation, but they must be careful not to cough on others and should meet with others only in well-ventilated places. Smear-negative patients still may be culture positive, so they still can transmit TB to others.

Clinical **Controversy...**

Effective therapy exists for the treatment of patients latently infected with drug susceptible TB; however, the data are limited for the latent treatment of drug-resistant strains of *M. tuberculosis.* Data for treatments of MDR-TB exposure are even more limited and treatment is often based on the resistance profile. Two or three drugs are used for 6 to 12 months while the patient is monitored in hopes that active disease does not develop. Randomized controlled trials are still needed to determine the best approach to treating those with exposure to MDR-TB.[48]

Patients who are slow to respond clinically, those who remain culture-positive at 2 months of treatment, those with cavitary lesions on chest radiograph, and perhaps HIV-positive patients should be treated for a total of 9 months and for at least 6 months from the time that they convert to smear and culture negativity.[37] Some authors

TABLE 112-3 Drug Regimens for Culture-Positive Pulmonary TB Caused by Drug-Susceptible Organisms

	Initial Phase		Continuation Phase			Rating[a] (Evidence)[b]	
Regimen	Drugs	Interval and Dose[c] (Minimal Duration)	Drugs	Interval and Doses[c,d] (Minimal Duration)	Range of Total Doses (Minimal Duration)	HIV–	HIV+
1	Isoniazid, rifampin, pyrazinamide, ethambutol	Seven days per week for 56 doses (8 weeks) or 5 days/wk for 40 doses (8 weeks)[e]	Isoniazid/ rifampin	Seven days per week for 126 doses (18 weeks) or 5 days/wk for 90 doses (18 weeks)[e]	182-130 (26 weeks)	A (I)	A (II)
			Isoniazid/ rifampin	Twice weekly for 36 doses (18 weeks)	92-76 (26 weeks)	A (I)	A (II)[f]
			Isoniazid/ rifapentine[g]	Once weekly for 18 doses (18 weeks)	74-58 (26 weeks)	B (I)	E (I)
2	Isoniazid, rifampin, pyrazinamide, ethambutol	Seven days per week for 14 doses (2 weeks), then twice weekly for 12 doses (6 weeks) or 5 days/wk for 10 doses (2 weeks),[e] and then twice weekly for 12 doses (6 weeks)	Isoniazid/ rifampin	Twice weekly for 36 doses (18 weeks)	62-58 (26 weeks)	A (II)	B (II)[f]
			Isoniazid/ rifapentine[g]	Once weekly for 18 doses (18 weeks)	44-40 (26 weeks)	B (I)	E (I)
3	Isoniazid, rifampin, pyrazinamide, ethambutol	Three times weekly for 24 doses (8 weeks)	Isoniazid/ rifampin	Three times weekly for 54 doses (18 weeks)	78 (26 weeks)	B (I)	B (II)
4	Isoniazid, rifampin, ethambutol	Seven days per week for 56 doses (8 weeks) or 5 days/wk for 40 doses (8 weeks)[e]	Isoniazid/ rifampin	Seven days per week for 217 doses (31 weeks) or 5 days/wk for 155 doses (31 weeks)[e]	273-195 (39 weeks)	C (I)	C (II)
			Isoniazid/ rifampin	Twice weekly for 62 doses (31 weeks)	118-102 (39 weeks)	C (I)	C (II)

[a]Ratings: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given.

[b]Evidence ratings: I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion.

[c]When directly observed therapy is used, drugs may be given 5 days/wk, and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.

[d]Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (31-week; either 217 doses [daily] or 62 doses [twice weekly]) continuation phase.

[e]Five-day-a-week administration is always given by directly observed therapy. Rating for 5-day-per-week regimens is A (III).

[f]Not recommended for HIV-infected patients with CD4+ cell counts <100 cells/μL (<100 × 10^6/L).

[g]Should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

Adapted from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep *2003;52(RR-11):1–77*.

recommend therapeutic drug monitoring (TDM) the use of serum drug concentrations to optimize therapy for such patients.[40,42,49] When isoniazid and rifampin cannot be used, treatment durations become 2 years or more regardless of immune status.[37,40]

Adjustments to the regimen should be made once the susceptibility data are available.[37] If the organism is drug-resistant, careful consideration of the remaining therapeutic options must be made. Two or more drugs with in vitro activity against the patient's isolate and that the patient has not received previously should be added to the regimen, as needed.[37,40,48] 10 There is no standard regimen for MDR-TB.[37,48] Each patient's exposure history, treatment history (including toxicity and adherence issues), and current susceptibility data must be considered simultaneously. *It is critical to avoid monotherapy, and it is critical to never add a single drug to a failing regimen.*[37,40] Adding one drug at a time leads to the sequential selection of drug resistance until there are no drugs left. TB specialists should be consulted regarding cases of MDR-TB. It may take several months for a patient with MDR-TB to become culture-negative because the drugs used lack the potency of isoniazid and rifampin.[37,40] Consequently, prolonged respiratory isolation may be required.

Drug resistance should be considered in the following situations:

1. Patients who have received prior therapy for TB.
2. Patients from areas with a high prevalence of resistance (South Africa, Dominican Republic, Peru, Southeast Asia, the Baltic countries, and the former Soviet states).
3. Patients who are homeless, institutionalized, IV drug abusers, or infected with HIV.
4. Patients who still have AFB-positive sputum smears after 1 to 2 months of therapy.
5. Patients who still have positive cultures after 2 to 4 months of therapy.
6. Patients who fail treatment or relapse after treatment.
7. Patients known to be exposed to MDR-TB cases.

Empirical therapy with four or more drugs may be needed for acutely ill patients.[37] These regimens may be altered when the susceptibility pattern becomes known. If the index case is known, then the same effective regimen should be employed for the new

case. Again, MDR-TB cases should be referred to specialists. A new term in use, *XDR-TB*, refers to "extensively drug-resistant TB." Such organisms are resistant to at least isoniazid, rifampin, a fluoroquinolone, and one second-line injectable drug (amikacin, capreomycin, or kanamycin).[48-50]

Special Populations

Tuberculous Meningitis and Extrapulmonary Disease Patients with CNS TB usually are treated for longer periods (9-12 months instead of 6 months).[37] In general, isoniazid, pyrazinamide, ethionamide, and cycloserine penetrate the cerebrospinal fluid readily, but rifampin, ethambutol, and streptomycin have variable CNS penetration.[43] Of the quinolones, levofloxacin may be preferred based on current data. Extrapulmonary TB of the soft tissues can be treated with conventional regimens.[37] TB of the bone typically is treated for 9 months, occasionally with surgical debridement.[37]

Children TB in children may be treated with regimens similar to those used in adults, although some physicians still prefer to extend treatment to 9 months.[17,18,37] Pediatric doses of isoniazid and rifampin on a milligram-per-kilogram basis are higher than those used in adults (Table 112-4).[37]

Pregnancy Women with TB should be cautioned against becoming pregnant because the disease poses a risk to the fetus and to the mother. If already pregnant, the usual treatment is isoniazid, rifampin, and ethambutol for 9 months.[51] Isoniazid and ethambutol are relatively safe for use in pregnant women.[37,43,51] B vitamins are particularly important during pregnancy and should be provided to women being treated for TB. Rifampin is associated rarely with birth defects, including limb reduction and CNS lesions.[43] In general, rifampin is used in pregnant women with TB. Pyrazinamide has not been studied in large numbers of pregnant women, but anecdotal data suggest that it may be safe.[37]

Streptomycin use during pregnancy may lead to hearing loss in the newborn, including complete deafness. Streptomycin and the other aminoglycosides must be reserved for critical situations where alternatives do not exist.[37] Although the polypeptide capreomycin has not been studied, it probably carries the same risks.

Ethionamide may cause premature delivery and congenital deformities when used during pregnancy.[37,43] Down syndrome also has been reported with ethionamide, so it cannot be recommended in this setting. *p*-Aminosalicylic acid has been used safely in pregnancy, but specific data are lacking.[37,43] Cycloserine is known to cross the placenta, but the effects on the developing fetus are not known. Therefore, cycloserine generally cannot be recommended during pregnancy.[43]

Ciprofloxacin, levofloxacin, moxifloxacin, and the other quinolones are associated with permanent damage to cartilage in the weight-bearing joints of immature animals, especially dogs and rabbits.[37,43] Although these drugs do not frequently cause joint problems in humans, other anti-TB agents should be used during pregnancy.

Pregnant women with LTBI are not at the same level of risk compared with those with active disease. Therapy with isoniazid for LTBI may be delayed until after pregnancy. However in the case of recent infection documented by a skin-test conversion or a newly positive IGRA and in immunosuppressed women who are found to have LTBI while pregnant, treatment for LTBI is started during the second trimester of pregnancy.[37,43,51] Although most anti-TB drugs are excreted in breast milk, the amount of drug received by the infant through nursing is insufficient to cause toxicity. Quinolones should be avoided in nursing mothers, if possible.

HIV Infection For drug susceptible strains of tuberculosis, patients with AIDS and other immunocompromised hosts may be managed with chemotherapeutic regimens similar to those used in immunocompetent individuals, although treatment is often extended to 9 months (see Table 112-3).[37] The precise duration to recommend remains a matter of debate. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients. Rifamycin based treatments are most effective; however, agents should be selected based on susceptibility and HIV drug interactions. Prognosis has been particularly poor for HIV-infected patients infected with MDR-TB, so all efforts should be made to reduce the time between clinical presentation, diagnosis of TB, and start of appropriate treatment. Recommendations for management of HIV and TB published by the World Health Organization and others have provided guidance on monitoring of treatment, side effects, and drug interactions of HIV and TB, MDR, XDR-TB.[5,50,52,53] Differentiation must be made between infection with *M. tuberculosis* and nontuberculous mycobacteria, such as *Mycobacterium avium* complex (MAC), because the drugs used are different. While awaiting laboratory results, the patient can be treated empirically for TB if there is any doubt about the causative organism. Some patients with AIDS malabsorb their oral medications; this is discussed in Therapeutic Drug Monitoring below.[40,42,49]

Renal Failure For nearly all patients, isoniazid and rifampin do not require dose modification in renal failure. They are eliminated primarily by the liver.[40,43,54] In the unlikely event that peripheral neuropathies develop, the frequency of isoniazid dosing may be reduced. Pyrazinamide and ethambutol typically require a reduction in dosing frequency from daily to three times weekly (Table 112-5).[37,54]

Renally cleared TB drugs include the aminoglycosides (amikacin, kanamycin, and streptomycin), capreomycin, ethambutol, cycloserine, and levofloxacin.[37,43,55] Dosing intervals need to be extended for these drugs (Table 112-5). Ciprofloxacin and moxifloxacin are approximately 50% cleared by the kidneys but may not require a change in dose from once daily, as used for TB. The metabolites of isoniazid, pyrazinamide, and *p*-aminosalicylic acid are cleared primarily by the kidneys. The role of these metabolites in causing toxicity is unknown, so their accumulation in renal failure may carry some risk.

Ethionamide and its sulfoxide metabolite are hepatically cleared, so dosing is unchanged.[37,55] *p*-Aminosalicylic acid is converted largely to metabolites prior to renal elimination; these metabolites may accumulate in renal failure.[55] For patients on hemodialysis, the usual 12-hour dosing interval for *p*-aminosalicylic acid granules seems to be safe. Dialysis will remove the metabolites. Serum concentration monitoring must be performed for cycloserine to avoid dose-related toxicities in renal failure patients.[40,42,55]

Hepatic Failure Anti-TB drugs that rely on hepatic clearance for most of their elimination include isoniazid, rifampin, pyrazinamide, ethionamide, and *p*-aminosalicylic acid.[43] Ciprofloxacin and moxifloxacin are approximately 50% cleared by the liver. Elevations of serum transaminase concentrations generally are not correlated with the residual capacity of the liver to metabolize drugs, so these markers cannot be used as guides for drug dosing. Furthermore, isoniazid, rifampin, pyrazinamide, and, to a lesser degree, ethionamide, *p*-aminosalicylic acid, and, rarely, ethambutol may cause hepatotoxicity.[37,40,43] For some patients with drug-susceptible TB, a "liver-sparing" regimen of streptomycin, levofloxacin, and ethambutol may be used, at least temporarily.[37,40,43] Because this regimen requires 18 or more months of treatment to be successful, patients usually are switched to isoniazid- and rifampin-containing regimens as soon as they are able.

Morbid Obesity Data are not available for dosing the TB drugs for patients with morbid obesity.[43] Relatively hydrophilic drugs (isoniazid, pyrazinamide, the aminoglycosides, capreomycin, ethambutol,

TABLE 112-4 Doses[a] of Antituberculosis Drugs for Adults and Children[b,c]

Drug	Preparation	Adults/ Children	Typical Doses			
			Daily	1× Per Week	2× Per Week	3× Per Week
First-Line Drugs						
Isoniazid	Tablets (50, 100, 300 mg); elixir (50 mg/5 mL); aqueous solution (100 mg/mL) for IV or intramuscular injection	Adults[c] Children[c]	5 mg/kg 10-15 mg/kg	15 mg/kg —	15 mg/kg 20-30 mg/kg	15 mg/kg —
Rifampin	Capsule (150, 300 mg); powder may be suspended for oral administration; aqueous solution for IV injection	Adults[d,c] Children[c]	10 mg/kg 10-20 mg/kg	— —	10 mg/kg 10-20 mg/kg	10 mg/kg —

Higher doses of rifampin and rifapentine are being studied. Rifabutin dose may need to be adjusted when there is concomitant use of protease inhibitors or non-nucleoside reverse transcriptase inhibitors.

[a]Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

[b]For purposes of this document, adult dosing begins at age 15 years.

[c]The authors of this chapter do not agree with the use of maximum doses, since this arbitrarily caps doses for patients who otherwise might need larger doses. These maximum doses were not based on prospective studies in large or overweight individuals, and do not consider patients with documented malabsorption of their medications. Clinical judgment should be used in such circumstances.

[d]The drug can likely be used safely in older children but should be used with caution in children younger than 5 years, in whom visual acuity cannot be monitored. In younger children, ethambutol at the dose of 15 mg/kg/day can be used if there is suspected or proven resistance to isoniazid or rifampin.

[e]It should be noted that, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.

[f]The single daily dose can be given at bedtime or with the main meal.

[g]Dose: 15 mg/kg/day (1 g), and 10 mg/kg in persons older than 59 years (750 mg). Usual dose: 750–1,000 mg administered intramuscularly or IV, given as a single dose 5–7 days/wk and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.

[h]The long-term (more than several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both isoniazid and rifampin. The optimal dose is not known.

[i]The long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

Data from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep *2003;52(RR-11):1–77.*

p-aminosalicylic acid, and cycloserine) can be dosed initially based on ideal body weight. Very low or very high serum concentrations can be avoided by checking the serum concentrations.[42]

The TB Drugs

The interested reader is referred to several other publications for more detailed information regarding these drugs.[37,40,42,43] Note that although the 2003 ATS/CDC guidelines recommend "maximum" doses (see Table 112-4),[37] in the authors' view, the "maximum" dose for a given patient is the dose that produces the desired response with an acceptable level of toxicity.[40,42] This can only be determined on a case-by-case basis. Artificially capping doses may deprive patients of needed drug.

Primary Antituberculosis Drugs

Isoniazid Isoniazid is one of the two most important TB drugs. It is highly specific for mycobacteria, with a MIC against *M. tuberculosis* of 0.01 to 0.25 mcg/mL (mg/L). It is bactericidal and is thought to inhibit mycolic acid synthesis and disruption of the cell wall in susceptible organisms. Most nontuberculous mycobacteria such as *M. avium* are resistant to isoniazid, although *Mycobacterium kansasii* and *Mycobacterium xenopi* are susceptible. The most common mechanisms of resistance result from mutations in the *katG* or *inhA* genes.

Isoniazid is readily absorbed from the GI tract and from intramuscular injection sites. It also can be given as a short IV infusion over 5 minutes if diluted in about 20 mL of normal saline.[56] Isoniazid should be given on an empty stomach whenever possible.[57] *N*-Acetyltransferase 2 forms the principal metabolite acetylisoniazid, which lacks antimycobacterial activity. The rate at which humans acetylate isoniazid is determined genetically; slow acetylation is an autosomal recessive trait and reflects a relative lack of *N*-acetyltransferase 2. Fast acetylators have isoniazid half-lives of less than 2 hours. Approximately 50% of whites and blacks and 80% to 90% of Asians and Native Alaskans are rapid acetylators. Slow acetylators have isoniazid half-lives of 3 to 4 hours and may be at an increased risk of neurotoxicity. The association of acetylator status and risk of hepatotoxicity, however, appears to be weak.[58] Poor absorption and rapid clearance of isoniazid for patients receiving highly intermittent therapy are associated with poor clinical outcomes.[59,60]

Transient elevations of the serum transaminases occur in 12% to 15% of patients receiving isoniazid and usually occur within the first 8 to 12 weeks of therapy.[37] Overt hepatotoxicity, however, occurs in only 1% of cases. Risk factors for hepatotoxicity include patient age, preexisting liver disease, excessive alcohol intake, pregnancy, co-administration of other medications that are potentially hepatotoxic, and the postpartum state. Isoniazid also may result in neurotoxicity, most frequently presenting as peripheral neuropathy or, in overdose, as seizures and coma. Patients with pyridoxine deficiency, such as pregnant women, alcoholics, children, and the malnourished, are at increased risk. Isoniazid may inhibit the metabolism of phenytoin, carbamazepine, primidone, and warfarin.[40] Patients who are being treated with these agents should be monitored closely, and appropriate dose adjustments should be made when necessary.

Rifampin The introduction of rifampin into routine use during the 1970s allowed for true short-course treatment of TB (6-9 months).[37] Without rifampin, treatment is generally 18 months or longer. Drug resistance to rifampin is an ominous prognostic factor because it is frequently associated with isoniazid resistance and leaves the patient with few good therapeutic options. Clinicians *must* take care to protect susceptibility to rifampin by carefully treating their patients. Rifampin shows bactericidal activity against *M. tuberculosis* and several other mycobacterial species, including

TABLE 112-5 Dosing Recommendations for Adult Patients with Reduced Renal Function and for Adult Patients Receiving Hemodialysis

Drug	Change in Frequency?	Recommended Dose and Frequency for Patients with Creatinine Clearance <30 mL/min (<0.50 mL/s) or for Patients Receiving Hemodialysis[a,b,c,d]
Isoniazid	No change	300 mg once daily, or 900 mg three times per week
Rifampin	No change	600 mg once daily, or 600 mg three times per week
Pyrazinamide	Yes	25-35 mg/kg per dose three times per week (not daily)
Ethambutol	Yes	15-25 mg/kg per dose three times per week (not daily)
Levofloxacin	Yes	750-1,000 mg per dose three times per week (not daily)
Cycloserine	Yes	250 mg once daily, or 500 mg/dose three times per week[e]
Ethionamide	No change	250-500 mg/dose daily
p-Aminosalicylic acid	No change	4 g/dose, twice daily
Streptomycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Capreomycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Kanamycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Amikacin	Yes	12-15 mg/kg per dose two or three times per week (not daily)

[a]Standard doses are given unless there is intolerance.

[b]The medications should be given after hemodialysis on the day of hemodialysis.

[c]Monitoring of serum drug concentrations should be considered to ensure adequate drug absorption, without excessive accumulation, and to assist in avoiding toxicity.

[d]Data currently are not available for patients receiving peritoneal dialysis. Until data become available, begin with doses recommended for patients receiving hemodialysis and verify adequacy of dosing, using serum concentration monitoring.

[e]The appropriateness of 250-mg daily doses has not been established. There should be careful monitoring for evidence of neurotoxicity.

Adapted from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep *2003;52(RR-11):1–77*.

Mycobacterium bovis and *M. kansasii*.[61] It also is active against a broad array of other bacteria. Alteration of the target site on RNA polymerase, primarily through changes in the *rpoB* gene, leads to most forms of rifampin resistance.[37,61]

Rifampin usually is given orally, but it also can be given as a 30-minute IV infusion.[61] Oral doses are best given on an empty stomach.[62] Patients with AIDS, diabetes, and other GI problems appear to have difficulty absorbing rifampin after oral doses, and this has been associated with therapeutic failures in some cases.[40,42,60,63] Rifampin is metabolized to 25-desacetyl rifampin, which retains some of rifampin's activity; most of rifampin and its metabolite are cleared in the bile. Rifampin generally is given at 600 mg daily or intermittently, although this dose does not take full advantage of rifampin's concentration-dependent killing.[40,42] Higher doses should be tested in humans within the context of clinical trials.

Elevations in hepatic enzymes have been attributed to rifampin in 10% to 15% of patients, with overt hepatotoxicity occurring in less than 1%.[37,61] More frequent adverse effects of rifampin include rash, fever, and GI distress. Allergic reactions to rifampin have been reported and occur more frequently with intermittent rifampin doses 900 mg or more twice weekly. These reactions may take the form of a flu-like syndrome with development of fever, chills, headache, arthralgias, and, rarely, hypotension and shock.[37] Alternatively, hemolytic anemia or acute renal failure may occur, requiring permanent discontinuation.

Rifampin's potent induction of hepatic enzymes, especially cytochrome P450 3A4, may enhance the elimination of many other drugs, most notably the protease inhibitors used to treat HIV (Table 112-6). HIV-positive patients may benefit from the use of rifabutin instead of rifampin.[25,37,52,64] Furthermore, women who use oral contraceptives must use another form of contraception during therapy because increased clearance of the hormones may lead to unexpected pregnancies. Patient records should be reviewed for potential drug interactions before dispensing rifampin. Rifampin may turn urine and other secretions orange-red and may permanently stain some types of contact lenses.

Other Rifamycins Rifabutin is used for disseminated *M. avium* infection in AIDS patients and is quite active against *M. tuberculosis*. Most rifampin-resistant organisms are resistant to rifabutin. Because rifabutin is a less potent enzyme inducer than rifampin, it may be used for patients who are receiving protease inhibitors.[37,52,64,65] For HIV-positive patients, the ATS/CDC recommends regimens with three or more doses of the TB drugs per week (see Table 112-3). Rifapentine is a long-acting rifamycin that can be used once weekly in the continuation phase of treatment (after the first 2 months) in carefully selected HIV-negative patients. It is approximately as potent an enzyme inducer as rifampin, so similar drug interactions are likely.[37,52,64,65]

Pyrazinamide Adding pyrazinamide to the first 2 months of treatment with isoniazid and rifampin shortens the duration to 6 months for most patients.[37] Pyrazinamide may be bacteriostatic or bactericidal depending on the concentration and the susceptibility of the organism. It is usually well absorbed and displays a fairly long half-life.[66,67] The most common toxicities of pyrazinamide are GI distress, arthralgias, and elevations in the serum uric acid concentrations.[37] Most patients do not experience true gout. Hepatotoxicity is the major limiting adverse effect and is dose-related when pyrazinamide is given daily.

A fixed-combination product (Rifater, Aventis) of rifampin 120 mg, isoniazid 50 mg, and pyrazinamide 300 mg is designed to prevent drug resistance by keeping the self-medicating patient from using only one drug at a time. If the patient is receiving DOT, there is no particular advantage to this product. The typical dose of Rifater will be five to six tablets daily. When pyrazinamide is discontinued after 2 months of treatment, the combination product Rifamate (isoniazid 150 mg and rifampin 300 mg) can be substituted.

Ethambutol Ethambutol replaced *p*-aminosalicylic acid as a first-line agent in the 1960s because it was better tolerated by patients.[37] It is used as a fourth drug for TB while awaiting susceptibility data.[37] If the organism is susceptible to isoniazid, rifampin, and pyrazinamide, ethambutol can be stopped. Ethambutol is active against most mycobacteria, by inhibiting synthesis of metabolites and impairing cell metabolism, and is generally bacteriostatic.

Ethambutol should not be given with antacids.[68] For patients with renal failure, the ethambutol dose should be reduced to three times per week.[54,69] Retrobulbar neuritis is the major adverse effect. Patients may complain of a change in visual acuity, the inability to see the color green, or both. They should be monitored monthly while on the drug using Snellen wall charts for visual acuity and Ishihara red-green color discrimination cards.[31,37]

Second-Line Antituberculosis Drugs

Streptomycin Streptomycin is one of three aminoglycoside antibiotics (along with amikacin and kanamycin) that are active

TABLE 112-6 Recommended Regimens for the Concomitant Treatment of TB and HIV Infection in Adults

Combined Regimen for Treatment of HIV and TB	PK Effect of the Rifamycin	Tolerability/Toxicity	Antiviral Activity When Used with Rifamycin	Recommendations (Comments)
Efavirenz-based antiretroviral therapy[a] with rifampin-based TB treatment	Well-characterized, modest decrease in concentrations in some patients	Low rates of discontinuation	Excellent	Preferred (efavirenz should not be used during the first trimester of pregnancy)
PI-based antiretroviral therapy[a] with rifabutin-based TB treatment	Little effect of rifabutin on PI concentrations, but marked increases in rifabutin concentrations	Low rates of discontinuation (if rifabutin is appropriately dose-reduced)	Favorable, although published clinical experience is not extensive	Preferred for patients unable to take efavirenz[b] (caution to ensure patients who discontinue PI not to continue to receive reduced rifabutin dose)
Nevirapine-based antiretroviral therapy with rifampin-based TB treatment	Moderate decrease in concentrations	Concern about hepatotoxicity when used with isoniazid, rifampin, and pyrazinamide	Suboptimal when nevirapine is initiated using once-daily dosing largely favorable when nevirapine is given twice daily throughout co-treatment	Alternative for patients who cannot take efavirenz, though efavirenz is preferred (nevirapine should not be initiated among women with CD4>250 [>200 × 10^6/L] or men with CD4>400 cells/μL[>400 ×10^6/L])
Raltegravir-based antiretroviral therapy with rifampin-based TB treatment	Significant decrease in concentrations with standard dosing	Limited experience	Limited published clinical experience	Alternative at higher doses for patients who cannot take efavirenz and who have baseline viral load <100,000 copes/mL (<100 × 10^6/L)
Zidovudine/lamivudine/abacavir/tenofovir with rifampin-based TB treatment	50% decrease in zidovudine, possible effect on abacavir not evaluated	Anemia	No published clinical experience, but this regimen is less effective than efavirenz or atazanavir basd regimens in person not taking rifampin	Alternative for patients who cannot take efavirenz or nevirapine and if rifabutin not available
Zidovudine/lamivudine/tenofovir with rifampin-based TB treatment	50% decrease in zidovudine, no other effects predicted	Anemia	Favorable, but not evaluated in a randomized trial	Alternative for patients who cannot take efavirenz and abacavir and if rifabutin not available
Zidovudine/lamivudine/abacavir with rifampin-based TB treatment	50% decrease in zidovudine, possible effect on abacavir not evaluated	Anemia	Early favorable experience, but this combination is less effective than efavirenz or nevirapine based regimens in persons not taking rifampin	Alternative for patients who cannot take efavirenz and tenofovir and if rifabutin not available
Superboosted[c] lopinavir-based antiretroviral therapy or double dose lopinavir/ritonavir based therapy with rifampin-based TB treatment	Moderate decrease in concentrations	Hepatitis	Early favorable experience of super-boosting among young children and double dose among adults already on antiretroviral drugs at the time of rifampin initiation	Alternative if rifabutin not available; double dose an option among adults already taking lopinavir based antiretroviral therapy and virologically suppressed at the time of tuberculosis treatment initiation; super boosting has not been adequately tested in adults ut may be effective

ART, antiretroviral therapy; HIV, human immunodeficiency virus; TB, tuberculosis.

[a]With two nucleoside analogues.

[b]Includes patients with NNRTI-resistant HIV, those unable to tolerate efavirenz, and women during the first one to two trimesters of pregnancy.

[c]Super boosting of lopinavir is achieved by giving lopinavir 400 mg together with 400 mg ritonavir twie daily. Doble dose lopinavir/ritonavir is lopinavir 800 mg plus ritonavir 200 mg twice daily.

Adapted from Centers for Disease Control and Prevention. Managing Drug Interactions in the Treatment of HIV Related Tuberculosis. 2013.

against mycobacteria. It is quite active against MAC and several other mycobacteria, enterococci, *Brucella, Yersinia*, and various other bacteria. Although labeled only for intramuscular dosing, streptomycin can be given safely as IV infusions (100 mL of 5% dextrose in water or normal saline) over 30 minutes, similar to the other aminoglycosides.[70] Streptomycin, like other aminoglycosides, is renally cleared by glomerular filtration and must be given less often to patients with renal dysfunction.[37,40]

Streptomycin occasionally causes nephrotoxicity, although it tends to be mild and reversible. It also is capable of causing ototoxicity (vestibular and cochlear), which may become permanent with continued use.[37] Older patients and those receiving long durations of treatment are most likely to experience hearing loss, whereas vestibular toxicity is highly unpredictable.

Resistance to amikacin and kanamycin is frequently linked but independent of resistance to streptomycin and independent

of resistance to capreomycin. Therefore, susceptibility tests should guide the selection of these injectable drugs.

p-Aminosalicylic Acid In the United States, only the enteric-coated, sustained-release granule form (Paser) is available.[71-73] GI disturbances are the most common adverse effects from *p*-aminosalicylic acid. Diarrhea is usually self-limited, with symptoms improving after the first 1 to 2 weeks of therapy. Occasionally, a few doses of an opioid will resolve the problem. It also is important to tell the patient that the empty granules will appear in the stool. Although FDA-approved for three daily doses, pharmacokinetic data support twice-daily dosing.[72]

Various types of malabsorption, including steatorrhea, were reported with previous dosage forms of *p*-aminosalicylic acid. Hypersensitivity and, rarely, severe hepatitis may occur. *p*-Aminosalicylic acid is known to produce goiter, with or without myxedema, which seems to occur more frequently with concomitant ethionamide therapy.

Cycloserine Cycloserine is only used to treat MDR-TB. It is well absorbed orally and is best taken on an empty stomach.[74] It is cleared primarily through the kidneys by glomerular filtration and requires dosage reduction in renal failure. Cycloserine can produce dose-related CNS toxicity, including lethargy, confusion, or unusual behavior. Seizures, although reported, are exceedingly rare in US patients.[37] Therapy is improved by maintaining 2-hour postdose serum concentrations between 20 and 35 mcg/mL (mg/L; 200 and 349 µmol/L).[40,42] Most patients reach a dose of 750 mg daily, divided unevenly into two doses. This can be achieved by starting with 250 mg daily for 2 days, followed by 250 mg increments over 2-day intervals. This dose of cycloserine can be maintained if the patient complains of only occasional mild CNS effects, such as difficulty concentrating. Serum concentrations can be checked 1 to 2 weeks into therapy. The addition of pyridoxine 50 mg daily may improve patient tolerance of cycloserine.

Ethionamide Ethionamide shares structural features with two other antimycobacterial agents, isoniazid and, more distantly, thiacetazone, a drug not used in the United States. Prothionamide, the *n*-propyl derivative of ethionamide, is used in Europe. Ethionamide is only active against organisms of the genus *Mycobacterium*, and it should be considered primarily bacteriostatic because it is difficult to achieve serum concentrations that would be bactericidal.[37,40,42]

GI toxicity is the dose-limiting adverse effect. The drug should be introduced gradually in 250 mg increments, as described earlier for cycloserine. Rarely will a patient tolerate more than 1,000 mg daily in divided oral doses. Ethionamide may be administered with a light snack or prior to bedtime to minimize GI intolerance. Food does not affect absorption significantly.[75] Little ethionamide is recovered in the urine, so doses remain the same in renal failure. Ethionamide may cause goiter with or without hypothyroidism (especially when given with *p*-aminosalicylic acid), gynecomastia, alopecia, impotence, menorrhagia, photodermatitis, and acne. The management of diabetes also may be more difficult for patients receiving ethionamide. Because of these problems, ethionamide only is used when necessary.

Clofazimine Clofazimine is a drug with good activity against *Mycobacterium leprae* and some activity against *M. tuberculosis* and *M. avium*. It is used in doses of 100 mg daily in advanced cases of MDR-TB or MAC, especially when therapeutic options are limited.[37,40] The drug has a terminal elimination half-life that is weeks long. GI distress and skin discoloration are the most important adverse reactions. Although uncommon, severe GI pain may occur because of deposition of clofazimine crystals within the intestines; this may require surgical correction.

Thiacetazone This is a weak agent used rarely in parts of the developing world because of its low cost. Skin reactions, including rash and Stevens-Johnson syndrome, may occur. Thiacetazone must be discontinued permanently as soon as a rash appears. Similar to trimethoprim–sulfamethoxazole, the incidence of skin reactions is much higher for AIDS patients.[76]

Quinolones Levofloxacin, moxifloxacin, and gatifloxacin (outside of the United States), are sometimes used to treat MDR-TB because of their excellent activity against *M. tuberculosis*. Several studies have suggested a potential role for moxifloxacin as a possible replacement for certain first-line agents.[40,77-79] Moxifloxacin has been compared with isoniazid and ethambutol during the first 8 weeks of therapy for pulmonary TB. It did not demonstrate a significant increase in 8-week culture negativity when compared with isoniazid. However, shorter time to culture conversion was seen when compared with ethambutol.[78] Quinolones are useful because most are available in oral and IV dosage forms, so they can be used in critically ill patients. However, resistance of MTB to the fluoroquinolones is a major concern. Resistance is attributed to mutations in the *gyrA* and *gyrB* genes and can develop in a relatively short period of time.[80]

Macrolides/Azalides The macrolide clarithromycin and azalide azithromycin represent substantial advances in the treatment of MAC but demonstrate limited activity against *M. tuberculosis* and are not used frequently for TB.[37,40]

New Drugs and Delivery Systems Several promising compounds are currently under development for the treatment of MTB.

Bedaquiline is a diarylquinoline, approved for use by the FDA, which works through targeting the ATP synthase pump, and does not demonstrate cross-resistance with existing TB drugs. The WHO and CDC have issued recommendations stating that bedaquiline may be used at a dose of 400 mg daily for 2 weeks and then 200 mg three times a week for 22 weeks of treatment in adults with pulmonary MDR-TB when an effective treatment regimen cannot otherwise be provided.[81] Bedaquiline may be used on a case-by-case basis in children, HIV-infected persons, pregnant women, and extrapulmonary TB. Patients treated with bedaquiline should be closely monitored every week for potential side effects and an electrocardiogram (QT monitoring) should be performed at baseline and at weeks 2, 12, and 24.[81] The QT monitoring is required due to a black box warning issued by the FDA as a result of increased rates of death due to QT prolongation in patients receiving bedaquiline.

Delamanid, PA-824 and TBA-354 are all nitroimidazole derivatives which are chemically related to metronidazole and work through inhibiting mycolic acid synthesis. All of these agents have potent in vitro and in vivo activity with very low MICs against *M. tuberculosis*.[82-84] Delamanid has centralized marketing authorization by the European Medicines Agency for use in the European Union.[81,83,85] PA-824 is undergoing phase two studies and TBA-354 has shown benefit in preclinical trials. Combinations of PA-824 with other anti-TB drugs are also being investigated. AZD-5847 is another potentially new drug currently being investigated in Phase 2a trials.[86] Linezolid has also been used in some patients with MDR-TB.[87] Long-term use of linezolid requires careful monitoring of hematologic indices for potential anemia and thrombocytopenia. It may be possible to reduce the incidences of these toxicities by giving linezolid 600 mg daily or 300 mg twice daily for the slow-growing *M. tuberculosis* rather than the usual 600 mg twice-daily dose used for gram-positive organisms. Liposomes have been investigated as delivery systems for various agents against mycobacteria, including isoniazid, rifampin, and the aminoglycosides. By changing the pharmacokinetic profile of such agents, their use in the treatment of mycobacterial infections could be enhanced greatly. Currently, no such product is licensed for use against TB.

Corticosteroids Adjunctive therapy with corticosteroids may be of benefit for some patients with tuberculous meningitis or pericarditis to relieve inflammation and pressure.[37] They should be avoided in most other circumstances because they detract from the immune response to TB.

Bacille Calmette-Guérin Vaccine The BCG vaccine is an attenuated, hybridized strain of *M. bovis*. It was developed in 1921 and is used as a prophylactic vaccine against TB. Administration of BCG vaccine is compulsory in many developing countries and is officially recommended in many others. Vaccination with BCG produces a subclinical infection resulting in sensitization of T lymphocytes and cross-immunity to *M. tuberculosis*, as well as cutaneous hypersensitivity and, in many cases, a positive tuberculin skin test.

The efficacy of several different BCG preparations ranged from negative 56% (some patients did worse with the vaccine) to positive 80%.[37] Trials within the United States and Puerto Rico have shown efficacy rates of 6% to 29%. The primary benefit of BCG vaccination appears to be the prevention of severe forms of TB in children. Data from the BCG trials show that the incidence of tuberculous meningitis and miliary TB is 52% to 100% lower and that the incidence of pulmonary TB is 2% to 80% lower in vaccinated children younger than 15 years than it was in unvaccinated controls.

Unfortunately, BCG does not appear to be reliable in preventing disease by *M. tuberculosis* in other segments of the population. Side effects occur in 1% to 10% of vaccinated persons and usually include severe or prolonged ulceration at the vaccination site, lymphadenitis, and lupus vulgaris. Pregnant women and patients with impaired immune systems, including those with HIV infection, should avoid vaccination. The World Health Organization had recommended, however, that in populations where the risk of TB is high, HIV-infected infants who are asymptomatic should receive BCG vaccine at birth or as soon as possible thereafter. Because BCG infection has occurred in AIDS patients given the vaccine, individuals with symptomatic HIV infection should not be vaccinated.[37]

In the United States, BCG vaccination is recommended only for uninfected children who are at unavoidable risk of exposure to TB and for whom other methods of prevention and control have failed or are not feasible.[37] Its use is very limited.

PERSONALIZED PHARMACOTHERAPY

Desired treatment outcomes for tuberculosis infections require aggressive treatment and rapid identification and both latent and active disease states. Treatment must be individualized based antimicrobial susceptibilities. Appropriate treatment selection is critical to avoid resistance. TDM may be necessary in certain populations. Extended durations of therapy are required for treatment of Mycobacterial diseases so health care professionals should develop a plan to monitor efficacy, adherence, adverse drug reactions, and interactions to TB therapy through regular assessments and monitoring. Directly observed therapy may be required to assure compliance. Patients coinfected with HIV will require special attention because of their immunocompromised state and increased risk of drug interactions.

Therapeutic Drug Monitoring

TDM, or applied pharmacokinetics, generally should be used if patients are failing appropriate treatment (no clinical improvement after 2-4 weeks or smear positive after 4-6 weeks).[40,42,88,89] Patients with AIDS, diabetes, obesity, cystic fibrosis, various GI disorders, or MDR-TB may be tested prospectively, before problems arise, to ensure adequate treatment. Blood samples collected at 2 and 6 hours after a dose have been used with some success, although they may not be the optimal sampling times for all the drugs. Finally, TDM of the TB and HIV drugs is perhaps the most logical way to untangle the complex drug interactions that take place.[90,91]

Clinical **Controversy...**

Some TB centers employ TDM for many of their patients at the outset of treatment in order to identify drug-delivery problems early. Other centers wait to see how the patient responds and perform TDM only if problems arise. An argument can be made for either approach. The latter can save money in the short-term, but delays in effective treatment can affect the patient's outcome adversely.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

The most serious problem with TB therapy is patient nonadherence to the prescribed regimens.[92] Unfortunately, there is no reliable way to identify such patients a priori. Noncompliance rates of up to 89% have been reported with TB therapy.[92] It is critical to the control of TB that such adherence rates be improved dramatically. The most effective way to achieve this end is with DOT.[37] Despite criticisms that it will cost more money, it is far cheaper in the long run to prevent the further spread of disease with DOT than to track down and treat additional cases of TB continuously.

The homeless and other underprivileged individuals are assumed to constitute the group of patients considered "unreliable," and DOT should be reserved for them; it is also assumed that "responsible" patients cared for by private physicians may be treated with daily, unsupervised therapy. A study conducted in Baltimore, however, compared outcomes (sputum culture conversion to negative at 3 months) for patients with pulmonary TB who were treated by private physicians with outcomes for patients treated via DOT in a city-run clinic. Surprisingly, 3-month culture conversion occurred in only 40% of the private-care patients, compared with 90% in the city clinic-care patients.[3] Clearly, expansion of the use of DOT to nearly all patients with TB may be of benefit.

Patients who are AFB-smear positive should have sputum samples sent for AFB stains every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment.[37] Once on maintenance therapy, sputum cultures can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, drug susceptibility testing should be repeated, and serum concentrations of the drugs should be checked.

Serum chemistries, including blood urea nitrogen, creatinine, aspartate transaminase, and alanine transaminase, and a complete blood count with platelets should be performed at baseline and periodically thereafter, depending on the presence of other factors that may increase the likelihood of toxicity (eg, advanced age, alcohol abuse, pregnancy)[37] (Table 112-7). Hepatotoxicity should be suspected for patients whose serum transaminases exceed five times the upper limit of normal or whose total bilirubin concentration exceeds 3 mg/dL (51.3 μmol/L) and for patients with symptoms such as nausea, vomiting, or jaundice. At this point, the offending agent(s) should be discontinued. Sequential reintroduction of the drugs with frequent testing of liver enzymes is often successful in identifying the offending agent; other agents may be continued.

TABLE 112-7 Antituberculosis Drug Monitoring Table

Drug	Adverse Effects	Monitoring
Isoniazid	Asymptomatic elevation of aminotransferases, clinical hepatitis, fatal hepatitis, peripheral neurotoxicity, CNS effects, lupus-like syndrome, hypersensitivity, monoamine poisoning, diarrhea	LFT monthly in patients who have preexisting liver disease or who develop abnormal liver function that does not require discontinuation of drug; dosage adjustments may be necessary in patients receiving anticonvulsants or warfarin
Rifampin	Cutaneous reactions, GI reactions (nausea, anorexia, abdominal pain), flu-like syndrome, hepatotoxicity, severe immunologic reactions, orange discoloration of bodily fluids (sputum, urine, sweat, tears), drug interactions due to induction of hepatic microsomal enzymes	Liver enzymes and interacting drugs as needed (eg, warfarin)
Rifabutin	Hematologic toxicity, uveitis, GI symptoms, polyarthralgias, hepatotoxicity, pseudojaundice (skin discoloration with normal bilirubin), rash, flu-like syndrome, orange discoloration of bodily fluids (sputum, urine, sweat, tears)	Drug interactions are less problematic than rifampin
Rifapentine	Similar to those associated with rifampin	Drug interactions are being investigated and are likely similar to rifampin
Pyrazinamide	Hepatotoxicity, GI symptoms (nausea, vomiting), nongouty polyarthralgia, asymptomatic hyperuricemia, acute gouty arthritis, transient morbilliform rash, dermatitis	Serum uric acid can serve as a surrogate marker for adherence; LFTs in patients with underlying liver disease
Ethambutol	Retrobulbar neuritis, peripheral neuritis, cutaneous reactions	Baseline visual acuity testing and testing of color discrimination; monthly testing of visual acuity and color discrimination in patients taking >15–20 mg/kg, having renal insufficiency, or receiving the drug for >2 months
Streptomycin	Ototoxicity, neurotoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr Monthly assessments of renal function and auditory or vestibular symptoms
Amikacin/kanamycin	Ototoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr; monthly assessments of renal function and auditory or vestibular symptoms
Capreomycin	Nephrotoxicity, ototoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr Monthly assessments of renal function and auditory or vestibular symptoms Baseline and monthly serum K^+ and Mg^{2+}
p-Aminosalicylic acid	Hepatotoxicity, GI distress, malabsorption syndrome, hypothyroidism, coagulopathy	Baseline LFTs and TSH TSH every 3 months
Moxifloxacin	GI disturbance, neurologic effects, cutaneous reactions	No specific monitoring recommended

CNS, central nervous system; GI, gastrointestinal; LFT, liver function test; SCr, serum creatinine; TSH, thyroid-stimulating hormone.

Adapted from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep *2003;52(RR-11):1-77*.

Alternative agents should be selected as needed. Audiometric testing should be performed at baseline and monthly for patients who must receive aminoglycosides for more than 1 to 2 months. Vision testing (Snellen visual acuity charts and Ishihara color discrimination plates) should be performed on all patients who receive ethambutol. All patients diagnosed with TB should be tested for HIV infection.

ABBREVIATIONS

AFB	acid-fast bacillus
ATS	American Thoracic Society
BCG	bacillus Calmette-Guérin
CDC	Centers for Disease Control and Prevention
CMI	cell-mediated immunity
DOT	directly observed treatment
DTH	delayed-type hypersensitivity
ELISA	enzyme-linked immunosorbent assay
HIV	human immunodeficiency virus
IGRA	interferon-γ release assay
IL	interleukin
INF	interferon
LAM	lipoarabinomannan
LTBI	latent tuberculosis infection
MAC	*Mycobacterium avium* complex
MDR	multidrug resistant
MIC	minimal inhibitory concentration
MTD	*M. tuberculosis* direct
PCR	polymerase chain reaction
PPD	purified protein derivative
QFT-G	QuantiFERON-TB Gold test
rRNA	ribosomal ribonucleic acid
SDA	strand-displacement amplification
TB	tuberculosis
TDM	therapeutic drug monitoring
TH_1	T-helper type 1
TH_2	T-helper type 2
TNF	tumor necrosis factor
WBC	white blood cell
XDR	extensively drug-resistant

Gastrointestinal Infections and Enterotoxigenic Poisonings

113

Andrew Roecker, Brittany Bates, and Steven Martin

KEY CONCEPTS

1. Infectious diarrhea is a disease that causes significant morbidity and mortality worldwide. Its etiology includes various bacteria, viruses, and protozoans, with viral causes being most predominant globally.
2. Two types of infectious diarrhea include watery or enterotoxigenic diarrhea and dysentery or bloody diarrhea. Common pathogens responsible for watery diarrhea are viruses and enterotoxigenic *Escherichia coli*. Common pathogens responsible for dysentery diarrhea are *Shigella* spp., *Campylobacter jejuni*, nontyphoid *Salmonella*, and enterohemorrhagic *E. coli*.
3. Fluid and electrolyte replacement is the cornerstone of therapy for diarrheal illnesses. Oral rehydration therapy is preferred in most cases of mild and moderate diarrhea.
4. The use of antibacterial therapy for infectious diarrhea is not commonly indicated due to the mild and self-limited nature of the infection, or viral etiology. Antibiotic therapy is recommended in cases of severe diarrhea, moderate-to-severe cases of traveler's diarrhea, most cases of febrile dysenteric diarrhea, and culture-proven bacterial diarrhea in high-risk patients.
5. Loperamide and diphenoxylate/atropine may offer symptomatic relief in patients with moderate watery diarrhea; however, use of antimotility agents should be avoided in patients with watery and dysentery diarrhea.
6. Diarrheal illness can be largely prevented by procedures to prevent contaminated food or water supplies and with appropriate personal hygiene.
7. Oral vancomycin is recommended in patients with severe *Clostridium difficile* infection (CDI). Metronidazole is the drug of choice for mild to moderate disease and fidaxomicin may offer an advantage in patients at high risk for disease recurrence.
8. Common traveler's diarrheal pathogens include enterotoxigenic *E. coli*, *Shigella* spp., *Campylobacter* spp., *Salmonella* spp., and viruses.
9. Patient education on prevention strategies and appropriate self-treatment of traveler's diarrhea is preferred, and prophylaxis with antibacterials is not recommended.
10. Pathogens commonly responsible for food poisoning include *Staphylococcus* spp., *Salmonella* spp., *Shigella* spp., and *Clostridium* spp.

Gastrointestinal (GI) infections and enterotoxigenic poisonings encompass a wide variety of medical conditions characterized by inflammation of the GI tract. Inflammation-induced vomiting and diarrhea are responsible for much of the morbidity and mortality of these conditions. Diarrhea is defined as a decrease in consistency of bowel movements (ie, unformed stool) and an increase in frequency of stools to three or more per day.[1,2] Acute disease is commonly associated with diarrhea lasting 14 days or less in duration while persistent diarrhea lasts more than 14 days.

This chapter focuses on infectious etiologies of acute GI infections and enterotoxigenic poisonings. A wide variety of viral, bacterial, and parasitic pathogens are responsible for these infections. Chapter e115 discusses the common protozoans that cause gastroenteritis. This chapter will focus on pathogenesis and management of common viral and bacterial etiologies. Because the clinical consequences of dysenteric diarrhea can be more severe compared with cases of watery diarrhea, the chapter is organized accordingly. Epidemiology, clinical presentation, diagnosis, treatment, and prevention strategies are discussed for all GI infections generally, and further elaborated in subsequent sections for specific diseases such as *Clostridium difficile*–associated diarrhea, traveler's diarrhea, and foodborne illnesses.

EPIDEMIOLOGY

Dehydration resulting from acute infectious diarrhea is the second leading cause of mortality in children younger than 5 years, killing 760,000 annually.[2] Globally, 1.7 billion cases of infectious diarrhea occur yearly and cause over 2 million deaths.[2] The incidence of diarrhea for all children younger than age 5 years is estimated to be 2.9 episodes per child per year. The incidence of diarrhea is higher in younger children, with 4.5 episodes per child per year among children aged 6 to 11 months, compared with 2.3 episodes per child per year for children aged 24 to 59 months.[3] Younger children also have a higher risk of death from acute dehydrating diarrhea, and diarrheal disease is still the leading global cause of malnutrition in children younger than 5 years.[2] Although the incidence of childhood diarrhea has been declining, diarrhea remains a major health problem in children, especially in those younger than 1 year.

In the United States, 179 million episodes of acute gastroenteritis occur each year, resulting in more than 600,000 hospitalizations and more than 5,000 deaths.[4,5] The highest mortality risk from infectious diarrhea in the United States occurs in the elderly, which contrasts to the developing world where the risk of death is highest among young children.[4] A study of the McDonnell-Douglas Health Information System database revealed that 25% of all hospitalizations and 85% of all mortality associated with diarrhea involved the elderly (age 60 years and older).[4] In addition to children and the elderly, other groups at risk for GI infections include travelers and campers, patients in chronic care facilities, military personnel stationed abroad, and immunocompromised patients.

ETIOLOGY

1 The etiology of GI infections and enterotoxigenic poisonings includes a wide variety of viruses, bacteria, and parasites, although the specific incidence of each is difficult to quantify. Etiologic agents

TABLE 113-1 Acute Infectious Diarrhea Clinical Syndromes: Watery versus Dysentery

	Watery	Dysentery
Percentage of patients	90-95	5-10
Stools		
Appearance	Watery	Bloody
Volume	Increased: ++/+++	Increased: +/++
Number per day	<10	>10
Reducing substances	0 to +++	0
pH	5-7.5	6-7.5
Occult blood	Negative	Positive
Fecal polymorphonuclear cells	Absent or few	Many
Mechanisms	Toxins Reduced absorption	Toxins Mucosal invasion
Complications		
Dehydration	Could be severe	Mild
Others	Acidosis, shock, electrolyte imbalance	Tenesmus, rectal prolapse, seizures
Etiology	*Vibrio cholerae*	*Shigella* spp.
	Enterotoxigenic *Escherichia coli* (ETEC)	*Salmonella* spp.
	Rotaviruses	*Campylobacter* spp.
	Noroviruses	*Yersinia* spp.
		Enterohemorrhagic *E. coli* (EHEC)
		Clostridium difficile

are rarely identified due to the infrequent collection of stool samples, or inability of many laboratories to detect the full range of pathogenic organisms. In this chapter, discussions of pathogens responsible for enterotoxigenic diarrhea focus on viral pathogens (rotavirus and norovirus), enterotoxigenic *Escherichia coli* (ETEC), and cholera. Common pathogens associated with dysenteric diarrhea discussed will be *Shigella* spp., *Salmonella* spp., *Campylobacter* spp., enterohemorrhagic *E. coli* (EHEC), *Yersinia enterocolitica*, and *Clostridium difficile*. Characteristics of watery and dysenteric diarrhea and common pathogens responsible for them are outlined in Table 113-1.

Viruses are now recognized as the leading global cause of infectious diarrhea. Noroviruses, previously known as Norwalk-like viruses, account for greater than 90% of viral gastroenteritis among all age groups, and 50% of outbreaks worldwide. In the United States, noroviruses have been estimated to cause 21 million cases of acute gastroenteritis annually including more than 70,000 hospitalizations and nearly 800 deaths.[5,6] Outbreaks occur throughout the year and have been documented in families, healthcare systems, cruise ships, and college dormitories.

In infants and children, rotavirus, a double-stranded, wheel-shaped, RNA virus, is the most common cause of infectious diarrhea globally, and 1 million people die annually from the infection.[7] In the United States, approximately 3.5 million cases of diarrhea, 500,000 physician visits, 50,000 hospitalizations, and 20 deaths occur each year in children younger than 5 years.[7] Rotavirus is a ubiquitous contagion, infecting the vast majority of children younger than 5 years. After the initial infection, 40% of children are protected against subsequent rotavirus infection, 75% are protected against subsequent gastroenteritis, and up to 88% are protected against severe gastroenteritis. Other viral etiologies include astrovirus, enteric adenovirus, pestivirus, coronavirus, and enterovirus. These viruses are increasingly identified as causative etiologies of diarrhea. Characteristics of viral pathogens causing gastroenteritis are outlined in Table 113-2.

2 In the United States, bacterial causes of acute gastroenteritis account for more than 5.2 million cases of diarrhea annually, including 46,000 hospitalizations and 1,500 deaths.[4] However, there appears to be substantial underreporting of disease, and the cause is identified in less than 3% of cases. Common pathogens responsible for watery diarrhea in the United States are norovirus and ETEC, while those most commonly associated with dysentery diarrhea are *Campylobacter* spp., EHEC, *Salmonella* spp., and *Shigella* spp. Other organisms that are responsible for dysentery include *Aeromonas* spp., noncholera *Vibrio*, and *Y. enterocolitica*. Characteristics of acute bacterial pathogens causing gastroenteritis are summarized in Table 113-3.

Cholera has been rare in the United States because of advanced water and sanitation systems; although slight increases in its incidence have occurred in recent years without clear causes.[8] It is endemic on the Indian subcontinent and sub-Saharan Africa. *Vibrio cholerae* is a gram-negative bacillus sharing similar characteristics with the family Enterobacteriaceae. Cholera is caused by toxigenic *V. cholerae* serogroups O1 or O139. Infections due to *V. cholerae* result in severe and voluminous diarrhea that can quickly result in dehydration. Approximately half of those persons infected with *V. cholerae* O1 are symptomatic, whereas only 1% to 5% of those infected with *V. cholerae* O139 manifest symptoms.[9]

E. coli is a gram-negative bacillus commonly found in the human GI tract, and *E. coli*-associated diarrhea may be differentiated into several distinct categories based on pathogenic features of diarrheal disease: enteroaggregative *E. coli* (EAEC), EHEC, enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), and ETEC. ETEC occurs most commonly, and accounts for about half of all

TABLE 113-2 Characteristics of Agents Responsible for Acute Viral Gastroenteritis

Virus	Peak Age of Onset	Time of Year	Duration	Mode of Transmission	Common Symptoms
Rotavirus	6 months to 2 years	October to April	3-7 days	Fecal–oral, water, food	Nausea, vomiting, diarrhea, fever, abdominal pain, lactose intolerance
Norovirus	All age groups	Peak in winter	2-3 days	Fecal–oral, food, water, environment	Nausea, vomiting, diarrhea, abdominal cramps, myalgia
Astrovirus	<7 years	Winter	1-4 days	Fecal–oral, water, shellfish	Diarrhea, headache, malaise, nausea
Enteric adenovirus	<2 years	Year-round	7-9 days	Fecal–oral	Diarrhea, respiratory symptoms, vomiting, fever
Pestivirus	<2 years	NR	3 days	NR	Mild
Coronavirus-like particles	<2 years	Fall and early winter	7 days	NR	Respiratory disease
Enterovirus	NR	NR	NR	NR	Mild diarrhea, secondary organ damage

NR, not reported.

TABLE 113-3 Characteristics of Acute Bacterial Gastroenteritis

Bacteria	Incubation Period	Duration	Mode of Transmission	Common Symptoms
Watery Diarrhea				
Vibrio cholerae	2-3 days	1-3 days	Contaminated food or water with human feces usually in areas of inadequate treatment of sewage and drinking water	Profuse watery diarrhea, vomiting, and leg cramps Death can occur within hours without treatment
Enteroaggregative *E. coli*	NR	NR	Contaminated food or water with animal or human feces	Chronic, watery, mucoid, secretory diarrhea with low-grade fever in immunocompromised persons (HIV infections)
Enteroinvasive *E. coli*	10-18 hours	NR	Contaminated food or water with animal or human feces	Watery diarrhea in young children in the developing world
Enteropathogenic *E. coli*	9-12 hours	NR	Contaminated food or water with animal or human feces	Acute onset of profuse watery diarrhea, vomiting, and low-grade fever in young children (<2 years of age) in the developing world
Enterotoxigenic *E. coli*	1-3 days	3-4 days	Contaminated food or water with animal or human feces	Watery diarrhea and abdominal cramping
Dysentery Diarrhea				
Campylobacter jejuni	2-5 days	5-7 days	Contaminated food (particularly poultry), water, or contact with infected animals	Diarrhea (often bloody), cramping, abdominal pain, and fever
Enterohemorrhagic *E. coli*	3-4 days	5-7 days	Contaminated food (particularly cattle) or water with animal or human feces	Severe stomach cramps, diarrhea (often bloody), and vomiting Approximately 5-10% develop hemolytic uremic syndrome
Nontyphoid *Salmonella*	12-36 hours	1-5 days	Contaminated food, water, or contact with infected animals	Diarrhea (sometimes bloody), fever, and abdominal cramps
Shigella	1-3 days	1-7 days	Fecal–oral Contaminated food or water with infected human feces	Watery or bloody diarrhea (8-10 stools/day), severe abdominal pain, fever, and malaise
Yersinia	4-7 days	1-3 weeks	Contaminated food or water	Fever, abdominal pain, and diarrhea (often bloody)

NR, not reported.

cases of *E. coli* diarrhea. There are an estimated 79,000 cases of ETEC in the United States each year.[4] ETEC is also the most common cause of traveler's diarrhea and a common cause of food- and water-associated outbreaks. Infections with EIEC and EPEC are primarily a disease of children in developing countries.[10] EAEC strains are implicated in persistent diarrhea (≥14 days) in human immunodeficiency virus (HIV)-infected patients.[11] EHEC, also known as Shiga toxin–producing *E. coli* (STEC), causes watery diarrhea that becomes bloody in 1 to 5 days in 80% of patients.[10]

EHEC is believed to be the major etiologic factor responsible for the development of hemorrhagic colitis and hemolytic uremic syndrome (HUS). The annual disease burden of STEC in the United States is more than 20,000 infections and as many as 250 deaths; however, the failure of many clinical laboratories to screen for this organism greatly complicates any estimates.[12] In the United States, STEC causes 50% to 60% of all EHEC infections, but in the southern hemisphere, including Argentina, Australia, Chile, and South Africa, non-STEC serotypes are often more prevalent. Non-STEC strains generally produce a lower frequency of dysentery than STEC-positive strains (62% vs 85%).

The *Campylobacter* spp., are flagellated, curved, gram-negative rods. Although there are 14 different species, *Campylobacter jejuni* is the species responsible for more than 99% of *Campylobacter*-associated gastroenteritis. Approximately 2.4 million persons are affected each year in the United States, involving almost 1% of the entire population.[4]

Salmonella enterica is a gram-negative bacilli belonging to the family Enterobacteriaceae. The most prevalent *S enterica* serotypes are Typhi and Paratyphi, which cause enteric fever. Gastroenteritis is caused by *S enterica* serotypes Typhimurium or Enteritidis. In the United States, the largest burden of *Salmonella* infection is due to nontyphoidal serotypes, causing approximately 1.4 million cases of salmonellosis, 16,000 hospitalizations, and 600 deaths, occurring annually.[13]

Approximately 165 million cases of shigellosis occur worldwide with 450,000 cases from the United States annually.[14] *Shigella* spp., are gram-negative bacilli belonging to the family Enterobacteriaceae. Four species most often associated with disease are *Shigella dysenteriae* type 1, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*.[14] *Shigella sonnei* and *S. flexneri* are the most common causes of gastroenteritis in the United States. The other two *Shigella* spp., are more commonly acquired during travel to developing countries. Poor sanitation or personal hygiene, inadequate water supply, malnutrition, and increased population density are associated with an increased risk of *Shigella* gastroenteritis epidemics.

Yersinia spp., are non–lactose-fermenting gram-negative coccobacilli that are widely distributed in nature. The genus *Yersinia* includes six species known to cause disease in humans. *Yersinia enterocolitica* and, to a lesser extent, *Y. pseudotuberculosis* are most likely associated with intestinal infection, but overall both are a relatively infrequent cause of diarrhea and abdominal pain. More than 50 serotypes of *Y. enterocolitica* exist; of these, serotypes 0:3, 0:8, and 0:9 are associated most frequently with enterocolitis.[15] Children are most likely to experience illness with *Y. enterocolitica* infection.

PATHOPHYSIOLOGY

Acute gastroenteritis and its resulting diarrhea are caused by altered movement of ions and water resulting in increased colonic secretion. Under normal conditions, the GI tract has tremendous capacity to absorb fluid and electrolytes, allowing only 100 to 200 mL of fluid to be excreted in the stool daily.[16] The classic enteric pathogen that causes secretary diarrhea is *V. cholerae*, but ETEC and rotavirus also cause watery diarrhea and are much more predominant etiologies in the United States.

V. cholerae is an enteric pathogen that causes classical secretory diarrhea due to changes in ion secretion and absorption. Among the toxins produced by *V. cholerae*, the most important is cholera toxin.[9] Cholera toxin consists of two subunits, A and B. The B subunits are responsible for delivery of the A subunit into the cell. The A subunit stimulates adenylate cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) and results in protein kinase A-mediated activation of cystic fibrosis transmembrane conductance regulator. This leads to increased chloride secretion and decreased sodium absorption producing the severe watery diarrhea characteristic of the disease.[17] The toxin likely acts along the entire intestinal tract, but most fluid loss occurs in the duodenum. The net effect of the cholera toxin is isotonic fluid secretion early in the intestinal tract that exceeds the absorptive capacity of the latter intestinal tract.

ETEC also causes watery diarrhea characterized by severe intestinal water secretion by producing plasmid-mediated enterotoxins: heat-labile toxin and heat-stable toxin. The heat-labile toxin has two subunits (A and B) that have similar antigenic properties and action on the gut mucosa as cholera toxin. Heat-labile toxins increase chloride secretion via activation of cAMP. The net effect is luminal accumulation of electrolytes that draws water into the intestine, and production of a cholera-like secretory diarrhea.[18] Heat-stable toxin is thought to be non-antigenic and produces watery diarrhea by acting on the small intestine.

Rotavirus induces changes in transepithelial fluid balance, and causes malabsorption as a consequence of destruction of the epithelial lining of intestine, and vascular damage and ischemia in villi. Once rotavirus infects small intestinal villus cells, viroplasms are formed and its toxin, nonstructural protein 4, is released. The viral enterotoxin increases intracellular calcium, and the increase in calcium disrupts microvillus cytoskeleton, as well as barrier function. Changes to the villi include shortening of villus height, crypt hyperplasia, and mononuclear cell infiltration of the lamina propria.[19]

Inflammatory diarrhea is caused by two groups of organisms—enterotoxin-producing, noninvasive bacteria (eg, EAEC, EHEC) or invasive organisms (eg, *Campylobacter* spp., *Salmonella* spp., *Shigella* spp.). The enterotoxin-producing organisms adhere to the mucosa, activate cytokines, and stimulate the intestinal mucosa to release inflammatory mediators. Invasive organisms, which can also produce enterotoxin, invade the intestinal mucosa to induce an acute inflammatory reaction, involving the activation of local and systemic cytokines and inflammatory mediators.

Ingestion of as few as 10 to 200 viable organisms of the *Shigella* spp., causes disease in healthy adults.[14] *Shigella* multiply and spread within the submucosa of the small bowel, but they rarely extend beyond the mucosa. Inflammatory diarrhea is caused by the pathogens invading the epithelial barrier through M cells where they encounter and eliminate macrophages. The destruction of macrophages after emergence from M cells causes an initial release of interleukin (IL)-1β. This initial inflammatory process is exacerbated by free bacteria binding to toll-like receptor that causes the production of IL-6 and IL-8. Both IL-1β and IL-8 attract polymorphonucleocytes.[20] Release of polymorphonucleocytes activates chloride secretion and subsequent diarrhea. Degranulation and release of toxic substances by neutrophils cause ulceration of the epithelium, distortion of the crypts, death to intestinal epithelium, sloughing of mucosal cells, bloody mucoid exudate into the gut lumen, and submucosal accumulation of inflammatory cells with microabscess formation.[21] Microabscesses eventually may coalesce, forming larger abscesses. *Shigella* will frequently affect the entire colon. In addition to the virulence characteristics of invasiveness, *S. dysenteriae* type 1 and, to a lesser degree, *S. flexneri* and *S. sonnei* produce a cytotoxin or Shiga toxin, which can lead to HUS.[10]

The pathogenicity of EHEC is related to the production of Shiga-like toxins, so named because of their resemblance to the Shiga toxin of *S. dysenteriae*.[16] The cytotoxic effect of Shiga-like toxins disrupts the mucosal integrity of the large intestine, causing diarrhea. In addition, the toxin is able to pass through the intestinal epithelium to reach the endothelial cells lining small blood vessels that supply the gut, kidney, and other viscera, causing the myriad metabolic events that could eventually lead to HUS.

CLINICAL PRESENTATION

Gastroenteritis is an illness characterized by diarrhea, which may be accompanied by nausea, vomiting, fever, and abdominal pain. For effective diagnosis and management, it is important to distinguish noninflammatory diarrhea that produces watery diarrhea from inflammatory diarrhea or dysentery. Most enteric pathogens produce acute diarrhea and pathogens associated with dysentery will often result in grossly bloody stools and mucus. Systemic symptoms of gastroenteritis, such as fever, are often associated with dysentery of infectious origin. Symptoms of enteric pathogens that cause watery and dysentery diarrhea are listed in Table 113-1.

A physical examination and careful history that includes information about symptoms and symptom duration, the number of individuals affected, and recent history of travel, diet, and medications are important factors in making a diagnosis. Infections with norovirus or ETEC will often result in mild, self-limiting disease, whereas cholera will commonly produce severe dehydrating diarrhea. Infections with enteric pathogens such as *Campylobacter* spp., EHEC, *Salmonella* spp., *Shigella* spp., and *Y. enterocolitica* can result in severe symptomatology due to dysentery. The utilization of serum C-reactive protein (CRP) in young adult patients with infectious diarrhea may be able to help differentiate between noninflammatory and inflammatory causes.[22] Assessing CRP could assist with diagnosis, prognosis, and treatment selection. The clinical presentation of acute viral and bacterial gastroenteritis is summarized in Tables 113-2 and 113-3, respectively.

3 Stool culture is an important tool in making an organism-specific diagnosis and determining susceptibility to antimicrobial agents. Due to the low yield, stool cultures are not recommended in most mild to moderate watery diarrhea. Instead, indications for stool cultures include dysenteric diarrhea, persistent diarrhea in immunocompromised patients (ie, persons aged 65 years and older with comorbid diseases, neutropenia, or HIV infection), and diarrhea where an outbreak is suggested.[1] An appropriately-obtained stool culture identifies the presence of *Campylobacter*, *Salmonella*, and *Shigella* spp. The yield of stool cultures for other pathogens is increased if the test is ordered specifically based on history and physical examination. For dysenteric diarrhea, the laboratory should be instructed to evaluate for EHEC including STEC (*E. coli* O157:H7). In hospitalized patients who develop diarrhea 3 days after hospitalization or in those with recent exposure to antimicrobials or chemotherapy, stool specimen should be sent for *C. difficile* toxins A and B. In addition to stool cultures, microscopic examination for fecal polymorphonuclear cells, or a simple immunoassay for the neutrophil marker lactoferrin, can further provide evidence of an inflammatory process and increase the yield of cultures in patients presenting with dysenteric diarrhea.[1]

Complications

Complications associated with acute diarrhea most likely result from dehydration so treatment focuses primarily on rehydration therapy, regardless the etiology. Dysenteric diarrhea is more likely to have severe complications, especially in children younger than 5 years and in elderly. Bacteremia is the most common complication of gastroenteritis and can be seen after infections with nontyphoid *Salmonella*, *C. jejuni* or *C. fetus*, and *Y. enterocolitica*.[12] Nontyphoid *Salmonella* is most common in children younger than 5 years, elderly, and patients with hemoglobinopathy, malaria, or immunosuppression. Bacteremia due to *Campylobacter* spp., has been reported in

patients with HIV infection, malignancy, transplantation, and hypogammaglobulinemia. *Y. enterocolitica* bacteremia has been rarely reported, but has an increased prevalence in patients with diabetes mellitus, severe anemia, hemochromatosis, iron overload (frequent transfusion), cirrhosis, malignancy, and in the elderly.[23] Persistent bacteremia with these pathogens will commonly result in prolonged intermittent fever with chills. Potentially complicating the diagnosis, stool cultures frequently are negative and leukocyte counts are often within the normal range. Vascular complications such as seeding of atherosclerotic plaques or aneurysms in arterial vessels occur in 10% to 25% of adults with bacteremia. Localized infections involving bone, cysts, heart, kidney, liver, lungs, pericardium, and spleen develop in 5% to 10% of patients with bacteremia.

A severe complication in patients infected with EHEC is HUS. HUS is defined by the triad of acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia and is more commonly observed in children younger than 5 years and in the elderly.[24] Approximately 2% to 7% of cases infected with STEC strains are complicated by development of HUS, which increases mortality associated with this infection. *S. dysenteriae* type 1 can also cause HUS, although more rarely than observed with EHEC.[14]

Shigella infection may also lead to complications such as generalized seizures, sepsis, toxic megacolon, perforated colon, arthritis, and protein-losing enteropathy. Mortality is rare, but it may be more likely with *S. dysenteriae* type I. Less than 3% of persons who are infected with *S. flexneri* will later develop Reiter syndrome, characterized by pains in the joints, irritation of the eyes, and painful urination. This can lead to chronic arthritis.[25]

Infection with *C. jejuni* has been associated with Guillain-Barré syndrome (GBS), but the relationship is not well understood.[26] The risk of developing GBS after *C. jejuni* infection appears to be low (approximately 1 case of GBS per 1,000 *C. jejuni* infections). The weakness associated with GBS usually starts in the legs, with difficulty in walking, and may progress to a complete paralysis of all extremities that lasts several weeks and usually requires intensive care.

Approximately 10% to 30% of adult patients develop a reactive arthritis 1 to 2 weeks after recovery from gastroenteritis secondary to *S. flexneri*, *Salmonella* spp., *C. jejuni*, and *Y. enterocolitica*. This arthritis, involving the knees, ankles, toes, fingers, and wrists, usually resolves in 1 to 4 months but may persist in approximately 10% of patients.[26] This complication is more common in persons with the HLA-B27 antigen.

A general complication that could occur long after an infectious gastroenteritis, especially with dysentery and toxin-mediated dysentery, is postinfectious irritable bowel syndrome (IBS). This is classified as IBS symptoms for at least 3 months following an episode of gastroenteritis or traveler's diarrhea showing recurrent abdominal pain or discomfort.[27] Albeit rare, some long-term complications associated with these infections strengthen the need for appropriate diagnosis and treatment.

TREATMENT

Mortality associated with infectious diarrhea has declined substantially in the past 2 decades, especially among children younger than 1 year. Preventative measures including improved sanitation, breastfeeding and weaning practices, and increased use of oral rehydration therapy (ORT) for affected individuals, are responsible for the decrease in case-fatality rates.

General Approach to Treatment

The cornerstone of management for all GI infections and enterotoxigenic poisonings is to prevent dehydration by correcting fluid and electrolyte imbalances. In mild, self-limiting acute gastroenteritis, a diet of oral fluids and easily digestible foods is recommended. In patients with severe dehydrating watery diarrhea and dysenteric diarrhea, IV rehydration therapy, antibiotics, and/or antimotility treatments are needed.

Rehydration Therapy

Initial assessment of fluid loss is essential for successful rehydration therapy and should include acute weight loss, as it is the most reliable means of determining the extent of water loss. However, if accurate baseline weight is not available, clinical signs are helpful in determining approximate deficits (Table 113-4). Physical assessment generally is more reliable in young children and infants than in adults.

3 Fluid replacement is the cornerstone of therapy for dehydration due to diarrhea regardless of etiology. For the treatment of mild to moderate dehydration, ORT is superior to administration of IV fluids. Oral replacement therapy reverses dehydration in nearly all patients with mild to moderate diarrhea with 94% to 97% efficacy.[1] It offers advantages of being inexpensive, noninvasive, and not requiring inpatient administration. Moreover, thirst drives use of ORT and provides a safeguard against overhydration. Replacement of ongoing losses as well as continuation of normal feeding should also be addressed.

The necessary components of oral rehydration solutions (ORS) include carbohydrates (typically glucose), sodium, potassium, chloride, and water. Using both salt and glucose in the ORS takes advantage of glucose-coupled sodium transport in the small bowel and enhances sodium and subsequently water transport across intestinal walls. In 2002, the World Health Organization/United Nations Children's Fund (WHO/UNICEF) endorsed a reduced osmolarity solution (osmolarity ≤250 mOsm/L) as the use of these solutions reduced stool volume, shortened duration of diarrhea, and decreased need for unscheduled IV therapy when compared with previously used ORS more than or equal to 310 mOsm/L.[28] The newer formulation of ORS less than or equal to 250 mOsm/L was, however, more likely to cause hyponatremia (blood sodium levels <130 mmol/L).[29] If commercial ORS are unavailable, one can be roughly duplicated by mixing ½ teaspoon of salt with 6 teaspoons of sugar in 1 L of water.[30]

In restoring fluid and electrolyte balance in cholera infections, polymer-based ORS may be more efficacious than glucose-based ORS. Polymer-based ORS contains rice, wheat, sorghum, or maize. This polymer-based ORS releases glucose more slowly after digestion, and when absorbed in the small bowel, enhances the reabsorption of water and electrolyte secreted into the bowel lumen during diarrhea. In a meta-analysis of 34 trials, polymer-based ORS has been shown to reduce the duration of diarrhea in adults with cholera when compared with glucose-based ORS more than or equal to 310 and less than or equal to 270 mOsm/L.[31]

Guidelines for rehydration therapy based on the degree of dehydration and replacement of ongoing losses are outlined in Table 113-4. ORS should be given in small and frequent volumes (5 mL every 2 to 3 minutes in a teaspoon or oral syringe). Nasogastric administration of ORS is an alternative method of administration in a child with persistent vomiting. For breast-fed infants, nursing should be continued. The composition of commercial ORS and commonly consumed beverages is listed in Table 113-5. Clear fluids, such as soft drinks, sweetened fruit drinks, chicken broth, and sports drinks, should be avoided in the treatment of dehydration. These hyperosmolar solutions may cause an osmotic diarrhea.

In the treatment of severe dehydration, the primary goal of therapy is rapid restoration of fluid losses, correction of metabolic acidosis, and replacement of potassium deficiency. Severely dehydrated patients should be resuscitated initially with IV lactated Ringer solution or normal saline to restore hemodynamic stability.

TABLE 113-4 Clinical Assessment of Degree of Dehydration in Children Based on Percentage of Body Weight Loss[a]

Variable	Minimal or No Dehydration (<3% Loss of Body Weight)	Mild to Moderate (3%-9% Loss of Body Weight)	Severe (≥10% Loss of Body Weight)
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Weak, thready, or not palpable
Heart rate	Normal	Normal to increased	Increased (bradycardia in severe cases)
Breathing	Normal	Normal to fast	Deep
Mental status	Normal	Normal to listless	Apathetic, lethargic, or comatose
Eyes	Normal	Sunken orbits/decreased tears	Deeply sunken orbits/absent tears
Mouth and tongue	Moist	Dry	Parched
Thirst	Normal	Eager to drink	Drinks poorly; too lethargic to drink
Skin fold	Normal	Recoil in <2 seconds	Recoil in >2 seconds
Extremities	Warm, normal capillary refill	Cool, prolonged capillary refill	Cold, mottled, cyanotic, prolonged capillary refill
Urine output	Normal to decreased	Decreased	Minimal
Hydration therapy	None	ORS 50-100 mL/kg over 3-4 hours	Lactated Ringer's solution or normal saline 20 mL/kg over 15-30 minutes IV until mental status or perfusion improves Followed by 5% dextrose/0.45% sodium chloride IV at higher maintenance rates or ORS 100 mL/kg over 4 hours.
Replacement of ongoing losses	For each diarrheal stool or emesis <10 kg body weight: 60-120 mL ORS >10 kg body weight: 120-240 mL ORS	Same as minimal dehydration	If unable to tolerate ORS, administer through nasogastric tube or administer 5% dextrose/0.45% sodium chloride with 20 mEq/L (20 mmol/L) potassium chloride IV

ORS, oral rehydration solution.

[a]Percentages vary among authors for each dehydration category; hemodynamic and perfusion status is most important; when unsure of category, therapy for more severe category is recommended.

Lactated Ringer solution is preferred initially over normal saline because normal saline does not assist in correcting a metabolic acidosis. As GI and renal perfusion should be addressed aggressively, rapid IV administration is preferred over prolonged administration regimens for restoring extracellular fluids and electrolytes.[32] After rehydration, maintenance fluid is given based on accurate recording of intake and output volumes. ORT should be instituted as soon as it can be tolerated.

Early refeeding with age-appropriate unrestricted diet is recommended in children. A meta-analysis of 12 trials showed that early refeeding during or immediately following the start of rehydration did not increase the risk of complications such as unscheduled IV fluids, vomiting, or development of persistent diarrhea compared with late refeeding that ranged from 20 to 48 hours after start of rehydration.[32] Initially, easily digested foods such as bananas, applesauce, and cereal should be introduced and foods high in fiber, sodium, and sugar should be avoided. One caveat would be that lactase deficiency may be exacerbated among known lactase-deficient patients and may persist up to 10 days.

Antimicrobial Therapy

4 The indiscriminate use of antimicrobial therapy produces increases in antimicrobial resistance, side effects of antimicrobial agents, and the threat of superinfections owing to eradication of normal flora. Increasing fluoroquinolone resistance in *Campylobacter* and multidrug resistance in *Salmonella* spp. worldwide reinforces the importance of judicious use of antibiotics and prudent infection control measures.[33,34] Antibiotic therapy is recommended in severe cases of diarrhea, moderate-to-severe cases of traveler's diarrhea, most cases of febrile dysenteric diarrhea, and culture-proven bacterial diarrhea. Antimicrobial therapy is not recommended in EHEC diarrhea as it may increase HUS risk.

Antibiotic therapy is recommended in severe cases of cholera and ETEC diarrhea. In cases of cholera, antibiotics shorten the

TABLE 113-5 Comparison of Common Solutions Used in Oral Rehydration and Maintenance

Product	Na (mEq/L)[b]	K (mEq/L)[b]	Base (mEq/L)	Carbohydrate (mmol/L)	Osmolarity (mOsm/L)

[a]These solutions should be avoided in dehydration.

[b]Concentration of monovalent ions expressed in mEq/L is numerically equivalent to mmol/L concentration.

duration of diarrhea, decrease fluid loss, and shorten the duration of the carrier state.[9] It is important to consider local susceptibility patterns in the selection of the antimicrobial regimen. In areas of high fluoroquinolone resistance, azithromycin has been effective in patients with cholera. In patients with ETEC diarrhea, empiric antibiotics reduce severity and duration of diarrhea. A short course of therapy with fluoroquinolones is the most commonly recommended therapy due to increased resistance among other drug classes.[35] Rifaximin has been effective for ETEC for travel in Mexico.[36] Further discussions of antibiotic prophylaxis and treatment can be found in the section on traveler's diarrhea. Table 113-6 summarizes antibiotic recommendations. Further details regarding treatment of *C. difficile*–associated diarrhea, traveler's diarrhea, and foodborne illnesses are discussed in respective sections.

Antibiotic therapy is indicated in at-risk and febrile patients with dysenteric diarrhea. In shigellosis, antibiotics shorten the period of fecal shedding and attenuate the clinical illness. Antibiotic therapy is reserved for the elderly, those who are immunocompromised, children in daycare centers, malnourished children, and healthcare workers. In the United States, *Shigella* spp., remain susceptible to fluoroquinolones. Fluoroquinolone resistance among *Shigella* spp., is of increasing concern in developing countries, and azithromycin may be a better choice in patients with a recent history of travel to a developing region.[14] Similar antibiotic regimens can be used for high-risk patients who develop *Yersinia* bacteremia (ie, infants younger than 3 months and patients with cirrhosis or iron overload) or in patients with bone and joint infections.[37] With Campylobacteriosis, antibiotics are not useful unless started within 4 days of the start of the illness because they do not shorten the duration or severity of diarrhea and only shorten the duration of bacterial excretion. Antibiotics are warranted in patients with high fevers, severe bloody diarrhea, prolonged illnesses (more than 1 week), pregnancy, and immunocompromised states, including HIV infection. Fluoroquinolone resistance among *Campylobacter* spp., has increased, and is now 10% to 13% in the United States and 41% to 88% in Europe and Asia. Resistance may be the result of the use of fluoroquinolone antibiotics in poultry and other animal feed, and the frequent use of these agents internationally in treating enteric infections. Macrolides such as erythromycin and azithromycin are recommended especially in patients with a recent history of travel to Asia.[35]

Nontyphoid *Salmonella* infection leads to bacteremia in approximately 8% of otherwise healthy adults. However, patients with increased risk of bacteremia should be treated with antibiotics if appropriate diagnosis is made. High-risk patients include neonates or infants younger than 1 year, persons older than 50 years, and patients with primary or secondary immunodeficiency such as acquired immunodeficiency syndrome (AIDS) or chemotherapy-induced inflammatory bowel disease, sickle cell disease, vascular abnormalities (prostatic heart valve or abdominal aneurysm), or prosthetic joints.[14] If cultures are positive for Salmonellosis and antibacterial therapy is warranted, susceptibility testing should be done for appropriate targeted therapy due to concern of resistance.

Outcomes of some bacterial diarrheal illnesses may be worsened by the use of antibacterials, therefore precluding their use. In patients infected with EHEC, use of a fluoroquinolone or

TABLE 113-6 Recommendations for Antibiotic Therapy

Pathogen	Children	Adults
Watery Diarrhea		
Enterotoxigenic *Escherichia coli*	Azithromycin 10 mg/kg/day given orally once daily × 3 days; ceftriaxone 50 mg/kg/day given IV once daily × 3 days	Ciprofloxacin 750 mg orally once daily × 1-3 days. Alternatives: rifaximin 200 mg orally three times daily × 3 days; azithromycin 1,000 mg orally × 1 day *or* 500 mg orally daily × 3 days
Vibrio cholerae O1	Erythromycin 30 mg/kg/day divided every 8 hours orally × 3 days; azithromycin 10 mg/kg/day given orally once daily × 3 days	Doxycycline 300 mg orally × 1 day Alternatives: tetracycline 500 mg orally four times daily × 3 days; erythromycin 250 mg orally every 8 hours × 3 days; azithromycin 500 mg orally once daily × 3 days
Dysenteric Diarrhea		
Campylobacter species[a]	Azithromycin 10 mg/kg/day given orally once daily × 3-5 days; erythromycin 30 mg/kg/day divided into two to four doses orally × 3-5 days	Azithromycin 500 mg orally once daily × 3 days; erythromycin 500 mg orally every 6 hours × 3 days
Salmonella Nontyphoidal[a]	Ceftriaxone 100 mg/kg/day divided IV every 12 hours × 7-10 days; azithromycin 20 mg/kg/day orally once daily × 7 days	Ciprofloxacin 750 mg orally once daily × 7-10 days; levofloxacin 500 mg orally once daily × 7-10 days Alternatives: azithromycin 500 mg orally once daily × 7 days For immunocompromised patients, duration should be increased to 14 days for both fluoroquinolones and azithromycin
Shigella species[a]	Azithromycin 10 mg/kg/day given orally once daily × 3 days; ceftriaxone 50 mg/kg/day given IV once daily × 3 days	Ciprofloxacin 750 mg orally once daily × 3 days; levofloxacin 500 mg orally once daily × 3 days Alternatives: azithromycin 500 mg orally once daily × 3 days
Yersinia species[a]	Treat as shigellosis	Treat as shigellosis
***Clostridium difficile*-Associated Diarrhea**		
Clostridium difficile	Metronidazole 7.5 mg/kg (maximum: 500 mg) orally or IV every 8 hours × 10-14 days; vancomycin 10 mg/kg (maximum: 125 mg) orally every 6 hours × 10-14 days	Mild to moderate disease: metronidazole 500 mg orally or IV every 8 hours daily × 10-14 days Severe disease: vancomycin 125 mg orally every 6 hours × 10-14 days Alternatives: fidaxomicin 200 mg orally every 12 hours × 10-14 days
Traveler's Diarrhea		
Prophylaxis[a]		Norfloxacin 400 mg or ciprofloxacin 750 mg orally daily; rifaximin 200 mg one to three times daily up to 2 weeks
Treatment		Ciprofloxacin 750 mg orally × 1 day or 500 mg orally every 12 hours × 3 days; levofloxacin 1,000 mg orally × 1 day or 500 mg orally daily × 3 days; rifaximin 200 mg three times daily × 3 days; azithromycin 1,000 mg orally × 1 day or 500 mg orally daily × 3 days

[a]For high-risk patients only. See the preceding text for the high-risk patients in each infection.

trimethoprim–sulfamethoxazole may increase the risk of HUS by increasing the production of Shiga-like toxin.[37] Empiric antimicrobial therapy should be withheld when clinical suspicion is high due to the high local prevalence EHEC, patient clinical presentation suggestive of EHEC infection, or a known foodborne outbreak of dysentery with an incubation period of longer than 2 days. Antibiotics should not be given to infants or children due to a higher incidence of HUS in this population. Treatment of EHEC infection is primarily limited to supportive care, which may include fluid replacement therapy, hemodialysis, hemofiltration, transfusion red blood cells and/or platelets, and other interventions as indicated clinically. Severe disease may lead to chronic kidney failure and potential need of renal transplantation.

Antimotility Agents

5 Antimotility drugs such as diphenoxylate/atropine and loperamide offer symptomatic relief in patients with watery diarrhea by reducing the number of stools. However, in both enterotoxigenic and dysenteric diarrhea, slowing of fecal transit time with these agents is thought to result in extended toxin-associated damage, worsening symptomatology and leads to complications. Therefore, antimotility drugs should be avoided if possible and are not recommended in patients with toxin-mediated dysenteric diarrhea (ie, EHEC, pseudomembranous colitis, shigellosis). However, some evidence suggests that in adults with dysenteric diarrhea these agents do not appear to be harmful if given concomitantly with antibacterial therapy.[37]

Clinical **Controversy...**

Diphenoxylate/atropine and loperamide slow gastric motility and can prolong exposure to enterotoxins in watery and toxin-mediated dysentery diarrheas. Caution is warranted with use of these agents in infectious diarrhea and further, these agents should not be administered to patients with dysenteric symptomatology.

Probiotics

Probiotics are preparations of microorganisms and most commercial products have been derived from food sources, particularly cultured milk products (ie, lactobacilli and bifidobacteria). When used in the treatment or prophylaxis of infectious diarrhea and antibiotic-associated diarrhea, efficacy is variable. Most individual studies have not shown significant benefit from the use of probiotics and meta-analyses have shown conflicting results, with one demonstrating efficacy when trials were assessed in aggregate[38] and another demonstrating no benefit.[39] No serious adverse effects have been reported in otherwise healthy persons, however, there are data suggesting a rare but increased incidence of fungemia or bacterial sepsis with probiotic use. With these potential adverse events and limited efficacy data, probiotics should not be recommended for prophylaxis or treatment of initial antibiotic-associated diarrhea.

Oral Zinc Supplementation

Zinc deficiency is largely due to inadequate dietary intake and is common in many developing countries where morbidity and mortality associated with acute diarrhea in children remains high. In children older than 6 months who demonstrate moderate signs of malnutrition, zinc supplementation may shorten the duration of diarrhea by approximately 27 hours (95% CI –14.62 to –39.34).[40] Therefore, oral zinc supplementation of 20 mg/day for 1 to 2 weeks may have an additional benefit over ORS alone in reducing childhood mortality in developing countries. Common side effects include metallic taste and vomiting. At high doses, zinc supplementation may cause epigastric pain, lethargy, and fatigue.

PREVENTION OF GASTROINTESTINAL INFECTIONS

6 Public health measures of improved water supply and sanitation facilities and the quality control of commercial products are important for the control of the majority of GI infections. In addition, following simple rules of personal hygiene and safe food preparation can prevent many diarrheal diseases. Hand washing with soap and running water is instrumental in preventing the spread of illness and should be emphasized for caregivers and persons with diarrheal illnesses. Safe food handling and preparation practices can significantly decrease the incidence of certain enteric infections.

Reporting suspected outbreaks and cases of notifiable illness to local health authorities is vital to investigation of threats of enteric infection arising from increasingly global and industrialized food supplies. The reporting of specific infectious diseases to the appropriate public health authorities is the cornerstone of public health surveillance, outbreak detection, and prevention and control efforts.

Vaccines are used to boost specific immune processes directed against the bacteria themselves or against adherence appendages, cytotoxins, or enterotoxins. Unfortunately, there are only a few vaccines available for prevention of gastroenteritis. Vaccines for typhoid fever are the parenteral Vi capsular polysaccharide vaccine (ViCPS) and the oral live-attenuated Ty21a vaccine.[41] Efficacy rates for both vaccines range from 50% to 80%. The ViCPS is indicated for children who are 2 years or older a booster dose is administered 2 years later. The Ty21a vaccine is indicated for children 6 years or older; one capsule should be swallowed whole every other day for a total of four doses at least 1 week before the potential exposure. A booster should be taken every 5 years if continued protection is needed.

In the United States, routine rotavirus vaccination is recommended for all infants beginning at age 2 months. There are two vaccines, RotaTeq (RV5) and Rotarix (RV1), available for reducing rotaviral gastroenteritis.[42] The RV5 vaccine is a live, oral vaccine that offers 74% efficacy against gastroenteritis of any severity and 98% efficacy against severe disease. This vaccine also decreased office visits by 86%, emergency department visits by 94%, and hospitalizations by 96%. The RV1 vaccine is a live-attenuated human rotavirus vaccine. This vaccine has clinical efficacy of 79% against gastroenteritis of any severity and 96% efficacy against severe rotavirus disease. Rotarix reduced hospitalizations by 100% and medically attended visits by 92% in the first rotavirus season, and reduced hospitalizations by 96% through two seasons.[42] The RV5 vaccine is administered orally in a three-dose series at ages 2, 4, and 6 months while the RV1 vaccine is administered orally in a two-dose series at ages 2 and 4 months. The first dose may be given between 6 weeks and 14 weeks and 6 days of age and all doses should be given before 8 months of age. The vaccines are contraindicated in infants with severe allergic reactions to vaccine components, diagnosed with severe combined immunodeficiency, and with history of intussusception.[43]

Although not available in the United States, two oral vaccines against diarrheal pathogens are available in other countries. Dukoral consists of killed *V. cholerae* O1 organisms and the cholera B subunit, and is licensed in over 60 countries. Shanchol consists of killed whole cells from a mix of pathogenic strains of *V. cholerae* (O1 and O139) and is licensed in India.[9] Both vaccines are given in two doses (three doses of Dukoral are required for children aged 2-5 years) and administered about 7 to 14 days apart (up to 42 days apart for Dukoral). Dukoral must be administered with a buffer that requires 75 to 150 mL of clean water while Shanchol does not require the buffer. Both vaccines demonstrated protective efficacy of 47% to 87% after two doses but almost none after a single dose. Protection is achieved in approximately 1 week following the last dose and persists for approximately 2 years. The common side effects of the

vaccines were considered mild and included abdominal pain, headache, fever, and nausea. The WHO does not require vaccination for international travel to or from endemic areas because vaccines require two doses and provide incomplete protection for a relatively short period of time.

There are vaccines in development for common enteric pathogens including ETEC and *Shigella* spp., with the potential for combining them in a single vaccine. These are still in preliminary and animal-based studies, but could significantly affect global public health if they come to fruition for human administration, especially in the infants and children.[44]

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate follow-up care of patients with acute diarrhea is based on successful restoration of fluid losses. The clinical signs and symptoms that lead to the diagnosis also can assess adequate rehydration, and should be monitored frequently. With ORT preferred, routine laboratory testing often is unnecessary. Electrolytes should be measured in those receiving IV fluids, when oral replacement fails, or when signs of hypernatremia or hypokalemia are present. Follow-up stool samples to ensure complete evacuation of the infecting pathogen may be necessary only in patients who are at high risk to initiate or contribute to a community outbreak. All patients should be monitored for complications associated with the infecting pathogen, resolution of the diarrhea, and adverse reactions to the pharmacologic agents used. Prompt discharge of hospitalized patients is recommended when rehydration is achieved, IV fluids have not been required, oral intake equals or exceeds losses, or adequate education and medical follow-up are ensured. For most patients, discharge can occur in 16 to 24 hours.

CLOSTRIDIUM DIFFICILE

Epidemiology

C. difficile is the most commonly recognized cause of infectious diarrhea in healthcare settings with high rates of disease in long-term care facilities and in the elderly. CDI is associated with use of broad-spectrum antimicrobials and accounts for approximately 20% to 30% of all cases of antibiotic-associated diarrhea.[45] The antibiotics most commonly associated with CDI include clindamycin, ampicillin, cephalosporins, and fluoroquinolones. Other agents that have been implicated, albeit at a lower incidence rate, include aminoglycosides, macrolides, trimethoprim-sulfamethoxazole, vancomycin, and metronidazole. CDI often occurs during or shortly after completion of antimicrobial therapy, however, disease onset can be delayed for 2 or more months.[46] Those at high risk for CDI include the elderly or debilitated, patients undergoing surgery or nasogastric intubation, those with cancer, and those receiving antibiotics, proton pump inhibitors (PPIs), or frequent laxatives. A meta-analysis of 23 studies (~300,000 patients) suggests that PPIs increase the incidence of CDI by 65%.[47,48]

Clinical **Controversy...**

Decreasing gastric acid has been suggested as the mechanism by which PPIs may allow for *C. difficile* toxins to proliferate. This relationship has been observed in both chronic PPI users, as well as inpatients on PPIs for stress ulcer prophylaxis. PPIs have been successful in reducing ICU-related upper GI hemorrhage; however, PPI use has been identified as an independent risk factor for CDI.

Attributable mortality from CDI has been steadily increasing over the past 2 decades and has been reported as high as 38%, with many studies demonstrating a mortality rate of 15% or greater.[49] Increased mortality is thought to be due to the emergence of a hypervirulent strain, North American pulsed-field type [NAP-1], which carries a gene mutation producing higher concentrations of toxin, and responsible for more serious disease.[50] The NAP-1 strain has been associated with fluoroquinolone use, and may be refractory to standard antibiotic therapy.

Pathogenesis

C. difficile is a gram-positive spore-forming anaerobic bacillus and causes a toxin-mediated disease. Once antibiotics disrupt normal colonic flora and colonization of *C. difficile* occurs, two toxins (A and B) are released to mediate diarrhea and colitis. Toxin production is essential for disease manifestation. Toxin A is the major pathogenic factor and has been characterized as an enterotoxin that causes intestinal fluid secretion, mucosal injury, and inflammation through actin disaggregation, intracellular calcium release, and damage to neurons. Toxin B is a nonenterotoxic cytotoxin that causes depolymerization of filamentous actin and mediates more potent damage to human colonic mucosa than toxin A. Initially, raised white and yellowish plaques form in the colon, and the surrounding mucosa may be inflamed. With progression of disease, pseudomembranous plaques become enlarged and scatted over the colorectal mucosa.[46]

Clinical Presentation

Clinical diagnosis is based on the onset of diarrhea, defined as 3 unformed stools in 24 hours, during or after antimicrobial use, and often associated with abdominal discomfort, fever, and polymorphonuclear leukocytosis. The spectrum of disease ranges from mild diarrhea to life-threatening toxic megacolon and pseudomembranous entercolitis.[45,46] In colitis without pseudomembrane formation, patients present with malaise, abdominal pain, nausea, anorexia, watery diarrhea, low-grade fever, and leukocytosis. Fulminant disease is characterized by severe abdominal pain, perfuse diarrhea, high fever, marked leukocytosis, and classic pseudomembrane formation evident with sigmoidoscopic examination.

CDI should be suspected in patients experiencing diarrhea with a recent history of antibiotic use (within the previous 3 months) or in those whose diarrhea began 72 hours after hospitalization. Diagnosis can be established by detection of toxin A or B in the stool, stool culture for *C. difficile*, or endoscopy. The most common methods of laboratory diagnosis includes cytotoxin assay, enzyme-linked immunosorbent assay (ELISA), and molecular methods such as polymerase chain reaction (PCR) testing. The cytotoxin assay was the traditional gold standard, however, today its use is limited due to its long time to test completion (1-3 days) and high cost. ELISA tests are easy to perform and provide rapid results within hours, but have a low sensitivity leading to the possibility of false-negative results. PCR is quickly becoming the test of choice in the United States due to its high sensitivity and specificity coupled with a quick turnaround time of less than 2 hours.[50] Endoscopy should be reserved for situations where rapid diagnosis is needed, ileus is present, stool is not available, or other colonic diseases are in the differential diagnosis. Many hospitalized patients may be colonized with *C. difficile*, so a careful history should be taken and routine screening is not recommended.[45]

TREATMENT

Supportive care of CDI includes fluid and electrolyte replacement therapy, in addition to discontinuation of the offending antimicrobial if possible. Antibiotic therapy is based on disease severity and may

TABLE 113-7 *Clostridium difficile* Infection Severity and Treatment[45,51]

Severity	Markers of Disease Severity	Recommended Treatment
Mild to moderate	WBC ≤15,000 cells/mm^3 (15×10^9/L) SCr <1.5 × premorbid level	Metronidazole 500 mg orally every 8 hours for 10-14 days
Severe	WBC >15,000 cells/mm^3 (15×10^9/L) SCr >1.5 × premorbid level Temperature >38.3°C Albumin <2.5 g/dL (25 g/L) Age ≥60 Pseudomembranes present ICU admission	Vancomycin 125 mg orally every 6 hours for 10-14 days
Severe, complicated	Hypotension or shock Ileus and/or megacolon Organ failure Coagulopathy	Metronidazole 500 mg IV every 8 hours *PLUS* vancomycin 500 mg every 6 hours via NG or orally (if ileus present use rectally)

NG, nasogastric; SCr, serum creatinine; WBC, white blood cell.

vary for first episode or recurrent infection.[45,51] Table 113-7 outlines CDI disease severity and treatment regimens for initial episodes.

7 Once determination of disease severity has been made, treatment should be initiated with an antibiotic effective against *C. difficile*. In the United States, metronidazole, vancomycin, and fidaxomicin are the most commonly prescribed agents.[52] Treatment courses are typically 10 to 14 days and repeat stool testing is not recommended as a test of cure.[44] Metronidazole is the drug of choice for mild to moderate CDI because its oral formation is less expensive than vancomycin or fidaxomicin, and there are concerns for vancomycin resistant-enterococci with oral vancomycin use.[51] In patients with severe disease, contraindication or intolerance to metronidazole, and inadequate response to metronidazole, oral vancomycin or fidaxomicin is recommended. Vancomycin must be administered orally because IV vancomycin does not achieve adequate gut lumen concentrations for effective bacterial elimination. Due to cost, many institutions choose to use the injectable form of vancomycin to prepare an oral formulation. Fidaxomicin is a macrocyclic antibiotic (200 mg administered orally twice daily) that has minimal bioavailability, and is bacteriostatic against *C. difficile*. Fidaxomicin was approved by the FDA after the current Infectious Diseases Society of America (IDSA)/Society for Healthcare Epidemiology of America (SHEA) guidelines were published; thus its place in therapy remains unclear. When vancomycin has been compared to fidaxomicin, the rate of initial cure was not significantly different between treatment groups; however, fidaxomicin demonstrated a significant improvement in recurrence.[53]

In patients with severe or complicated CDI, practice guidelines suggest combination therapy with IV metronidazole and vancomycin. The route of vancomycin administration is patient-dependent; oral is preferred, but if ileus is present, rectal administration via retention enema is suggested. This recommendation for combination therapy was based on expert opinion and has been supported by a small retrospective study of 88 patients, but further studies are suggested to define optimal regimens and dosing.[54]

Recurrence of CDI occurs in approximately 25% of cases within 30 days and the risk doubles after two or more recurrences.[55] Risk factors for recurrent CDI include a history of recurrence, emergency hospital admission, previous GI hospital admission, recent (within 4-12 weeks) hospitalization, increasing age, use of additional antimicrobials, and an inadequate protective immune response to *C. difficile* toxins.[56] Management of the first relapse is identical to a primary episode because relapse is rarely due to resistance to the initial agent of treatment. Instead, relapse occurs because treatment fails to eradicate the spore forms of the pathogen, or treatment leads to opportunistic infection. Fidaxomicin inhibits *C. difficile* spore production. Clinical trials have demonstrated fewer episodes of recurrence with fidaxomicin treatment compared to vancomycin.[54,57]

The optimal management of patients with multiple relapses is not clear. A prolonged tapered and pulse-dosing of oral vancomycin has been suggested for second episodes of relapse.[58] Other regimens that have shown efficacy include stepped therapy with vancomycin followed by rifaximin.[59] Alternative treatments effective against CDI include intravenous immunoglobulin (IVIG) and fecal microbiota transplantation (FMT). Individuals with low concentration of circulating IgG antitoxin are susceptible to more severe disease and frequent relapses. IVIG has been investigated in patients with intractable, recurrent CDI, and while case reports suggest promising results, high cost may preclude its use.[60] Initial methods of FMT involved preparing a small amount of fresh feces from a healthy donor suspended in saline, filtering the suspension and administering through a nasogastric tube or by retention enema. Data from case series show that FMT is efficacious; however, many practitioners are reluctant to offer this therapy to patients. Administering frozen, prepared capsules of FMT from healthy volunteers is safe and effective in treating CDI, resulting in a 90% resolution rate.[61] The FDA states that FMT should only be used in patients with recurrent CDI who have signed consents and if donor stool has been tested for transmittable diseases.

Agents in clinical trials for treatment or prevention of CDI include new antibiotics, monoclonal antibodies, and *C. difficile* toxoid vaccines.[55] Rifampin, bacitracin, and fusidic acid have lost favor in the treatment of CDI. Concerns with these regimens include drug interactions, development of resistance, and a potential increase in mortality with rifampin observed in several studies.[52] Anion exchange resins such as cholestyramine and colestipol have been used to treat CDI; however, they bind vancomycin and are no longer recommended. Drugs that inhibit peristalsis, such as diphenoxylate/atropine and loperamide, are contraindicated in CDI.[46] Slowing of fecal transit time is thought to result in extended toxin-associated damage.

Prevention of CDI involves both preventing the acquisition of the infection and stopping transmission of *C. difficile* and its spores to other patients. CDI has become the focus of antimicrobial stewardship efforts aimed at eliminating unnecessary antibiotics and reducing durations of therapy. The use of probiotics to prevent CDI has been studied in adults and children. While some studies and meta-analyses have shown no benefit, some evidence supports probiotic safety and efficacy in preventing CDI.[55] Hand washing and contact precautions are imperative measures in preventing the spread of the organism. Alcohol-based hand gels are ineffective against *C. difficile* spores; use of soap and water is recommended to prevent disease transmission. Proper environmental disinfecting measures in healthcare settings include use of chloride-containing cleaning agents or other sporicidial agents.[45]

TRAVELER'S DIARRHEA

Traveler's diarrhea describes the clinical syndrome manifested by malaise, anorexia, and abdominal cramps followed by the sudden onset of diarrhea that incapacitates many travelers. It interferes with planned activities or work in 30% of those affected. In particular, an increased risk lies with North Americans and Northern Europeans traveling to Latin America, southern Europe, Africa, and Asia. The highest risk is observed with patients with immunocompromised conditions, achlorhydria, inflammatory bowel disease, and people with chronic debilitating medical conditions. Overall, 20% to 50% of people traveling to high-risk areas will develop the illness.[35]

8 The onset of symptoms usually occurs during the first week of travel but can occur anytime during the visit or after returning home.

Traveler's diarrhea is caused by contaminated food or water. The most common pathogens are bacterial and include ETEC (20%-72%), *Shigella* spp., (3%-25%), *Campylobacter* spp., (3%-17%), and *Salmonella* spp., (3%-7%).[8] Viral causes could occur in up to 30% of cases. Parasitic etiologies are rare during short-term travels, accounting for less than 5% of cases of traveler's diarrhea. Enterotoxigenic *E. coli* is predominantly pathogenic in Latin America, Africa, and South Asia. The invasive enteric pathogens (*Campylobacter* spp., *Salmonella* spp., and *Shigella* spp.) are more important causes of traveler's diarrhea in Asia.

The severity of the syndrome is determined by the number of stools per day and the presence of cramping, nausea, and vomiting. Mild diarrhea is defined as 1 to 3 loose stools per day that are associated with abdominal cramps lasting less than 14 days. Moderate diarrhea indicates more than 4 loose stools daily associated with dehydration, and severe diarrhea is defined as the presence of blood in stools or a fever. Traveler's diarrhea is rarely life-threatening and in most cases, symptoms resolve in several days without treatment. Travelers to high-risk areas should pack a kit that includes a thermometer, loperamide, antibiotics (3-day course) (see "Treatment" section below), ORS salts, and a water purification method.[35]

Prevention

9 Patient education in avoiding high-risk food and beverages should be the best method for minimizing the risk. High-risk foods and beverages include raw or undercooked meat and seafood, moist foods served at room temperature, fruits that cannot be peeled, vegetables, milk from a questionable source, hot sauces on the table, tap water, unsealed bottled water, iced drinks, and food from street vendors. Although education is readily available, a meta-analysis concluded that the incidence of diarrhea was similar in travelers who followed advice and those who engaged in riskier eating habits.[62] Rationales for this include that cooking foods does not always kill pathogens and food should not be considered safe unless it is cooked until steaming hot. Nonetheless, advisement of avoidance measures regarding safe foods, beverages, and eating establishments is recommended to heighten awareness.

Bismuth subsalicylate 524 mg (2 tablets or 2 tablespoonfuls) orally four times daily for up to 3 weeks is a commonly recommended prophylactic regimen.[35] Bismuth subsalicylate may inhibit enterotoxin activity and prevent diarrhea. Persons taking this regimen should be informed of adverse events, including temporary black discoloration of tongue and stools, and, rarely, tinnitus.

Although the efficacy of prophylactic antibiotics has been documented, their use is not recommended for most travelers due to the potential side effects of antibiotics (eg, photosensitivity), predisposition to other infections such as CDI or vaginal candidiasis, the increased risk of selection of drug-resistant organisms, cost, lack of data on the safety and efficacy of antibiotics given for more than 2 or 3 weeks, and availability of rapidly effective antibiotics for treatment. Prophylactic antibiotics are recommended only in high-risk individuals or in situations in which short-term illness could ruin the purpose of the trip, such as a military mission. A fluoroquinolone is the drug of choice when traveling to most areas of the world.[35] Due to fluoroquinolone resistance among *Campylobacter* spp., azithromycin can be considered when traveling to South and Southeast Asia.

Rifaximin is a nonabsorbed oral rifamycin that has activity against enteric pathogens and may have a role in the prevention of traveler's diarrhea in select populations. A randomized, double-blind trial of rifaximin 200 mg once, twice, or three times daily with meals for 2 weeks resulted in equal protection of 72% for each of the three dosing regimens compared with placebo.[36] Since rifaximin is effective against traveler's diarrhea due to noninvasive strains of *E. coli*, this agent should be reserved for travel regions where *E. coli* predominates, such as Latin America and Africa. Rifaximin has a tolerability and safety profile comparable to that of placebo. The concern with the class rifamycin is the emergence of resistance when used as monotherapy.

TREATMENT

The goals of treatment are to avoid dehydration, reduce the severity and duration of symptoms, and prevent interruption of planned activities. Fluid and electrolyte replacement should be initiated at the onset of diarrhea. ORT is generally not required in otherwise healthy individuals; flavored mineral water offers a good source of sodium and glucose. In infants and young children, elderly, and those with chronic debilitating medical conditions, ORT is recommended. For symptom relief, loperamide is preferred because of its quicker onset and longer duration of relief relative to bismuth. Standard dosing of loperamide is 4 mg orally initially and then 2 mg with each subsequent loose stool to a maximum of 16 mg/day in patients without bloody diarrhea and fever. Loperamide should be discontinued if symptoms persist for more than 48 hours. Other symptomatic therapy in mild diarrhea includes bismuth subsalicylate 524 mg every 30 minutes for up to eight doses.[35] As previously discussed, there is insufficient evidence to warrant the recommendation of probiotics.

Since behavioral modification has limited efficacy and chemoprophylaxis is not recommended in most travelers, the current recommendation relies on self-treatment. A single dose of antibiotic and up to 3 days of treatment will improve the condition within 24 to 36 hours, shortening the duration of diarrhea by 1 to 2 days.[35] A single dose of fluoroquinolone is recommended initially and if diarrhea is improved within 12 to 24 hours, antibiotics should be discontinued. Otherwise, it can be continued for up to 3 days. A fluoroquinolone is recommended when traveling to most areas of the world. Where fluoroquinolone-resistant *Campylobacter* is common, such as in South and Southeast Asia, azithromycin should be used.[35] Azithromycin can also be used in pregnant women and children younger than age 16 years. Empiric treatment of young children should be instituted with caution.

Rifaximin was as effective as a 3-day course of ciprofloxacin in shortening the duration of diarrhea in noninvasive traveler's diarrhea. However, rifaximin was not as effective in patients with fever and bloody diarrhea and in those with invasive pathogens. Therefore, a 3-day course of rifaximin has been approved for the treatment of traveler's diarrhea caused by noninvasive strains of *E. coli* in people 12 years or older and can be considered when traveling to areas where *E. coli*–associated traveler's diarrhea is common, such as Mexico and Jamaica.[35]

For rapid improvement in symptoms, antibiotic therapy with adjunctive treatment with loperamide has shown benefit.[63] All clinical trials concluded that the combination therapy was safe, and the worsening of the disease with the use of antimotility treatment has not been encountered.

Clinical **Controversy...**

Prevention strategies are the most important measure for traveler's diarrhea. Although rifaximin is indicated for some traveler's diarrhea associated with ETEC, its cost and availability versus fluoroquinolones and macrolides may make it a nonpreferred choice.

FOOD POISONING

10 Foodborne illnesses result from the ingestion of food containing pathogenic microorganisms that cause GI infections or preformed toxins that were produced by microorganisms that cause enterotoxigenic poisonings. In the United States, foodborne diseases cause approximately 76 million illnesses, 325,000 hospitalizations, and 5,200 deaths each year.[4] Foodborne transmission may account

for up to 80% of acute gastroenteritis. However, the incidence and outbreaks of foodborne illness has declined in recent years.[64] Common enteric pathogens responsible for foodborne diseases have been discussed in the previous sections (*Campylobacter* spp., *E. coli*, norovirus, nontyphoidal *Salmonella*, *Shigella*). Common foodborne pathogens that cause enterotoxigenic poisonings include *Bacillus cereus*, *Clostridium botulinum, Clostridium perfringens*, and *Staphylococcus aureus*. Characteristics of pathogens responsible for foodborne illnesses are summarized in Table 113-8.

Because foodborne disease can appear as sporadic cases or outbreaks, the diagnosis should be suspected whenever two or more people present with acute GI or neurologic manifestations after sharing a meal within the previous 72 hours. Important clues about etiologic agents can be gathered from demographic information (age, gender, etc.), the clinical syndrome, incubation period, and medical history, type of foods consumed, seasonality, and geographic location of the outbreak.

Enterotoxigenic poisonings result from ingestion of food contaminated by preformed toxins. Therefore, symptoms are rapid in onset, but most cases of food poisoning are of short duration with recovery occurring within 1 to 2 days. *B. cereus* causes two different types of clinical syndromes. The first one is characterized by a short incubation period and vomiting. The second syndrome has a longer incubation period and is characterized by diarrhea. Foodborne *C. perfringens* infection may present as two distinct syndromes. Type A organisms are seen in Western Hemisphere nations and result in a 24-hour illness characterized by watery diarrhea and epigastric pain. Type C organisms can be found in undercooked pork and occur in underdeveloped tropical regions. They can produce a toxin-related syndrome called *enteritis necroticans*, which is a coagulative transmural necrosis of the intestinal wall.[65] This syndrome can result in intestinal perforation leading to sepsis and mortality in approximately 40% of victims.

Foodborne botulism results from the ingestion of food contaminated with preformed toxins or toxin-producing spores from *C. botulinum*. *C. botulinum* poisoning is rare; only 110 cases are reported per year in the United States.[65] Botulism is almost always associated with improper preparation or storage of food. Seven distinct toxins (A to G) have been described. The toxins prevent the release of acetylcholine at the peripheral cholinergic nerve terminal. Toxin activity has prompted the use of minute locally injected doses to treat select spastic disorders, such as blepharospasm, hemifacial spasm, and certain dystonias. Foodborne botulism is suspected when patients present with acute GI symptoms concurrently or just prior to the onset of a symmetric descending paralysis without sensory or central nervous system involvement. Diagnosis is made by culturing *C. botulinum* from the stool. The clinical presentation may resemble GBS associated with *C. jejuni* infection. The difference lies in the onset of neurologic symptoms, which typically occur 1 to 3 weeks after the onset of *C. jejuni* infection, and the condition usually is manifested by an ascending paralysis in *C. jejuni*–associated GBS.

Treatment consists primarily of respiratory support and use of botulinum antitoxin.[66] If evaluation is performed within several hours of ingestion, gastric lavage or induction of vomiting is suggested.

TABLE 113-8 Food Poisonings

Organism	Principal Foods	Peak Incidence (United States)	Time to Symptoms	Duration	Common Symptoms
Enterotoxigenic Poisonings					
Bacillus cereus	Fried rice, dairy products, spices, bean sprouts, vegetables	None	1-6 hours 6-24 hours	1 day 1 day	Nausea, vomiting Diarrhea
Clostridium botulinum	Home-canned fruits, vegetables, meats, honey	None	18-36 hours		Double vision, blurred vision, drooping eyelids, slurred speech, difficulty swallowing, dry mouth, and muscle weakness
Clostridium perfringens (type A)	Meats, poultry, gravies, dried or precooked foods	Fall, winter, spring	8-12 hours	1 day	Abdominal cramps, diarrhea
Staphylococcus aureus	Salad, pastries, ham, sandwiches, puddings, unpasteurized milk, cheese products	Summer	1-6 hours	1 day	Nausea, vomiting, abdominal cramps, diarrhea
GI Infections					
Campylobacter spp.	Poultry, dairy products, clams, water	Spring, summer	2-5 days	7 days	Diarrhea (may be bloody), cramping, abdominal pain, fever
Enteropathogenic *E. coli*	Water	None	1-3 days	5-7 days	Severe diarrhea, vomiting, dehydration
Enterotoxigenic *E. coli*	Water, ice, food	None	1-3 days	3-4 days	Profuse watery diarrhea, abdominal cramping
Salmonella spp.	Beef, poultry, water, eggs, dairy products	Summer	12-72 hours	4-7 days	Diarrhea (sometimes bloody), fever, abdominal cramps
Shigella spp.	Salad, water	Summer	1-2 days	5-7 days	Diarrhea (often bloody), fever, abdominal cramps
Vibrio cholerae	Water	None	2 hours to 5 days	2-3 days	Profuse watery diarrhea, vomiting, leg cramps
Vibrio parahemolyticus	Shellfish (oysters)	Spring, summer, fall	24 hours	3 days	Watery diarrhea, abdominal cramping, nausea, vomiting, fever, chills
Yersinia enterocolitica	Dairy products, raw or undercooked pork products	None	4-7 days	1-3 weeks	Fever, abdominal pain, diarrhea (often bloody)

Cathartics and enemas also can be used to remove residual toxin from the bowel, but they are contraindicated in cases of ileus. Botulinum antitoxin is a concentrated preparation of equine globulins obtained from horses immunized with toxins A, B, and E. Because trivalent antitoxin is equine in origin, patients should be tested for hypersensitivity before receiving the product intravenously. Newer and more effective methods of treatment and prevention are under development, including a botulinum toxin vaccine consisting of nontoxic botulinum fragments. Prevention always should be stressed. Botulinum toxins are heat labile and readily destroyed by 10 minutes of boiling. All home-canned foods should be processed according to directions and boiled, not just warmed, prior to consumption.

In foodborne illnesses, the cornerstone of therapy remains supportive care. ORT is preferred in replenishing and maintaining fluid and electrolyte balance, and IV fluid therapy should be reserved for those who are severely ill and cannot tolerate oral therapy. Antiemetics and antimotility agents offer symptomatic relief, but the latter should not be given in patients who present with high fever, bloody diarrhea, or fecal leukocytes. Antimicrobial therapy is not effective in the management of *S. aureus*, *C. perfringens*, or *B. cereus* food poisonings. In developed countries, many of the foodborne illnesses can be prevented with proper food selection, preparation, and storage. However, in developing countries, sanitation and clean water supply are larger concerns.

ABBREVIATIONS

AIDS	acquired immunodeficiency syndrome
cAMP	cyclic adenosine monophosphate

114 Intra-Abdominal Infections

Alan E. Gross, Keith M. Olsen and Joseph T. DiPiro

KEY CONCEPTS

1. Most intra-abdominal infections are "secondary" infections that are polymicrobial and are caused by a defect in the gastrointestinal (GI) tract that must be treated by surgical drainage, resection, and/or repair.
2. Primary peritonitis is generally caused by a single organism (*Staphylococcus aureus* in patients undergoing chronic ambulatory peritoneal dialysis [CAPD] or *Escherichia coli* in patients with cirrhosis).
3. Secondary intra-abdominal infections are usually caused by a mixture of bacteria, including enteric Gram-negative bacilli and anaerobes, which enhance the pathogenic potential of the bacteria.
4. For peritonitis, early and aggressive IV fluid resuscitation and electrolyte replacement therapy are essential. A common cause of early death is hypovolemic shock caused by inadequate intravascular volume and tissue perfusion.
5. Treatment is generally initiated on a "presumptive" or empirical basis and should be based on the likely pathogen(s) and local resistance patterns.
6. Antimicrobial regimens for secondary intra-abdominal infections should include coverage for enteric Gram-negative bacilli and anaerobes. Antimicrobials that may be used for the treatment of secondary intra-abdominal infections depending on severity of illness and microbiology data include (a) third-generation cephalosporin (ceftriaxone) with metronidazole, (b) piperacillin–tazobactam, (c) a carbapenem (imipenem, meropenem, doripenem, and ertapenem), and (d) quinolone (levofloxacin or ciprofloxacin) plus metronidazole or moxifloxacin alone.
7. Treatment of patients with peritoneal dialysis-associated peritonitis should include an antistaphylococcal antimicrobial such as a first-generation cephalosporin (cefazolin) or vancomycin (intraperitoneal administration is preferred).
8. The duration of antimicrobial treatment should be for 4 days after source control for most secondary intra-abdominal infections.
9. Patients treated for intra-abdominal infections should be assessed for the occurrence of drug-related adverse effects, particularly hypersensitivity reactions (β-lactam antimicrobials), diarrhea (most agents), fungal infections (most agents), and nephrotoxicity (aminoglycosides).

Intra-abdominal infections are those contained within the peritoneal cavity or retroperitoneal space. The peritoneal cavity extends from the undersurface of the diaphragm to the floor of the pelvis and contains the stomach, small bowel, large bowel, liver, gallbladder, and spleen. The duodenum, pancreas, kidneys, adrenal glands, great vessels (aorta and vena cava), and most mesenteric vascular structures reside in the retroperitoneum. Intra-abdominal infections may be generalized or localized, complicated or uncomplicated, and community or healthcare-associated. Uncomplicated intra-abdominal infections are confined within visceral structures, such as the liver, gallbladder, spleen, pancreas, kidney, or female reproductive organs while complicated intra-abdominal infections involve anatomical disruption, extend beyond a single organ, and yield peritonitis and/or abscess. *Peritonitis* is defined as the acute inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign-body injury. This chapter deals only with peritonitis of infectious origin.

An *abscess* is a purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells. These processes differ considerably in presentation and approach to treatment.

EPIDEMIOLOGY

Peritonitis may be classified as primary, secondary, or tertiary.[1-5] Primary peritonitis, also called *spontaneous bacterial peritonitis*, is an infection of the peritoneal cavity without an evident source in the abdomen.[6] Bacteria may be transported from the bloodstream to the peritoneal cavity, where the inflammatory process begins. In secondary peritonitis, a focal disease process is evident within the abdomen. Secondary peritonitis may involve perforation of the gastrointestinal (GI) tract (possibly because of ulceration, ischemia, or obstruction), postoperative peritonitis, or posttraumatic peritonitis (blunt or penetrating trauma). Tertiary peritonitis occurs in critically ill patients and is infection that persists or recurs at least 48 hours after apparently adequate management of primary or secondary peritonitis.[7,8]

1 Primary peritonitis occurs in both children and adults, although the incidence and mortality rates in both populations have been declining.[4] Primary peritonitis develops in up to 10% to 30% of patients with alcoholic cirrhosis.[4-6,9,10] Patients undergoing chronic ambulatory peritoneal dialysis (CAPD) average one episode of peritonitis every 20 to 33 months.[11,12] Epidemiologic data for secondary and tertiary intra-abdominal infections are less understood. Secondary peritonitis may be caused by perforation of a peptic ulcer; traumatic perforation of the stomach, small or large bowel, uterus, or urinary bladder; appendicitis; pancreatitis; diverticulitis; bowel infarction; inflammatory bowel disease; cholecystitis; operative contamination of the peritoneum; or diseases of the female genital tract, such as septic abortion, postoperative uterine infection, endometritis, and salpingitis. Appendicitis is one of the most common causes of intra-abdominal infection. In 2010, 305,000 appendectomies were performed in the United States for suspected appendicitis.[13] Most healthcare-associated intra-abdominal infections occur as complications following intra-abdominal surgeries.

ETIOLOGY

Primary peritonitis in adults occurs most commonly in association with alcoholic cirrhosis, especially in its end stage, or with ascites caused by postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, malignancy, systemic lupus erythematosus, or nephritic syndrome. It may also result from the use of a peritoneal catheter for dialysis or CNS ventriculoperitoneal shunting for hydrocephalus. Rarely, primary peritonitis occurs without apparent underlying disease.

Table 114-1 summarizes many of the potential causes of bacterial peritonitis. Causes include inflammatory processes of the GI tract or abdominal organs, bowel obstruction, vascular occlusions that may lead to gangrene of the intestines, and neoplasia that may cause intestinal perforation or obstruction. Other possible causes include those resulting from traumatic injuries, postoperative infections, or solid organ transplant in the abdomen.

Abscesses are the result of chronic inflammation and may occur without preceding generalized peritonitis. They may be located within one of the spaces of the peritoneal cavity or within one of the visceral organs, and may range from a few milliliters to a liter or more in volume. These collections often have a fibrinous capsule and may take from a few weeks to years to form.

The causes of intra-abdominal abscess overlap those of peritonitis and, in fact, may occur sequentially or simultaneously. Appendicitis is the most frequent cause of abscess. Other potential causes of intra-abdominal abscess include pancreatitis, diverticulitis, lesions of the biliary tract, genitourinary tract infections, perforation in the abdomen, trauma, and leaking intestinal anastomoses. In addition, pelvic inflammatory disease in women may lead to tuboovarian abscess. For some diseases, such as appendicitis and diverticulitis, abscesses occur more frequently than generalized peritonitis.

Microflora of the Gastrointestinal Tract and Female Genital Tract

A full appreciation of intra-abdominal infection requires an understanding of the normal microflora within the GI tract. There are striking differences in bacterial species and concentrations of flora within the various segments of the GI tract (Table 114-2), and this bacterial environment usually determines the severity of infectious processes in the abdomen. Generally, the low gastric pH eradicates bacteria that enter the stomach. With achlorhydria, bacterial counts may rise to 10^5 to 10^7 organisms/mL (10^8 to 10^{10}/L). The normally low bacterial count may also increase by 1,000-or 10,000-fold with gastric outlet obstruction, hemorrhage, gastric cancer, and in patients receiving histamine 2 (H2)-receptor antagonists, proton pump inhibitors, or antacids.[14,15] A two to threefold increase in Spontaneous bacterial peritonitis has been demonstrated with the use of proton pump inhibitors.

The biliary tract (gallbladder and bile ducts) is sterile in most healthy individuals, but in people older than 70 years, those with acute cholecystitis, jaundice, or common bile duct stones, it is likely to be colonized by aerobic Gram-negative bacilli (particularly *Escherichia coli* and *Klebsiella* spp.) and enterococci.[16,17] Patients with biliary tract bacterial colonization are at greater risk of intra-abdominal infection.

In the distal ileum, bacterial counts of aerobes and anaerobes are quite high. In the colon, there may be 500 to 600 different types of bacteria in stool, with concentrations often reaching 10^{11} organisms/mL (10^{14}/L) and anaerobic bacteria outnumbering aerobic bacteria by more than 1,000 to 1.[2,18] In fact, up to 50% of the dry mass of stool is *Bacteroides* spp. Fortunately, most colonic bacteria are not pathogens because they cannot survive in environments outside the colon. Perforation of the colon results in the release of large numbers of anaerobic and aerobic bacteria into the peritoneum.

The colonic flora are generally consistent unless broad-spectrum antimicrobials have been used. Depending on the type of antibiotic and spectrum, the duration of use, route of administration, and the pharmacokinetic and pharmacodynamic properties, antibiotics can cause shifts in the normal GI microflora including causing increased drug resistance.[19]

The lower female genital tract is generally colonized by a large number of aerobic and anaerobic bacteria. Anaerobes may number 10^9 organisms/mL (10^{12}/L) and often include lactobacilli, eubacteria, clostridia, anaerobic streptococci, and, less frequently, *Bacteroides fragilis*. Aerobic bacteria most often are streptococci and *Staphylococcus epidermidis*, and these may number 10^8 organisms/mL (10^{11}/L).

TABLE 114-1 Causes of Bacterial Peritonitis

Primary (spontaneous) bacterial peritonitis
Peritoneal dialysis
Cirrhosis with ascites
Nephrotic syndrome
Secondary bacterial peritonitis
Miscellaneous causes
Diverticulitis
Appendicitis
Inflammatory bowel diseases
Salpingitis
Biliary tract infections
Necrotizing pancreatitis
Neoplasms
Intestinal obstruction
Perforation
Mechanical GI problems
Any cause of small bowel obstruction (adhesions, hernia)
Vascular causes
Mesenteric arterial or venous occlusion (atrial fibrillation)
Mesenteric ischemia without occlusion
Trauma
Blunt abdominal trauma with rupture of intestine
Penetrating abdominal trauma
Iatrogenic intestinal perforation (endoscopy)
Intraoperative events
Solid organ transplant in the abdomen
Peritoneal contamination during abdominal operation
Leakage from GI anastomosis

GI, gastrointestinal.

TABLE 114-2 Usual Microflora of the GI Tract

Site	Commonly Found Bacteria	Approximate Concentration (No. Organisms/mL [$\times 10^3$/L])	
		Aerobes	Anaerobes
Stomach[a]	*Streptococcus, Lactobacillus*	10-100	Rare
Biliary tract	Normally sterile (*Escherichia coli, Klebsiella*, or enterococci in some patients)	0	0
Proximal small bowel	*Streptococcus* (including enterococci), *E. coli, Klebsiella, Lactobacillus*, diphtheroids	100	Few
Distal ileum	*E. coli, Klebsiella, Enterobacter*, enterococci, *Bacteroides fragilis, Clostridium*, peptostreptococci	10^4-10^6	10^5-10^7
Colon	*Bacteroides* spp., peptostreptococci, *Clostridium, E. coli, Klebsiella*, enterococci, *Enterobacter, Candida*, and many others	10^5-10^8	10^9-10^{11}

GI, gastrointestinal.

[a]With achlorhydria, acid suppressive therapy, gastric cancer, or gastric outlet obstruction, bacterial counts may rise to 10^5/mL (10^8/L).

PATHOPHYSIOLOGY

Intra-abdominal infection results from bacterial entry into the peritoneal or retroperitoneal spaces or from bacterial collections within intra-abdominal organs. In primary peritonitis, bacteria may enter the abdomen via the bloodstream or the lymphatic system by transmigration through the bowel wall, through an indwelling peritoneal dialysis catheter, or via the fallopian tubes in females. Hematogenous bacterial spread (through the bloodstream) occurs more frequently with tuberculosis peritonitis or peritonitis associated with cirrhotic ascites. When peritonitis results from peritoneal dialysis, skin surface flora are introduced via the peritoneal catheter. In secondary peritonitis, bacteria most often enter the peritoneum or retroperitoneum as a result of perforation of the GI or female genital tracts caused by diseases or traumatic injuries. In addition, peritonitis or abscess may result from contamination of the peritoneum during a surgical procedure or following anastomotic leak.

The physiologic characteristics of the peritoneal cavity determine the nature of the response to infection or inflammation within it.[1,4] The peritoneum is lined by a highly permeable serous membrane with a surface area approximately that of skin. The peritoneal cavity is lubricated with less than 100 mL of sterile, clear yellow fluid, normally with fewer than 250 cells/mm^3 (0.25×10^9/L), a specific gravity below 1.016, and protein content below 3 g/dL (30 g/L). These conditions change drastically with peritoneal infection or inflammation, as described below.

After bacteria are introduced into the peritoneal cavity, there is an immediate response to contain the insult. Humoral and cellular defenses respond first; then the omentum adheres to the affected area. A limited bacterial inoculum is handled rapidly by defense mechanisms, including complement activation and a leukocyte response. Under certain conditions, the bacterial insult is not contained, and bacteria disseminate throughout the peritoneal cavity, resulting in peritonitis. This is more likely to occur in the presence of a foreign body, hematoma, dead tissue, a large bacterial inoculum, continuing bacterial contamination, and contamination involving a mixture of synergistic organisms. Protein–calorie malnutrition, antecedent steroid therapy, and diabetes mellitus may also contribute to the formation of an intra-abdominal abscess.

When bacteria become dispersed throughout the peritoneum, the inflammatory process involves most of the peritoneal lining. There is an outpouring into the peritoneum of fluid containing leukocytes, fibrin, and other proteins that form exudates on the inflamed peritoneal surfaces and begin to form adhesions between peritoneal structures. This process, combined with a paralysis of the intestines (ileus), may result in confinement of the contamination to one or more locations within the peritoneum. Fluid also begins to collect in the bowel lumen and wall, and distension may result.

The fluid and protein shift into the abdomen (called *third-spacing*) may be so dramatic that circulating blood volume is decreased, which may cause decreased cardiac output and hypovolemic shock. Accompanying fever, vomiting, or diarrhea may worsen the fluid imbalance. A reflex sympathetic response, manifested by sweating, tachycardia, and vasoconstriction, may be evident. With an inflamed peritoneum, bacteria and endotoxins are absorbed easily into the bloodstream (translocation), and this may result in septic shock.[1,4,5] Other foreign substances present in the peritoneal cavity potentiate peritonitis. These adjuvants, notably feces, dead tissues, barium, mucus, bile, and blood, have detrimental effects on host defense mechanisms, particularly on bacterial phagocytosis.

Many of the manifestations of intra-abdominal infections, particularly peritonitis, result from cytokine activity. Inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), interleukin (IL) 1, IL-6, IL-8, and interferon γ (INF-γ), are produced by macrophages and neutrophils in response to bacteria and bacterial products or in response to tissue injury resulting from the surgical incision.[1,4] These cytokines produce wide-ranging effects on the vascular endothelium of organs, particularly the liver, lungs, kidneys, and heart. With uncontrolled activation of these mediators, sepsis may result (see Chapter 119 Sepsis and Septic Shock).[20-22]

Peritonitis may result in death because of the effects on major organ systems. Fluid shifts, cytokines and endotoxin may result in hypovolemia, hypoperfusion, and shock. Hypoalbuminemia may result from protein loss into the peritoneum exacerbating intravascular volume loss. Pulmonary function may be compromised by the inflamed peritoneum, producing splinting (muscle rigidity caused by pain) that inhibits adequate diaphragmatic movement leading to atelectasis and pneumonia. Increased lung vascular permeability and resulting shunting of blood may induce onset of the respiratory distress syndrome and associated hypoxemia and hypercarbia. With fluid loss and hypotension, renal and hepatic perfusion may be compromised, and acute renal and hepatic failure are potential threats.

If peritoneal contamination is localized but bacterial elimination is incomplete, an abscess results. This collection of necrotic tissue, bacteria, and white blood cells may be at single or multiple sites and may be within one of the spaces of the peritoneal cavity or in one of the visceral organs. The location of the abscess is often related to the site of primary disease. For example, abscesses resulting from appendicitis tend to appear in the right lower quadrant or the pelvis; those resulting from diverticulitis tend to appear in the left lower quadrant or pelvis.

An abscess begins by the combined action of inflammatory cells (such as neutrophils), bacteria, fibrin, and other inflammatory mediators. Bacteria may release heparinases that cause local thrombosis and tissue necrosis or fibrinolysins, collagenases, or other enzymes that allow extension of the process into surrounding tissues. Neutrophils gathered in the abscess cavity die in 3 to 5 days, releasing lysosomal enzymes that liquefy the core of the abscess. A mature abscess may have a fibrinous capsule that isolates bacteria and the liquid core from antimicrobials and immunologic defenses.

Within the abscess, the oxygen tension is low and anaerobic bacteria thrive; thus, the size of the abscess may increase because it is hypertonic, resulting in an additional influx of fluid. Hypertonicity promotes the formation of bacterial L forms, which are resistant to antimicrobial agents that disrupt cell walls. Abscess formation may continue and mature for long periods of time and may not be readily evident to either patient or physician. In some instances, the abscess may resolve spontaneously, and, infrequently, it may erode into adjacent organs or rupture and cause diffuse peritonitis. If the abscess erodes through the skin, it may result in an enterocutaneous fistula, connecting bowel to skin, or in a draining sinus tract.

The overall outcome from an intra-abdominal infection depends on key factors: inoculum size, virulence of the contaminating organisms, the presence of adjuvants within the peritoneal cavity that facilitate infection, the adequacy of host defenses, source control, and the adequacy of initial treatment.[9,23,24]

Microbiology of Intra-Abdominal Infection

2 Primary bacterial peritonitis is often caused by a single organism. In children, the pathogen is usually group A *Streptococcus*, *E. coli*, *Streptococcus pneumoniae*, or *Bacteroides* species.[4,25-28] When peritonitis occurs in association with cirrhotic ascites, *E. coli* is isolated most frequently. Other potential pathogens are: *Haemophilus influenzae*, *Klebsiella* spp., *Pseudomonas* spp., anaerobes, and *S. pneumoniae*.[29] Occasionally, primary peritonitis may be caused by *Mycobacterium tuberculosis.* Peritonitis in patients undergoing peritoneal dialysis is caused most often by common skin organisms, such as coagulase-negative staphylococci, *Staphylococcus aureus*, streptococci, and enterococci. Gram-negative bacteria associated with peritoneal dialysis infections include *E. coli*, *Klebsiella* spp., and *Pseudomonas* spp.[6] The mortality rate from primary peritonitis caused by Gram-negative bacteria is much greater than that from Gram-positive bacteria.[4,5]

TABLE 114-3 Pathogens Isolated from Patients with Intra-Abdominal Infection

	Secondary Peritonitis[3,33] (%)	Community-Acquired Infection[33] (%)	Nosocomial Infection[33] (%)
Gram-Negative Bacteria			
Escherichia coli	32-61	29	22.5
Enterobacter	8-26	5.2	8.0
Klebsiella	6-26	2.8	4.5
Proteus	4-23	1.7	2.4
Pseudomonas	5-13	5	13
Gram-Positive Bacteria			
Enterococcus	18-24	10.6	18
Streptococcus	6-55	13.7	10
Staphylococcus	6-16	3.1	4.8
Anaerobic Bacteria			
Bacteroides	25-80	13.7	10.3
Clostridium	5-18	3.5	3.4
Fungi	2-5	3	4

3 Because of the diverse bacteria present in the GI tract, secondary intra-abdominal infections are often polymicrobial.[2] The mean number of different bacterial species isolated from infected intra-abdominal sites ranged from 2.9 to 3.7, including an average of 1.3 to 1.6 aerobes and 1.7 to 2.1 anaerobes.[29,30] With proper anaerobic specimen collection, anaerobic organisms are isolated in most patients. In one report of patients with gangrenous and perforated appendicitis, an average of 10.2 different organisms was isolated from each patient, including 2.7 aerobes and 7.5 anaerobes.[31] Purely aerobic or anaerobic infections are uncommon, as are infections caused by fungi. Table 114-3 gives the frequencies with which specific bacteria were isolated from patients with peritonitis and other intra-abdominal infections.[3,32] Nosocomial infections tend to have a more diverse array of pathogens, are more likely to involve *Pseudomonas* spp., and have a higher likelihood of multidrug-resistance compared with isolates from community-acquired infections.[33]

Visceral organ abscesses differ in character from the typical intra-abdominal abscess. Hepatic abscesses may be polymicrobial (involving *E. coli*, *Klebsiella* spp., and anaerobes) or occasionally may be caused by amoeba.[18] Pancreatic abscesses are often polymicrobial, involving enteric bacteria that ascend through the biliary system. Splenic abscesses usually result from hematogenous dissemination of bacteria, such as *E. coli, S. aureus*, *Proteus mirabilis*, *Enterococcus* spp., and *Klebsiella pneumoniae*, as well as anaerobes.[18] Pelvic inflammatory disease is associated initially with *Neisseria gonorrhoeae* or *Chlamydia trachomatis.* However, tuboovarian abscesses are usually polymicrobial, having a mix of Gram-positive and Gram-negative aerobes and anaerobes.

Bacterial Synergism

The size of the bacterial inoculum and the number and types of bacterial species present in intra-abdominal infections influence patient outcome. The combination of aerobic and anaerobic organisms appears to greatly increase the severity of infection. In animal studies, combinations of aerobic and anaerobic bacteria were much more lethal than infections caused by aerobes or anaerobes alone.

Facultative bacteria may provide an environment conducive to the growth of anaerobic bacteria.[2] Although many bacteria isolated in mixed infections are nonpathogenic by themselves, their presence may be essential for the pathogenicity of the bacterial mixture.[9] The role of facultative bacteria in mixed infections can include (a) promotion of an appropriate environment for anaerobic bacterial growth through oxygen consumption, (b) production of nutrients necessary for anaerobes, and (c) production of extracellular enzymes that promote tissue invasion by anaerobes.

Rat models of intra-abdominal infection demonstrate that uncontrolled infection with an implanted mix of aerobes and anaerobes leads to a two-stage (biphasic) infectious process. There is an early peritonitis phase with a high mortality rate and isolation of *E. coli* from blood and a late abscess formation phase in all survivors with isolation of anaerobes such as *B. fragilis* and *Fusobacterium varium*. These experiments and others support the concept that aerobic enteric organisms and anaerobes are pathogens in intra-abdominal infection. Aerobic bacteria, particularly *E. coli*, appear responsible for the early mortality from peritonitis, whereas anaerobic bacteria are major pathogens in abscesses, with *B. fragilis* predominating.[34]

Enterococcus can be isolated from many intra-abdominal infections in humans, but its role as a pathogen is not clear. Enterococcal infection occurs more commonly in postoperative peritonitis, in the presence of specific risk factors indicating failure of the host's defenses (immunocompromised patients), or with the use of broad-spectrum antibiotics.[35,36]

CLINICAL PRESENTATION

Intra-abdominal infections have a wide spectrum of clinical features often depending on the specific disease process, the location and magnitude of bacterial contamination, and concurrent host factors. Peritonitis is usually recognized easily, but intra-abdominal abscess may often continue for considerable periods of time, either going unrecognized or being attributed to an unrelated disease process. Patients with primary and secondary peritonitis present quite differently (Table 114-4).[1,4,5]

Primary peritonitis can develop over a period of days to weeks and is usually a more indolent process than secondary peritonitis. The first sign of peritonitis may be a cloudy dialysate in patients undergoing peritoneal dialysis or worsening encephalopathy in a cirrhotic patient.

The patient with generalized bacterial peritonitis presents most often in acute distress. The patient lies still, usually on his or her back, possibly with the hips slightly flexed. Any movement of the patient, including rocking the bed or breathing, worsens the generalized abdominal pain.

If peritonitis continues untreated, the patient may experience hypovolemic shock from third-space fluid loss into the peritoneum, bowel wall, and lumen. This may be accompanied by sepsis because the inflamed peritoneum absorbs bacteria and toxins into mesenteric blood vessels and lymph nodes, initiating production of inflammatory cytokines. Hypovolemic shock is the major factor contributing to mortality in the early stage of peritonitis.

Intra-abdominal abscess may pose a difficult diagnostic challenge because the symptoms are neither specific nor dramatic. The patient may complain of abdominal pain or discomfort, but these symptoms are not reliable. Fever is usually present; often it is low grade, but it may be high, with a spiking pattern. The patient may have a paralytic ileus and abdominal distension. The abdominal examination is unreliable; tenderness and pain may be present, and a mass may be palpated.

Peritonitis may result from an abscess that ruptures, spreading bacteria and toxins throughout the peritoneum. In other patients, the entry of bacterial toxins into the systemic circulation from the abscess may lead to sepsis and progressive multisystem organ failure (eg, renal, hepatic, pulmonary, or cardiovascular).

Laboratory studies are not generally helpful in the diagnosis of intra-abdominal abscess, although most patients will have leukocytosis. Some patients may have positive blood cultures, whereas

TABLE 114-4 Clinical Presentation of Peritonitis

Primary Peritonitis
General
The patient may not be in acute distress, particularly with peritoneal dialysis
Signs and symptoms
The patient may complain of loss of appetite, bloating, nausea, vomiting (sometimes with diarrhea), and abdominal tenderness
Temperature may be only mildly elevated or not elevated in patients undergoing peritoneal dialysis
Bowel sounds are hypoactive
The cirrhotic patient may have worsening encephalopathy
Cloudy dialysate fluid with peritoneal dialysis
Laboratory tests
The patient's WBC count may be only mildly elevated
Ascitic fluid usually contains greater than 250 leukocytes/mm^3 (0.25×10^9/L), and bacteria may be evident on Gram stain of a centrifuged specimen
In 60%-80% of patients with cirrhotic ascites, the Gram stain is negative
Other diagnostic tests
Culture of peritoneal dialysate or ascitic fluid should be positive, particularly if collected prior to initiation of antibiotics
Procalcitonin in conjunction with clinical findings is a sensitive test for bacterial peritonitis[37]
Secondary Peritonitis
Signs and symptoms
Generalized abdominal pain
Tachypnea
Tachycardia
Nausea and vomiting
Temperature is normal initially then increases to 37.8-38.9°C (100-102°F) within the first few hours and may continue to rise for the next several hours
Hypotension, hypoperfusion, and shock if volume is not restored
Decreased urine output due to vascular volume depletion
Physical examination
Voluntary abdominal guarding changing to involuntary guarding and a "board-like abdomen"
Abdominal tenderness and distension
Faint bowel sounds that cease over time
Laboratory tests
Leukocytosis (15,000-20,000 WBC/mm^3 [15×10^9 to 20×10^9/L]), with neutrophils predominating and an elevated percentage of immature neutrophils (bands)
Elevated hematocrit and blood urea nitrogen because of dehydration
Patient progresses from early alkalosis because of hyperventilation and vomiting to metabolic acidosis
Other diagnostic tests
Abdominal radiographs may be useful because free air in the abdomen (indicating intestinal perforation) or distension of the small or large bowel is often evident

WBC, white blood cell.

others, particularly diabetics, may have hyperglycemia. The finding of *Bacteroides* or any two enteric bacteria in the bloodstream is often indicative of an intra-abdominal infectious process.

Radiographic methods are used to make the diagnosis of an intra-abdominal abscess. Plain radiographs may show air–fluid levels or a shift of normal intra-abdominal contents by the abscess mass. GI contrast studies may also demonstrate this displacement of abdominal structures. Both of these modalities provide indirect evidence of abscess presence but are not generally helpful in precisely locating the abscess.

Ultrasound is a frequent first diagnostic method used when an intra-abdominal abscess is suspected. The procedure may be done at the bedside, which is particularly helpful when the patient is in the intensive care unit.

Computed tomographic (CT) scanning is the preferred modality used to evaluate the abdomen for the presence of an abscess and is the imaging study of greatest value. If not contraindicated, an oral radiocontrast agent should be given to allow differentiation of the abscess from the bowel. IV radiocontrast material will be taken up preferentially in the wall of the abscess, creating a unique radiographic appearance, so-called rim enhancement. Magnetic resonance imaging offers no significant advantage when compared with CT scanning.

Intra-abdominal infection caused by disease processes at specific sites often produces characteristic manifestations that are helpful in diagnosis. For example, a patient with diverticulitis may exhibit stabbing left-lower-quadrant abdominal pain and constipation. Fever and leukocytosis are frequently present, and a tender mass is sometimes palpable. With appendicitis, the findings may be inconsistent, but many patients have a sudden onset of periumbilical or epigastric pain that is usually colicky and later shifts to the right lower quadrant. The location of pain may vary because the appendix can be in many locations (eg, retrocecal or pelvic) in the abdomen. A mass may be palpable on abdominal, pelvic, or rectal examination. The patient's temperature is generally mildly elevated early and then increases. If perforation and peritonitis occur, findings would include diffuse abdominal pain, rigidity, and sustained fever. More often, however, appendiceal perforation results in a local abscess.

TREATMENT

Desired Outcome

The primary goals of treatment are correction of the intra-abdominal disease processes or injuries that have caused infection and the drainage of purulent collections (abscesses). A secondary objective is to achieve a resolution of infection without major organ system complications (pulmonary, hepatic, cardiovascular, or renal failure) or adverse drug effects. Ideally, the patient should be discharged from the hospital after treatment with full function for self-care and routine daily activities.

General Approach to Treatment

The treatment of intra-abdominal infection most often requires hospitalization and the coordinated use of three major modalities: (a) prompt drainage of the infected site, (b) hemodynamic resuscitation and support of vital organ functions, and (c) early administration of appropriate antimicrobial therapy to treat infection not eradicated by surgery.[2]

Antimicrobials are an important adjunct to drainage procedures in the treatment of secondary intra-abdominal infections; however, the use of antimicrobial agents without surgical intervention is usually inadequate. For most cases of primary peritonitis, drainage procedures may not be required, and antimicrobial agents become the mainstay of therapy.

4 In the early phase of serious intra-abdominal infections, attention should be given to the maintenance of organ system functions. With generalized peritonitis, large volumes of IV fluids are required to restore vascular volume, to improve cardiovascular function, and to maintain adequate tissue perfusion and oxygenation. Adequate urine output should be maintained to ensure adequate resuscitation and proper renal function. Respiratory function can be assisted by a variety of methods, including oxygen therapy, pulmonary physiotherapy, and ventilatory support in severely ill patients. Often the critically ill patient with intra-abdominal infection will require intensive care management, particularly if there is cardiovascular or respiratory instability. In addition, isolation procedures may be required if the infectious process poses a threat to other hospitalized patients.

An additional important component of therapy is nutrition. Intra-abdominal infections often directly involve the GI tract or disrupt its function (paralytic ileus). The return of GI motility may

take days, weeks, and, occasionally, months. In the interim, enteral or parenteral nutrition as indicated facilitates improved immune function and wound healing to ensure recovery.

Nonpharmacologic Treatment

Drainage Procedures

Primary peritonitis is treated with antimicrobials and rarely requires drainage. Secondary peritonitis requires surgical correction of the underlying pathology. The drainage of the purulent material is the critical component of management of an intra-abdominal abscess. Without adequate drainage of the abscess, antimicrobial therapy and fluid resuscitation can be expected to fail.

Secondary peritonitis is treated surgically; this is often called *source control*, which refers to all the physical measures undertaken to eradicate the focus of infection.[2,5] At the time of laparotomy (surgical opening and exploration of the abdomen), attempts are made to correct the cause of the peritonitis. This may include patching a perforated ulcer with omentum, removal of a segment of perforated colon, or excision of a portion of gangrenous small intestine. In addition, the surgeon may elect to leave the abdomen open after the laparotomy, plan a re-laparotomy at a later time regardless of the patient's condition, or, perform re-laparotomy if the patient develops reinfection.[5] The goal of all these procedures is to repair or remove the inflamed or gangrenous viscus and to prevent further bacterial contamination. The presence of active inflammation increases the difficulty of the surgical procedure, which results in a higher morbidity and mortality rate than if the same procedures were performed in an elective setting without inflammation.

The presence of active inflammation may make it technically impossible to perform the definitive surgical procedure. In this situation, attempts are made to provide drainage of the infected or gangrenous structures. If an intra-abdominal abscess, separate from any intra-abdominal organ, is discovered during an exploratory laparotomy, it may be debrided, excised, or drained. If the intra-abdominal abscess involves an abdominal structure, then a resection of part or of the entire organ may be required. An example of this situation is an abscess associated with diverticular disease of the colon. Management may include drainage of the abscess and resection of the involved part of the colon. All foreign material, necrotic tissue, feces, blood, or pus should be removed from the operative field, and the peritoneum should be copiously irrigated with 0.9% sodium chloride to decrease the concentrations of bacteria or other noxious substances.

After an abscess is located, it must be drained. This may be performed surgically or with percutaneous, image-guided techniques.[5,38] Typically, image-guided techniques employ ultrasonography or CT scanning. The management of an intra-abdominal abscess with percutaneous catheter drainage may be sufficient to resolve the infection. Some patients may require a subsequent procedure to treat the underlying GI conditions; however, a significant advantage is obtained by first draining the abscess percutaneously. This allows the surgical procedure to be performed on a patient who is no longer suffering the systemic manifestations of uncontrolled infection. Drainage techniques may be performed using endoscopy or laparoscopy. These minimal-access techniques may offer advantages when compared with traditional surgery but will probably be used less often than radiologically assisted percutaneous drainage techniques.

The most valuable microbiologic information may be obtained at the time of percutaneous or operative abscess drainage. If pus or fluid is found that is believed to be infected, it is best to aspirate 2 to 3 mL into a syringe, remove any air, and tightly cap the syringe. The specimen should be taken promptly to the microbiology laboratory, where a Gram stain should be performed immediately and cultures prepared for identification of aerobic and anaerobic bacteria. If no fluid is available for collection, culture swab devices may be applied to the infected area; however, anaerobic organisms often are not isolated from swabs.

Fluid Therapy

4 Patients should be evaluated for signs of hypovolemia, hypoperfusion, and shock. Aggressive fluid repletion and management are required for successful treatment of intra-abdominal infections. The Surviving Sepsis Campaign: International Guidelines for Management of Severe Sepsis and Septic Shock recommend treatment goals during the first 6 hours or resuscitation: (a) central venous pressure (CVP) 8 to 12 mm Hg, (b) mean arterial pressure (MAP) more than or equal to 65 mm Hg, and (c) maintain urine output more than or equal to 0.5 mL/kg/h.[39,40] If the patient is mechanically ventilated a target CVP 12 to 15 mm Hg should be achieved.[39] Fluid therapy is instituted for the purposes of achieving or maintaining proper intravascular volume to ensure adequate cardiac output, tissue perfusion, and correction of acidosis. Loss of fluid through vomiting, diarrhea, or nasogastric suction contributes to dehydration. Intravascular volume can be assessed by blood pressure and heart rate but more accurately by measurement of CVP or urinary output. When a contracted vascular volume is accompanied by hemorrhage, the initial hematocrit may be normal, but if there is no associated hemorrhage, the hematocrit is usually elevated as an indication of hemoconcentration. Urine output should be monitored continuously in severely ill patients by use of a urinary bladder catheter, quantitated hourly, and should equal or exceed 0.5 mL/kg of body weight per hour.

In patients with peritonitis, hypovolemia is often accompanied by metabolic acidosis. IV fluids should consist of a bolus of crystalloids or colloids with additional fluids targeting predefined therapeutic goals.[39,40] In the initial hour of treatment, large volumes of solution may be required to restore intravascular volume. Thereafter, fluids may be required at a rate of 1 L/h or higher. Once targeted therapeutic goals are reached, maintenance fluids should be instituted with 0.9% sodium chloride and potassium chloride (20 mEq/L [mmol/L]) or 5% dextrose and 0.45% sodium chloride with potassium chloride (20 mEq/L [mmol/L]). The administration rate should be based on estimated daily fluid loss through urine and nasogastric suction, including 0.5 to 1 L for insensible fluid loss. Potassium would not be included routinely if the patient is hyperkalemic or has renal insufficiency. If appropriate fluid management fails to restore target goals of perfusion, vasopressor therapy should be initiated.[39] A more thorough discussion of fluid and vasopressor therapy are presented elsewhere in this text (23, 24, and 119).

In patients with significant blood loss, blood transfusion may be indicated. This is generally in the form of packed red blood cells. The criteria for blood transfusion are controversial, but a hematocrit of 25% is generally accepted. In the individual patient, the decision is often determined by the overall clinical status and the ability of the patient to compensate for the reduction in oxygen-carrying capacity associated with an acute anemia. Additional blood component therapy with fresh-frozen plasma or platelets is also based on the needs of the individual patient. Aggressive fluid therapy must often be continued in the postoperative period because fluid will continue to sequester in the peritoneal cavity, bowel wall, and lumen.

Pharmacologic Treatment

Antimicrobial Therapy

The goals of antimicrobial therapy are (a) to control any bacteremia and prevent the establishment of metastatic foci of infection, (b) to reduce suppurative complications (eg, abscess formation) after bacterial contamination, and (c) to prevent local spread of existing

TABLE 114-5 Likely Intra-Abdominal Pathogens

Type of Infection	Aerobes	Anaerobes
Primary (Spontaneous) Bacterial Peritonitis		
Children	Group A *Streptococcus*, *E. coli*, pneumococci	—
Cirrhosis	*E. coli*, *Klebsiella*, pneumococci (many others)	—
Peritoneal dialysis	*Staphylococcus*, *Streptococcus*, *E. coli*, *Klebsiella*, *Pseudomonas*	—
Secondary Bacterial Peritonitis		
Gastroduodenal	*Streptococcus*, *E. coli*	—
Biliary tract	*E. coli*, *Klebsiella*, enterococci	*Clostridium* or *Bacteroides* (infrequent)
Small or large bowel	*E. coli*, *Klebsiella*, *Proteus*	*B. fragilis* and other *Bacteroides*, *Clostridium*
Appendicitis	*E. coli*, *Pseudomonas*	*Bacteroides*
Abscesses	*E. coli*, *Klebsiella*, *Streptococcus*, enterococci	*B. fragilis* and other *Bacteroides*, *Clostridium*, anaerobic cocci
Liver	*E. coli*, *Klebsiella*, *Streptococcus*, enterococci, *Staphylococcus*, amoeba	*Bacteroides* (infrequent)
Spleen	*Staphylococcus*, *Streptococcus*, *E. coli*, *Salmonella*	

infection. After suppuration has occurred, a cure by antibiotic therapy alone is very difficult to achieve; antimicrobials may serve to improve the results obtained with surgery.

5 An empirical antimicrobial regimen should be started as soon as the presence of intra-abdominal infection is suspected. Therapy must be initiated based on the likely pathogens, potential resistance, and severity of patient illness. Increased resistance among Gram-negative pathogens to fluoroquinolones and ampicillin–sulbactam emphasize the importance of using local susceptibility data to guide empiric therapy and tailoring the antibiotic regimen based on susceptibility results. Predominant pathogens, as discussed in the preceding section, vary depending on the site of intra-abdominal infection and the underlying disease process. Table 114-5 lists the likely pathogens against which antimicrobial agents should be directed.

Antimicrobial Experience Many studies have been conducted evaluating or comparing the effectiveness of antimicrobials for the treatment of intra-abdominal infections. Substantial differences in patient outcomes from treatment with a variety of agents have not generally been demonstrated.[41]

Important findings from over 20 years of clinical trials regarding selection of antimicrobials for intra-abdominal infections are the following:

1. Antimicrobial regimens used for secondary infections should cover a broad spectrum of aerobic and anaerobic bacteria from the GI tract. Empiric treatment should be guided by the local epidemiology of resistant pathogens, patient-specific risk factors for resistant pathogens, and patient severity of illness.
2. Single-agent regimens (such as cephalosporins with anaerobic activity, extended-spectrum penicillins with β-lactamase inhibitors, and carbapenems) are as effective but have the benefit of being less nephrotoxic compared to combinations of aminoglycosides with antianaerobic agents. This is also true for antimicrobial treatment of acute bacterial contamination from penetrating abdominal trauma.[42,43]
3. Resistance is prevalent among *B. fragilis* to clindamycin and cefotetan and Enterobacteriaceae to ampicillin–sulbactam and quinolones and therefore these agents should not be routinely used empirically for complicated intra-abdominal infections.[44,45]
4. If the causative pathogens are susceptible and the patient has clinically responded, antimicrobial treatment can be completed orally with amoxicillin–clavulanate, metronidazole with either ciprofloxacin or levofloxacin, or moxifloxacin.[46]
5. Four days of antimicrobial treatment is sufficient for most intra-abdominal infections with adequate source control.[47,48]

Intra-abdominal infections present in many different ways and with a wide spectrum of severity. The regimen employed and duration of treatment depends on the specific clinical circumstances (ie, the nature of the underlying disease process, severity of illness, and risk of resistant pathogens).

Recommendations 6 For most intra-abdominal infections, the antimicrobial regimen should be effective against both aerobic and anaerobic bacteria.[48,49] When initial antimicrobial therapy is inactive, morbidity and mortality rates are higher than when initially active therapy is used.[48] Generally, agents with activity against enteric Gram-negative bacilli such as *E. coli* and *Klebsiella* spp., and anaerobes including *B. fragilis* should be administered. If most of the organisms can be eliminated through drainage or antimicrobials, the synergistic effect may be removed, and the patient's defenses may be able to resolve the remaining infection.

Table 114-6 presents the recommended agents for treatment of community-acquired complicated intra-abdominal infections from the Infectious Diseases Society of America and the Surgical

TABLE 114-6 Recommended Agents for the Treatment of Community-Acquired Complicated Intra-Abdominal Infections in Adults

Agents Recommended for Mild-to-Moderate Infections	Agents Recommended for High Risk or High Severity Infections
Single Agent	
Cefoxitin[a]	Piperacillin–tazobactam
Moxifloxacin[b] Ertapenem[c]	Imipenem–cilastatin,[c] meropenem,[c] doripenem[c]
Combination Regimens	
Cefazolin,[a] cefuroxime,[a] ceftriaxone, cefotaxime each in combination with metronidazole	Cefepime or ceftazidime each in combination with metronidazole
Ciprofloxacin[b] or levofloxacin[b] each in combination with metronidazole	Ciprofloxacin[b] or levofloxacin[b] each in combination with metronidazole

[a]Empiric first- and second-generation cephalosporin use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to these agents.

[b]Use of quinolones may be associated with treatment failure due to increasing resistance of enteric pathogens including *E. coli*. Empiric quinolone use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to quinolones.

[c]Carbapenems should be reserved for settings where there is a high risk of resistance to other agents.

Data from reference 48.

Infection Society.[48] These recommendations were formulated using an evidence-based approach. Table 114-7 lists additional evidence-based recommendations for the treatment of complicated intra-abdominal infections. Most community-acquired infections are of mild-to-moderate severity whereas healthcare-associated infections tend to be more severe, more difficult to treat, and more commonly due to resistant pathogens. Table 114-8 presents guidelines for treatment and alternative regimens for specific situations. These are general guidelines; there are many factors that cannot be incorporated into such a table including local resistance patterns to commonly used agents such as quinolones.

Most patients with severe intra-abdominal infection, sepsis of intra-abdominal source, or healthcare-associated infection should be placed on piperacillin–tazobactam, cefepime with metronidazole, or a carbapenem with *Pseudomonas* activity such as imipenem, doripenem, or meropenem. In patients with IgE-mediated allergic reactions to β-lactams (hives/urticaria, bronchospasm, angioedema, or anaphylaxis), combination therapy with aztreonam, vancomycin and metronidazole may be used. The benefits of systemic empiric antifungal (with fluconazole or an echinocandin antifungal) have not been established for intra-abdominal infection and should not be routinely used.[50]

Aminoglycoside-based treatment regimens are not routinely recommended due to their narrow therapeutic index (nephrotoxicity, ototoxicity) relative to the recommended agents such as β-lactams. Aminoglycosides are reserved primarily for infections due to presumed or proven multidrug-resistant pathogen(s) or perhaps in patients with IgE-mediated allergic reactions to alternative agents.[41,48]

The initial dosage for aminoglycosides should be determined based on the patient's weight and renal function. Traditionally, gentamicin and tobramycin were administered multiple times daily with specific peak (6-10 mcg/mL) [mg/L; 13-21 μmol/L]) and trough (less than 1-2 mcg/mL) [mg/L; less than 2-4 μmol/L]) concentration targets. Because aminoglycosides have concentration-dependent killing and have a relatively long postantibiotic effect for aerobic Gram-negative bacilli, extended-interval dosing of aminoglycosides is possible. For most patients and indications, extended-interval aminoglycoside dosing (ie, 5-7 mg/kg once daily for tobramycin or gentamicin, 15-20 mg/kg once daily for amikacin) has replaced traditional dosing given equivalent efficacy and decreased nephrotoxicity.[51-53]

Antimicrobial resistance continues to rise worldwide.[54-56] These problematic multidrug-resistant bacteria include enteric pathogens producing extended-spectrum β-lactamases (ESBL) which have been increasingly isolated from intra-abdominal cultures.[44] For patients with ESBL-producing pathogens, carbapenems are typically the drugs of choice. With the increased use of carbapenems, pathogens continue to evolve with the development of β-lactamases that hydrolyze carbapenems (e.g., *Klebsiella pneumoniae* carbapenemase [KPC]), multidrug-resistant *Pseudomonas* spp., and carbapenem-resistant *Acinetobacter* spp. Especially in patients with healthcare-associated intra-abdominal infections, these multidrug-resistant pathogens have forced clinicians to use more toxic and potentially less effective agents such as the polymyxins, tigecycline, and aminoglycosides. For example, the product labeling for tigecycline now carries a Black Box Warning as it has been associated with an increased risk of mortality relative to comparator agents based on pooled data collected from randomized controlled trials including patients with intra-abdominal infections, skin and skin structure infections, and ventilator-associated pneumonia.[57-59] The limited safe and effective therapeutic options for resistant organisms highlights the need, from an individual patient and public health standpoint, for pharmacists and other clinicians to ensure that antimicrobials are selected appropriately, at the optimal dose, and for the correct duration.[60,61]

Clinical **Controversy...**

Ceftolozane/tazobactam and ceftazidime/avibactam were FDA-approved in 2014 and 2015, respectively, for the treatment of complicated intra-abdominal infections in combination with metronidazole.[62,63] These agents are useful as they may be active against multidrug-resistant pathogens including *Pseudomonas* spp., ESBL-producing *Enterobacteriaceae* and KPC-producing *Enterobacteriaceae* (ceftazidime/avibactam only). However, clinical effectiveness and safety data are limited, especially with ceftazidime/avibactam, which was approved prior to completion of Phase III studies. Ceftolozane/tazobactam may not be as effective as meropenem and metronidazole in the treatment of complicated intra-abdominal infections.[64-66] Despite this, these agents are highly valuable in terms of their activity against multidrug-resistant pathogens and as such, their use should be reserved for patients with a suspected or confirmed infection due to a pathogen resistant to all other β-lactams, including carbapenems.

With intra-abdominal contamination from the upper GI tract (perforation of a peptic ulcer or biliary tract disease), anaerobes such as *B. fragilis* are uncommon pathogens, and therefore other empiric agents such as ampicillin, penicillin, or first-generation cephalosporins are reasonable. Anaerobic coverage is also not necessary for primary peritonitis associated with cirrhosis and third-generation cephalosporins, such as cefotaxime or ceftriaxone, remain the treatments of choice.[67]

Coverage of *Enterococcus* in mild-to-moderate community-acquired intra-abdominal infections is not recommended.[48] The failure of host defenses may be a critical factor in the pathogenicity of enterococci. In patients with severe community-acquired intra-abdominal infection or patients with healthcare-associated infection, it is recommended to include coverage of *Enterococcus faecalis* in the initial regimen.[48] Ampicillin remains the drug of choice for this indication because it is most active in vitro against *E faecalis*. Vancomycin is active against most enterococci; however, rates of vancomycin-resistant enterococci are increasing, particularly in select patient populations (eg, liver transplantation, immunocompromised patients).[68] Agents including linezolid or daptomycin are commonly used for vancomycin-resistant *Enterococcus* infections. Table 114-7 lists additional evidence-based recommendations for *Enterococcus* spp. coverage.

7 Intraperitoneal administration of antibiotics is preferred over IV therapy in the treatment of peritonitis that occurs in patients undergoing CAPD.[69] The International Society of Peritoneal Dialysis guidelines for the diagnosis and pharmacotherapy of peritoneal dialysis-associated infections provide dosing recommendations for intermittent and continuous therapy based on the modality of dialysis (continuous or intermittent) and the extent of the patient's residual renal function.[70]

Antimicrobial agents effective against both Gram-positive (including *S. aureus*) and Gram-negative organisms should be used for initial intraperitoneal empiric therapy for peritonitis in peritoneal dialysis patients. The most important factors to take into consideration for initial antimicrobial selection are the dialysis center's and the patient's history of infecting organisms and their sensitivities. For empiric intraperitoneal therapy in patients on continuous peritoneal dialysis, cefazolin (loading dose [LD] 500 mg/L; maintenance dose [MD] 125 mg/L) or vancomycin (LD 1,000 mg/L; MD 25 mg/L) in cases of high prevalence of methicillin-resistant *S. aureus* (MRSA) or β-lactam allergy may be used for Gram-positive coverage. A meta-analysis based on a limited

TABLE 114-7 Evidence-Based Recommendations for Treatment of Complicated Intra-abdominal Infections

	Grade of Recommendation[a]
Elements of Appropriate Intervention	
An appropriate source control procedure to drain infected foci, control ongoing peritoneal contamination by diversion or resection, and restore anatomic and physiological function to the extent feasible is recommended for nearly all patients with intra-abdominal infection	B-2
Community-Acquired Infections of Mild-to-Moderate Severity in Adults	
Antibiotics used for empiric treatment of community-acquired intra-abdominal infections should be active against enteric Gram-negative aerobic and facultative bacilli and enteric Gram-positive streptococci	A-1
For patients with mild-to-moderate community-acquired infections regimens with substantial anti-pseudomonal activity are not required (Table 114-6)	A-1
Empiric coverage of *Enterococcus* is not necessary in patients with mild-to-moderate severity community-acquired intra-abdominal infection	A-1
The use of agents listed as appropriate for higher-severity community-acquired infection and healthcare-associated infection is not recommended for patients with mild-to-moderate community-acquired infection, because such regimens may carry a greater risk of toxicity and facilitate acquisition of more resistant organisms	B-2
High-Risk or High-Severity Community-Acquired Infections in Adults[b]	
The empiric use of antimicrobial regimens with broad-spectrum activity against Gram-negative organisms including *Pseudomonas* spp., such as meropenem, imipenem–cilastatin, doripenem, piperacillin–tazobactam, ciprofloxacin or levofloxacin in combination with metronidazole, or ceftazidime or cefepime in combination with metronidazole, is recommended for patients with high-severity community-acquired intra-abdominal infection (Table 114-6)	A-1
Aztreonam plus metronidazole is an alternative, but addition of an agent effective against Gram-positive cocci is recommended	B-3
Healthcare-Associated Infections in Adults	
Empiric antibiotic therapy for healthcare-associated intra-abdominal infection should be driven by local microbiologic results	A-2
To achieve empiric coverage of likely pathogens, multidrug regimens that include agents with expanded spectra of activity against Gram-negative aerobic and facultative bacilli may be needed. These agents include meropenem, imipenem–cilastatin, doripenem, piperacillin–tazobactam, or ceftazidime or cefepime in combination with metronidazole. Aminoglycosides or colistin may be required	B-3
Antimicrobial Agents Not Recommended	
Ampicillin–sulbactam is not recommended for use because of high rates of resistance to this agent among community-acquired *E. coli*	B-2
Quinolone-resistant *E. coli* have become common in some communities, and quinolones should not be used unless hospital surveys indicate 90% susceptibility of *E. coli* to quinolones	A-2
Cefotetan and clindamycin are not recommended for use because of increasing prevalence of resistance to these agents among *Bacteroides fragilis*	B-2
Because of the availability of less toxic agents demonstrated to be at least equally effective, aminoglycosides are not recommended for routine use in adults with community-acquired intra-abdominal infection	B-2
Oral Completion Therapy	
For adults recovering from intra-abdominal infection, completion of the antimicrobial course with oral forms of moxifloxacin, ciprofloxacin plus metronidazole, levofloxacin plus metronidazole, an oral cephalosporin with metronidazole, or amoxicillin–clavulanic acid is acceptable in patients able to tolerate an oral diet and in patients in whom susceptibility studies do not demonstrate resistance	B-2
Duration of Therapy	
Antimicrobial therapy of established infection should be limited to 4 days, unless it is difficult to achieve adequate source control. Longer durations of therapy have not been associated with improved outcome[c]	A-1
For acute stomach and proximal jejunum perforations, in the absence of acid-reducing therapy or malignancy and when source control is achieved within 24 hours, prophylactic anti-infective therapy directed at aerobic Gram-positive cocci for 24 hours is adequate	B-2
Bowel injuries attributable to penetrating, blunt, or iatrogenic trauma that are repaired within 12 hours and any other intraoperative contamination of the operative field by enteric contents should be treated with antibiotics for ≤24 hours	A-1
Acute appendicitis without evidence of perforation, abscess, or local peritonitis requires only prophylactic administration of narrow spectrum regimens active against aerobic and facultative and obligate anaerobes; treatment should be discontinued within 24 hours	A-1
The administration of prophylactic antibiotics to patients with severe necrotizing pancreatitis prior to the diagnosis of infection is not recommended	A-1
Anaerobic Coverage	
Coverage for obligate anaerobic bacilli should be provided for distal small bowel, appendiceal, and colon-derived infection and for more proximal GI perforations in the presence of obstruction or paralytic ileus	A-1
Antifungal Therapy	
Antifungal therapy for patients with severe community-acquired or healthcare-associated infection is recommended if *Candida* is grown from intra-abdominal cultures	B-2
Anti-MRSA Therapy	
Empiric antimicrobial coverage directed against MRSA should be provided to patients with healthcare-associated intra-abdominal infection who are known to be colonized with the organism or who are at risk of having an infection due to this organism because of prior treatment failure and significant antibiotic exposure	B-2
Vancomycin is recommended for treatment of suspected or proven intra-abdominal infection due to MRSA	A-3

(*continued*)

TABLE 114-7 Evidence-Based Recommendations for Treatment of Complicated Intra-abdominal Infections (*Continued*)

	Grade of Recommendation[a]
Antienterococcal Therapy	
Antimicrobial therapy for enterococci should be given when enterococci are recovered from patients with healthcare-associated infection	B-III
Empiric antienterococcal therapy is recommended for patients with high-risk community-acquired infections and healthcare-associated intra-abdominal infections, particularly those with postoperative infection, those who have previously received cephalosporins or other antimicrobial agents selecting for *Enterococcus* species, immunocompromised patients, and those with valvular heart disease or prosthetic intravascular materials	B-II
Initial empiric antienterococcal therapy should be directed against *Enterococcus faecalis*. Antibiotics that can potentially be used against this organism, on the basis of susceptibility testing of the individual isolate, include ampicillin, piperacillin/tazobactam, and vancomycin	B-III
Empiric therapy directed against vancomycin-resistant *Enterococcus faecium* is not recommended unless the patient is at very high risk for an infection due to this organism, such as a liver transplant recipient with an intra-abdominal infection originating in the hepatobiliary tree or a patient known to be colonized with vancomycin-resistant *E. faecium*	B-III

MRSA, methicillin-resistant *Staphylococcus aureus*.

[a]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from ≥1 properly randomized, controlled trial. 2 = Evidence from ≥1 well-designed clinical trial without randomization, from cohort or case-controlled analytic studies; from multiple time series, or from dramatic results from uncontrolled experiments. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

[b]Criteria for high risk or high severity community-acquired infection: APACHE II score ≥15, delay in initial intervention >24 hours), advanced age, comorbidity and degree of organ dysfunction, low albumin level, poor nutritional status, degree of peritoneal involvement or diffuse peritonitis, inability to achieve adequate debridement or control of drainage, and presence of malignancy.

[c]After IDSA/SIS guideline publication a randomized controlled trial was published and demonstrated that 4 days of therapy after source control is adequate[47]

Data from reference 48.

number of studies found that glycopeptide-containing regimens (vancomycin or teicoplanin) were more likely to achieve complete cure compared to first generation cephalosporins.[69] However the study contributing most of the weight in this meta-analysis used a lower than recommended cefazolin dose.[71] One of these Gram-positive agents should be combined with a Gram-negative agent such as ceftazidime (LD 500 mg/L; MD 125 mg/L) or cefepime (LD 500 mg/L; MD 125 mg/L) or an aminoglycoside (gentamicin or tobramycin LD 8 mg/L; MD 4 mg/L). Another option is monotherapy with cefepime or imipenem–cilastatin (LD 250 mg/L; MD 50 mg/L). Antimicrobial doses should empirically be increased by 25% in patients with residual renal function (more than 100 mL/day urine output).[70] Antimicrobial therapy should be continued for at least 1 week after the dialysate fluid is clear and for a total of at least 14 days. The reader is referred to these guidelines for additional information.[70]

After acute bacterial contamination, such as with abdominal trauma where GI contents spill into the peritoneum, antibiotics should be administered. If the patient is seen soon after injury (within 2 hours) and surgical measures are instituted promptly, antianaerobic cephalosporins (such as cefoxitin), a third-generation cephalosporin (such as ceftriaxone) with metronidazole, or piperacillin/tazobactam are effective in preventing most infectious complications. Antimicrobials should be administered as soon as possible after injury.

For appendicitis, the antimicrobial regimen used should depend on the appearance of the appendix at the time of operation, which may be normal, inflamed, gangrenous, or perforated. Because the condition of the appendix is unknown preoperatively, it is advisable to begin antimicrobial agents before the appendectomy is performed. Reasonable regimens would be antianaerobic cephalosporins or, if the patient is seriously ill, piperacillin–tazobactam or an anti-pseudomonal carbapenem. If, at operation, the appendix is normal or inflamed, postoperative antimicrobials are not required. If the appendix is gangrenous or perforated, a treatment course of 4 days with the agents listed in Table 114-6 is appropriate.

8 Acute intra-abdominal contamination, such as after a traumatic injury, may be treated with a very short antimicrobial course (24 hours).[72] For established infections (ie, peritonitis or intra-abdominal abscess), an antimicrobial course limited to 4 days is appropriate.[47] This allows eradication of bacteria remaining in the peritoneum after a surgical procedure that may enter the peritoneum through healing suture lines. Under certain conditions, therapy for longer than 4 days would be justified (eg, when a focus of infection in the abdomen is still present). For some abscesses, such as pyogenic liver abscess, antimicrobials may be required for a month or longer.

Clinical **Controversy...**

The Infectious Diseases Society of America/Surgical Infection Society guidelines for complicated intra-abdominal infections recommend 4 to 7 days of antimicrobial therapy after attainment of source control.[48] Despite this, therapy has historically continued for longer durations, likely due to an initial lack of high quality data supporting this recommendation.[73] A subsequent randomized controlled trial of 518 patients with intra-abdominal infection and adequate source control compared the clinical outcomes of 4 days of antimicrobial therapy after the index source control procedure versus 2 days of therapy after normalization of leukocytosis, temperature, and diet (median 8 days of therapy).[47] This study found no difference in the rate of surgical site infections, recurrent intra-abdominal infections, or mortality between treatment groups; this suggests 4 days of therapy after source control is likely adequate. Although the study was stopped after enrolling approximately 50% of the patients initially planned, the proportion of patients meeting primary or secondary outcomes were similar in the total cohort as well as in multiple patient subgroups defined a priori. Because the study only assessed patients with source control, the optimal duration of antimicrobial therapy in patients with uncontrolled sources of intra-abdominal infection remains unknown. In these cases, should antimicrobial therapy be continued until the source is controlled? Or, if source control is not possible in the near term and the patient is clinically stable with minimal signs of systemic inflammatory response, can antimicrobial therapy be safely withheld and the patient closely monitored so as to limit long durations of antimicrobial therapy and associated adverse effects?

TABLE 114-8 Guidelines for Empiric Antimicrobial Agents for Intra-Abdominal Infections[48,70]

	Primary Agents	Alternatives
Primary (Spontaneous) Bacterial Peritonitis		
Cirrhosis	Ceftriaxone, cefotaxime	1. Piperacillin–tazobactam, carbapenems 2. Aztreonam combined with an agent active against *Streptococcus* spp. (eg, vancomycin) or quinolones with significant *Streptococcus* spp. activity (levofloxacin, moxifloxacin)
Peritoneal dialysis	Initial empiric regimens should be active against both Gram-positive (including *S. aureus*) and Gram-negative pathogens: Gram-positive agent (first-generation cephalosporin or vancomycin) plus a Gram-negative agent (third-generation cephalosporin or aminoglycoside)	1. Cefepime or carbapenems may be used alone 2. Aztreonam or an aminoglycoside may be used in place of ceftazidime or cefepime as long as combined with a Gram-positive agent 3. Quinolones may be used in place of Gram-negative agents if local susceptibilities allow
	1. *Staphylococcus* spp.: oxacillin/nafcillin or first-generation cephalosporin	1. Vancomycin should be used if concern for methicillin-resistant *Staphylococcus* spp. 2. Add rifampin for 5-7 days with vancomycin for methicillin-resistant *S. aureus*
	2. *Streptococcus* or *Enterococcus*: ampicillin	1. An aminoglycoside may be added for *Enterococcus* spp. 2. Linezolid or daptomycin should ideally be used to treat vancomycin-resistant *Enterococcus* spp. not susceptible to ampicillin
	3. Aerobic Gram-negative bacilli: ceftazidime or cefepime	1. The regimen should be based on in vitro sensitivity tests
	4. *Pseudomonas aeruginosa*: two agents with differing mechanisms of action, such as an oral quinolone plus ceftazidime, cefepime, tobramycin, or piperacillin	
Secondary Bacterial Peritonitis		
Perforated peptic ulcer	First-generation cephalosporins	1. Ceftriaxone, cefotaxime, or antianaerobic cephalosporins[a]
Other	Third- or fourth-generation cephalosporin with metronidazole, piperacillin–tazobactam or carbapenem	1. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or *moxifloxacin*[b] alone 2. Aztreonam with vancomycin and metronidazole 3. Antianaerobic cephalosporins[a]
Abscess		
General	Third- or fourth-generation cephalosporin with metronidazole, or piperacillin–tazobactam	1. Imipenem–cilastatin, meropenem, doripenem, or ertapenem 2. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or moxifloxacin alone
Liver	As above	Use metronidazole if amoebic liver abscess is suspected
Spleen	Ceftriaxone or cefotaxime	Moxifloxacin[b] or levofloxacin[b]
Other Intra-abdominal Infections		
Appendicitis	Same management as for community-acquired complicated intra-abdominal infections as listed in Table 114-6[39]	
Community-acquired acute cholecystitis	Ceftriaxone or cefotaxime	Severe infection, piperacillin/tazobactam, antipseuodomonal carbapenem, aztreonam with metronidazole
Cholangitis	Ceftriaxone or cefotaxime each with or without metronidazole	Vancomycin with aztreonam with or without metronidazole
Acute contamination from abdominal trauma	Antianaerobic cephalosporins[a] or metronidazole with either ceftriaxone or cefotaxime	1. Piperacillin/tazobactam or a carbapenem 2. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or moxifloxacin alone

[a]Cefoxitin or ceftizoxime; these agents should be avoided empirically unless local antibiograms show >80% to 90% susceptibility of *E. coli* to these agents.

[b]Use of quinolones may be associated with treatment failure due to increasing resistance of enteric pathogens including *E. coli*. Empiric quinolone use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to quinolones.

Intraperitoneal irrigation of antimicrobial agents for treatment of intra-abdominal infection has been studied, often with conflicting results.[74] Intraoperative antimicrobial irrigation does not improve patient outcomes in comparison with copious intraoperative irrigation with normal saline. Possibly the most important aspect of peritoneal irrigation is the dilutional effect on bacteria and adjuvants that promotes infection (intestinal contents and hemoglobin). Most systemically administered antimicrobials easily cross the peritoneal membrane so that peritoneal fluid concentrations are similar to serum. Confined areas, such as an abscess, can be expected to attain much lower antimicrobial concentrations.

EVALUATION OF THERAPEUTIC OUTCOMES

Whichever antimicrobial regimen is chosen, the patient should be reassessed continually to determine the success or failure of therapies. The clinician should recognize that there are many reasons for poor patient outcomes with intra-abdominal infections; improper antimicrobial administration is only one. The patient may be immunocompromised, which decreases the likelihood of successful outcome with any regimen. There may be surgical reasons for poor patient outcome. Failure to identify all intra-abdominal foci of infection or leaks from a GI anastomosis may cause continued infection. Finally, antimicrobial resistance may contribute to treatment failure as isolates from intra-abdominal infections are increasingly drug resistant.[75]

The outcome from intra-abdominal infection is not determined solely by what transpires in the abdomen. Unsatisfactory outcomes in patients with intra-abdominal infections may result from complications that arise in other organ systems, including renal or respiratory failure. Furthermore, pneumonia is a complication that is commonly associated with mortality after intra-abdominal infection.[76] A high APACHE (Acute Physiology and Chronic Health Evaluation) II score, low serum albumin concentration, and high New York Heart Association cardiac function status were independently associated with increased mortality from intra-abdominal infection.[77]

9 Once antimicrobials are initiated and the other important therapies described earlier are used, most patients should show improvement within 2 to 3 days. Usually, temperature will return to near normal, vital signs should stabilize, and the patient should not appear in distress, with the exception of recognized discomfort and pain from incisions, drains, and the nasogastric tube. At 24 to 48 hours, aerobic bacterial culture results should return. If a suspected pathogen is not sensitive to the antimicrobial agents being given, the regimen should be changed if the patient has not shown sufficient improvement. If the isolated pathogen is susceptible to a narrower spectrum agent, therapy should be deescalated.

With anaerobic culturing techniques and the slow growth of these organisms, anaerobes are often not identified until 4 to 7 days after culture. A report indicating that anaerobes were not isolated should not be the sole justification for discontinuing antianaerobic drugs because anaerobic bacteria that were present in the infectious process may not have been transported properly to the microbiology laboratory, or other problems may have led to cell death in vitro.

Reasons for antimicrobial failure may not always be apparent. Even when antimicrobial susceptibility tests indicate that an organism is susceptible in vitro to the antimicrobial agent, therapeutic failures may occur. Possibly there is poor penetration of the antimicrobial agent into the focus of infection, or bacterial resistance may develop after initiation of antimicrobial therapy. In addition, it is possible that an antimicrobial regimen may encourage the development of infection by organisms not susceptible to the regimen being used. Superinfection in patients being treated for intra-abdominal infection can be caused by *Candida*; however, enterococci or opportunistic Gram-negative bacilli such as *Pseudomonas* may be involved.

Treatment regimens for intra-abdominal infection can be judged as successful if the patient recovers from the infection without recurrent peritonitis or intra-abdominal abscess and without the need for additional antimicrobials. A regimen can be considered unsuccessful if a significant adverse drug reaction occurs, reoperation or percutaneous drainage is necessary, or patient improvement is delayed beyond 1 or 2 weeks. The costs of treatment can be significantly reduced if parenteral antimicrobials can be switched to oral agents for completion of therapy.[78]

ABBREVIATIONS

APACHE	acute physiology and chronic health evaluation
CAPD	chronic ambulatory peritoneal dialysis
CT	computed tomography
CVP	central venous pressure
ESBL	extended-spectrum β-lactamase
IL	interleukin
INF	interferon
KPC	*Klebsiella pneumoniae* carbapenemase
LD	loading dose
MAP	mean arterial pressure
MD	maintenance dose
MRSA	methicillin-resistant *Staphylococcus aureus*
TNF	tumor necrosis factor

Parasitic Diseases

e115

Jason M. Cota and JV Anandan

KEY CONCEPTS

1. Nitazoxanide and tinidazole are Food and Drug Administration (FDA)-approved for giardiasis treatment. While the FDA has not approved metronidazole for this indication, it has been widely accepted as the mainstay of giardiasis therapy for the past 50 years.
2. Human immunodeficiency virus (HIV)-infected patients with cryptosporidiosis must receive antiretroviral therapy as the mainstay of therapy in addition to antiparasitic therapy.
3. Serologic detection assays are required to diagnose *Entamoeba histolytica* infection because stool sample analysis is insensitive and does not distinguish between *E. histolytica* and the nonpathogenic *E. dispar* or *E. moshkovskii*.
4. Metronidazole and tinidazole are tissue-acting agents against amoeba; whereas, paromomycin, iodoquinol, and diloxanide furoate are luminal amebicides.
5. The drugs that have been used to treat *Trypanosoma cruzi* infections include benznidazole and nifurtimox, but are not currently approved by the FDA. Both are available from the Centers for Disease Control and Prevention (CDC) under an Investigational New Drug program.
6. Chloroquine has been the recommended drug for malaria chemoprophylaxis, but clinicians have increasingly prescribed alternative antimalarial drugs such as atovaquone-proguanil, doxycycline, primaquine, and mefloquine because these regimens retain effectiveness in areas where chloroquine-resistant *Plasmodium falciparum* exposure is likely.
7. Administration of corticosteroids or other immunosuppressive drugs to an infected individual can result in hyperinfections and disseminated strongyloidiasis.
8. Antihelminthic therapy destroys parasites and may cause increased inflammation and worsening of neurocysticercosis symptoms.
9. For head lice, the American Academy of Pediatrics recommends either nonprescription 1% permethrin or pyrethrins plus piperonyl butoxide topical preparations as agents of choice unless local resistance to these agents is documented.
10. A single application of 5% permethrin results in cure rates in more than 90% of subjects with scabies at 14 and 28 days, but a second dose should be applied 1 week later because its ovicidal efficacy remains unclear.

Parasitic diseases remain a significant global health problem causing approximately one million deaths per year and affecting more than 1.7 billion people worldwide.[1-5] In the United States, immunocompromised patients, ethnic/racial minorities, immigrants, those with recent travel to developing regions, individuals living in poor sanitary conditions, and people who lack access to basic health care services appear to be at highest risk for developing parasitic disease.[6] However, people in every income and social strata can become infected. In fact, the Centers for Disease Control and Prevention (CDC) has referred to five diseases as neglected parasitic infections and has prioritized these for increased public health action.[7] They include Chagas disease, cysticercosis, toxocariasis, toxoplasmosis, and trichomoniasis.[8]

This chapter discusses the major parasitic diseases including protozoan disease (giardiasis, cryptosporidiosis, Chagas disease, amebiasis, and malaria), helminthic infections (strongyloidiasis, cysticercosis, and toxocariasis), and ectoparasitic infestations (lice and scabies).

HOST–PARASITE RELATIONSHIP

Symbiosis is the association of two species for the purpose of obtaining food for either one or the other. *Parasitism* is a symbiotic relationship in which one species, the host, is injured through the activities of the other. Through evolution, parasites have made specific morphologic adaptations. Adaptation to the host has taken a number of forms: loss of locomotor organelles in the protozoan *Sporozoa*; partial and complete lack of digestive systems in the trematodes and cestodes, respectively; elaboration of proteolytic enzymes to penetrate the host intestinal mucosa by *Entamoeba histolytica*; the cercariae of the blood fluke that penetrate the skin of the host by elaborate enzymes; and, finally, the ability to infect an intermediate host to increase reproductive capacity, as seen among the cestodes and trematodes.[9]

Parasites normally inflict some degree of injury to the host, the extent of which depends on such factors as parasite load, nutritional status, and immunologic competence of the host. *E. coli* is considered commensal because it subsists on the bacterial flora of the gut and does not cause any harm to the host. Unlike *E. coli*, *Fasciolopsis buski*, the giant intestinal fluke, can produce severe local damage to the intestinal wall. *Ascaris*, the roundworm, can perforate the bowel wall, cause intestinal obstruction, and invade the appendix and bile duct. Malarial parasites destroy red blood cells by multiplying inside them. *Diphyllobothrium latum*, or the broad fish tapeworm, removes vitamin B_{12} from the gastrointestinal (GI) tract, resulting in megaloblastic anemia.[9]

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com.**

Urinary Tract Infections and Prostatitis

116

Elizabeth A. Coyle and Randall A. Prince

KEY CONCEPTS

1. Urinary tract infections (UTIs) can be classified as uncomplicated and complicated. *Uncomplicated* refers to an infection in an otherwise healthy, premenopausal female who lacks structural or functional abnormalities of the urinary tract. Most often complicated infections are associated with a predisposing lesion of the urinary tract; however, the term may be used to refer to all other infections, except for those in the otherwise healthy, premenopausal adult female.
2. Recurrent UTIs are considered either reinfections or relapses. Reinfection usually happens more than 2 weeks after the last UTI and is treated as a new uncomplicated UTI. Relapse usually happens within 2 weeks of the original infection, and is a relapse of the original infection either because of unsuccessful treatment of the original infection, a resistant organism, or anatomical abnormalities.
3. Majority (75%-90%) of uncomplicated UTIs are caused by *Escherichia coli* and the remainder are caused primarily by *Staphylococcus saprophyticus*, *Proteus* spp., and *Klebsiella* spp. Complicated infections may be associated with other gram-negative organisms and *Enterococcus faecalis*.
4. Symptoms of lower UTIs include dysuria, urgency, frequency, nocturia, and suprapubic heaviness, whereas upper UTIs involve more systemic symptoms such as fever, nausea, vomiting, and flank pain.
5. Significant bacteriuria traditionally has been defined as bacterial counts of greater than 10^5 organisms (colony-forming unit [CFU])/mL (10^8 CFU/L) of a midstream clean catch urine. However, this is too general and significant bacteriuria in patients with symptoms of a UTI may be defined as greater than 10^2 organisms (CFU)/mL (10^5 CFU/L).
6. The goals of treatment of UTIs are to eradicate the invading organism(s), prevent or treat systemic consequences of infections, prevent the recurrence of infection, and prevent antimicrobial resistance.
7. Uncomplicated UTIs can be managed most effectively with short-course therapy (3 days) with either trimethoprim–sulfamethoxazole, one dose of fosfomycin, or 5 days of nitrofurantoin. Fluoroquinolones should be reserved for suspected pyelonephritis or complicated infections.
8. In choosing appropriate antibiotic therapy, practitioners need to be cognizant of antibiotic resistance patterns, particularly to *E. coli*. Trimethoprim–sulfamethoxazole has diminished activity against *E. coli* in some areas of the country, with reported resistance in some areas greater than 20%.
9. Acute bacterial prostatitis can be managed with many agents that have activity against the causative organism. Chronic prostatitis requires prolonged therapy with an agent that penetrates the prostatic tissue and secretions. Therapy with fluoroquinolone or trimethoprim–sulfamethoxazole is preferred for up to 6 weeks.

Infections of the urinary tract represent a wide variety of syndromes, including urethritis, cystitis, prostatitis, and pyelonephritis. Urinary tract infections (UTIs) are the most commonly occurring bacterial infections and one of the most common reasons for antibiotic exposure, especially in females of childbearing age.[1-3] Approximately 60% of females will develop a UTI during their lifetime with about one-fourth having a recurrence within a year.[2] Infections in men occur much less frequently until the age of 65 years at which point the incidence rates in men and women are similar.

A UTI is defined as the presence of microorganisms in the urinary tract that cannot be accounted for by contamination. The organisms present have the potential to invade the tissues of the urinary tract and adjacent structures. Infection may be limited to the growth of bacteria in the urine, which frequently may not produce symptoms. A UTI can present as several syndromes associated with an inflammatory response to microbial invasion and can range from asymptomatic bacteriuria (ASB) to pyelonephritis with bacteremia or sepsis.

UTIs are classified by lower and upper UTIs. Typically, they have been described by anatomic site of involvement. Lower tract infections correspond to cystitis (bladder), and pyelonephritis (an infection involving the kidneys) represents upper tract infection.

1 Also, UTIs are designated as uncomplicated or complicated. Uncomplicated infections occur in individuals who lack structural or functional abnormalities of the urinary tract that interfere with the normal flow of urine or voiding mechanism. These infections occur in premenopausal females of childbearing age (15-45 years) who are otherwise normal, healthy individuals. Infections in males generally are not classified as uncomplicated because these infections are rare and most often represent a structural or neurologic abnormality.

Complicated UTIs are usually the result of a predisposing lesion of the urinary tract, such as a congenital abnormality or distortion of the urinary tract, a stone, indwelling catheter, prostatic hypertrophy, obstruction, or neurologic deficit that interferes with the normal flow of urine and urinary tract defenses. Complicated infections occur in both genders and frequently involve the upper and lower urinary tract.

2 Recurrent UTIs in healthy nonpregnant women—two or more UTIs occurring within 6 months or three or more UTIs within 1 year—are a common problem. They are characterized by multiple symptomatic infections with asymptomatic periods occurring between each episode and may be either reinfections or relapses. Reinfections are caused by a different organism than originally isolated and account for the majority of recurrent UTIs. Relapses are

TABLE 116-1 Diagnostic Criteria for Significant Bacteriuria

$\geq 10^2$ CFU coliforms/mL ($\geq 10^5$ CFU/L) or $\geq 10^5$ CFU noncoliforms/mL ($\geq 10^8$ CFU/L) in a symptomatic female
$\geq 10^4$ CFU bacteria/mL ($\geq 10^7$ CFU/L) in a symptomatic male
$\geq 10^5$ CFU bacteria/mL ($\geq 10^8$ CFU/L) in asymptomatic individuals on two consecutive specimens
Any growth of bacteria on suprapubic catheterization in a symptomatic patient
$\geq 10^{2-5}$ CFU bacteria/mL ($\geq 10^{5-8}$ CFU/L) in a catheterized patient

CFU, colony-forming unit.

the development of repeated infections with the same initial organism and usually indicate a persistent infectious source.[2]

ASB is a common finding, particularly among those 65 years of age and older when there is significant bacteriuria (more than 10^5 bacteria/mL [more than 10^8/L] of urine) in the absence of symptoms. Symptomatic abacteriuria or acute urethral syndrome consists of symptoms of frequency and dysuria in the absence of significant bacteriuria. This syndrome is commonly associated with *Chlamydia* infections.

Significant abacteriuria is a term used to distinguish the presence of microorganisms that represent true infection versus contamination of the urine as it passes through the distal urethra prior to collection. Historically, bacterial counts equal to or greater than 100,000 organisms/mL (10^8/L) of urine in a "clean-catch" specimen were judged to indicate true infection.[4-6] Counts less than 100,000 organisms/mL (10^8/L) of urine, however, may represent true infection in certain situations. For example, with concurrent antibacterial drug administration, rapid urine flow, low urinary pH, or upper tract obstruction.[6] Table 116-1 lists the clinical definitions of significant bacteriuria, which are dependent on the clinical setting and the method of specimen collection.[6] These criteria allow for more appropriate specificity and sensitivity in documenting infection under differing clinical circumstances.

EPIDEMIOLOGY

The prevalence of UTIs varies with age and gender. In newborns and infants up to 6 months of age, the prevalence of abacteriuria is approximately 1% and is more common in boys. Most of these infections are associated with structural or functional abnormalities of the urinary tract and also have been correlated with noncircumcision.[7] Between the ages of 1 and 6 years, UTIs occur more frequently in females. The prevalence of abacteriuria in females and males of this age group is 3% to 7% and 1% to 2%, respectively.[7,8] Infections occurring in preschool boys usually are associated with congenital abnormalities of the urinary tract. These infections are difficult to recognize because of the age of the patient, but they often are symptomatic. In addition, the majority of renal damage associated with UTI develops at this age.[7,8]

Through grade school and before puberty, the prevalence of UTI is approximately 1%, with 5% of females reported to have significant bacteriuria prior to leaving high school. This percentage increases dramatically to 1% to 4% after puberty in nonpregnant females primarily as a result of sexual activity. Approximately one in five women will suffer a symptomatic UTI at some point in their lives. Many women have recurrent infections with a significant proportion of these women having a history of childhood infections. In contrast, the prevalence of bacteriuria in adult men is very low (less than 0.1%).[9]

In the elderly, the ratio of bacteriuria in women and men is dramatically altered and is approximately equal in persons older than 65 years.[10] The overall incidence of UTI increases substantially in this population with the majority of infections being asymptomatic. The rate of infection increases further for elderly persons who are residing in nursing homes, particularly those who are hospitalized frequently. The increase is probably the result of factors such as obstruction from prostatic hypertrophy in males, poor bladder emptying as a result of prolapse in females, fecal incontinence in demented patients, and neuromuscular disease including strokes and increased urinary instrumentation (catheterization).

ETIOLOGY

3 The bacteria causing UTIs usually originate from bowel flora of the host. Although virtually every organism is associated with UTIs, certain organisms predominate as a result of specific virulence factors. The most common cause of uncomplicated UTIs is *Escherichia coli*, which accounts for 80% to 90% of community-acquired infections. Additional causative organisms in uncomplicated infections include *Staphylococcus saprophyticus*, *Klebsiella pneumoniae*, *Proteus* spp., *Pseudomonas aeruginosa*, and *Enterococcus* spp.[11] Because *S. epidermidis* is frequently isolated from the urinary tract, it should be considered initially a contaminant. Repeat cultures should be performed to help confirm the organism as a real pathogen.

Organisms isolated from individuals with complicated infections are more varied and generally are more resistant than those found in uncomplicated infections. *E. coli* is a frequently isolated pathogen, but it accounts for less than 50% of infections. Other frequently isolated organisms include *Proteus* spp., *K. pneumoniae*, *Enterobacter* spp., *P. aeruginosa*, staphylococci, and enterococci. Enterococci represent the second most frequently isolated organisms in hospitalized patients.[11-13] In part, this finding may be related to the extensive use of third-generation cephalosporin antibiotics, which are not active against the enterococci. Vancomycin-resistant *E. faecalis* and *E. faecium* (vancomycin-resistant enterococci) have become more widespread, especially in patients with long-term hospitalizations or underlying malignancies. Vancomycin-resistant enterococci are major therapeutic and infection control issues because these organisms are susceptible to few antimicrobials.[12,13]

S. aureus infections may arise from the urinary tract, but they are more commonly a result of bacteremia producing metastatic abscesses in the kidney. *Candida* spp. are common causes of UTI in the critically ill and chronically catheterized patient.

Most UTIs are caused by a single organism; however, in patients with stones, indwelling urinary catheters, or chronic renal abscesses, multiple organisms may be isolated. Depending on the clinical situation, the recovery of multiple organisms may represent contamination and a repeat evaluation should be done.

PATHOPHYSIOLOGY

Route of Infection

Organisms typically gain entry into the urinary tract via three routes: the ascending, hematogenous (descending), and lymphatic pathways. The female urethra usually is colonized by bacteria believed to originate from the fecal flora. The short length of the female urethra and its proximity to the perirectal area make colonization of the urethra likely. Other factors that promote urethral colonization include the use of spermicides and diaphragms as methods of contraception.[2,3] Although there is evidence in females that bladder infections follow colonization of the urethra, the mode of ascent of the microorganisms is incompletely understood. Massage of the female urethra and sexual intercourse allow bacteria to reach the bladder.[14] Once bacteria have reached the bladder, the organisms quickly multiply and can ascend the ureters to the kidneys. This sequence of events is more likely to occur if vesicoureteral reflux (reflux of urine into the ureters and kidneys while voiding) is present. UTIs are more common in females than in males because the anatomic differences in location

and length of the urethra tend to support the ascending route of infections as the primary acquisition route.

Infection of the kidney by hematogenous spread of microorganisms usually occurs as the result of dissemination of organisms from a distant primary infection in the body. Infections via the descending route are uncommon and involve a relatively small number of invasive pathogens. Bacteremia caused by *S. aureus* may produce renal abscesses. Additional organisms include *Candida* spp., *Mycobacterium tuberculosis*, *Salmonella* spp., and enterococci. Of particular interest, it is difficult to produce experimental pyelonephritis by IV administration of common gram-negative organisms such as *E. coli* and *P. aeruginosa*. Overall, less than 5% of documented UTIs result from hematogenous spread of microorganisms.

There appears to be little evidence supporting a significant role for renal lymphatics in the pathogenesis of UTIs. There are lymphatic communications between the bowel and kidney, as well as between the bladder and kidney. There is no evidence, however, that microorganisms are transferred to the kidney via this route.

After bacteria reach the urinary tract, three factors determine the development of infection: the size of the inoculum, the virulence of the microorganism, and the competency of the natural host defense mechanisms. Most UTIs reflect a failure in host defense mechanisms.

Host Defense Mechanisms

The normal urinary tract generally is resistant to invasion by bacteria and is efficient in rapidly eliminating microorganisms that reach the bladder. The urine under normal circumstances is capable of inhibiting and killing microorganisms. The factors thought to be responsible include a low pH, extremes in osmolality, high urea concentration, and high organic acid concentration. Bacterial growth is further inhibited in males by the addition of prostatic secretions.[14,15]

The introduction of bacteria into the bladder stimulates micturition with increased diuresis and efficient emptying of the bladder. These factors are critical in preventing the initiation and maintenance of bladder infections. Patients who are unable to void urine completely are at greater risk of developing UTIs and frequently have recurrent infections. Also, patients with even small residual amounts of urine in their bladder respond less favorably to treatment than patients who are able to empty their bladders completely.[16]

An important virulence factor of bacteria is their ability to adhere to urinary epithelial cells resulting in colonization of the urinary tract, bladder infections, and pyelonephritis. Various factors that act as anti-adherence mechanisms are present in the bladder preventing bacterial colonization and infection. The epithelial cells of the bladder are coated with a urinary mucus or slime called *glycosaminoglycan*. This thin layer of surface mucopolysaccharide is hydrophilic and strongly negatively charged. When bound to the uroepithelium, it attracts water molecules and forms a layer between the bladder and urine. The anti-adherence characteristics of the glycosaminoglycan layer are nonspecific and when the layer is removed by dilute acid solutions, rapid bacterial adherence results.[17]

In addition, the Tamm–Horsfall protein is a glycoprotein produced by the ascending limb of Henle and distal tubule that is secreted into the urine and contains mannose residues. These mannose residues bind *E. coli* that contain small surface-projecting organellae on their surfaces called *pili* or *fimbriae*. Type 1 fimbriae are mannose-sensitive and this interaction prevents the bacteria from binding to similar receptors present on the mucosal surface of the bladder. Other factors that possibly prevent adherence of bacteria include immunoglobulins (Ig) G and A. Investigators have documented both systemic and local kidney Ig synthesis in upper tract infections. The role of Igs in preventing bladder infection is less clear. Patients with reduced urinary levels of secretory IgA are, however, at increased risk of infections of the urinary tract.

After bacteria have invaded the bladder mucosa, an inflammatory response is stimulated with the mobilization of polymorphonuclear leukocytes (PMNs) and resulting phagocytosis. PMNs are primarily responsible for limiting the tissue invasion and controlling the spread of infection in the bladder and kidney. They do not play a role in preventing bladder colonization or infections and actually contribute to renal tissue damage.

Other host factors that may play a role in the prevention of UTIs are the presence of *Lactobacillus* in the vaginal flora and circulating estrogen levels. In premenopausal women, circulating estrogen supports the vaginal tract growth of lactobacilli, which produce lactic acid to help maintain a low vaginal pH, thereby preventing *E. coli* vaginal colonization.[18] Topical estrogens are used for the prevention of UTI in postmenopausal women who have more than three recurrent UTI episodes per year and are not on oral estrogens.[19]

Bacterial Virulence Factors

Pathogenic organisms have differing degrees of pathogenicity (virulence), which play a role in the development and severity of infection. Bacteria that adhere to the epithelium of the urinary tract are associated with colonization and infection. The mechanism of adhesion of gram-negative bacteria, particularly *E. coli*, is related to bacterial fimbriae that are rigid, hair-like appendages of the cell wall.[9] These fimbriae adhere to specific glycolipid components on epithelial cells. The most common type of fimbriae is type 1, which binds to mannose residues present in glycoproteins. Glycosaminoglycan and Tamm–Horsfall protein are rich in mannose residues that readily trap those organisms that contain type 1 fimbriae, which are then washed out of the bladder.[20] Other fimbriae are mannose resistant and are associated more frequently with pyelonephritis, such as P fimbriae, which bind avidly to specific glycolipid receptors on uroepithelial cells. These bacteria are resistant to washout or removal by glycosaminoglycan and are able to multiply and invade tissue, especially the kidney. In addition, PMNs, as well as secretory IgA antibodies, contain receptors for type 1 fimbriae, which facilitate phagocytosis, but are lacking receptors for P fimbriae.

Other virulence factors include the production of hemolysin and aerobactin.[21] Hemolysin is a cytotoxic protein produced by bacteria that lyses a wide range of cells, including erythrocytes, PMNs, and monocytes. *E. coli* and other gram-negative bacteria require iron for aerobic metabolism and multiplication. Aerobactin facilitates the binding and uptake of iron by *E. coli*; however, the significance of this property in the pathogenesis of UTIs remains unknown.[22]

PREDISPOSING FACTORS TO INFECTION

The normal urinary tract typically is resistant to infection and colonization by pathogenic bacteria. In patients with underlying structural abnormalities of the urinary tract, the typical host defenses previously discussed usually are lacking or compromised. There are several known abnormalities of the urinary tract system that interfere with its natural defense mechanisms, the most important of which is obstruction. Obstruction can inhibit the normal flow of urine disrupting the natural flushing and voiding effect in removing bacteria from the bladder and resulting in incomplete emptying. Common conditions that result in residual urine volumes include prostatic hypertrophy, urethral strictures, calculi, tumors, bladder diverticula, and drugs such as anticholinergic agents. Additional causes of incomplete bladder emptying include neurologic malfunctions associated with stroke, diabetes, spinal cord injuries, tabes dorsalis, and other neuropathies. Vesicoureteral reflux represents a condition in which urine is forced up the ureters to the kidneys. Urinary reflux is associated not only with an increased incidence of UTIs and pyelonephritis, but also with renal damage.[8,16] Reflux may

CLINICAL PRESENTATION Urinary Tract Infections in Adults

Signs and Symptoms

- Lower UTI: Dysuria, urgency, frequency, nocturia, and suprapubic heaviness
- Gross hematuria
- Upper UTI: Flank pain, fever, nausea, vomiting, and malaise

Physical Examination

- Upper UTI: Costovertebral tenderness

Laboratory Tests

- Bacteriuria
- Pyuria (WBC count more than 10/mm^3 [more than 10×10^6/L])
- Nitrite-positive urine (with nitrite reducers)
- Leukocyte esterase-positive urine
- Antibody-coated bacteria (upper UTI)

be the result of a congenital abnormality or, more commonly, bladder overdistension from obstruction.

Other risk factors include urinary catheterization, mechanical instrumentation, pregnancy, and the use of spermicides and diaphragms.

CLINICAL PRESENTATION

4 The presenting signs and symptoms of UTIs in adults are recognized easily. Women frequently will report gross hematuria. Systemic symptoms, including fever, typically are absent in this setting. Unfortunately, large numbers of patients with significant bacteriuria are asymptomatic. These patients may be normal, healthy patients, elderly patients, children, pregnant patients, and patients with indwelling catheters. It is important to note that attempts at differentiating upper tract from lower tract infections on the basis of symptoms alone are not reliable.

Elderly patients frequently do not experience specific urinary symptoms, but they will present with altered mental status, change in eating habits, or gastrointestinal (GI) symptoms. In addition, patients with indwelling catheters or neurologic disorders commonly will not have lower tract symptoms. Instead, they may present with flank pain and fever. Many of the aforementioned patients, however, frequently will develop upper tract infections with bacteremia and no or minimal urinary tract symptoms.

Symptoms alone are unreliable for the diagnosis of bacterial UTIs. The key to the diagnosis of UTI is the ability to demonstrate significant numbers of microorganisms in an appropriate urine specimen to distinguish contamination from infection. The type and extent of laboratory examination required depends on the clinical situation.

Urine Collection

Examination of the urine is the cornerstone of laboratory evaluation for UTIs. There are three acceptable methods of urine collection. The first is the *midstream clean-catch method*. After cleaning the urethral opening area in both men and women, 20 to 30 mL of urine is voided and discarded. The next part of the urine flow is collected and should be processed immediately (refrigerated as soon as possible). Specimens that are allowed to sit at room temperature for several hours may result in falsely elevated bacterial counts. The midstream clean-catch is the preferred method for the routine collection of urine for culture. When a routine urine specimen cannot be collected or contamination occurs, alternative collection techniques must be used.

The two acceptable alternative methods include catheterization and suprapubic bladder aspiration. Catheterization may be necessary for patients who are uncooperative or who are unable to void urine. If catheterization is performed carefully with aseptic technique, the method yields reliable results. Note, however, that introduction of bacteria into the bladder may result and the procedure is associated with infection in 1% to 2% of patients. Suprapubic bladder aspiration involves inserting a needle directly into the bladder and aspirating the urine. This procedure bypasses the contaminating organisms present in the urethra and any bacteria found using this technique generally are considered to represent significant bacteriuria.[23-26] Suprapubic aspiration is a safe and painless procedure that is most useful in newborns, infants, paraplegics, seriously ill patients, and others in whom infection is suspected and routine procedures have provided confusing or equivocal results.

Bacterial Count

5 The diagnosis of UTI is based on the isolation of significant numbers of bacteria from a urine specimen. Microscopic examination of a urine sample is an easy-to-perform and reliable method for the presumptive diagnosis of bacteriuria. The examination may be performed by preparing a Gram stain of unspun or centrifuged urine. The presence of at least one organism per oil-immersion field in a properly collected uncentrifuged specimen correlates well with more than 100,000 CFU/mL (10^5 CFU/mL or 10^8 CFU/L) of urine. For detecting smaller numbers of organisms, a centrifuged specimen is more sensitive. Such examinations detect more than 10^5 bacteria (CFU)/mL (10^8 CFU/L) with a sensitivity of greater than 90% and a specificity of greater than 70%.[23,24] A quantitative count of greater than or equal to 10^5 CFU/mL (10^8 CFU/L) is considered indicative of a UTI; however, up to 50% of women will present with clinical symptoms of a UTI with lower counts (10^3 CFU/mL) [10^6 CFU/L].[4]

Pyuria, Hematuria, and Proteinuria

Microscopic examination of the urine for leukocytes is used to determine the presence of pyuria. The presence of pyuria in a symptomatic patient correlates with significant bacteriuria.[25] Pyuria is defined as a white blood cell (WBC) count of greater than 10 WBC/mm^3 (10×10^6/L) of urine. A count of 5 to 10 WBC/mm^3 (5×10^6 to 10×10^6/L) is accepted as the upper limit of normal. It should be emphasized that pyuria is nonspecific and signifies only the presence of inflammation and not necessarily infection. Thus patients with pyuria may or may not have infection. Sterile pyuria has long been associated with urinary tuberculosis, as well as chlamydial and fungal urinary infections.

Hematuria, microscopic or gross, is frequently present in patients with UTI, but is nonspecific. Hematuria may indicate the presence of other disorders, such as renal calculi, tumors, or glomerulonephritis. Proteinuria is found commonly in the presence of infection.

Chemistry

Several biochemical tests have been developed for screening urine for the presence of bacteria. A common dipstick test detects the

presence of nitrite in the urine, which is formed by bacteria that reduce nitrate normally present in the urine. False-positive tests are uncommon. False-negative tests are more common and frequently are caused by the presence of gram-positive organisms or *P. aeruginosa* that do not reduce nitrate.[26] Other causes of false tests include low urinary pH, frequent voiding, and dilute urine.

The leukocyte esterase dipstick test is a rapid screening test for detecting the presence of pyuria. Leukocytes esterase is found in primary neutrophil granules and indicates the presence of WBCs. The leukocyte esterase test is a sensitive and highly specific test for detecting more than 10 WBC/mm^3 (10×10^6/L) of urine. When the leukocyte esterase test is used with the nitrite test, the reported positive predictive value and specificity is 79% and 82%, respectively, for the detection of bacteriuria.[27,28] These tests can be useful in the outpatient evaluation of uncomplicated UTIs. However, urine culture is still the "gold standard" test in determining the presence of UTIs.

Culture

The most reliable method of diagnosing UTI is by quantitative urine culture. Urine in the bladder is normally sterile making it statistically possible to differentiate contamination of the urine from infection by quantifying the number of bacteria present in a urine sample. This criterion is based on a properly collected midstream clean-catch urine specimen. Patients with infection usually have greater than 10^5 bacteria/mL (10^8/L) of urine. It should be emphasized that as many as one-third of women with symptomatic infection have less than 10^5 bacteria/mL (10^8/L). Also, a significant portion of patients with UTIs, either symptomatic or asymptomatic, have less than 10^5 bacteria/mL (10^8/L) of urine.

Several laboratory methods are used to quantify bacteria present in the urine. The most accurate method is the pour-plate technique. This method is unsuitable for a high-volume laboratory because it is expensive and time-consuming. The streak-plate method is an alternative that involves using a calibrated-loop technique to streak a fixed amount of urine on an agar plate. This method is used most commonly in diagnostic laboratories because it is simple to perform and less costly.

After identification and quantification are complete, the next step is to determine the susceptibility of the organism. There are several methods by which bacterial susceptibility testing may be performed. Knowledge of bacterial susceptibility and achievable urine concentration of the antibiotics puts the clinician in a better position to select an appropriate agent for treatment.

Infection Site

Several methods have been evaluated to determine the location of infection within the urinary system and differentiate upper tract from lower tract involvement. The most direct method is a ureteral catheterization procedure as described by Stamey and colleagues.[29] The method involves the passage of a catheter into the bladder and then into each ureter, where quantitative cultures are obtained. History and physical examination were of little value in predicting the site of infection. Although this method provides direct quantitative evidence for UTI, it is invasive, technically difficult, and expensive. The Fairley bladder washout technique is a modification of the Stamey procedure that involves Foley catheterization only.[30] After the catheter is passed into the bladder, bladder samples are obtained and the bladder is washed out with culture samples taken at 10, 20, and 30 minutes. The procedure shows that up to 50% of patients have renal involvement, regardless of signs and symptoms. Other investigators found 10% to 20% of tests to be equivocal.[30]

Noninvasive methods of localization may be more acceptable for routine use; however, they have limited clinical value. Patients with pyelonephritis can have abnormalities in urinary concentrating ability. The use of concentrating ability for localization of UTIs, however, is associated with high false-positive and false-negative responses and is not useful clinically.[26] The antibody-coated bacteria test is an immunofluorescent method that detects bacteria coated with Ig in freshly voided urine indicating upper UTI. The sensitivity and specificity of this test to localize the site of infection are reported to average 88% and 76%, respectively.[31] Because of the high incidence of false-positive and false-negative results, antibody-coated bacteria testing is not used routinely in the management of UTIs.

Virtually all patients with uncomplicated lower tract infections can be cured with a short course of antibiotic therapy and this assumption sometimes can be used to distinguish between patients with lower and upper tract infections. Patients who do not respond or who relapse may do so because of upper tract involvement. It is rarely necessary to localize the site of infection to direct the clinical management of such patients.

TREATMENT

Desired Outcomes

6 The goals of UTI treatments are (a) to eradicate the invading organism(s), (b) to prevent or to treat systemic consequences of infection, (c) to prevent the recurrence of infection, and (d) to decrease the potential for collateral damage with too broad of antimicrobial therapy.

Management

The management of a patient with a UTI includes initial evaluation, selection of an antibacterial agent, and duration of therapy and follow-up evaluation. The initial selection of an antimicrobial agent for the treatment of UTI is based primarily on the severity of the presenting signs and symptoms, the site of infection and whether the infection is determined to be uncomplicated or complicated. Other considerations include antibiotic susceptibility, side-effect potential, cost, current antimicrobial exposure, and the comparative inconvenience of different therapies.[1]

Various pharmacologic factors may affect the action of antibacterial agents. Certainly, the ability of the agent to achieve appropriate concentrations in the urine is of utmost importance. Factors that affect the rate and extent of excretion through the kidney include the patient's glomerular filtration rate and whether or not the agent is actively secreted. Filtration depends on the molecular size and degree of protein binding of the agent. Agents such as sulfonamides, tetracyclines, and aminoglycosides enter the urine via filtration. As the glomerular filtration rate is reduced, the amount of drug that enters the urine is reduced. Most β-lactam agents and quinolones are filtered and are actively secreted into the urine. For this reason, most of these agents achieve high urinary concentrations despite unfavorable protein-binding characteristics or the presence of renal dysfunction.

The ability to eradicate bacteria from the urine is related directly to the sensitivity of the microorganism and the achievable concentrations of the antimicrobial agent in the urine. Unfortunately, most susceptibility testing is directed at achievable concentrations in the blood. There is a poor correlation between achievable blood concentrations of antimicrobial agents and the eradication of bacteria from the urine.[32] In the treatment of lower tract infections, plasma concentrations of antibacterial agents may not be important, but achieving appropriate plasma concentrations appears critical in patients with bacteremia and renal abscesses.

Nonspecific therapies have been advocated in the treatment and prevention of UTIs. Fluid hydration has been used to produce rapid dilution of bacteria and removal of infected urine by increased voiding. A critical factor appears to be the amount of residual volume

remaining after voiding. As little as 10 mL of residual urine can alter the eradication of infection significantly.[16] Paradoxically, increased diuresis also may promote susceptibility to infection by diluting the normal antibacterial properties of the urine. Often in clinical practice the concentrations of antimicrobial agents in the urine are so high that dilution has little effect on efficacy.

The antibacterial activity of the urine is related to the low pH, which is the result of high concentrations of various organic acids. Large volumes of cranberry juice increase the antibacterial activity of the urine and prevent the development of UTIs.[3,33,34] Apparently, the fructose and other unknown substances (condensed tannins, proanthocyanidin) in cranberry juice may act to interfere with adherence mechanisms of some pathogens, thereby preventing infection or reinfection. Acidification of the urine by cranberry juice does not appear to play a significant role. The use of other agents (ascorbic acid) to acidify the urine to hinder bacterial growth does not achieve significant acidification. Consequently, attempts to acidify urine with systemic agents are not recommended. *Lactobacillus* probiotics also may aid in the prevention of female UTIs by decreasing the vaginal pH, thereby decreasing *E. coli* colonization.[19,34,35] In postmenopausal women, estrogen replacement may be of help in the prevention of recurrent UTIs. After 1 month of topical estrogen replacement, decreases in vaginal *Lactobacillus*, as well as decreases in vaginal pH and *E. coli* colonization, have been found.[18,34]

Clinical **Controversy...**

The use of cranberry juice or lactobacilli in the prevention of UTIs has long been discussed. *Lactobacillus* potentially helps keep the vaginal pH in the normal range (pH 4-4.5), regulating genitourinary bacteria therefore aiding in the prevention of UTIs.[33] Possible clinical benefits with cranberry juice in sexually active adult women with recurrent UTI by decreasing the adherence of bacteria to the bladder epithelial cells. However, adhesion research and clinical trials show no significant effectiveness with cranberry juice.[33,36] Unfortunately, the consistency of study results has varied, as have the types of cranberry products tested, leading to overall inconclusive evidence.[33,34,37,38] More reliable and thorough studies on the overall effectiveness of cranberry juice or lactobacilli need to be performed before a uniform opinion on the role of these agents in UTIs can be stated.

Urinary analgesics such as phenazopyridine hydrochloride are used frequently by many clinicians.[3] If the pain or dysuria present in a UTI is a consequence of infection, then urinary analgesics have little clinical role because most patients' symptoms respond quite rapidly to appropriate antibacterial therapy. Also, urinary analgesics may mask signs and symptoms of UTIs not responding to antimicrobial therapy.[35,39,40]

Clinical **Controversy...**

Phenazopyridine hydrochloride is an over-the-counter urinary anesthetic/analgesic that can be used for symptom relief in UTIs. Common brand names are Pyridium®, Azo-Standard®, and Uristat®. It is used frequently by patients as self-medication to alleviate the dysuria associated with UTIs. The use of phenazopyridine in the treatment of UTIs is controversial. It has no antimicrobial properties and has a number of adverse effects such as red-orange discoloration of body fluids, rash, anaphylaxis, and rare effects such as hemolytic anemia, methemoglobinemia, and acute renal failure. In addition, its use can mask the symptoms of an untreated or inappropriately treated UTI. Unfortunately, there are not any guidelines for its role in the treatment of UTIs; however, experts agree that if phenazopyridine is used, only use the recommended dose (maximum 200 mg three times a day) and it should be limited to 1 to 2 days for symptomatic relief of the dysuria with UTIs.[35,39] In addition, it should be used with the combination of appropriate antibiotic therapy.

Pharmacologic Therapy

Ideally, the antimicrobial agent chosen should be well tolerated, well absorbed, achieve high urinary concentrations, and have a spectrum of activity limited to the known or suspected pathogen(s). Table 116-2 lists the most common agents used in the treatment of UTIs along with comments concerning their general use. Table 116-3 presents an overview of various therapeutic options for outpatient therapy of UTI. Table 116-4 describes empirical treatment regimens for selected clinical situations.

8 The therapeutic management of UTIs is best accomplished by first categorizing the type of infection: acute uncomplicated cystitis, symptomatic abacteriuria, ASB, complicated UTIs, recurrent infections, or prostatitis. In choosing the appropriate antibiotic therapy, it is important to be aware of the increasing resistance of *E. coli* and other pathogens to many frequently prescribed antimicrobials.[41] Resistance to *E. coli* is as high as 37% for amoxicillin and ampicillin.[1,42] Overall, most *E. coli* remain susceptible to trimethoprim–sulfamethoxazole, although resistance is continuing to increase and has been reported as high as 27%.[43] Although resistance to the fluoroquinolones remains low, these agents are being used more frequently and the incidence of fluoroquinolone-resistant *E. coli* is increasingly being reported and is of great concern.[42-48] Current or recent antibiotic exposure is the most significant risk factor associated with *E. coli* resistance and with the extensive use of the fluoroquinolones and trimethoprim–sulfamethoxazole for various infections, including UTIs, resistance will continue to increase.[42-47] In addition, broad-spectrum antimicrobials such as fluoroquinolones and broad-spectrum cephalosporins have a high impact on GI flora, increasing the risk of collateral damage (term used to refer to ecological adverse effects of antibiotic therapy) or the selection of resistant *E. coli* pathogens.[42-45,48,49] In light of rising resistance and in order to decrease the overuse of broad-spectrum antimicrobials, agents such as nitrofurantoin and fosfomycin are now considered first-line treatments along with trimethoprim–sulfamethoxazole in acute uncomplicated cystitis. Both nitrofurantoin and fosfomycin have little effects on the gut flora and *E. coli* susceptibility still remains high.[33,49-53] Antibiotic therapy should be determined based on the geographic resistance patterns, as well as the patient's recent history of antibiotic exposure.

Acute Uncomplicated Cystitis

Acute uncomplicated cystitis is the most common form of UTI. These infections typically occur in women of childbearing age and often are related to sexual activity. Although the presence of dysuria, frequency, urgency, and suprapubic discomfort frequently is associated with lower tract infection, a significant number of patients have upper tract involvement as well.[3] Because these infections are predominantly caused by *E. coli*, antimicrobial therapy initially should be directed against this organism. Other common causes include *S. saprophyticus* and occasionally *K. pneumoniae* and *Proteus mirabilis*. Because the causative organisms and their susceptibility generally are known, many clinicians advocate a cost-effective approach to management. This approach includes a urinalysis and initiation of empirical therapy without a urine culture (Fig. 116-1).[1]

TABLE 116-2 Commonly Used Antimicrobial Agents in the Treatment of UTIs

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Oral Therapy			
Trimethoprim–sulfamethoxazole	Rash, Stevens–Johnson Syndrome, renal failure, photosensitivity, hematologic (neutropenia, anemia, etc.)	Serum creatinine, BUN, electrolytes, signs of rash, and CBC	This combination is highly effective against most aerobic enteric bacteria except *P. aeruginosa*. High urinary tract tissue concentrations and urine concentrations are achieved, which may be important in complicated infection treatment. Also effective as prophylaxis for recurrent infections
Nitrofurantoin	GI intolerance, neuropathies, and pulmonary reactions	Baseline serum creatinine and BUN	This agent is effective as both a therapeutic and prophylactic agent in patients with recurrent UTIs. Main advantage is the lack of resistance even after long courses of therapy
Fosfomycin trometamol	Diarrhea, headache, and angioedema	No routine tests recommended	Single-dose therapy for uncomplicated infections, low levels of resistance, use with caution in patients with hepatic dysfunction
Fluoroquinolones Ciprofloxacin Levofloxacin	Hypersensitivity, photosensitivity, GI symptoms, dizziness, confusion, and tendonitis (black box warning)	CBC, baseline serum creatinine, and BUN	The fluoroquinolones have a greater spectrum of activity, including *P. aeruginosa*. These agents are effective for pyelonephritis and prostatitis. Avoid in pregnancy and children. Moxifloxacin should not be used owing to inadequate urinary concentrations
Penicillins Amoxicillin–clavulanate	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	Due to increasing *E. coli* resistance, amoxicillin–clavulanate is the preferred penicillin for uncomplicated cystitis
Cephalosporins Cefaclor Cefpodoxime-proxetil	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	There are no major advantages of these agents over other agents in the treatment of UTIs, and they are more expensive. These agents are not active against enterococci
Parenteral Therapy			
Aminoglycosides Gentamicin Tobramycin Amikacin	Ototoxicity, nephrotoxicity	Serum creatinine and BUN, serum drug concentrations, and individual pharmacokinetic monitoring	These agents are renally excreted and achieve good concentrations in the urine. Amikacin generally is reserved for multidrug-resistant bacteria
Penicillins Ampicillin–sulbactam Piperacillin–tazobactam	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	These agents generally are equally effective for susceptible bacteria. The extended-spectrum penicillins are more active against *P. aeruginosa* and enterococci and often are preferred over cephalosporins. They are very useful in renally impaired patients or when an aminoglycoside is to be avoided
Cephalosporins Ceftriaxone Ceftazidime Cefepime	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	Second- and third-generation cephalosporins have a broad spectrum of activity against gram-negative bacteria, but are not active against enterococci and have limited activity against *P. aeruginosa*. Ceftazidime and cefepime are active against *P. aeruginosa*. They are useful for nosocomial infections and urosepsis due to susceptible pathogens
Carbapenems/monobactams Imipenem–cilistatin Meropenem Doripenem Ertapenem Aztreonam	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	Carbapenems have a broad spectrum of activity, including gram-positive, gram-negative, and anaerobic bacteria. Imipenem, meropenem, and doripenem are active against *P. aeruginosa* and enterococci, but ertapenem is not. Aztreonam is a monobactam that is only active against gram-negative bacteria, including some strains of *P. aeruginosa*. Generally useful for nosocomial infections when aminoglycosides are to be avoided and in penicillin-sensitive patients
Fluoroquinolones Ciprofloxacin Levofloxacin	Hypersensitivity, photosensitivity, GI symptoms, dizziness, confusion, and tendonitis (black box warning)	CBC, baseline serum creatinine, and BUN	These agents have broad-spectrum activity against both gram-negative and gram-positive bacteria. They provide urine and high-tissue concentrations and are actively secreted in reduced renal function

BUN, blood urea nitrogen; CBC, complete blood count; GI, gastrointestinal; UTIs, urinary tract infections.

TABLE 116-3 Overview of Outpatient Antimicrobial Therapy for Lower Tract Infections in Adults

Indications	Antibiotic	Dose	Interval	Duration
Lower tract infections				
Uncomplicated	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	3 days
	Nitrofurantoin monohydrate	100 mg	Twice a day	5 days
	Fosfomycin trometamol	3 g	Single dose	1 day
	Ciprofloxacin	250 mg	Twice a day	3 days
	Levofloxacin	250 mg	Once a day	3 days
	Amoxicillin–clavulanate	500 mg	Every 8 hours	5-7 days
	Pivmecillinam	400 mg	Twice a day	3 days
Complicated	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	7-10 days
	Ciprofloxacin	250-500 mg	Twice a day	7-10 days
	Levofloxacin	250 mg	Once a day	10 days
		750 mg	Once a day	5 days
	Amoxicillin–clavulanate	500 mg	Every 8 hours	7-10 days
Recurrent infections	Nitrofurantoin	50 mg	Once a day	6 months
	Trimethoprim–sulfamethoxazole	1/2 SS tablet	Once a day	6 months
Acute pyelonephritis	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	14 days
	Ciprofloxacin	500 mg	Twice a day	14 days
		1,000 mg ER	Once a day	7 days
	Levofloxacin	250 mg	Once a day	10 days
		750 mg	Once a day	5 days
	Amoxicillin–clavulanate	500 mg	Every 8 hours	14 days

DS, double strength; SS, single strength.

Dosing intervals for normal renal function.

TABLE 116-4 Evidence-Based Empirical Treatment of UTIs and Prostatitis

Diagnosis	Pathogens	Treatment Recommendation	Comments
Acute uncomplicated cystitis	*Escherichia coli*, *Staphylococcus saprophyticus*	1. Nitrofurantoin × 5 days (A,I)[a] 2. Trimethoprim–sulfamethoxazole × 3 days (A,I)[a] 3. Fosfomycin trometamol × 1 dose (A,I)[a] 4. Fluoroquinolone × 3 days (A,I)[a] 5. β-Lactams × 3-7 days (B,I)[a] 6. Pivmecillinam × 3-7 days (A,I)	Short-course therapy more effective than single dose Reserve fluoroquinolones as alternatives to development of resistance (A-III)[a] β-Lactams as a group are not as effective in acute cystitis then trimethoprim–sulfamethoxazole or the fluoroquinolones, do not use amoxicillin or ampicillin[a] Pivmecillinam not available in United States
Pregnancy	As above	1. Amoxicillin–clavulanate × 7 days 2. Cephalosporin × 7 days 3. Trimethoprim–sulfamethoxazole × 7 days	Avoid trimethoprim–sulfamethoxazole during the third trimester
Acute pyelonephritis			
Uncomplicated	*E. coli*	1. Quinolone × 7 days (A,I)[a] 2. Trimethoprim–sulfamethoxazole (if susceptible) × 14 days (A,I)[a]	Can be managed as outpatient
	Gram-positive bacteria	1. Amoxicillin or amoxicillin–clavulanic acid × 14 days	
Complicated	*E. coli* *P. mirabilis* *K. pneumoniae* *P. aeruginosa* *Enterococcus faecalis*	1. Quinolone × 14 days 2. Extended-spectrum penicillin plus aminoglycoside	Severity of illness will determine duration of IV therapy; culture results should direct therapy Oral therapy may complete 14 days of therapy
Prostatitis	*E. coli* *K. pneumoniae* *Proteus* spp. *P. aeruginosa*	1. Trimethoprim–sulfamethoxazole × 4-6 weeks 2. Quinolone × 4-6 weeks	Acute prostatitis may require IV therapy initially Chronic prostatitis may require longer treatment periods or surgery

UTI, urinary tract infection.

[a]Strength of recommendations: A, good evidence for; B, moderate evidence for; C, poor evidence for and against; D, moderate against; E, good evidence against. Quality of evidence: I, at least one proper randomized, controlled study; II, one well-designed clinical trial; III, evidence from opinions, clinical experience, and expert committees.

Data from reference 1.

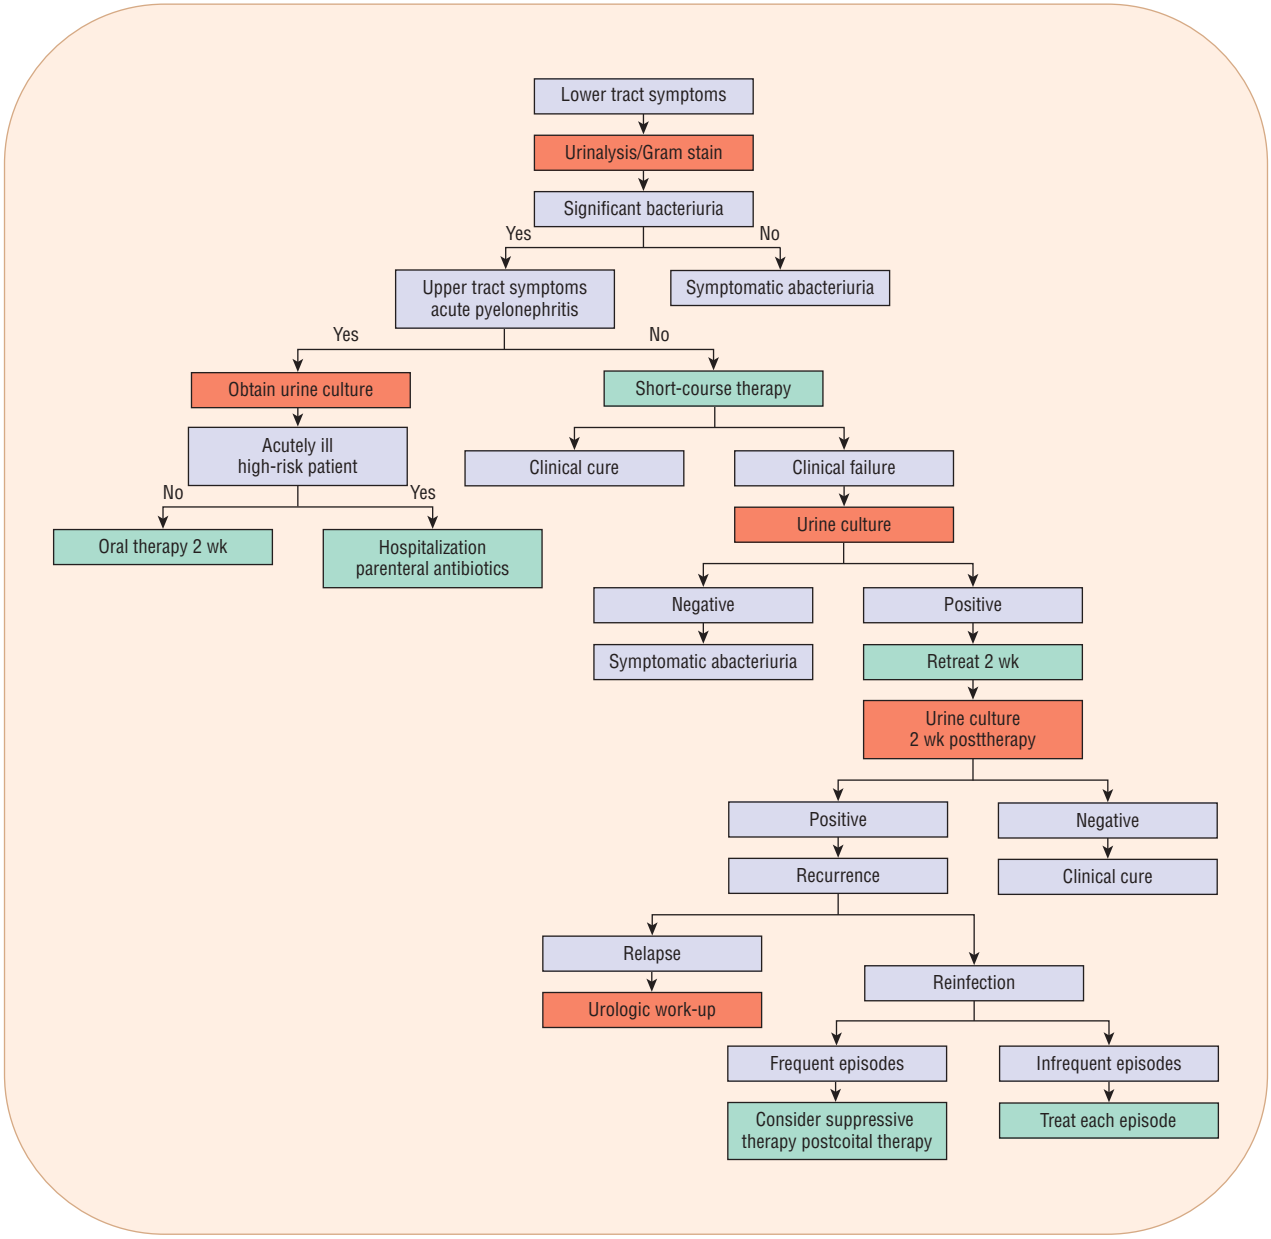

FIGURE 116-1 Management of urinary tract infections in females.

Therefore, the susceptibility patterns of the geographic area drive the choice of empiric therapy.

The goal of treatment for uncomplicated cystitis is to eradicate the causative organism and to reduce the incidence of recurrence caused by relapse or reinfection. The ability to reduce the chance of recurrence depends on the agent's efficacy in eradicating the uropathogenic bacteria from the vaginal and GI reservoir. In the past, conventional therapy consisted of an effective oral antibiotic administered for 7 to 14 days. However, acute cystitis is a superficial mucosal infection that can be eradicated with much shorter courses of therapy (3 days). Advantages of short-course therapy include increased adherence, fewer side effects, decreased cost, and less potential for the development of resistance.

7 Three-day courses of trimethoprim–sulfamethoxazole or a fluoroquinolone (eg, ciprofloxacin or levofloxacin, not moxifloxacin) are superior to single-dose therapies.[52,54-56] Although the fluoroquinolones have shown excellent efficacy in acute cystitis, the newest guidelines recommend reserving these agents for patients with suspected or possible pyelonephritis due to the collateral damage risk. Instead, a 3-day course of trimethoprim–-sulfamethoxazole, a 5-day course of nitrofurantoin, or a one-time dose of fosfomycin should be considered as first-line therapy[1,50,51,55,57] In areas where there is more than 20% resistance of *E. coli* to trimethoprim–sulfamethoxazole, nitrofurantoin or fosfomycin should be used. Amoxicillin or ampicillin should not be used due to the high incidence of resistant *E. coli*. Instead, if a β-lactam must be used, amoxicillin/-clavulanate, cefdinir, cefaclor, or cefpodoxime proxetil for 3 to 7 days are the preferred choices. For most adult females, short-course therapy is the treatment of choice for uncomplicated lower UTIs. Short-course therapy is inappropriate for patients who have had previous infections caused by resistant bacteria, for male patients, and for patients with complicated UTIs. If symptoms recur or do not respond to therapy, a urine culture should be obtained and conventional therapy with a suitable agent instituted.[1]

Symptomatic Abacteriuria

Symptomatic abacteriuria or acute urethral syndrome represents a clinical syndrome in which females present with dysuria and pyuria, but the urine culture reveals less than 10^5 bacteria/mL

(10^8/L) of urine. Acute urethral syndrome accounts for more than half the complaints of dysuria seen in the community today. These women most likely are infected with small numbers of coliform bacteria, including *E. coli*, *Staphylococcus* spp., or *Chlamydia trachomatis*. Additional causes include *Neisseria gonorrhoeae*, *Gardnerella vaginalis*, and *Ureaplasma urealyticum*.

Most patients presenting with pyuria will, in fact, have infection that requires treatment. If antimicrobial therapy is ineffective, a culture should be obtained. If the patient reports recent sexual activity, therapy for *C. trachomatis* should be considered. Chlamydial treatment should consist of 1 g azithromycin or doxycycline 100 mg twice daily for 7 days. Often, concomitant treatment of all sexual partners is required to cure chlamydial infections and prevent reacquisition (see Chapter 117).

Asymptomatic Bacteriuria

ASB is the finding of two consecutive urine cultures with more than 10^5 organisms/mL (more than 10^8/L) of the same organism in the absence of urinary symptoms. Most patients with ASB are elderly and female. Also, pregnant women frequently present with ASB. Although this group of patients typically responds to treatment, relapse and reinfection are very common and chronic ASB is difficult to eradicate.

The management of ASB depends on the age of the patient and whether or not the patient is pregnant. In children, because of a greater risk of developing renal scarring and long-standing renal damage, treatment should consist of the same conventional courses of therapy as used for symptomatic infection. The greatest risk of renal damage occurs during the first 5 years of life.[58] In nonpregnant females, therapy is controversial; however, treatment has little effect on the natural course of infections. Two groups characterize ASB in the elderly: those with persistent bacteriuria and those with intermittent bacteriuria.

Several studies in hospitalized elderly subjects, however, have not found antimicrobial therapy to be efficacious for abacteruria.[59-62] A number of questions remain unanswered. For example: What is the effect of eradication of bacteriuria on life expectancy? What are the cost-effectiveness and risk-to-benefit ratio of therapy? What is the effect on morbidity? Certainly with the information available and the high adverse reaction rate in the elderly, vigorous treatment and screening programs cannot be advocated.

Complicated Urinary Tract Infections

Acute Pyelonephritis

The presentation of high-grade fever (more than 38.3°C [more than 100.9°F]) and severe flank pain should be treated as acute pyelonephritis and warrants aggressive management. Severely ill patients with pyelonephritis should be hospitalized and IV antimicrobials administered initially (see Table 116-4). However, milder cases may be managed with orally administered antibiotics in an outpatient setting. Signs and symptoms of nausea, vomiting, and dehydration may require hospitalization.

At the time of presentation, a Gram stain of the urine should be performed along with a urinalysis, culture, and sensitivity tests. The Gram stain should indicate the morphology of the infecting organism(s) and help direct the selection of an appropriate antibiotic. However, the precise identity and susceptibility of the infecting organism(s) will be unknown initially, warranting empirical therapy. The goals of treatment include the achievement of therapeutic concentrations of an antimicrobial agent in the bloodstream and urinary tract to which the invading organism is susceptible and sufficient therapy to eradicate residual infection in the tissues of the urinary tract.

In the mildly to moderately symptomatic patient in whom oral therapy is considered, an effective agent should be administered for 7 to 14 days, depending on the agent used.[1,63-68] Oral antibiotics that are highly active against the probable pathogens and that are sufficiently bioavailable are preferred. Fluoroquinolones (ciprofloxacin or levofloxacin) orally for 7 to 10 days are the first-line choice in mild to moderate pyelonephritis. Other options include trimethoprim–sulfamethoxazole for 14 days. If amoxicillin/clavulanate or an oral cephalosporin is used, it is recommended to give an initial long-acting parenteral antimicrobial such as ceftriaxone first and continue the oral agent for 10 to 14 days. If a Gram stain reveals gram-positive cocci, *Enterococcus faecalis* should be considered and treatment directed against this potential pathogen (ampicillin). Close follow-up of outpatient treatment is mandatory to ensure success.

In the seriously ill patient, parenteral therapy should be administered initially. Therapy should provide a broad spectrum of coverage and should be directed toward bacteremia or sepsis, if present. A number of antibiotic regimens have been used as empirical therapy, including an IV fluoroquinolone, an aminoglycoside with or without ampicillin, and extended-spectrum cephalosporins with or without an aminoglycoside.[1,69] Other options include aztreonam, the β-lactamase inhibitor combinations (eg, ampicillin–sulbactam, ticarcillin–clavulanate, and piperacillin–tazobactam), carbapenems (eg, imipenem, meropenem, doripenem, or ertapenem), or IV trimethoprim–sulfamethoxazole.[70] If the patient has been hospitalized within the past 6 months, has a urinary catheter, or is a nursing home resident, the possibility of *P. aeruginosa* and enterococci, as well as multiple resistant organisms, should be considered. In this setting, ceftazidime, ticarcillin–clavulanate, piperacillin, aztreonam, meropenem, or imipenem in combination with an aminoglycoside is recommended. Ertapenem should not be used in this situation owing to its inactivity against enterococci and *P. aeruginosa*.[67] The rationale for combination therapy is that in experimental animals 3 days of aminoglycoside combination therapy followed by non-aminoglycoside single-agent therapy for 7 days resulted in a 100% cure rate.[63,68] If the patient responds to initial combination therapy, the aminoglycoside may be discontinued after 3 days. Although the aminoglycoside therapy is stopped, renal tissue concentrations of the aminoglycoside will persist for days. Based on antimicrobial sensitivity data, the patient then can be maintained or switched to a less expensive single agent and ultimately, an appropriate oral agent may be used.

Effective therapy should stabilize the patient within 12 to 24 hours. A significant reduction in urine bacterial concentrations should occur in 48 hours. If bacteriologic response has not occurred, an alternative agent should be considered based on susceptibility testing. If the patient fails to respond clinically within 3 to 4 days or has persistently positive blood or urine cultures, further investigation is needed to exclude bacterial resistance, possible obstruction, papillary necrosis, intrarenal or perinephric abscess, or some other disease process. Usually by the third day of therapy, the patient is afebrile and significantly less symptomatic. In general, after the patient has been afebrile for 24 hours, parenteral therapy may be discontinued and oral therapy instituted to complete a 2-week course. Follow-up urine cultures should be obtained 2 weeks after completion of therapy to ensure a satisfactory response and detect possible relapse.

Urinary Tract Infections in Males

The management of UTIs in males is distinctly different and often more difficult than in females. Infections in male patients are considered to be complicated because endogenous bacteria in the presence of functional and/or structural abnormalities that disrupt the normal defense mechanisms of the urinary tract cause them. The incidence of infections in males younger than 60 years is much less than the incidence in females. During the adult years, the occurrence of infection can be related directly to some manipulation of the urinary tract. The most common causes are instrumentation of the urinary tract, catheterization, and renal and urinary stones.

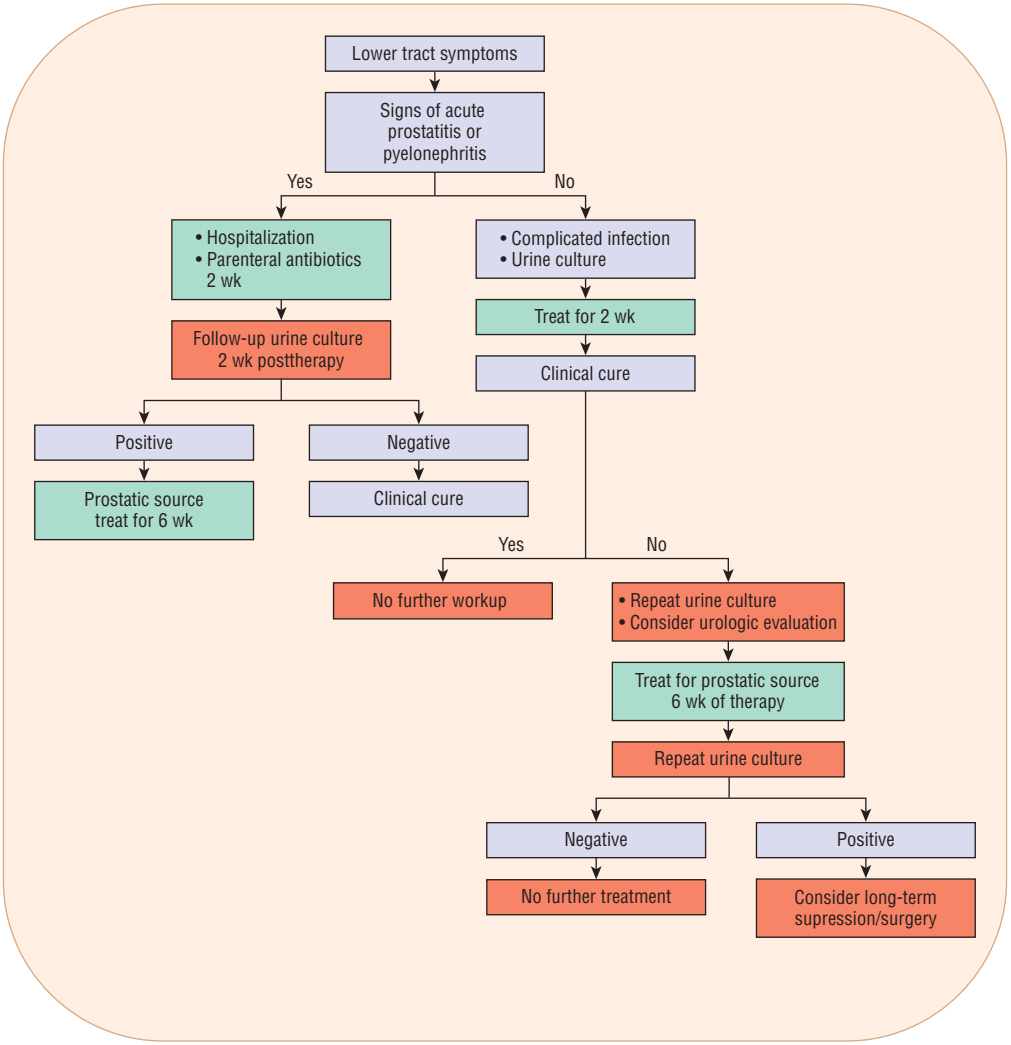

FIGURE 116-2 Management of urinary tract infections in males.

Uncomplicated infections are rare, but they may occur in young males as a result of homosexual activity, noncircumcision, and having sex with partners who are colonized with uropathogenic bacteria. As the patient ages, the most common cause of infection is related to bladder outlet obstruction because of prostatic hypertrophy. In addition, the prostate gland may become infected and provide a nidus for recurrent infection in males.

The conventional view is that therapy in males requires prolonged treatment (Fig. 116-2). A urine culture should be obtained before treatment because the cause of infection in men is not as predictable as in women. Single-dose or short-course therapy is not recommended in males. Considerably fewer data are available comparing various antimicrobial agents in males as compared with females. If gram-negative bacteria are presumed, trimethoprim–sulfamethoxazole or the quinolone antimicrobials should be considered because these agents achieve high renal tissue, urine, and prostatic concentrations.[71]

Initial therapy should be for 10 to 14 days. Factors associated with treatment success are isolation of a single organism, the absence of significant obstruction or anatomic abnormalities, a normally functioning urinary tract, and the absence of prostatic involvement. Parenteral therapy may be required in certain situations, such as in severely ill patients, in the presence of acute prostatitis or epididymitis and in patients who cannot tolerate oral medications. A comparison of 2-week versus 6-week therapy in males with recurrent infections who were given trimethoprim–sulfamethoxazole had cure rates of 29% and 62%, respectively.[72] Other investigators advocate longer treatment periods in males, as well.[73] Follow-up cultures at 4 to 6 weeks after treatment are important in males to ensure bacteriologic cure. Many patients require longer periods of treatment and possible alterations in antibiotics, depending on culture and sensitivity results and clinical response.

Recurrent Infections

Recurrent episodes of UTI account for a significant portion of all UTIs. Of the patients suffering from recurrent infections, 80% can be considered reinfections, that is, the recurrence of infection by an organism different from the organism isolated from the preceding infection. These patients most commonly are female and recurrence develops in approximately 20% of females with cystitis. Reinfections can be divided into two groups: those with less than three episodes per year and those who develop more frequent infections. Treatment strategies are continuing to develop, as well as, an understanding of the role of the microbiome.[74,75] An excellent overview of the various treatment modalities for recurrent UTI in women has been published.[76]

Management strategies depend on predisposing factors, number of episodes per year, and the patient's preference. Factors commonly associated with recurrent infections include sexual intercourse and diaphragm or spermicide use for birth control. Therapeutic options include self-administered therapy, postcoital therapy, and continuous low-dose prophylaxis. In patients with infrequent infections (less than three infections per year), each episode may be treated as a separately occurring infection. Short-course therapy is appropriate in this setting. Many women have been treated

successfully with self-administered short-course therapy at the onset of symptoms.[40,77]

In patients with more frequent symptomatic infections and no apparent precipitating event, long-term prophylactic antimicrobial therapy may be instituted. Prophylactic therapy reduces the frequency of symptomatic infections in elderly men, women, and children. In women, most studies show a reinfection rate of two to three per patient-year reduced to 0.1 to 0.2 per patient-year with treatment.[77] Before prophylaxis is initiated, patients should be treated conventionally with an appropriate agent. Trimethoprim–sulfamethoxazole (one-half of a single-strength tablet), trimethoprim (100 mg daily), a fluoroquinolone (levofloxacin 500 mg daily), and nitrofurantoin (50 or 100 mg daily) all reduce the rate of reinfection as single-agent therapy.[77] Full-dose therapy with these agents is unnecessary and single daily doses can be used. Therapy generally is prescribed for a period of 6 months, during which time urine cultures are followed monthly. If symptomatic episodes develop, the patient should receive a full course of therapy with an effective agent and then resume prophylactic therapy. Therapy with methenamine hippurate for short term use may be beneficial, but its overall utility is not well documented, especially for long-term prophylaxis.[78] The utility of OM-89 oral immunotherapy has been demonstrated to be an effective therapy for some women with recurrent UTI; however, its use is not approved in the United States.[79]

In women who experience symptomatic reinfections in association with sexual activity, voiding after intercourse may help prevent infection. Also, single-dose prophylactic therapy with trimethoprim–sulfamethoxazole taken after intercourse reduces the incidence of recurrent infection significantly.[77]

In postmenopausal women with recurrent infections, the lack of estrogen results in changes in the bacterial flora of the vagina, resulting in increased colonization with uropathogenic *E. coli*. Topically administered estrogen cream reduces the incidence of infections in this population.[18,19]

The remaining 20% of recurrent UTIs are relapses, that is, persistence of infection with the same organism after therapy for an isolated UTI. The recurrence of symptomatic or ASB after therapy usually indicates that the patient has renal involvement, a structural abnormality of the urinary tract or chronic bacterial prostatitis. In the absence of structural abnormalities, relapse often is related to renal infection and requires a long duration of treatment. Women who relapse after short-course therapy should receive a 2-week course of therapy. In patients who relapse after 2 weeks of therapy, therapy should be continued for another 2 to 4 weeks. If relapse occurs after 6 weeks of therapy, urologic evaluation should be performed and any obstructive lesion should be corrected. If this is not possible, therapy for 6 months or longer may be considered. Asymptomatic adults who have no evidence of urinary obstruction should not receive long-term therapy.

In males, relapse usually indicates bacterial prostatitis, the most common cause of persistent bacteriuria. Although many agents have been used for long-term therapy of relapses, trimethoprim–sulfamethoxazole and the fluoroquinolones appear to be highly effective.

Special Conditions

Urinary Tract Infections in Pregnancy

During pregnancy, significant physiologic changes occur to the entire urinary tract that dramatically alter the prevalence of UTIs and pyelonephritis. Severe dilation of the renal pelvis and ureters, decreased ureteral peristalsis, and reduced bladder tone occur during pregnancy.[80] These changes result in urinary stasis and reduced defenses against reflux of bacteria to the kidneys. In addition, increased urine content of amino acids, vitamins, and nutrients encourages bacterial growth. All of these factors increase the incidence of bacteriuria resulting in symptomatic infections, especially during the third trimester.

ASB occurs in 4% to 7% of pregnant patients. Of these, 20% to 40% will develop acute symptomatic pyelonephritis during pregnancy. If untreated, ASB has the potential to cause significant adverse effects, including prematurity, low birth weight, and stillbirth.[81,82] Because pyelonephritis is associated with significant adverse events during pregnancy, routine screening tests for bacteriuria should be performed at the initial prenatal visit and again at 28 weeks gestation. In patients with significant bacteriuria, symptomatic or asymptomatic, treatment is recommended so as to avoid possible complications. Organisms associated with bacteriuria are the same as those seen in uncomplicated UTIs with *E. coli* isolated most frequently.

Therapy should consist of an agent administered for 7 days that has a relatively low adverse effect potential and is safe for the mother and baby. The administration of amoxicillin, amoxicillin–clavulanate, or cephalexin is effective in 70% to 80% of patients. Nitrofurantoin has been used in pregnancy; however, it must be used with caution as occurrences of birth defects have been reported. Tetracyclines should be avoided because of teratogenic effects and sulfonamides should not be administered during the third trimester because of the possible development of kernicterus and hyperbilirubinemia. In addition, the available fluoroquinolones should not be given because of their potential to inhibit cartilage and bone development in the newborn. A follow-up urine culture 1 to 2 weeks after completing therapy and then monthly until gestation is complete is recommended. Optimal treatment for preventing recurrent UTI and ASB has yet to be defined.[83]

Catheterized Patients

The use of an indwelling catheter frequently is associated with infection of the urinary tract and represents the most common cause of hospital-acquired infection. The incidence of catheter-associated infection is related to a variety of factors, including method and duration of catheterization, the catheter system (open or closed), the care of the system, the susceptibility of the patient, and the technique of the healthcare personnel inserting the catheter. Catheter-related infections are reasonably preventable infections and are now considered one of the hospital-acquired complications chosen by the Centers for Medicare and Medicaid Services in which hospitals will no longer receive reimbursement for treatment.[84,85]

Bacteria may enter the bladder in a number of ways. During the catheterization, bacteria may be introduced directly into the bladder from the urethra. Once the catheter is in place, bacteria may pass up the lumen of the catheter via the movement of air bubbles, by motility of the bacteria, or by capillary action. In addition, bacteria may reach the bladder from around the exudative sheath that surrounds the catheter in the urethra. Cleaning the periurethral area thoroughly and applying an antiseptic (povidone-iodine) can minimize infection occurring during insertion of the catheter. The use of closed drainage systems has reduced significantly the ability of bacteria to pass up the lumen of the catheter and cause infection. Presently, a bacterium passing around the catheter sheath in the urethra is probably the most important pathway for infection. Avoiding manipulation of the catheter and trauma to the urethra and urethral meatus can minimize this path of acquisition.

Patients with indwelling catheters acquire UTIs at a rate of 5% per day.[84-86] The closed systems are capable of preventing bacteriuria in most patients for up to 10 days with appropriate care. After 30 days of catheterization, however, there is a 78% to 95% incidence of bacteriuria, despite use of a closed system.[85,87] Unfortunately, UTI symptoms in catheterized patient are not clearly defined. Fever, peripheral leukocytosis, and urinary signs and symptoms may be of little predictive value.[84,85] When bacteriuria occurs in the asymptomatic, short-term catheterized patient (less than 30 days), the use of systemic antibiotics should be withheld and the catheter removed as soon as possible. If the patient becomes symptomatic, the catheter should be removed and treatment as described for complicated infections started.

The optimal duration of therapy is unknown. In the long-term catheterized patient (more than 30 days), bacteriuria is inevitable.[84,85] The administration of systemic antibiotics active against the infecting organism will sterilize the urine; however, reinfection occurs rapidly in more than 50% of patients. In addition, resistant organisms recolonize the urine. Symptomatic patients must be treated because they are at risk of developing pyelonephritis and bacteremia. Bacteria adhere to the catheter and produce a biofilm consisting of bacterial glycocalyces, Tamm–Horsfall protein, as well as apatite and struvite salts, that act to protect the bacteria from antibiotics.[86] Biofilm mechanisms and their treatment continue to be examined and more fully understood.[88] Recatheterization with a new sterile unit should be performed in those symptomatic patients, if the existing catheter has been in place for more than 2 weeks.

Various methods have been proposed to prevent the development of bacteriuria and infection in the patient with an indwelling catheter (see Table 116-4). The success of these methods depends on the type of catheter and the length of time it is in place. The use of constant bladder irrigation with antiseptic or antibacterial solutions reduces the incidence of infection in those with open drainage systems, but this approach has no advantage in those with closed systems. The use of prophylactic systemic antibiotics in patients with short-term catheterization reduces the incidence of infection over the first 4 to 7 days.[85,87] In long-term catheterized patients, however, antibiotics only postpone the development of bacteriuria and lead to the emergence of resistant organisms. Therefore, antibiotic prophylaxis should not be utilized in short-term or long-term catheterized patients.

PROSTATITIS

Bacterial prostatitis is an inflammation of the prostate gland and surrounding tissue as a result of infection. It is classified as either acute or chronic. By definition, pathogenic bacteria and significant inflammatory cells must be present in prostatic secretions and urine to make the diagnosis of bacterial prostatitis. Prostatitis occurs rarely in young males, but it is commonly associated with recurrent infections in persons older than 30 years. As many as 50% of all males develop some form of prostatitis at some period in their life.[89-91] The acute form typically is an acute infectious disease characterized by a sudden onset of fever, tenderness, and urinary and constitutional symptoms. Chronic prostatitis presents with few symptoms related to the prostate but rather symptoms of urinating difficulty, low back pain, perineal pressure, or a combination of these. It represents a recurring infection with the same organism that results from incomplete eradication of bacteria from the prostate gland.

Pathogenesis and Etiology

The exact mechanism of bacterial infection of the prostate is not well understood. The possible routes of infection are the same as those for UTIs. Reflux of infected urine into the prostate gland is thought to play an important role in causing infection. Intraprostatic reflux of urine occurs commonly and results in direct inoculation of infected urine into the prostate.[89-91] In addition, intraprostatic reflux of sterile urine can result in a chemical prostatitis and may be the cause of nonbacterial prostatitis. Sexual intercourse may contribute to infection of the prostate gland because prostatic secretions from men with chronic prostatitis and vaginal cultures from their sexual partners grow identical organisms. Other known causes of bacterial prostatitis include indwelling urethral and condom catheterization, urethral instrumentation, and transurethral prostatectomy in patients with infected urine.

Physiologic factors are believed to contribute to the development of prostatitis. Functional abnormalities found in bacterial prostatitis include altered prostate secretory functions. Prostatic fluid obtained from normal males contains prostatic antibacterial factor. This heat-stable, low-molecular-weight cation is a zinc-complexed polypeptide that is bactericidal to most urinary tract pathogens.[92] The antibacterial activity of prostatic antibacterial factor is related directly to the zinc content of prostatic fluid. Prostate fluid zinc levels and prostatic antibacterial factor activity also appear diminished in patients with prostatitis, as well as in the elderly.[92] Whether these changes are a cause or effect of prostatitis remains to be determined.

The pH of prostatic secretions in patients with prostatitis is altered.[93] Normal prostatic secretions have a pH in the range of 6.6 to 7.6. With increasing age, the pH tends to become more alkaline. In patients with inflammation of the prostate, prostatic secretions may have an alkaline pH in the range of 7 to 9. These changes suggest a generalized secretory dysfunction of the prostate that not only can affect the pathogenesis of prostatitis but also can influence the mode of therapy.

Gram-negative enteric organisms are the most frequent pathogens in acute bacterial prostatitis.[89-91] *E. coli* is the predominant organism, occurring in 75% of cases. Other gram-negative organisms frequently isolated include *K. pneumoniae*, *P. mirabilis*, and less frequently, *P. aeruginosa*, *Enterobacter* spp., and *Serratia* spp. Infrequently, cases of gonococcal and staphylococcal prostatitis occur.

E. coli most commonly causes chronic bacterial prostatitis with other gram-negative organisms isolated less frequently. The importance of gram-positive organisms in chronic bacterial prostatitis remains controversial. *S. epidermidis*, *S. aureus*, and diphtheroids have been isolated in some studies.

Clinical Presentation

Acute bacterial prostatitis presents as other acute infections. Massage of the prostate will express a purulent discharge that will readily grow the pathogenic organism. Prostatic massage is contraindicated in acute bacterial prostatitis, however, because of the risk of inducing bacteremia and the associated local pain. The diagnosis of acute bacterial prostatitis can be made from the patient's clinical presentation

CLINICAL PRESENTATION Bacterial Prostatitis

Signs and Symptoms

- Acute bacterial prostatitis: High fever, chills, malaise, myalgia, localized pain (perineal, rectal, sacrococcygeal), frequency, urgency, dysuria, nocturia, and retention
- Chronic bacterial prostatitis: Voiding difficulties (frequency, urgency, dysuria), low back pain, and perineal and suprapubic discomfort

Physical Examination

- Acute bacterial prostatitis: Swollen, tender, tense, or indurated gland
- Chronic bacterial prostatitis: Boggy, indurated (enlarged) prostate in most patients

Laboratory Tests

- Bacteriuria
- Bacteria in EPSs

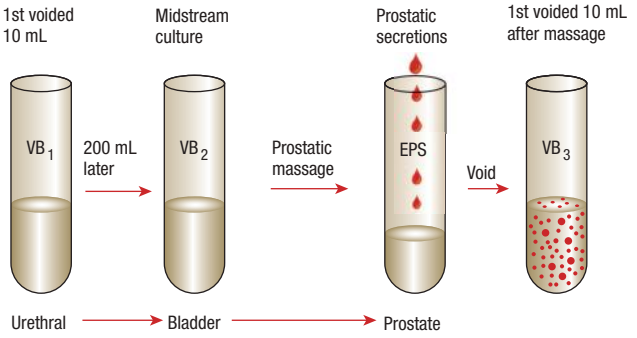

FIGURE 116-3 Segmented cultures of the lower tract in men. (EPS, expressed prostatic secretions; VB_1, voiding bladder 1; VB_2, voiding bladder 2; VB_3, voiding bladder 3.)

and the presence of significant bacteriuria. As with other UTIs, the infecting organism can be isolated from a midstream specimen.

In contrast, chronic bacterial prostatitis is more difficult to diagnose and treat. Chronic bacterial prostatitis typically is characterized by recurrent UTIs with the same pathogen and is the most common cause of recurrent UTI in males. The patient's clinical presentation can vary widely. Many adults, however, are asymptomatic.

Because physical examination of the prostate is often normal, urinary tract localization studies are critical to the diagnosis of chronic bacterial prostatitis. The method of quantitative localization culture, as described by Meares and Stamey,[15,94] remains the diagnostic standard (Fig. 116-3). The method compares the bacterial growth in sequential urine and prostatic fluid cultures obtained during micturition. The first 10 mL of voided urine is collected (voiding bladder 1, or VB_1) and constitutes urethral urine. After approximately 200 mL of urine has been voided, a 10-mL midstream sample is collected (VB_2). This specimen represents bladder urine. After the patient voids, the prostate is massaged and expressed prostatic secretions (EPS) are collected. After prostatic massage, the patient voids again and 10 mL of urine is collected (VB_3).

The diagnosis of bacterial prostatitis is made when the number of bacteria in EPS is 10 times that of the urethral sample (VB_1) and midstream sample (VB_2). If no EPS is available, the urine sample following massage (VB_3) should contain a bacterial count 10-fold greater than that of VB_1 or VB_2. If significant bacteriuria is present, ampicillin, cephalexin, or nitrofurantoin should be given for 2 to 3 days to sterilize the urine prior to performing the localization study.

TREATMENT

9 In general, the goals in the management of bacterial prostatitis are the same as those for UTIs. Acute bacterial prostatitis responds well to appropriate antimicrobial therapy that is directed at the most commonly isolated organisms. Prostatic penetration of antimicrobials occurs because the acute inflammatory reaction alters the cellular membrane barrier between the bloodstream and the prostate. Most patients can be managed with oral antimicrobial agents, such as trimethoprim–sulfamethoxazole and the fluoroquinolones (eg, ciprofloxacin, levofloxacin) (see Table 116-4). Other effective agents in this setting include cephalosporins and β-lactam–β-lactamase combinations. Although IV therapy is rarely necessary for total treatment, IV to oral sequential therapy with trimethoprim–sulfamethoxazole or the fluoroquinolones is appropriate. The conversion to an oral antibiotic can be considered after the patient is afebrile for 48 hours or after 3 to 5 days of IV therapy. The total course of antibiotic therapy should be 4 weeks in order to reduce the risk of development of chronic prostatitis, although in some cases 2 weeks may be sufficient. Therapy may be prolonged with chronic prostatitis (6-12 weeks). Long-term suppressive therapy also may be initiated for recurrent infections, such as three times weekly ciprofloxacin, trimethoprim–sulfamethoxazole regular-strength tablet daily, or nitrofurantoin 100 mg daily.[94]

Chronic bacterial prostatitis often presents a more vexing situation because cures are obtained rarely. Despite high serum concentrations of antibacterial drugs in excess of the minimal inhibitory concentrations of the infecting organisms, bacteria persist in prostatic fluid. Most likely the failure to eradicate sensitive bacteria is caused by the inability of antibiotics to reach sufficient concentrations in the prostatic fluid and cross the prostatic epithelium.

Several factors that determine antibiotic diffusion into prostatic secretions were delineated from the canine model. Lipid solubility is a major determinant in the ability of drugs to diffuse from plasma across epithelial membranes. The degree of ionization in plasma also affects the diffusion of drugs. Only unionized molecules can cross the lipid barrier of prostatic cells, and the drug's pK_a (negative logarithm of acid ionization constant) directly determines the fraction of unchanged drug.

The pH gradient across the membrane has an influence on tissue penetration, as well. A pH gradient of at least one pH unit between separate compartments allows for ion trapping. As the unionized drug crosses the epithelial barrier into prostatic fluid, it becomes ionized allowing less drug to diffuse back across the lipid barrier. In early studies with the canine model, the prostatic pH was reported to be acidic (6.4).[93] In humans, however, the pH of prostatic secretions from an inflamed prostate is actually basic (8.1-8.3).[93]

The choice of antibiotics in chronic bacterial prostatitis should include agents that are capable of reaching therapeutic concentrations in the prostatic fluid and which possess the spectrum of activity to be effective. Agents that achieve therapeutic prostatic concentrations include trimethoprim and the fluoroquinolones. Sulfamethoxazole penetrates poorly and probably contributes very little to trimethoprim activity when used in combination. The fluoroquinolones appear to provide the best therapeutic options in the management of chronic bacterial prostatitis. Therapy should be continued for 4 to 6 weeks initially. Longer treatment periods may be necessary in some cases. If therapy fails with these regimens, chronic suppressive therapy may be used or surgery considered.

PERSONALIZED PHARMACOTHERAPY

Patient-centered pharmacotherapy and management of UTIs require knowledge of the pathogenesis and causative organisms associated with the various clinical syndromes described in this chapter.[22] Individualizing the antimicrobial therapy will depend on many factors, first and foremost being the susceptibility of the offending pathogen. As was discussed in the chapter, *E. coli* resistance is continuing to increase, therefore, it is imperative for the healthcare professional to be familiar with the resistance trends in their geographical area when prescribing therapy. In addition, the prevention of increasing resistance and collateral damage should be considered when selecting antimicrobial therapy.[1] Other factors to consider in selecting therapy would be a patient's allergies and recent antimicrobial exposure. Lastly, cost may factor into compliance enhancing the effectiveness of therapy. The costs include both direct and indirect costs associated with treatment.

Direct costs are those associated with diagnosis, treatment, and follow-up. The cost of pharmaceuticals varies according to the agents used and the duration of therapy. Trimethoprim–sulfamethoxazole and amoxicillin–clavulanate are rather inexpensive. However, when considering rates of resistance leading to therapeutic failure, overall costs increase dramatically. The fluoroquinolones also are highly effective agents, but generally are more expensive and a rise in their utilization is now being associated with increasing resistance.[69,95]

In general, the outcome and total cost depend on whether therapy is empirical or definitive (based on a culture diagnosis for acute infection) and if the individual patient is adherent with the regimen. As a healthcare professional, working with and/or within the healthcare team is necessary to select appropriate therapies and maximize the possibility of positive therapeutic outcomes.

ABBREVIATIONS

ASB	asymptomatic bacteriuria
CFU	colony-forming unit
EPS	expressed prostatic secretions
GI	gastrointestinal
PMN	polymorphonuclear leukocyte
UTI	urinary tract infection
WBC	white blood cell

Sexually Transmitted Diseases

117

Leroy C. Knodel, Bryson Duhon, and Jacqueline Argamany

The editors are deeply appreciative for the excellent contributions of Dr Leroy Knodel over all 10 editions of this book. This chapter was in preparation at the time of Dr Knodel's death. We thank Dr. Bryson Duhon for his timely work to complete the chapter.

KEY CONCEPTS

1. All recommended treatment regimens for gonorrhea include antibiotic therapy directed against *Chlamydia* species because of the high prevalence of coexisting infections, unless chlamydia has been ruled out.
2. Parenteral penicillin is the treatment of choice for all syphilis infections. For patients who are penicillin-allergic, few well-studied alternative agents are available, and most are oral medications that require 2 to 4 weeks of therapy to be effective. Patient compliance and thus efficacy are a concern when alternative regimens must be used.
3. Chlamydia genital tract infections represent the most frequently reported communicable disease in the United States. In females, these infections are frequently asymptomatic or minimally symptomatic and, if left untreated, are associated with the development of pelvic inflammatory disease and attendant complications such as ectopic pregnancy and infertility. As a result, all sexually active females younger than 25 years and sexually active women with multiple sexual partners should be screened annually for this infection.
4. Oral acyclovir, famciclovir, and valacyclovir are effective in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. The benefit of these agents for recurrent infections has not been demonstrated. Patient-initiated, episodic antiviral therapy started within one day of lesion onset or during the prodrome preceding an outbreak offers an alternative to continuous suppressive therapy of recurrent infection in some individuals.
5. Metronidazole and tinidazole are the only agents currently approved in the United States to treat trichomoniasis. Although a single 2-g dose of either agent is widely used for compliance and other reasons, single-dose therapy should be avoided for treating recurrent infections.

The spectrum of sexually transmitted diseases (STDs) has broadened from the classic venereal diseases—gonorrhea, syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale—to include a variety of pathogens known to be spread by sexual contact (Table 117-1). Because of the large number of infected individuals, the diversity of clinical manifestations, the changing drug-susceptibility patterns of some pathogens, and the high frequency of multiple STDs occurring simultaneously in infected individuals, the diagnosis and management of patients with STDs are much more complex today than they were even a decade ago.[1-4] Approximately 20 million new infections occur annually in the United States, with a total prevalence of 110 million infections resulting in a total medical cost of $116 billion to the US health-care system.[5,6]

Although the annual number of new infections is roughly equal between genders, the complications of STDs generally are more frequent and severe in women.[5] In particular, serious effects on maternal and infant health during pregnancy are well documented.[1,4] Damage to reproductive organs, increased risk of cancer, complications associated with pregnancy, and transmission of disease to the fetus or newborn are associated with several STDs. As a result of the physiologic, psychosocial, and economic consequences of STDs, and because of the increasing prevalence of some viral STDs, such as human immunodeficiency virus (HIV) and genital herpes, for which curative therapy is not available, there is continuing research into STDs and the primary prevention of these diseases.[2-4,7]

With the exception of HIV infection, which is reviewed in detail in Chapter 126, the most frequently occurring STDs in the United States are discussed in this chapter. For other less common STDs, only recommended treatment regimens are presented. The most current information on the epidemiology, diagnosis, and treatment of STDs provided by the US Centers for Disease Control and Prevention (CDC) can be obtained at the CDC Web site (www.cdc.gov).

Numerous interrelated factors contribute to the epidemic nature of STDs. Sociocultural, demographic, and economic factors, together with patterns of sexual behavior, host susceptibility to infection, changing properties of the causative pathogens, disease transmission by asymptomatic individuals, and environmental factors, are important determinants of the frequency and distribution of STDs in the United States and worldwide.

Age is one of the most important demographic determinants of STD incidence. Approximately half of all new STD cases each year occur in persons in their teens and twenties, the peak years of sexual activity. With increasing age, the incidence of most STDs decreases exponentially. In sexually active teenagers, STD rates are highest in the youngest, suggesting that physiologic differences may contribute to increased susceptibility.[2-4,7]

Age-specific rates of STDs are historically higher in men than in women; however, reported rates may not represent true gender differences but rather may reflect greater ease of detection in men. In recent years, the ratio of male-to-female cases for most STDs has

Enterobiasis	*Enterobius vermicularis*

declined, and in some cases reversed, possibly reflecting improvements in the diagnosis of STDs in asymptomatic women or changes in female sexual behavior following the availability of improved methods of contraception. Although some racial disparity exists for rates of STD infection, it is possible that this is a reflection of socioeconomic differences.[1-5,7]

The single greatest risk factor for contracting STDs is the number of sexual partners. As the number of sexual partners increases, the risk of being exposed to someone infected with an STD increases. Sexual preference also plays a major role in the transmission of STDs. For all major STDs, rates are disproportionately greater in men who have sex with men (MSM) than in heterosexuals. In addition, a number of less common STDs, including several caused by enteric protozoans and bacterial pathogens, occur primarily in MSM. The major risk factors for MSM appear to be related to the greater number of sexual partners and the practice of unprotected anal–genital, oral–genital, and oral–anal intercourse. In addition, prostitution and illicit drug use are associated with a higher incidence of most STDs.[1-4,7]

Some of the most serious sequelae of STDs are associated with congenital or perinatal infections. Most neonatal infections are acquired at birth, after infant passage through an infected cervix or vagina. Neonatal *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex virus (HSV) infections are associated with this type of spread. For pregnant women with syphilis, infection is usually transmitted transplacentally, producing a congenital infection. Depending on the organism, neonatal infections can manifest in a variety of ways, produce significant morbidity, and in some cases result in infant death.[1-4]

Other than complete abstinence, the most effective way to prevent STD transmission is by maintaining a mutually monogamous sexual relationship between uninfected partners. Short of this, use of barrier contraceptive methods, such as the male and female condoms, diaphragm, cervical cap, vaginal sponges, and vaginal spermicides alone or in combination, provides varying degrees of protection from a number of STDs. When used correctly and consistently, male latex condoms with or without spermicide are more effective than natural skin condoms in protecting against STD transmission, including HIV, gonorrhea, chlamydia, trichomoniasis, HSV, and human papillomavirus (HPV). When lubrication is desired with latex condoms, water-based products, such as K-Y jelly, are recommended because oil-based agents (eg, petroleum jelly) can weaken latex condoms and reduce their effectiveness. For latex-allergic individuals, other synthetic condoms (eg, polyurethane) appear to possess efficacy against STD transmission similar to latex condoms. The female condom is a lubricated polyurethane sheath with a diaphragm-like ring on each end that can be used as a protective device for women with male sexual partners who do not desire to use a condom. Limited data suggest that the female condom blocks penetration of viruses, including HIV; for nonviral STDs, the female condom provides STD protection similar to the male condom.[1,3,7,8] At one time, use of nonoxynol-9, a vaginal spermicide with cytolytic activity, was advocated to reduce the transmissibility of several STDs. This was based in large part on in vitro and animal data. However, nonoxynol-9 does not reduce the risk of transmission of common STDs and actually can increase the risk of HIV transmission. Frequent use of nonoxynol-9 damages vaginal, cervical, and rectal epithelium, leading to increased transmissibility of HIV and possibly other STDs. Diaphragms may protect against cervical gonorrheal, chlamydial, and trichomonal infections.[1,7-10]

The varied spectrum of clinical syndromes produced by common STDs is determined not only by the etiologic pathogen(s) but also by differences in male and female anatomy and reproductive physiology. For a number of STDs, the signs and symptoms overlap sufficiently to prevent accurate diagnosis without microbiologic confirmation. Frequently, symptoms are minimal or absent despite the presence of infection. Table 117-2 lists common clinical syndromes associated with STDs.[1-4]

GONORRHEA

Epidemiology and Etiology

The gram-negative diplococcus *N. gonorrhoeae* is the causative organism of gonorrhea. Although the rate of reported cases in the United States has remained relatively stable over the past decade, 333,000 new cases were reported in 2013, representing an 8.2% increase from 2009.[11] Due to the increasing incidence of resistance to available antibiotics, there is concern that this number may continue to increase in the future.[1,12] Of concern also are the substantial number of infections that remain undiagnosed and unreported.[1,12] Humans are the only known natural host of this intracellular parasite. Because of its rapid incubation period and the large number of infected individuals with asymptomatic disease, gonorrhea is difficult to control.[1,13-18]

Although the risk of a female acquiring a cervical infection after a single episode of vaginal intercourse with an infected male

TABLE 117-2 Selected Syndromes Associated with Common Sexually Transmitted Pathogens

Syndrome	Commonly Implicated Pathogens	Common Clinical Manifestations[a]
Urethritis	*Chlamydia trachomatis*, herpes simplex virus, *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, *Ureaplasma Mycoplasma genitalium*	Urethral discharge, dysuria
Epididymitis	*C. trachomatis*, *N. gonorrhoeae*	Scrotal pain, inguinal pain, flank pain, urethral discharge
Cervicitis/ vulvovaginitis	*C. trachomatis*, *Gardnerella vaginalis*, herpes simplex virus, human papillomavirus, *N. gonorrhoeae*, *T. vaginalis*	Abnormal vaginal discharge, vulvar itching/irritation, dysuria, dyspareunia
Genital ulcers (painful)	*Haemophilus ducreyi*, herpes simplex virus	Usually multiple vesicular/pustular (herpes) or papular/pustular (*H. ducreyi*) lesions that can coalesce; painful, tender lymphadenopathy[b]
Genital ulcers (painless)	*Treponema pallidum*	Usually single papular lesion
Genital/anal warts	Human papillomavirus	Multiple lesions ranging in size from small papular warts to large exophytic condylomas
Pharyngitis	*C. trachomatis* (?), herpes simplex virus, *N. gonorrhoeae*	Symptoms of acute pharyngitis, cervical lymphadenopathy, fever[c]
Proctitis	*C. trachomatis*, herpes simplex virus, *N. gonorrhoeae*, *T. pallidum*	Constipation, anorectal discomfort, tenesmus, mucopurulent rectal discharge
Salpingitis	*C. trachomatis*, *N. gonorrhoeae*	Lower abdominal pain, purulent cervical or vaginal discharge, adnexal swelling, fever[d]

[a]For some syndromes, clinical manifestations can be minimal or absent.

[b]Recurrent herpes infection can manifest as a single lesion.

[c]Most cases of pharyngeal gonococcal infection are asymptomatic.

[d]Salpingitis increases the risk of subsequent ectopic pregnancy and infertility.

partner is high and increases with multiple exposures, the risk of transmission from an infected female to an uninfected male is not as great following a single act of coitus. No data are available on the risk of transmission after other types of sexual contact.[13-17]

Pathophysiology

On contact with a mucosal surface lined by columnar, cuboidal, or noncornified squamous epithelial cells, the gonococci attach to cell membranes by means of surface pili and are then pinocytosed. The virulence of the organism is mediated primarily by the presence of pili and other outer membrane proteins. After mucosal damage is established, polymorphonuclear (PMN) leukocytes invade the tissue, submucosal abscesses form, and purulent exudates are secreted.[13-18]

Clinical Presentation

Individuals infected with gonorrhea can be symptomatic or asymptomatic, have complicated or uncomplicated infections, and have infections involving several anatomic sites. Interestingly, most of the symptomatic patients who are not treated become asymptomatic within 6 months, with only a few becoming asymptomatic carriers of the disease.[13-16] Up to 50% of women experience nonspecific symptoms, including mucopurulent vaginal discharge and vaginal bleeding, especially following sexual intercourse. In comparison, 90% of males experience symptoms within 2 to 6 days following exposure, most commonly mucopurulent penile discharge and dysuria.[19] The most common clinical features of gonococcal infections are presented in Table 117-3.

Complications associated with untreated gonorrhea appear more pronounced in women, likely a result of a high percentage who experience signs and symptoms that are nonspecific and minimally symptomatic. As a result, many women do not seek treatment until after the development of serious complications, such as pelvic inflammatory disease (PID). Approximately 15% of women with gonorrhea develop PID. Left untreated, PID can be an indirect cause of infertility and ectopic pregnancies. In 0.5% to 3% of patients with gonorrhea, the gonococci invade the bloodstream and produce disseminated disease. Disseminated gonococcal infection (DGI) is three times more common in women than in men. The usual clinical manifestations of DGI are tender necrotic skin

TABLE 117-3 Presentation of Gonorrhea Infections

	Males	Females
General	Incubation period 1-14 days	Incubation period 1-14 days
	Symptom onset in 2-8 days	Symptom onset in 10 days
Site of infection	Most common: urethra	Most common: endocervical canal
	Others: rectum (usually caused by rectal intercourse in MSM), oropharynx, eye	Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	Commonly symptomatic, may be asymptomatic	Can be asymptomatic or minimally symptomatic
	Urethral infection: dysuria and urinary frequency	Endocervical infection: usually asymptomatic or mildly symptomatic
	Anorectal infection: asymptomatic to severe rectal pain	Urethral infection: dysuria, urinary frequency
	Pharyngeal infection: asymptomatic to mild pharyngitis	Anorectal and pharyngeal infection; symptoms same as for men
Signs	Purulent urethral or rectal discharge can be scant to profuse Anorectal: pruritus, mucopurulent discharge, bleeding	Abnormal vaginal discharge or uterine bleeding; purulent urethral or rectal discharge can be scant to profuse
Complications	Rare (epididymitis, prostatitis, inguinal lymphadenopathy, urethral stricture)	Pelvic inflammatory disease and associated complications (ie, ectopic pregnancy, infertility)
	Disseminated gonorrhea	Disseminated gonorrhea (three times more common than in men)

MSM, men who have sex with men.

lesions, tenosynovitis, and monoarticular arthritis.[1,13-17] Additionally, HIV infection is more easily transmitted in patients coinfected with gonorrhea.

Diagnosis

Diagnosis of gonococcal infections can be made by gram-stained smears, culture, or methods based on the detection of cellular components of the gonococcus (eg, enzymes, antigens, DNA, or lipopolysaccharide [LPS]) in clinical specimens. Various stains have been used to identify gonococci microscopically, with the Gram stain the most widely used in clinical practice. Gram-stained smears are positive for gonococci when gram-negative diplococci of typical kidney bean morphology are identified within PMN leukocytes.[1,13-17] In urethral smears from men with symptomatic urethritis, the smear is highly sensitive and specific, and is considered diagnostic for infection. However, due to lower sensitivity, gram-stained smears are not recommended in the diagnosis of endocervical, rectal, cutaneous, and asymptomatic male urethral infections. Because of the presence of nonpathogenic *Neisseria* in the pharynx, the Gram stain is not useful in the diagnosis of pharyngeal infection.[1,13,15-17]

Although culture is highly sensitive and specific, limitations including prolonged turnaround times and difficulty maintaining viable samples preclude widespread usage. Additionally, culture requires invasive specimen collection for processing (endocervical or urethral swab). As a result, direct culture is primarily utilized in cases of suspected or documented treatment failures, as a test of cure following use of an alternative treatment regimen, or for detection of rectal, oropharyngeal, and conjunctival gonococcal infections.[1]

With the exception of Gram stain for symptomatic gonococcal urethritis, alternative methods of diagnosis, including enzyme immunoassay (EIA), DNA probe techniques, and nucleic acid amplification techniques (NAATs) offer increased sensitivity and/or specificity over traditional diagnostic methods.[13,16,17,20] Additionally, many of these tests can provide a more rapid means of diagnosis than culture. Of particular clinical importance is the high sensitivity of NAATs for detecting *N. gonorrhoeae* using noninvasive specimens (eg, self-collected urine specimens, vaginal swabs). NAAT is recommended by the CDC for detection of gonorrhea in FDA-cleared specimen types specific to each NAAT manufacturer.[1] This technology is also being used to concurrently test for *C. trachomatis* using a single specimen. However, a major drawback of NAATs is their inability to provide resistance data on isolated gonococcal strains. In cases of documented treatment failure, antimicrobial susceptibility testing is recommended, as previously mentioned.[1,12,17,18,20]

TREATMENT

1 In 2010, the CDC issued an update to their recommended treatment regimens for gonorrhea. This update eliminated oral cephalosporins from the recommended treatment regimens for gonorrhea, leaving single-dose intramuscular ceftriaxone as the only recommended agent for treating gonorrhea[18] (**Table 117-4**). The ceftriaxone-based regimens are the only regimens that have well-documented efficacy in the treatment of urethral, cervical, rectal, and pharyngeal infections, curing 99.2% of uncomplicated cases and 98.9% of pharyngeal cases.[12] A 400 mg oral dose of cefixime may be substituted if ceftriaxone is unavailable, however, a test of cure is often recommended two weeks later due to reduced bactericidal levels and efficacy (97.5% in uncomplicated cases and 92.3% in pharyngeal gonorrhea) compared to ceftriaxone. Additionally, only ceftriaxone is effective in treating pharyngeal gonorrhea and eradicating both gonorrhea and incubating syphilis in a patient coinfected with both organisms. The latter is particularly beneficial in areas with a high rate of syphilis.[1,13,15-18]

Coexisting chlamydial infection, which is documented in up to 50% of women and 20% of men with gonorrhea, constitutes the major cause of postgonococcal urethritis, cervicitis, and salpingitis in patients treated for gonorrhea for whom concurrent chlamydial infection has not been ruled out.[1,17] As a result, concomitant treatment with azithromycin or doxycycline is recommended in all patients treated for gonorrhea. Azithromycin 1,000 mg given orally as a one-time dose is currently preferred to doxycyline due to advantages of single-dose therapy and increased resistance of gonococcal resistance to tetracycline. Doxycycline 100 mg orally twice a day may be used in cases of azithromycin allergy.[1] While azithromycin (2 g) as a single dose appears highly effective in eradicating both gonorrhea and chlamydia, it is not recommended as a preferred alternative to ceftriaxone because of concerns regarding the development of resistance. Alternative therapies can be used for in cephalosporin-allergic individuals. Single-dose regimens consisting of oral gemifloxacin or intramuscular gentamicin in combination with azithromycin were associated with high cure rates (99.5% and 100%, respectively), however, high rates gastrointestinal side effects may limit their applicability [1,17,21,22,23] Pregnant women infected with *N. gonorrhoeae* should be treated with ceftriaxone. For presumed or diagnosed concurrent *C. trachomatis* infection, azithromycin is the preferred treatment.[1,13,14]

Ceftriaxone is the recommended therapy for DGI, gonococcal meningitis, endocarditis, and any type of gonococcal infection in children. In cases of DGI, patients should be hospitalized and treated with ceftriaxone or one of the alternative parenteral cephalosporin antibiotics (see Table 117-4). Although marked improvement is usually noted within 48 hours of initiating therapy, treatment should be continued for at least 7 days, with longer durations necessary for serious infections, such as meningitis and endocarditis[1,16,17] Gonococcal ophthalmia is highly contagious in adults and neonates and requires ceftriaxone therapy. Single-dose therapy is adequate for gonococcal conjunctivitis, although some physicians recommend continuing therapy until cultures are negative at 48 to 72 hours. Topical antibiotics are not sufficiently effective when used alone for ocular infections and are not necessary with appropriate systemic therapy. Infants with any evidence of ocular infection should be evaluated for signs of DGI.[1,13,16,17,24]

Clinical **Controversy...**

The American College of Obstetricians and Gynecologists (ACOG) supports expedited partner therapy, or the treatment of sexual partners of those infected with gonorrhea and chlamydial without first examining these partners, in order to reduce reinfection rates. This is particularly useful in cases when the patient's partner is unwilling to seek medical care. However, many legal and social barriers exist which prevent widespread acceptance of this philosophy.

Treatment of gonorrhea during pregnancy is essential to prevent ophthalmia neonatorum. Gonococcal infection in newborns results primarily from passage through an infected birth canal, but it also can be transmitted in utero. Conjunctival involvement usually develops within 7 days of delivery and is characterized by intense, bilateral conjunctival inflammation with chemosis. If not treated promptly, corneal ulceration and blindness can develop. Because the law in most states requires neonatal prophylaxis with topical ocular antimicrobials, gonococcal ophthalmia neonatorum is rare in the United States. The CDC recommends that erythromycin (0.5%) ophthalmic ointment be instilled in each conjunctival sac immediately postpartum.[1,13-17,24]

TABLE 117-4 Treatment of Gonorrhea

Type of Infection	Recommended Regimens[a]	Alternative Regimens[a]
Uncomplicated infections of the cervix, urethra, and rectum in adults	Ceftriaxone 250 mg IM once *plus* Azithromycin 1 g orally once	Cefixime 400 mg orally once *plus* Azithromycin 1 g orally once, or doxycycline 100 mg PO twice daily for 7 days[b,c] or Gemifloxacin 320 mg orally once or gentamicin 240 mg IM[e] *plus* Azithromycin 2 g orally once
Uncomplicated infections of the pharynx	Ceftriaxone 250 mg IM once *plus* Azithromycin 1 g orally once	Consult with infectious disease expert
Disseminated gonococcal infection in adults (>45 kg)	Ceftriaxone 1-2 g IM or IV every 12-24 hour[e] *plus* Azithromycin 1 g orally once	Cefotaxime 1 g IV every 8 hours[e] or ceftizoxime 1 g IV every 8 hours[e] *plus* Azithromycin 1 g orally once
Uncomplicated infections of the cervix, urethra, pharynx, and rectum in children (<45 kg)	Ceftriaxone 25-50 mg/kg IV or IM once (not to exceed 125 mg)	
Disseminated gonococcal infection in children (<45 kg)	Ceftriaxone 50 mg/kg IV or IM once daily (not to exceed 1 g)	
Gonococcal conjunctivitis in adults	Ceftriaxone 1 g IM once[f]	
Ophthalmia neonatorum	Ceftriaxone 25-50 mg/kg IV or IM once (not to exceed 125 mg)	
Disseminated gonococcal infection in neonates	Ceftriaxone 25-50 mg/kg/day IV or IM once daily or cefotaxime 25 mg/kg IV or IM twice daily for 7 days, or 10-14 days if meningitis is suspected[h]	
Infants born to mothers with gonococcal infection (prophylaxis)	Erythromycin (0.5%) ophthalmic ointment in a single application[g] Ceftriaxone 25-50 mg/kg IM or IV once (not to exceed 125 mg)	

CDC, Centers for Disease Control and Prevention; *C. trachomatis*, *Chlamydia trachomatis*; NAAT, Nucleic Acid Amplification Test; *N. gonorrhoeae, Neisseria gonorrhoeae*.

[a]Recommendations are those of the CDC.

[b]Tetracyclines are contraindicated during pregnancy. Pregnant women should be treated with recommended cephalosporin-based combination therapy. In severe cephalosporin allergy, consulation with an infectious diseases expert is recommended.

[c]Patients who are treatment failures with alternative regimens should be treated with ceftriaxone 250 mg IM once plus azithromycin 1 g PO once in consultation with an infectious disease expert.

[d]For patients with severe cephalosporin allergy.

[e]Parenteral treatment duration should be determined in consultation with an infectious diseases expert. Parenteral therapy for meningitis should be continued for at least 10-14 days and at least 4 weeks in endocarditis.

[f]A single lavage of the infected eye with normal saline should be considered; empiric therapy for *C. trachomatis* is recommended.

[g]Efficacy in preventing chlamydial ophthalmia is unclear.

[h]Caution should be taken when administering ceftriaxone to hyperbilirubinemic neonates.

Recent sex partners (within 60 days of preceding onset of symptoms or diagnosis) should be referred to for evaluation and treatment. Sex partners should abstain from unprotected sexual intercourse for 7 days after both have completed treatment and symptoms have resolved.[1]

Evaluation of Therapeutic Outcomes

In the past, persistence of gonorrhea symptoms a short time following treatment with a recommended regimen against gonorrhea usually indicated reinfection rather than treatment failure and, as such, reflected the need for improved patient education and sex partner referral. However, with antimicrobial resistance increasingly being reported in recent years, reinfection can no longer be assumed as the cause. As a result, the CDC recommends that all apparent treatment failures be assessed using culture and sensitivity testing. Persistence of symptoms also can be due to other infectious causes, such as *C. trachomatis*.[1,13-18] While the CDC does not recommend a test-of-cure of patients treated with a recommended regimen, it is recommend that any patient treated for gonorrhea be retested 3 months after treatment, and if not possible, whenever the patient next presents for medical care in the following 12 months. Patients who require retreatment should be tested for cure 7-14 days following the second regiment.[1]

SYPHILIS

Epidemiology and Etiology

Although nearly eradicated in 2000, cases of syphilis more than doubled in the United States from 2005 to 2013, with an annual total of primary and secondary syphilis diagnoses of around 16,000. Of these newly diagnosed cases, 91% were reported in men, the majority of whom were reported as MSM.[25] In addition to being highly contagious, syphilis is of major concern because, if left untreated, it can progress to a chronic systemic disease that can be fatal or seriously disabling.[26-35] Syphilis usually is acquired by sexual contact with infected mucous membranes or cutaneous lesions, although on rare occasions it can be acquired by nonsexual personal contact, accidental inoculation, or blood transfusion. The causative organism of syphilis is *Treponema pallidum*, a spirochete. The risk of acquiring syphilis from an infected individual after a single sexual encounter is approximately 50% to 60%. After sexual contact, the organism penetrates the intact mucous membrane or a break in the cornified epithelium, and spirochetemia occurs.[27,30,31-35]

There is strong evidence of an association between syphilis and HIV infection. Syphilis, similar to other sexually transmitted genital ulcer diseases, can increase the risk of acquiring HIV in exposed

individuals. In addition, immunologic defects in HIV-infected individuals can produce an atypical serologic response to syphilis. In particular, the possibility of delayed seroreactivity, markedly elevated serologic titers, and increased false-positive results could complicate the diagnosis, as well as assessment of treatment efficacy, in HIV-positive individuals infected with syphilis. Furthermore, anecdotal evidence suggests that compromised immune function can result in an accelerated progression of syphilis, particularly to neurosyphilis, requiring more aggressive antibiotic therapy in comparison with an immunocompetent host. As a result of this association, the CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.[1,26,28-30,32,33]

Clinical Presentation

The clinical presentation of syphilis is varied with progression through multiple stages possible in untreated or inadequately treated patients (Table 117-5).

Primary Syphilis

The primary stage, characterized by the appearance of a chancre on cutaneous or mucocutaneous tissue exposed to the organism, is highly infectious. Even without treatment, chancres persist only for 1 to 8 weeks before healing spontaneously. Because syphilitic chancres can be confused with other infectious etiologies, appropriate diagnostic testing is important.[26-30,32,34]

TABLE 117-5 Presentation of Syphilis Infections

General	
Primary	Incubation period 10-90 days (mean, 21 days)
Secondary	Develops 2-8 weeks after initial infection in untreated or inadequately treated individuals
Latent	Develops 4-10 weeks after secondary stage in untreated or inadequately treated individuals
Tertiary	Develops in approximately 30% of untreated or inadequately treated individuals 10-30 years after initial infection
Site of Infection	
Primary	External genitalia, perianal region, mouth, and throat
Secondary	Multisystem involvement secondary to hematogenous and lymphatic spread
Latent tertiary	Potentially multisystem involvement (dormant)
	CNS, heart, eyes, bones, and joints
Signs and Symptoms	
Primary	Single, painless, indurated lesion (chancre) that erodes, ulcerates, and eventually heals (typical); regional lymphadenopathy is common; multiple, painful, purulent lesions possible but uncommon
Secondary	Pruritic or nonpruritic rash, mucocutaneous lesions, flulike symptoms, lymphadenopathy
Latent	Asymptomatic
Tertiary	Cardiovascular syphilis (aortitis or aortic insufficiency), neurosyphilis (meningitis, general paresis, dementia, tabes dorsalis, eighth cranial nerve deafness, blindness), gummatous lesions involving any organ or tissue

CNS, central nervous system.

Secondary Syphilis

The secondary stage of syphilis is characterized by a variety of mucocutaneous eruptions resulting from widespread hematogenous and lymphatic spread of *T. pallidum*. Skin lesions can be either generalized or localized to a small portion of the body and, with the exception of follicular lesions, are nonpruritic. Generalized lymphadenopathy also is seen in the majority of patients, as are nonspecific symptoms such as mild and transitory malaise, fever, pharyngitis, headache, anorexia, and arthralgia. If untreated, secondary syphilis disappears in 4 to 10 weeks; however, lesions can recur at any time within 4 years.[26-34]

Latent Syphilis

By definition, persons with a positive serologic test for syphilis but with no other evidence of disease have latent syphilis. Latent syphilis is further divided into early and late latency. During early latency, the patient is considered potentially infectious because of the 25% risk of spontaneous mucocutaneous relapse. The CDC defines early latency as 1 year from the onset of infection, although other investigators propose a longer interval, such as 2 to 4 years. With the exception of pregnancy in which the mother can pass the disease to the fetus, late latency is considered noninfectious, although the patient remains a host.[1,26-34]

Most untreated patients with late latent syphilis have no further sequelae; however, approximately 25% to 30% progress either to neurosyphilis or to late syphilis with clinical manifestations other than neurosyphilis. Treatment of all patients with latent syphilis is essential because there is no way to predict which patients will have progression of their disease.[26-34]

Tertiary Syphilis and Neurosyphilis

If left untreated, syphilis can slowly produce an inflammatory reaction in virtually any organ in the body. Manifestations of this disease progression were referred to previously as *tertiary syphilis*. These clinical manifestations now are differentiated into two subgroups based on the presence or absence of central nervous system (CNS) involvement: neurosyphilis or tertiary syphilis (ie, gumma and cardiovascular syphilis).[1,26-34]

Currently, the term *neurosyphilis* encompasses any patient with cerebrospinal fluid (CSF) abnormalities consistent with CNS infection. Approximately 40% of patients with primary or secondary syphilis exhibit such abnormalities, although most remain asymptomatic. Persistence of CSF abnormalities into late latency is associated with a greater risk of progression to symptomatic neurosyphilis. Although data are conflicting, some investigators suggest that HIV-infected patients are at greater risk of developing symptomatic neurosyphilis than patients with intact immune systems.[1,26-34]

Rarely seen, the most common manifestations of disease progression from late latency are benign gumma formation and cardiovascular syphilis. The gumma, a nonspecific granulomatous lesion, is the classic lesion of late syphilis and develops in 50% of patients with disease progression. These chronic, destructive lesions characteristically infiltrate the skin, bone, soft tissue, and liver but can be found in any organ or tissue. Gummas of critical organs, such as the heart or brain, can be fatal.[1,26-30,33]

Congenital Syphilis

In pregnant women with syphilis, *T. pallidum* can cross the placenta at any time during pregnancy. The risk of fetal infection is greatest in pregnant women with primary and secondary syphilis and declines in pregnant women with late disease. Transmission of syphilis during pregnancy occurs primarily transplacentally and can result in fetal death, prematurity, or congenital syphilis. Symptoms can be seen during the first months of life (early congenital syphilis) or later in childhood or adolescence (late congenital syphilis). Manifestations of early congenital syphilis resemble those of secondary

syphilis, whereas those of late congenital syphilis correspond to the tertiary stage in adults.[26,28-30]

Diagnosis

Because *T. pallidum* is difficult to culture in vitro, diagnosis is based primarily on microscopic examination of serous material from a suspected syphilitic lesion or on results from serologic testing. In primary syphilis, diagnosis is established by the presence of *T. pallidum* on dark-field microscopic examination of material from cutaneous lesions and enlarged lymph nodes in patients with secondary syphilis. In incubating syphilis, confirmation frequently is by dark-field microscopic examination because serologic tests can be unreactive early in the disease. Another method of direct microscopic examination, the direct fluorescent-antibody (test) for *T. pallidum* (DFA-TP), which uses monoclonal or polyclonal antibodies specific for *T. pallidum*, has greater specificity and sensitivity than dark-field examination, and does not require the immediate examination of fresh specimens.[30-35]

Serologic tests are the mainstay in the diagnosis of syphilis and traditionally are categorized as nontreponemal or treponemal. Common nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) slide test, rapid plasma reagin (RPR) card test, unheated serum reagin (USR) test, and the toluidine red unheated serum test (TRUST). Nontreponemal tests, which are inexpensive and easily performed, rely on the detection of treponemal antibodies directed against an alcoholic solution of cardiolipin, lecithin, and cholesterol contained in these tests. A positive nontreponemal test can indicate the presence of any stage of syphilis or congenital syphilis, although incubating syphilis and very early primary syphilis produce a negative reaction; however, because they are nonspecific tests, false-positive reactions occur, making them inappropriate to confirm the diagnosis alone. Transiently false-positive results can be seen in patients with acute febrile illnesses, after immunizations, and during pregnancy. Chronic false-positive results are commonly associated with heroin addiction, aging, chronic infections, autoimmune diseases, and malignant disease. In some cases, false-positive reactions are familial and are related to abnormal serum globulin levels. As such, patients with a positive nontreponemal test should always receive a treponemal test for diagnosis confirmation.[1,29-35]

Nontreponemal tests are used primarily as screening tests; however, because *T. pallidum* antibody titers also can be quantitated by testing serial dilutions of the patient's serum for reactivity, they are useful in following the progression of the disease, recovery after therapy, and possible reinfection. Because antibody titers vary to some extent between tests, it is important that sequential serologic testing be performed using the same method each time. In patients treated successfully for primary and secondary syphilis, nontreponemal tests usually decline over time and may return to seronegativity. If these tests are going to return to negative in patients with early latent syphilis, they will do so within the first 4 years after adequate therapy; patients with disease of longer duration usually remain seropositive for life. In addition to their use in serologic testing, nontreponemal tests often are used on CSF to diagnose neurosyphilis.[29-35]

In some patients with secondary syphilis, a prozone phenomenon occurs that produces a negative VDRL test despite the presence of high reaginic antibody titers. This is corrected by diluting the patient's serum prior to testing.[32,33] For HIV-positive individuals with syphilis, the reactivity of nontreponemal tests can vary depending on the stage of the HIV infection. In the early stages, reaginic titers higher than in non–HIV-infected patients have been seen, resulting in the prozone phenomenon. During the later stages of HIV infection, however, when immune function deteriorates to a greater extent, serologic responses can be reduced or delayed. As a result, the diagnosis of syphilis in HIV-infected individuals can be more difficult.[1,30-35]

Use of only one serologic test for diagnosis of syphilis is insufficient as false-positives can occur in those without syphilis and false-negatives in those with primary syphilis. In diagnosing all stages of syphilis, treponemal tests are more sensitive than nontreponemal tests. Because these tests are technically more demanding and are more expensive, they have been used as confirmatory rather than as screening tests. However, patients with a positive treponemal test should have a nontreponemal test with titer reflexively drawn in order to guide management decisions and to monitor response to therapy. If the nontreponemal test is negative, a different treponemal test should be used to confirm the initial positive result. If a second treponemal test is positive, previously untreated patients should be offered treatment. Those with a previous history of treatment require no further management unless sexual history indicates likelihood of re-exposure, in which case a repeat nontreponemal test is recommended in 2 to 4 weeks.[1]

For many years, the fluorescent treponemal antibody absorption (FTA-ABS) test was the most frequently used treponemal test. The FTA-ABS test uses the *T. pallidum* antigen to detect specific antibodies to treponemal organisms. However, the FTA-ABS test has largely been replaced by card assays such as the *T. pallidum* hemagglutination assay (TPHA), the microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP), and the *T. pallidum* particle agglutination assay (TPPA) which can be automated and are less expensive to perform. Despite adequate antibiotic therapy for any stage of syphilis, the antibody tests usually remain reactive for life and therefore are not useful in assessing serologic response to therapy, relapse, or reinfection, hence the need for a reflex nontreponemal test.[1,30-35]

Several EIAs for *T. pallidum* have become available and are gaining wide use as confirmatory tests. Polymerase chain reaction (PCR)-based tests also are being investigated, particularly in situations in which serologic testing has poor sensitivity and specificity (eg, congenital syphilis, early primary syphilis, and neurosyphilis). Additionally, multiplex PCR tests that can identify the presence of *T. pallidum*, herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2), and *Haemophilus ducreyi* from genital ulcer specimens are under study. The CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.[1,28-30,35]

TREATMENT

Table 117-6 presents the CDC's treatment recommendations.[1] Parenteral penicillin G is the treatment of choice for all stages of syphilis. Because *T. pallidum* multiplies slowly, single doses of short- or intermediate-acting penicillins do not provide the prolonged, low-level exposure to penicillin required for eradication of the treponeme. As a result, benzathine penicillin G is the only penicillin effective for single-dose therapy.[1,28-34]

The recommended treatment for syphilis of less than 1 year's duration is benzathine penicillin G 2.4 million units as a single dose. Although the relapse rate for this regimen is less than 3%, some investigators advocate that 2.4 million units be administered once a week for two consecutive weeks. In patients with late latent syphilis and normal CSF examination, benzathine penicillin G is administered weekly for three successive doses. Although not specifically recommended by the CDC, this three-dose regimen is used by some experts to treat HIV-infected patients with syphilis of less than 1 year's duration based on data suggesting a greater risk of treatment failure with single-dose therapy.[1,30-34]

Patients with abnormal CSF findings should be treated as having neurosyphilis. Preferred regimens for neurosyphilis provide treatment over 10 to 14 days with 18 to 24 million units per day of parenteral penicillin G administered as 3 to 4 million units every 4 hours

TABLE 117-6 Drug Therapy and Follow-up of Syphilis

Stage/Type of Syphilis	Recommended Regimens[a,b]	Follow-up Serology
Primary, secondary, or early latent syphilis (<1 year's duration)	Adults: Benzathine penicillin G 2.4 million units IM in a single dose Children: Benzathine penicillin G 50,000 units/kg IM in a single dose, up to 2.4 million units	Quantitative nontreponemal tests at 6 and 12 months for primary and secondary syphilis; at 6, 12, and 24 months for early latent syphilis[c]
Late latent syphilis (>1 year's duration) or latent syphilis of unknown duration or tertiary syphilis or retreatment	Adults: Benzathine penicillin G 2.4 million units IM once a week for 3 successive weeks (7.2 million units total) Children: Benzathine penicillin G 50,000 units/kg IM once a week for 3 successive weeks, up to 7.2 million units total	Quantitative nontreponemal tests at 6, 12, and 24 months[d,e]
Neurosyphilis	Aqueous crystalline penicillin G 18-24 million units IV (3-4 million units every 4 hours or by continuous infusion) for 10-14 days[f] *or* Aqueous procaine penicillin G 2.4 million units IM daily plus probenecid 500 mg orally four times daily, both for 10-14 days[f]	CSF examination every 6 months until the cell count is normal; if it has not decreased at 6 months or is not normal by 2 years, retreatment should be considered
Congenital syphilis (infants with proven or highly probable disease)	Aqueous crystalline penicillin G 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days *or* Procaine penicillin G 50,000 units/kg IM daily for 10 days	Serologic follow-up only recommended if antimicrobials other than penicillin are used
Penicillin-Allergic Patients[g]		
Primary, secondary, or early latent syphilis	Doxycycline 100 mg orally two times daily for 14 days[g,h] *or* Tetracycline 500 mg orally four times daily for 14 days[h] *or* Ceftriaxone 1-2 g IM or IV daily for 10-14 days	Same as for non–penicillin-allergic patients
Late latent syphilis (>1 year's duration) or syphilis of unknown duration	Doxycycline 100 mg orally twice a day for 28 days[h,i] *or* Tetracycline 500 mg orally four times daily for 28 days[h,i]	Same as for non–penicillin-allergic patients

CDC, Centers for Disease Control and Prevention; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus.

[a]Recommendations are those of the CDC.

[b]The CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.

[c]More frequent follow-up (ie, 3, 6, 9, 12, and 24 months) recommended for HIV-infected patients.

[d]More frequent follow-up (ie, 6, 12, 18, and 24 months) recommended for HIV-infected patients.

[e]No specific recommendations exist for tertiary syphilis because of the lack of available data.

[f]Some experts administer benzathine penicillin G 2.4 million units IM once per week for up to 3 weeks after completion of the neurosyphilis regimens to provide a total duration of therapy comparable to that used for late syphilis in the absence of neurosyphilis.

[g]For nonpregnant patients; pregnant patients should be treated with penicillin after desensitization.

[h]Pregnant patients allergic to penicillin should be desensitized and treated with penicillin.

[i]Limited data suggest that ceftriaxone may be effective, although the optimal dosage and treatment duration are unclear.

or by continuous infusion. Benzathine penicillin G alone in standard weekly doses and procaine penicillin G in doses under 2.4 million units do not consistently provide treponemicidal levels in the CSF and have resulted in treatment failures. Because *T. pallidum* resistance to penicillin has not emerged, the primary need for alternative drugs in treating syphilis is for penicillin-allergic patients.[1,30-34]

2 Alternative regimens recommended for penicillin-allergic patients are doxycycline 100 mg orally twice daily or tetracycline 500 mg orally four times daily for 2 to 4 weeks depending on the duration of syphilis infection. These regimens should be used only in cases of documented penicillin allergy, and given concerns regarding patient compliance with these regimens, follow-up serologic testing is of particular importance.[1,30-34]

Other antibiotics used successfully in treating syphilis include various beta lactam antibiotics; however, none offers significant advantages over benzathine penicillin G. Even though ceftriaxone is considered effective in eradicating incubating syphilis when given as a single 125-mg dose, higher doses and more frequent administration (eg, 1-2 g daily for 10-14 days) appear necessary for more advanced syphilis, and treatment failures are reported in HIV-infected patients. Although azithromycin 2 g as a single dose produces good results in patients with early syphilis, treatment failures and resistance to azithromycin are reported.[1,27,30-34]

Clinical **Controversy...**

One clinical trial recently reported positive results on the use of high dose amoxicillin (3 g) plus probenecid for treatment of patients coinfected with HIV and syphilis. This method might prove particularly useful in countries where benzathine penicillin is not available or for treatment of patients who are unlikely to follow-up for weekly injections.

For pregnant patients, penicillin is the treatment of choice at the dosage recommended for that particular stage of syphilis. To ensure treatment success and prevent transmission to the fetus, some experts advocate an additional IM dose of benzathine penicillin G 2.4 million units 1 week after completion of the recommended regimen. In women allergic to penicillin, safe and effective alternatives are not available; therefore, skin testing should be performed to confirm a penicillin allergy. It is recommended that women with positive skin tests undergo penicillin desensitization and receive the appropriate treatment regimen for their stage of disease.[1,28-30]

Most patients treated for primary and secondary syphilis experience the Jarisch-Herxheimer reaction after treatment. This benign, self-limiting reaction is characterized by flulike symptoms, such as

transient headache, fever, chills, malaise, arthralgia, myalgia, tachypnea, peripheral vasodilation, and aggravation of syphilitic lesions. The exact mechanism of the reaction is unknown, although proposed etiologies, including immunologic mechanisms and release of endotoxin or other toxic treponemal products, are not substantiated. The Jarisch-Herxheimer reaction is independent of the drug and dose used and should not be confused with penicillin allergy. It usually begins within 2 to 4 hours of initiating therapy, peaks at 8 hours, and is complete within 12 to 24 hours. Most reactions can be managed symptomatically with analgesics, antipyretics, and rest. Steroids and antihistamines have been administered prior to initiation of syphilitic therapy but are of limited value.[1,28-30]

Evaluation of Therapeutic Outcomes

Table 117-6 lists the CDC recommendations for serologic follow-up of patients treated for syphilis.[1] Quantitative nontreponemal tests should be performed at 6 and 12 months in all patients treated for primary and secondary syphilis and at 6, 12, and 24 months for early and late latent disease. Patients indicated for retreatment should receive three weekly treatments of IM 2.4 million units of benzathine penicillin G, unless neurosyphilis is present. The CDC recommends more frequent monitoring of HIV-infected individuals (ie, 3, 6, 9, 12, and 24 months after therapy). In general, the time to reach seronegativity is proportional to the duration of the disease. Table 117-6 also includes specific testing recommendations for other stages of syphilis. Despite adequate therapy, some patients can remain seropositive based on nontreponemal test results. In these cases, stabilization of low antibody titers is indicative of adequate therapy. For women treated during pregnancy, monthly quantitative nontreponemal tests are recommended in those at high risk of reinfection.[28-30]

CHLAMYDIA TRACHOMATIS

Epidemiology and Etiology

Based on CDC data for 2013, over 1.4 million cases of chlamydia infection were reported, making it the second most frequently reported infectious disease in the United States behind HPV.[1,5] Because of the silent nature of many infections, the presumptive treatment of many cases, and the underreporting of many cases, it is estimated that more than double this number of cases actually occur annually. Chlamydial infections also are the primary causes of nongonococcal urethritis (NGU), accounting for as much as 50% of such infections.[1,36-40]

Pathophysiology

C. trachomatis is an obligate intracellular parasite that shares properties of both viruses and bacteria. Like viruses, chlamydiae require cellular material from host cells for replication; however, unlike viruses, chlamydiae maintain their cellular identity throughout development. Although *C. trachomatis* lacks a cell-wall peptidoglycan, its major outer membrane is similar to gram-negative bacteria. At least 18 serovars (subspecies) of *C. trachomatis* exist, of which only the lymphogranuloma venereum strains produce potentially invasive infections. The remaining serovars are involved primarily with superficial infection of epithelial cells.[36-40]

The risk of transmissibility of chlamydia after exposure is unknown but is believed to be less than that following exposure to *N. gonorrhoeae*. Coinfection with chlamydia occurs in a substantial number of individuals with gonorrhea and all individuals diagnosed with *N. gonorrhoeae* should be assumed also to have *C. trachomatis* present, if chlamydial infection has not been ruled out.[1] Of major concern is that chlamydial infections are associated with a significantly increased risk of acquiring HIV infection. In addition to genital infections, ocular infections in adults owing to autoinoculation and infants owing to vaginal delivery through an infected birth canal are reported. Pharyngeal and rectal infections can develop secondary to orogenital or receptive anal intercourse, respectively, with an infected individual.[1,36-43]

Clinical Presentation

In comparison with gonorrhea, chlamydial genital tract infections are more frequently asymptomatic, and when present, symptoms tend to be less noticeable. Urethral discharge usually is less profuse and more mucoid or watery than the urethral discharge associated with gonorrhea.[37-40] Table 117-7 summarizes the usual clinical presentation of chlamydial infections.

Similar to gonorrhea, chlamydia can be transmitted to an infant during contact with infected cervicovaginal secretions. Nearly two-thirds of infants acquire chlamydial infection after endocervical exposure, with the primary morbidity associated with seeding of the infant's eyes, nasopharynx, rectum, or vagina. In exposed infants, neonatal conjunctivitis develops in as many as 50%, and pneumonia develops in up to 16%. Inclusion conjunctivitis in newborns is usually self-limited, but it can result in scarring and micropannus of the cornea. Interstitial pneumonitis occurring secondary to carriage in the nasopharynx typically is mild, but it can be severe and require hospitalization.[1,37-40,42]

Diagnosis

3 Because of the high rate of asymptomatic disease and the high prevalence of chlamydial infection in sexually active females 25 years of age or younger and sexually active women with new sex partners or multiple sex partners, the CDC recommends routine annual screening in these individuals. Laboratory confirmation of chlamydial infection is important because of the relative lack of specificity of symptoms when present.[1]

Cell culture is the reference standard against which all other diagnostic tests are measured. Because chlamydiae are obligate

TABLE 117-7 Presentation of *Chlamydia* Infections

	Males	Females
General	Incubation period: 35 days Symptom onset: 7-21 days	Incubation period: 7-35 days Usual symptom onset: 7-21 days
Site of infection	Most common: urethra Others: rectum (receptive anal intercourse), oropharynx, eye	Most common: endocervical canal Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	More than 50% of urethral and rectal infections are asymptomatic Urethral infection: mild dysuria, discharge Pharyngeal infection: asymptomatic to mild pharyngitis	More than 66% of cervical infections are asymptomatic Urethral infection: usually subclinical; dysuria and frequency uncommon Rectal and pharyngeal infection: symptoms same as for men
Signs	Scant to profuse, mucoid to purulent urethral or rectal discharge Rectal infection: pain, discharge, bleeding	Abnormal vaginal discharge or uterine bleeding, purulent urethral or rectal discharge can be scant to profuse
Complications	Epididymitis, Reiter's syndrome (rare)	Pelvic inflammatory disease and associated complications (ie, ectopic pregnancy, infertility) Reiter's syndrome (rare)

intracellular parasites, specimens for culture must be obtained from endocervical (women) or urethral (men) epithelial cell scrapings rather than from urine or urethral discharges. Although tissue culture techniques have close to 100% specificity, the sensitivity is reported to be as low as 70% in part because of problems of improper specimen collection, transport, or processing. Because of the technical demands, expense, and length of time until results are available (3-7 days), culture is not used widely for diagnostic purposes today. However, culture remains the diagnostic standard in medicolegal cases such as sexual assault and child abuse because of its high specificity and ability to detect only viable organisms.[37-40,43-46]

Tests that detect chlamydial antigens and nucleic acid provide more rapid results, are technically less demanding to perform, are less costly, and in some situations have greater sensitivity than culture. Commonly used nonculture tests for detection of *C. trachomatis* are the enzyme immunosorbent assay (EIA), DNA hybridization probe, and NAATs.[38,40,43,45]

Although still widely used both as rapid office tests and as laboratory-based tests, EIA methods for diagnosis of *C. trachomatis* are no longer recommended because of their poor sensitivity in comparison to NAATs. NAATs, which can detect small amounts of chlamydial DNA, are highly sensitive and specific for detecting infection in urogenital and anal specimens, as well as in urine. Use of self-collected vaginal or anal specimens or first-void urine samples offers greater patient acceptability, particularly when used to screen asymptomatic individuals. A further advantage of tests that can screen urine for the presence of infection is that up to 30% of women are reported to have urethral infection only, which would be missed using a test on endocervical samples. Because of their ability to detect as little as a single gene copy in a specimen, nucleic acid residues that persist following successful antibiotic therapy of a chlamydial infection can result in a false-positive test for several weeks following eradication of the organism.[39,40]

TREATMENT

A number of antimicrobials, including tetracyclines, macrolides, azithromycin, and some fluoroquinolones, display good in vitro and in vivo activity against *C. trachomatis*. In most clinical trials, cure rates exceeding 90% are reported for these agents. All these antimicrobials also appear to have good efficacy against *Ureaplasma urealyticum*, the second most common cause of NGU.[37-40]

Azithromycin 1 g orally as a single dose and doxycycline 100 mg orally twice daily for 7 days are the regimens of choice for the treatment of uncomplicated chlamydial infections[1] (Table 117-8). Because of its prolonged serum and tissue half-life, azithromycin is the only single-dose therapy that is effective in treating *C. trachomatis*. Delayed-release doxycycline (Doryx) given as 200 mg orally once daily for 7 days may be considered as an alternative regimen for the treatment of urogenital *C. trachomatis* infection. In a double-blind, randomized, controlled trial it was as effective as generic doxycycline and was associated with a lower frequency of gastrointestinal side effects, but this regimen is more costly.[47] Of the fluoroquinolones, ofloxacin and levofloxacin are included in the CDC recommendations, but neither appears to offer an advantage over other first-line nor alternative therapies. Although ciprofloxacin and some other fluoroquinolones have activity against *C. trachomatis* and *U. urealyticum*, high dosages have not consistently eradicated chlamydial infections.[1,37-43]

For pregnant women with chlamydial urogenital infections, treatment can reduce the risk of pregnancy complications and transmission to the newborn significantly. Because the use of tetracyclines and fluoroquinolones is contraindicated during pregnancy, azithromycin is the recommended drug treatment (see Table 117-8).

TABLE 117-8 Treatment of *Chlamydial* Infections

Infection	Recommended Regimens[a]	Alternative Regimen
Uncomplicated urethral, endocervical, or rectal infection in adults	Azithromycin 1 g orally once, or doxycycline 100 mg orally twice daily for 7 days	Erythromycin base 500 mg orally four times daily for 7 days, or erythromycin ethylsuccinate 800 mg orally four times daily for 7 days, or levofloxacin 500 mg orally once daily for 7 days, or ofloxacin 300 mg orally twice daily for 7 days
Urogenital infections during pregnancy	Azithromycin 1 g orally as a single dose or amoxicillin 500 mg orally three times daily for 7 days	Amoxicillin 500 mg orally three times daily for 7 days, or erythromycin base 500 mg orally four times daily for 7 days, or erythromycin base 250 mg orally four times daily for 14 days, or erythromycin ethylsuccinate 800 mg orally four times daily for 7 days, or erythromycin ethylsuccinate 400 mg orally four times daily for 14 days
Conjunctivitis of the newborn or pneumonia in infants	Erythromycin base or ethylsuccinate 50 mg/kg/day orally in four divided doses for 14 days[b,c]	Azithromycin suspension 20 mg/kg/day orally once daily for 3 days[c]

CDC, Centers for Disease Control and Prevention; IHPS, infantile hypertrophic pyloric stenosis.

[a]Recommendations are those of the CDC.

[b]Topical therapy alone is inadequate for ophthalmia neonatorum and is unnecessary when systemic therapy is administered. Effectiveness of erythromycin treatment is approximately 80%; therefore, a second course of therapy may be required.

[c]An association between oral erythromycin and azithromycin and IHPS has been reported in infants aged <6 weeks. Infants treated with either of these antimicrobials should be followed for signs and symptoms of IHPS.

When compliance with a multiday regimen is a concern, azithromycin is the preferred treatment in women, regardless of pregnancy status. Additionally, adherence can be maximized by providing onsite, directly observed single-dose therapy with azithromycin. It is recommended that test-of-cure be obtained for pregnant patients treated for chlamydial infections to ensure eradication of the infection. Persons treated for chlamydia should abstain from sexual intercourse for 7 days after single-dose therapy or until completion of a 7-day regimen and resolution of symptoms if present.[1,40-43,48,49]

C. trachomatis transmission during perinatal exposure can result in infections of the eye, oropharynx, lungs, urogenital tract, and rectum of the neonate or infant. Despite its efficacy in preventing gonococcal ophthalmia, topical erythromycin ointment (0.5%) appears less effective in preventing chlamydial ophthalmia. Additionally, topical therapy has no effect on nasal carriage or colonization of other parts of the infant's body, so the potential for other infections, including pneumonia, remains. Because of the high percentage of treatment failures, topical therapy is not recommended to treat ophthalmia caused by *C. trachomatis*. Instead, an oral erythromycin regimen is recommended.[1,37-40]

Evaluation of Therapeutic Outcomes

Treatment of chlamydial infections with the recommended regimens is highly effective; therefore, posttreatment laboratory testing

is not recommended routinely unless symptoms persist or there are other specific concerns (eg, pregnancy). Posttreatment tests should not be performed for at least 3 weeks following completion of therapy.[1] When posttreatment tests are positive, they usually represent noncompliance, failure to treat sexual partners, or laboratory error rather than inadequate therapy or resistance to therapy. Infants with pneumonitis should receive follow-up testing because erythromycin is only 80% effective, and a second course of therapy can be necessary.[1,37-40]

GENITAL HERPES

Epidemiology and Etiology

Genital herpes infections represent the most common cause of genital ulceration seen in the United States. More than 50 million Americans have genital herpes, and this number is increasing by at least 500,000 each year.[1,50-55] Because of its morbidity, recurrent nature, and potential for complications, as well as its ability to be transmitted asymptomatically, genital herpes is of major public health importance.[52-61] Of note, the CDC does not recommend screening for HSV in the general population.[1] Similar to syphilis and other STDs, the presence of genital herpes lesions is associated with an increased risk of acquiring HIV following exposure.[1,50-56]

Pathophysiology

Herpes comes from the Greek word meaning "to creep" and is used to describe two distinct but antigenically related serotypes of HSV. HSV-1 is associated most commonly with oropharyngeal disease, and HSV-2 is associated most closely with genital disease; however, each virus is capable of causing clinically indistinguishable infections in both anatomic areas.[50-52,55]

Humans are the sole known reservoir for HSV. Infection is transmitted via inoculation of virus from infected secretions onto mucosal surfaces (eg, urethra, oropharynx, cervix, and conjunctivae) or through abraded skin. Evidence that the virus survives for a limited time on environmental surfaces suggests the possibility of fomitic transfer as a nonvenereal route of transmission.[50-52,55]

The cycle of HSV infection occurs in five stages: primary mucocutaneous infection, infection of the ganglia, establishment of latency, reactivation, and recurrent infection. After viral inoculation, HSV infection is associated with cytoplasmic granulation, ballooning degeneration of cells, and production of mononucleated giant cells. Initially, the cellular response is predominantly PMN, followed by a lymphocytic response. Replication occurs with viral spread to contiguous cells and peripheral sensory nerves. Latency then is established in sensory or autonomic nerve root ganglia. Latency appears to be lifelong, interrupted only by reactivation of the viral infection. It is unclear what factors are important in maintaining latency, but immune responses and emotional and physical stresses appear important in reactivating latent virus.[50-52,55]

Clinical Presentation

The signs and symptoms of genital herpes infection are influenced by many factors, including previous exposure to HSV, viral type, and host factors such as age and site of infection. Because a high percentage of initial and recurrent infections are asymptomatic, and because viral shedding can occur in the absence of apparent lesions or symptoms, identification and education of individuals with genital herpes are essential in controlling its transmission.[50-59] A summary of the clinical presentation of genital herpes is provided in Table 117-9.

TABLE 117-9 Presentation of Genital Herpes Infections

General	Incubation period 2-14 days (mean, 4 days) Can be caused by either HSV-1 or HSV-2
Classification of infection	
First-episode primary	Initial genital infection in individuals lacking antibody to either HSV-1 or HSV-2
First-episode nonprimary	Initial genital infection in individuals with clinical or serologic evidence of prior HSV (usually HSV-1) infection
Recurrent	Appearance of genital lesions at some time following healing of first-episode infection
Signs and symptoms	
First-episode infections	Most primary infections are asymptomatic or minimally symptomatic Multiple painful pustular or ulcerative lesions on external genitalia developing over a period of 7-10 days; lesions heal in 2-4 weeks (mean, 21 days) Flulike symptoms (eg, fever, headache, malaise) during first few days after appearance of lesions Others—local itching, pain, or discomfort; vaginal or urethral discharge, tender inguinal adenopathy, paresthesias, urinary retention Severity of symptoms greater in females than in males Symptoms are less severe (eg, fewer lesions, more rapid lesion healing, fewer or milder systemic symptoms) with nonprimary infections Symptoms more severe and prolonged in the immunocompromised On average viral shedding lasts approximately 11-12 days for primary infections and 7 days for nonprimary infections
Recurrent	Prodrome seen in approximately 50% of patients prior to appearance of recurrent lesions; mild burning, itching, or tingling are typical prodromal symptoms Compared to primary infections, recurrent infections associated with (1) fewer lesions that are more localized, (2) shorter duration of active infection (lesions heal within 7 days), and (3) milder symptoms Severity of symptoms greater in females than in males Symptoms more severe and prolonged in the immunocompromised On average viral shedding lasts approximately 4 days Asymptomatic viral shedding is more frequent during the first year after infection with HSV
Therapeutic implications of HSV-1 versus HSV-2 genital infection	Primary infections caused by HSV-1 and HSV-2 virtually indistinguishable Recurrent infections and subclinical viral shedding are less frequent with HSV-1 Recurrent infections with HSV-2 tend to be more severe
Complications	Secondary infection of lesions; extragenital infection because of autoinoculation; disseminated infection (primarily in immunocompromised patients); meningitis or encephalitis; neonatal transmission

HSV-1, herpes simplex virus type 1; HSV-2, herpes simplex virus type 2.

Complications

Complications from genital herpes infections result from both genital spread and autoinoculation of the virus and occur most commonly with primary first episodes. Lesions at extragenital sites, such as the eye, rectum, pharynx, and fingers, are not uncommon. CNS involvement is seen occasionally and can take several forms, including an aseptic meningitis, transverse myelitis, or sacral radiculopathy syndrome.[50-59]

A major concern is the effect of genital herpes on neonates exposed during pregnancy. Neonatal herpes is associated with a high mortality and significant morbidity. It is transmitted to the newborn primarily through exposure to HSV in the birth canal but, in rare cases, also is transmitted transplacentally. The risk of transmission during birth appears much greater for first-episode primary infections than for recurrent infections. Neonatal herpes infection has a case-fatality rate of approximately 50%, with a large proportion of surviving infants experiencing significant morbidity, including permanent neurologic damage.[50,51,55]

Diagnosis

Confirmation of a genital herpes infection can be made only with laboratory testing. Tissue culture is the most specific (100%) and sensitive method (80%-90%) of confirming the diagnosis of first-episode genital herpes; however, culture is relatively insensitive in detecting HSV in ulcers in the latter stages of healing and in recurrent infections, as a result, in part, of reduced viral load. Viral culture is expensive and time-consuming, and improper collection or transport of specimens can result in false-negative results. In most situations, HSV isolation on tissue culture takes 48 to 96 hours. Following isolation, it is recommended that typing of the virus be performed because of prognostic implications. HSV-1 is associated with a lower rate of asymptomatic and symptomatic recurrence, while HSV-2 is characterized by more frequent recurrences and subclinical shedding. In instances in which rapid detection is necessary, such as an impending birth, other detection methods can be more useful. Amplified culture techniques that combine cell culture for 24 hours and subsequent staining for HSV antigen have sensitivities and specificities only slightly less than those of culture.[50-55,60-62]

Several serologic tests capable of distinguishing HSV-1 and HSV-2 antibodies are available. These tests detect antibodies to type-specific HSV-1 and HSV-2 proteins gG-1 and gG-2, respectively. Although antibody formation begins immediately following a primary herpes infection, complete seroconversion (ie, complete antibody development) can take several months. Until the full expression of all antigenic determinants of HSV-1 and HSV-2 occurs, these tests are not useful in differentiating HSV-1 and HSV-2 infection. Older antibody detection tests, some of which are still marketed, are unable to distinguish between HSV-1 and HSV-2 owing to the considerable cross-reactivity between the two serotypes. Given the high prevalence of HSV-1 antibody in the adult population, accurate interpretation of positive results is not possible.[50-55,60-62]

PCR assays that detect HSV DNA and differentiate HSV-1 and HSV-2 infections are more sensitive than culture and are considered the diagnostic test of choice for suspected CNS infections (ie, HSV encephalitis and HSV meningitis). PCR assays are highly sensitive in detecting asymptomatic viral shedding.[50-55,60-62]

Although the diagnosis of genital herpes can be confirmed only by laboratory tests, less stringent diagnostic criteria (eg, characteristic physical findings or clinical history) frequently are used in clinical practice. A presumptive diagnosis of genital herpes commonly is made based on the presence of dark-field-negative, vesicular, or ulcerative genital lesions. A history of similar lesions or recent sexual contact with an individual with similar lesions also is useful in making the diagnosis. Other STDs, including chancroid, lymphogranuloma venereum, and granuloma inguinale, and causes such as trauma, allergic reactions, and bacterial or fungal infections are considered in the differential diagnosis.[50-55,60-62]

TREATMENT

The most achievable goals in the management of genital herpes are to relieve symptoms and to shorten the clinical course, to prevent complications and recurrences, and to decrease disease transmission. Although research has focused primarily on the treatment of active infection and suppression of recurrences, increasing emphasis is being placed on various approaches, including immunotherapy that might provide protection from disease transmission or possibly eliminate established latency.[54-55]

Palliative and supportive measures are the cornerstone of therapy for patients with genital herpes. Pain and discomfort usually respond to warm saline baths or the use of analgesics, antipyretics, or antipruritics; good genital hygiene can prevent the development of bacterial superinfection.

4 Specific chemotherapeutic approaches to treating genital herpes include antiviral compounds, topical surfactants, photodynamic dyes, immune modulators, vaccines, and interferons. Few of these have undergone extensive evaluation, however, and only the antiviral agents have demonstrated any consistent clinical efficacy. The most recent CDC recommendations for the treatment of genital herpes include the antiviral agents acyclovir, valacyclovir, and famciclovir (**Table 117-10**).[1] The overall efficacy of these agents in treating genital HSV infection appears comparable, although patient compliance can be improved with regimens requiring less frequent dosing.[1,50,51]

First-Episode Infections

Oral formulations of acyclovir, famciclovir, and valacyclovir have demonstrated efficacy in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. Table 117-10 lists the recommended acyclovir, famciclovir, and valacyclovir oral regimens for first-episode infections. The CDC recommends that all patients with first episodes of genital herpes receive systemic antiviral therapy to prevent severe or prolonged symptoms associated with newly acquired genital herpes. Additionally, topical antiviral therapy offers minimal clinical benefit and is not recommended.[1] In immunocompromised patients or those with severe symptoms or complications necessitating hospitalization, parenteral acyclovir can be beneficial; however, the IV regimen has been associated with renal, GI, bone marrow, and CNS toxicity, particularly in patients with renal dysfunction receiving high doses. No antiviral regimen is known to prevent latency or alter the subsequent frequency and severity of recurrences in humans.[1,50-55,58,59,63-66]

Recurrent Infections

There are two approaches to management of recurrent episodes: episodic or chronic suppressive therapy. Episodic therapy is initiated early during the course of the recurrence, preferably within 6 to 12 hours of the onset of prodromal symptoms but no more than 24 hours after the appearance of lesions. Patients should be instructed to initiate treatment immediately when symptoms begin. In most patients, appreciable effects on symptomatology are not seen. Patients with prolonged episodes of recurrent infection or severe symptomatology are most likely to benefit from episodic therapy. Table 117-10 lists the recommended acyclovir, famciclovir, and valacyclovir suppressive regimens. One concern with episodic therapy is that some patients continue to shed virus despite the

TABLE 117-10 Treatment of Genital Herpes

Type of Infection	Recommended Regimens[a,b]	Alternative Regimen
First clinical episode of genital herpes[c]	Acyclovir 400 mg orally three times daily for 7-10 days,[d] *or* Acyclovir 200 mg orally five times daily for 7-10 days,[d] *or* Famciclovir 250 mg orally three times daily for 7-10 days,[d] *or* Valacyclovir 1 g orally twice daily for 7-10 days[d]	Acyclovir 5-10 mg/kg IV every 8 hours for 2-7 days or until clinical improvement occurs, followed by oral therapy to complete at least 10 days of total therapy[e]
Recurrent infection		
Episodic therapy	Acyclovir 400 mg orally three times daily for 5 days,[f] *or* Acyclovir 800 mg orally twice daily for 5 days,[f] *or* Acyclovir 800 mg orally three times daily for 2 days,[f] *or* Famciclovir 125 mg orally twice daily for 5 days,[f] *or* Famciclovir 1 g orally twice daily for 1 day,[f] *or* Famciclovir 500 mg orally once, followed by 250 mg orally twice daily for 2 days,[f] *or* Valacyclovir 500 mg orally twice daily for 3 days,[f] *or* Valacyclovir 1 g orally once daily for 5 days[f]	
Suppressive therapy	Acyclovir 400 mg orally twice daily, *or* Famciclovir 250 mg orally twice daily[h], *or* Valacyclovir 500 mg or 1,000 mg orally once daily[i]	

CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus; IV, intravenous.

[a]Recommendations are those of the CDC.

[b]HIV-infected patients can require more aggressive therapy.

[c]Primary or nonprimary first episode.

[d]Treatment duration can be extended if healing is incomplete after 10 days.

[e]Only for patients with severe symptoms or complications that necessitate hospitalization. HSV encephalitis requires 21 days of IV therapy.

[f]Requires initiation of therapy within 24 hours of lesion onset or during the prodrome that precedes some outbreaks.

[g]Consider discontinuation of treatment after one year to assess frequency of recurrence.

[h]Famcicolvir appears less effective for suppression of viral shedding.

[i]Valacyclovir 500 mg appears less effective than other valacyclovir and acyclovir regimens in patients with 10 or more recurrences per year.

absence of lesions or presence of prodromal symptoms. Because of the relative mildness and brevity of recurrent infections, parenteral administration of acyclovir usually is not justifiable.[1,50-55,58,59,63-66]

Suppressive therapy with recommended antivirals reduces the frequency and severity of recurrences in 70% to 80% of patients experiencing frequent recurrences. Furthermore, many patients with frequent recurrences experience an improved quality of life with suppressive therapy as compared to episodic therapy.[1,67] Asymptomatic viral shedding is markedly reduced in patients receiving suppressive therapy; however, the extent to which this decreases disease transmission to sexual partners remains to be determined. Despite antiviral suppressive therapy, low-level virus shedding still occurs. However, this virus shedding may be less than that seen in patients treated episodically for recurrences, and thus may be associated with a lower risk of disease transmission. Although antiviral therapy with acyclovir, famciclovir, or valacyclovir appears equally effective for episodic treatment, famciclovir appears somewhat less effective for suppression of viral shedding.[1,68] Because the frequency of recurrences tends to diminish over time, periodic "drug holidays" are advocated to assess changes in the underlying recurrence rate and determine if continued suppressive therapy is warranted.[1,50-55,58,59,63-66]

Resistant HSV isolates have been identified in some patients experiencing breakthrough recurrences while taking acyclovir. Strains resistant to acyclovir are also resistant to valacycylovir, and most are also resistant to famciclovir. Although there is concern about the development of resistant strains with suppressive therapy, clinical trials have found no evidence of cumulative toxicity or significant resistance in patients treated continuously with the recommended antivirals.[50-55]

Selected Populations

Immunocompromised patients are at greatest risk for severe and recurrent HSV infections. Acyclovir, valacyclovir, and famciclovir have been used to prevent reactivation of infection in patients seropositive for HSV who undergo transplantation procedures or induction chemotherapy for acute leukemia. Immunocompromised individuals, such as patients with acquired immunodeficiency syndrome (AIDS), who fail treatment or prophylaxis with recommended antiviral doses frequently demonstrate improved response with higher doses. If resistance is suspected or confirmed with recommended first-line antivirals, foscarnet is usually effective. However, its use is associated with a greater risk of serious adverse effects. Intravenous cidofovir or topical imiquimod may be effective alternatives to forscarnet. Lesional application of an extemporaneous compounded cidofovir (1%) gel or trifluridine ophthalmic solution appears to offer some benefits also.[1,50-55]

The safety of acyclovir, famciclovir, and valacyclovir during pregnancy is not established, although considerable experience with acyclovir in pregnant patients has produced no evidence of teratogenic effects. Because of the high maternal and infant morbidity associated with first-episode primary genital infections or severe recurrent infections at or near term, many clinicians advocate the use of systemic acyclovir as the standard of care in such cases; however, the effectiveness of such therapy is unknown. The use of acyclovir to suppress recurrent episodes near term is more controversial primarily because of the lack of data demonstrating significant benefits in this situation.[1,50-55,69-72]

With the increasing prevalence of genital herpes worldwide, the potential exists for widespread use and misuse of acyclovir, valacyclovir, and famciclovir, resulting in development of resistant HSV isolates. In vitro resistance to these three agents usually is mediated by alterations in viral thymidine kinase; most resistant isolates are either thymidine kinase-deficient or have altered thymidine kinase. The incidence and clinical implications of HSV resistance require further study particularly with respect to immunocompromised hosts, in whom resistance can develop with greater frequency and be of greater clinical importance. Importantly, a study in hematopoietic stem-cell transplant recipients found that persons receiving daily suppressive antiviral therapy were less likely to develop acyclovir-resistance as compared with those receiving episodic therapy.[73] Unlike acyclovir, valacyclovir, and famciclovir, foscarnet does not require the presence of thymidine kinase to be effective.[50-55]

Numerous agents for the prophylaxis and treatment of genital herpes infections are being studied. Neither topical nor systemic

interferons have demonstrated consistent beneficial effects in genital HSV infections; however, a reduction in pain and time of healing of lesions has been reported with an interferon preparation incorporated into a gel containing nonoxynol-9. Other treatments under investigation include cidofovir and immune modulators such as topical imiquimod and resiquimod.[50-55] Agents that can eliminate ganglionic latency and prevent recurrent HSV infections are not expected to be available in the near future. Development of vaccines capable of protecting against HSV infection has proved challenging given the relative lack of protection offered by humoral and cell-mediated immunity in preventing naturally occurring recurrent infections. Safety concerns with live attenuated virus vaccines resulted in research focused primarily on recombinant protein vaccines that have exhibited relatively poor immunogenicity. Use of heterologous vaccines (bacillus Calmette–Guérin and influenza vaccines) to stimulate the immune system in patients with recurrent genital herpes has proved of no significant benefit.[50-55,74]

Evaluation of Therapeutic Outcomes

Available antiviral compounds are of greatest benefit in patients experiencing first-episode primary infections, immunocompromised patients, and patients with frequent or severe recurrent infections. Antivirals, however, are palliative and not curative, and patients receiving these agents should be monitored closely for adverse drug effects. CDC guidelines suggest that discontinuation of suppressive therapy after 1 year should be considered to assess for possible changes in the patient's intrinsic pattern of recurrence. In many patients, decreases in recurrence rates and the severity of symptoms occur over time. However, some clinicians prefer to continue suppressive therapy indefinitely because it significantly reduces asymptomatic viral shedding, a potential benefit in reducing the risk of disease transmission to uninfected sexual partners.[1,50-55]

TRICHOMONIASIS

Epidemiology and Etiology

Trichomonas vaginalis, a flagellated, motile protozoan is responsible for 3 to 5 million cases of trichomoniasis annually in the United States. Humans are host to two other *Trichomonas* species, *T. tenax* and *T. hominis*, but *T. vaginalis* is the only species thought to be pathogenic. Although infection by nonsexual contact is reported, it is rare. Contamination of inanimate objects and spread of infection via communal bathing or contact with infected bath or toilet articles is possible because *T. vaginalis* can survive for up to 45 minutes on moist surfaces. Neonatal infections also represent another possible nonvenereal route of disease transmission.[75-79]

Coinfection with other STDs is not unusual in patients diagnosed with trichomoniasis. Women infected with *T. vaginalis* are three times more likely to have gonorrhea than those who do not have trichomoniasis; approximately 20% of men with gonococcal urethritis also have trichomoniasis.[65-69] In patients treated appropriately for genital *C. trachomatis* or *U. urealyticum* infection, persistent urethritis can result from coexisting trichomonal infection. Although not well documented, the inflammatory response produced by trichomoniasis may increase the risk of acquiring HIV by two- to threefold.[1,75-81]

Pathophysiology

Trichomonads typically can be isolated from the vagina, urethra, and paraurethral ducts and glands in the majority of infected women. Infrequently, they are recovered from the endocervix. Extragenital sites are epidemiologically important because infection can persist and result in reinfection of the vagina if local therapy alone is used. This may account for the higher relapse rates reported for local versus systemic therapy. After attachment to the vaginal or urethral mucosa, trichomonads usually elicit an inflammatory response that manifests as a discharge containing large numbers of PMN leukocytes.[75-80,82-85]

Clinical Presentation

Trichomonal infections are reported more commonly in women than in men. In part this might be because of the smaller number of organisms found in the male urethra making detection more difficult, greater disease transmission rates from males to females, and the nature of male infections, which have a high spontaneous cure rate even in the absence of treatment.[76,77,80,82,82,86] The typical clinical presentation of trichomoniasis in males and females is presented in Table 117-11.

Diagnosis

T. vaginalis produces nonspecific symptoms also consistent with bacterial vaginosis; as a result, laboratory diagnosis is required. Because *T. vaginalis* requires a pH range of 4.9 to 7.5 for survival, a vaginal discharge pH of greater than 5 usually indicates the presence of either *T. vaginalis* or *Gardnerella vaginalis*, a common cause of bacterial vaginosis. The simplest and most reliable means of diagnosis is a wet-mount examination of the vaginal discharge.[77,80,82,83,86] Trichomoniasis is confirmed if characteristic pear-shaped, flagellating

TABLE 117-11 Presentation of Trichomonas Infections

	Males	Females
General	Incubation period 3-28 days Organism can be detectable within 48 hours after exposure to infected partner	Incubation period 3-28 days
Site of infection	Most common: urethra Others: rectum (usually caused by rectal intercourse in MSM), oropharynx, eye	Most common: endocervical canal Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	Can be asymptomatic (more common in males than females) or minimally symptomatic Urethral discharge (clear to mucopurulent) Dysuria, pruritus	Can be asymptomatic or minimally symptomatic Scant to copious, typically malodorous vaginal discharge (50%-75%) and pruritus (worse during menses) Dysuria, dyspareunia
Signs	Urethral discharge	Vaginal discharge Vaginal pH 4.5-6 Inflammation/erythema of vulva, vagina, and/or cervix Urethritis
Complications	Epididymitis and chronic prostatitis (uncommon) Male infertility (decreased sperm motility and viability)	Pelvic inflammatory disease and associated complications (ie, ectopic pregnancy, infertility) Premature labor, premature rupture of membranes, and low–birth-weight infants (risk of neonatal infections is low) Cervical neoplasia

MSM, men who have sex with men.

organisms are observed. The wet mount is only 51% to 65% sensitive in detecting the presence of trichomonads, with lower sensitivities reported in men and in women with low-grade, subacute, or chronic infections.[78-80,83,85,87]

Although the presence of trichomonads may be reported on a Papanicolaou smear (Pap), the sensitivity of this cytologic technique is less than for wet mount and also is associated with a high number of false-positive and false-negative results. Stained smears of cervical specimens have been used in diagnosis, but they are less sensitive and more time-consuming than the wet mount and therefore are not recommended. Culture techniques for trichomonads are highly specific up to 100% and more sensitive, 75% to 96% than the wet mount, but they are not useful in rapid diagnosis because up to 48 hours or longer is necessary for growth. Cultures can be necessary, however, to confirm the diagnosis in the absence of a positive wet mount or to determine antimicrobial susceptibility in intractable cases.[1,75-80,82,83,85,86,88]

Newer diagnostic tests such as monoclonal antibody or DNA probe techniques, as well as PCR tests that can detect small amounts of trichomonal DNA, have been developed. These office-based tests are highly sensitive and specific for detecting infection in both vaginal specimens and urine. The CDC now recommends the use of these highly sensitive and specific tests for detecting *T. vaginalis*.[1,75-79]

In males, demonstration of trichomonads in urethral specimens or urine sediment by wet mount is difficult, and diagnosis depends largely on culture. Specimens from males should be taken prior to first voiding because the small number of trichomonads in males may be reduced by micturition.[75-80,82]

TREATMENT

Recommended and alternative treatment regimens for *T. vaginalis* include either metronidazole or tinidazole, both of which produce high cure rates in these infections. In only a few cases have *T. vaginalis* isolates been resistant to standard metronidazole or tinidazole doses. In these instances, longer courses of therapy or doses higher than those recommended routinely as initial therapy usually produce a cure.[1,75-79,83,86,89]

Table 117-12 provides treatment recommendations for trichomonas infections.[1] The standard therapy for trichomoniasis is either metronidazole or tinidazole 2 g orally as a single dose; cure rates are comparable with the recommended alternative regimen of metronidazole 500 mg twice daily for 7 days. When sexual partners are treated simultaneously, cure rates greater than 95% are reported. If sexual partners are not treated concurrently, cure rates are somewhat lower. In limited clinical testing, single metronidazole doses of less than 1.5 g are associated with high failure rates.[1,75-79,83,86,89]

Advantages of single-dose therapy over the multidose alternative regimen include better patient compliance, lower total dose, lower cost, and shorter exposure of the patient's GI and urogenital anaerobic bacterial flora to the drug. As a result of the latter, the likelihood of developing pseudomembranous colitis or symptomatic candidal vulvovaginitis is decreased.[75-79,83] Because high doses of metronidazole have mutagenic effects in bacteria and oncogenic effects in mice, a reduced time of exposure in humans can be beneficial. There is no conclusive evidence for either of these effects in humans after short-term therapy with recommended doses. GI complaints (eg, anorexia, nausea, vomiting, and diarrhea) are more common with the single 2-g dose of either metronidazole or tinidazole, occurring in 5% to 10% of treated patients. Some patients also complain of a bitter metallic taste in the mouth with metronidazole. Patients intolerant of the single 2-g dose because of GI adverse effects usually tolerate the alternative metronidazole multidose regimen.[75-79,83,86,89]

TABLE 117-12 Treatment of Trichomoniasis

Type	Recommended Regimen[a]	Alternative Regimen
Symptomatic and asymptomatic infections	Metronidazole 2 g orally in a single dose *or* Tinidazole 2 g orally in a single dose[b]	Metronidazole 500 mg orally two times daily for 7 days[c,d]
Persistent or recurrent infections	Metronidazole 500 mg orally two times daily for 7 days[c]	Metronidazole 2 g orally for 7 days[e] *or* Tinidazole 2 g orally for 7 days[e]
Treatment in pregnancy	Metronidazole 2 g orally in a single dose[e]	

CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus.

[a]Recommendations are those of the CDC.

[b]Randomized controlled trials comparing single 2 g doses of metronidazole and tinidazole suggest that tinidazole is equivalent to, or superior to, metronidazole in achieving parasitologic cure and resolution of symptoms.

[c]Metronidazole labeling approved by the FDA does not include this regimen. Dosage regimens for treatment of trichomoniasis included in the product labeling are the single 2 g dose; 250 mg three times daily for 7 days; and 375 mg twice daily for 7 days. The 250 mg and 375 mg dosage regimens are currently not included in the CDC recommendations.

[d]Recommended treatment regimen for women with HIV coinfection.

[e]For treatment failures with metronidazole 2 g as a single dose and metronidazole 500 mg orally two times daily for 7 days.

[f]Symptomatic pregnant women can be treated with this regimen at any stage of pregnancy.

5 To achieve maximal cure rates and prevent relapse with either metronidazole or tinidazole as a single 2-g dose, simultaneous treatment of infected sexual partners is necessary. Tinidazole is at least equivalent, or potentially superior, to metronidazole in achieving microbiologic and clinical cure.[90] In women treated with the alternative 7-day course, however, relapse rates are not appreciably different regardless of whether or not sexual partners are treated. It is speculated that in men, spontaneous resolution of trichomonal infection or a reduction in the number of trichomonads below the inoculum necessary to transmit disease may occur during the 7 days of a female's therapy. The 7-day metronidazole treatment regimen is also recommended in women coinfected with HIV and may be more effective than a single 2-g dose in these patients.[91] In patients who fail to respond to an initial course of metronidazole therapy, a second course of therapy with metronidazole 500 mg twice daily for 7 days or a single 2-g dose of tinidazole is recommended. Patients refractory to a second course of treatment usually respond to a regimen using higher 2 g daily for 7 days of either agent. Good response rates also are reported for tinidazole 2 to 3 g orally plus intravaginal tinidazole for 14 days.[1,70,75-79,82,89,92] Topical vaginal therapy alone is associated with low cure rates because infections involving the urethra or periurethral glands are unaffected and can serve as the source of reinfection.[77] Use of IV metronidazole can be warranted for rare cases of intolerance to oral medication or infections resistant to high-dose oral metronidazole. Sexual partners of all patients who require retreatment also should be treated or retreated because the majority of apparent treatment failures appear to be caused by reinfection or noncompliance.[75-79]

Concerns regarding the use of metronidazole in women who are pregnant or breast-feeding have been raised. Because metronidazole is secreted in breast milk, it is recommended that breast-feeding be interrupted for 12 to 24 hours after maternal ingestion of a single 2-g dose. Metronidazole (pregnancy category B) and tinidazole (pregnancy category C) are contraindicated during the first trimester of pregnancy based on FDA-approved labeling. Although some experts recommend avoiding use of either agent throughout pregnancy, others advocate the use of metronidazole during any stage of pregnancy

because of the potential adverse pregnancy outcomes associated with trichomoniasis. The CDC now recommends that all symptomatic pregnant women, regardless of pregnancy stage, be tested and considered for treatment with metronidazole 2 g orally in a single dose.[1,75-79]

Several other nitroimidazole antibiotics related to metronidazole and tinidazole (eg, nimorazole, ornidazole, and carnidazole) are being investigated worldwide for the treatment of trichomoniasis. Unfortunately, none of these agents differs significantly from metronidazole or tinidazole in terms of efficacy (ie, cross-resistance is high) or toxicity against metronidazole-susceptible strains of *T. vaginalis*.[75-79]

EVALUATION OF THERAPEUTIC OUTCOMES

Follow-up was previously considered unnecessary in patients who become asymptomatic after treatment with recommended therapy; however, retesting is now recommended for all sexually active women within 3 months following initial treatment due to the high rates or reinfection. When patients remain symptomatic, it is important to determine if reinfection has occurred. In these cases, a repeat course of therapy, as well as identification and treatment or retreatment of infected sexual partners, is recommended. In situations in which reinfection can be excluded, a relative resistance to metronidazole or tinidazole should be assumed, and an alternative regimen should be prescribed. Culture and sensitivity are warranted for infections unresponsive to alternative regimens.

HUMAN PAPILLOMAVIRUS AND OTHER SEXUALLY TRANSMITTED DISEASES

Several STDs other than those just discussed occur with varying frequency in the United States and throughout the world. Although an in-depth discussion of these diseases is beyond the scope of this chapter, Table 117-13 lists recommended treatment regimens.[1] Of notable importance among these other STDs, however, is genital HPV infection, the most common viral STD in the United States. More than 100 HPV types have been characterized by genomic makeup, with approximately 30 types associated with genital tract lesions.[94-96] Of these, types 6 and 11 are associated most commonly with the

TABLE 117-13 Treatment Regimens for Miscellaneous Sexually Transmitted Diseases

Infection	Recommended Regimen[a]	Alternative Regimen
Chancroid (*Haemophilus ducreyi*)	Azithromycin 1 g orally in a single dose, *or* Ceftriaxone 250 mg IM in a single dose, *or* Ciprofloxacin 500 mg orally twice daily for 3 days,[b] *or* Erythromycin base 500 mg orally four times daily for 7 days	
Lymphogranuloma venereum	Doxycycline 100 mg orally twice daily for 21 days[c]	Erythromycin base 500 mg orally four times daily for 21 days[d]
HPV infection		
External genital/perianal warts	*Provider-Administered Therapies:* Cryotherapy (eg, liquid nitrogen or cryoprobe); repeat weekly as necessary, *or* Podophyllin resin 10%-25% in compound tincture of benzoin applied to lesions; repeat weekly as necessary,[e,f] *or* TCA 80%-90% *or* BCA 80%-90% applied to warts; repeat weekly as necessary, *or* Surgical removal (tangential scissor excision, tangential shave excision, curettage, or electrosurgery) *Patient-Applied Therapies:* Podofilox 0.5% solution or gel applied twice daily for 3 days, followed by 4 days of no therapy; cycle is repeated as necessary for up to four cycles,[f] *or* Imiquimod 3.75% or 5% cream applied at bedtime three times weekly for up to 16 weeks,[f] *or* Sinecatechins 15% ointment applied three times daily for up to 16 weeks	Intralesional interferon *or* Photodynamic therapy *or* Topical cidofovir
Vaginal and anal warts	Cryotherapy with liquid nitrogen, or TCA or BCA 80%-90% as for external HPV warts; repeat weekly as necessary[g] Surgical removal (not for vaginal or urethral meatus warts)	
Urethral meatus warts	Cryotherapy with liquid nitrogen, or podophyllin resin 10%-25% in compound tincture of benzoin applied at weekly intervals[f,h]	
Prevention	Gardasil® (HPV quadrivalent [types 6, 11, 16, and 18]) recombinant vaccine 0.5 mL IM on day 1; a second and third dose are administered 2 and 6 months following the first dose[i,j,k] Cervarix® (HPV bivalent [types 16 and 18]) recombinant vaccine 0.5 mL IM on day 1; a second and third dose are administered 1 and 6 months following the first dose[i,l] Gardasil9®(HPV 9-valent [types 6, 11, 16, 18, 31, 33, 45, 52, 58]) recombinant vaccine 0.5 mL IM on day 1; a second and third dose are administered 1 and 6 months following the first dose[i]	

BCA, bichloracetic acid; HPV, human papillomavirus; TCA, trichloroacetic acid.

[a]Recommendations are those of the Centers for Disease Control and Prevention (CDC).

[b]Ciprofloxacin is contraindicated for pregnant and lactating women and for persons aged <18 years.

[c]Azithromycin 1 g PO once weekly for 3 weeks can be effective.

[d]Pregnant patients should be treated with erythromycin.

[e]Some experts recommended washing podophyllin off after 1-4 hours to minimize local irritation.

[f]Safety during pregnancy is not established.

[g]Surgical removal of anal warts is also a recommended treatment.

[h]Some specialists recommend the use of podofilox and imiquimod for treating distal meatal warts.

[i]CDC recommendations: vaccination is recommended in girls 11-12 years of age, and in females aged 13-26 years who either were not previously vaccinated, or who did not complete the vaccination series.

[j]FDA approved labeling for Gardasil®: indicated in girls and women 9 through 26 years of age for the prevention of cervical, vulvar, vaginal, and anal cancer caused by HPV types 16 and 18, genital warts (condyloma acuminata) caused by HPV types 6 and 11, and precancerous or dysplastic lesions caused by HPV types 6, 11, 16, and 18.

[k]Vaccination is recommended in males aged 9-26 years to prevent genital warts and anal cancer.

[l]FDA approved labeling for Cervarix®: indicated in females 9 through 25 years of age for the prevention of cervical cancer, cervical intraepithelial neoplasia grade 2 or worse, adenocarcinoma in situ, and cervical intraepithelial neoplasia grade 1 caused by HPV types 16 and 18.

development of low-grade dysplasia manifested as exophytic genital warts. In most individuals, genital infection with HPV is subclinical, and patients with visible acuminate warts represent less than 1% of all infected individuals. When present, genital warts can be large and multifocal, producing variable degrees of discomfort. Based on HPV DNA detection methods, most warts will regress spontaneously within 1 to 2 years of their initial appearance. However, reinfection is common in young, sexually active populations.[1,93,94]

Infection with several HPV types, particularly HPV-16 and HPV-18, is considered the major risk factor for the development of cervical neoplasia, the second most common cancer in women worldwide. Although epidemiologic, virologic, and clinical data strongly support this association, HPV infection alone is insufficient to cause cervical cancer development because only a small percentage of infected women develop the disease. It appears that the interplay of host immune defenses, genetic factors, and infection with HPV types containing a more aggressive variant all contribute to the risk of developing cervical neoplasia.[93,94]

The Pap smear is the most frequently used and cost-effective diagnostic test for detecting clinical and subclinical (ie, no visible signs of condylomata) HPV in women. However, Pap smears are neither specific for HPV nor useful in detecting latent infections. Frequently, visual inspection of genital surfaces under magnification can assist in making the diagnosis. Various tests for detecting HPV DNA, RNA, or capsid protein also are available, and unlike the Pap smear do not require subjective interpretation of the results. The HPV-specific tests are only approved in women with abnormal Pap smears or women older than 30 years. However, use of HPV DNA testing as a routine screening test in lieu of Pap smears is expected in the near future. In women identified to have high-risk HPV infections by these tests, follow-up cytology would be performed.[93,94]

No consensus exists on the best approach to treating patients with genital HPV infection, particularly because most cases appear to be transient with spontaneous regression of lesions. A number of treatments are recommended (see Table 117-13), but none is clearly superior to the others. Treatment generally is directed toward patients with manifestations of genital warts, with the goal of removing or destroying these lesions and grossly infected surrounding tissue. Because such treatment neither stops viral expression in surrounding tissue nor eliminates viral latency, recurrence of lesions is not uncommon.[93,94]

Clinical **Controversy...**

Recent research has indicated that HPV (particularly HPV-16) may be implicated in the development of intractable childhood epilepsy. As such, women of child-bearing age should be educated regarding the fetal risk associated with the HPV infection in order to improve vaccination rates.

Three HPV vaccines are marketed in the United States. Cervarix, a bivalent vaccine for HPV-16 and 18, Gardasil, a quadrivalent vaccine for HPV-6, 11, 16, and 18, and Gardasil 9, a 9-valent vaccine for HPV-6, 11, 16, 18, 31, 33, 45, 52, and 58. All vaccines are indicated for preventing cervical precancers and cervical cancer in females 9 to 26 years of age. In addition, Gardasil and Gardasil 9 are indicated in unvaccinated males 9 to 21 years of age. Specific populations (MSM, immunocompromised) are recommended to receive the vaccination up to the age of 26.[1] Clinically important differences in the magnitude and duration of the immune response, as well as prevention of HPV infections and cervical cancer remain to be determined.[95-97]

ABBREVIATIONS

AIDS	acquired immunodeficiency syndrome
CDC	Centers for Disease Control and Prevention
CSF	cerebrospinal fluid
DFA-TP	direct fluorescent-antibody (test) for *T. pallidum*
DGI	disseminated gonococcal infection
EIA	enzyme immunoassay
FTA-ABS	fluorescent treponemal antibody absorption
HIV	human immunodeficiency virus
HPV	human papillomavirus
HSV	herpes simplex virus
HSV-1	herpes simplex virus type 1
LPS	lipopolysaccharide
MHA-TP	microhemagglutination assay for antibodies to *T. pallidum*
MSM	men who have sex with men
NAATs	nucleic acid amplification tests
NGU	nongonococcal urethritis
Pap	Papanicolaou smear
PCR	polymerase chain reaction
PID	pelvic inflammatory disease
PMN	polymorphonuclear
RPR	rapid plasma reagin
STD	sexually transmitted disease
TPHA	*T. pallidum* hemagglutination assay
TPPA	*T. pallidum* particle agglutination assay
TRUST	toluidine red unheated serum test
USR	unheated serum reagin
VDRL	Venereal Disease Research Laboratory

118 Bone and Joint Infections

Marcella N. Honkonen, Ziad Shehab, and Edward P. Armstrong

KEY CONCEPTS

1. The most common cause of osteomyelitis (particularly that acquired by hematogenous spread) and infectious arthritis is *Staphylococcus aureus*.
2. Culture and susceptibility information are essential as a guide for antimicrobial treatment of osteomyelitis and infectious arthritis.
3. Joint aspiration and examination of synovial fluid are extremely important to evaluate the possibility of infectious arthritis.
4. The most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time.
5. Antibiotics generally are given in high doses so that adequate antimicrobial concentrations are reached within the infected bone and joints.
6. Oral antimicrobial therapies can be used for osteomyelitis to follow a parenteral regimen in children who have a good clinical response to IV antibiotics and in adults without diabetes mellitus or peripheral vascular disease when the organism is susceptible to the oral antimicrobial, a suitable oral agent is available, and adherence is ensured.
7. The standard duration of antimicrobial treatment for acute osteomyelitis is 4 to 6 weeks.
8. The three most important therapeutic approaches to the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest.
9. Monitoring of antibiotic therapy is important and typically involves noting clinical signs of inflammation, periodic white blood cell (WBC) counts, C-reactive protein, and erythrocyte sedimentation rate (ESR) determinations.

Bone and joint infections are comprised of two disease processes known, respectively, as *osteomyelitis* and *septic* or *infectious arthritis*. They are unique and separate infectious entities with different signs and symptoms and infecting organisms. Despite advances in therapy, these infections continue to cause significant morbidity from residual damage and chronic or recurring infections. Emphasis on initiating antibiotic therapy as soon as possible is important in reducing long-term complications.

EPIDEMIOLOGY

Osteomyelitis

1 Osteomyelitis generally is an uncommon disease. One classic publication reported that 247 patients had osteomyelitis in a prominent American teaching hospital during a 4-year period.[1] Acute osteomyelitis has an estimated annual incidence of 0.4 per 1,000 children. In adults, osteomyelitis caused by contiguous spread, including postoperative, direct puncture, and that associated with adjacent soft tissue infections, comprises 47% of infections. *Hematogenous osteomyelitis* comprises 19% of infections, and osteomyelitis occurring in patients with significant peripheral vascular disease comprises 34% of infections.

The bacteriology of *hematogeous osteomyelitis* is unique in that one pathogen, *Staphylococcus aureus*, is responsible for more than 80% of these infections, with group A Streptococci and *Streptococcus pneumoniae* accounting for a few cases. *Kingellakingae*, an organism that is part of the oral flora is emerging as a pathogen in children less than 3 years of age. *Haemophilus influenzae* type b which used to be an important pathogen has been almost completely eliminated with the use of the conjugate vaccine and is now a rare pathogen in bone and joint infections.[2] Pneumococcal disease will likely decrease in prevalence as invasive pneumococcal disease is prevented by the use of the conjugate pneumococcal vaccine in infants. *Osteomyelitis* in neonates can result from infections with group B streptococcus, *Escherichia coli*, and most commonly *S. aureus*.

Vertebral osteomyelitis has several unique features and occurs most commonly in adults 50 to 60 years of age typically presenting with recalcitrant back pain unresponsive to usual symptomatic therapies, elevated inflammatory markers and who may or may not be having fever.[3] The lumbar and thoracic regions are the locations of most infections. Hematogenous infections are most likely to develop in the vascular areas near the subchondral plate region of the vertebral body. These infections are typically monomicrobial and are caused principally by Staphylococci that cause approximately 60% of these infections; however, Gram-negative organisms now play a significant role.[3-5] These Gram-negative organisms are most commonly Enterobacteriaceae species, particularly *E. coli* and *Klebsiella pneumoniae*, and most likely originate within the urinary tract or intra-abdominal cavity.[5] *Mycobacterium tuberculosis* and *Coccidioidesimmitis/posadasii* also are known to cause infections in the spine. Skin and respiratory tract infections are other sources of infection known to lead to vertebral infections. While infections of the spine can involve the vertebrae in 1% to 2% of older children with osteomyelitis, they more commonly involve the disk space of the lumbar vertebrae in children less than 5 years of age.

Contiguous-spread disease has several important differences compared with *hematogeous osteomyelitis*. Although *S. aureus* is still the most common organism isolated, polymicrobial infections, including with Gram-negative bacilli, occur frequently. *Pseudomonas aeruginosa*, streptococcus, *E. coli*, *Staphylococcus epidermidis*, and anaerobes can be isolated.

When anaerobes are grown from cultures, they usually are found in association with other organisms, including aerobic bacteria. Predisposing factors in patients who have anaerobic osteomyelitis include vascular disease, bites, contiguous infections, peripheral neuropathy, hematogenous spread, and trauma. Osteochondritis

resulting from puncture injuries to the foot is associated with Gram-negative infection often times caused by *P. aeruginosa*. *S. aureus* is also a significant pathogen in these patients. The anaerobic infections in association with diabetes mellitus almost always involve the foot and are mixed. *Bacteroides fragilis* and *Bacteroides melaninogenicus* comprise the majority of anaerobic isolates.

Infectious Arthritis

Infectious or septic arthritis is an inflammatory reaction within the joint space. Septic arthritis is one of the most common causes of new cases of arthritis. The incidence of proven or likely septic arthritis is 4 to 10 cases per 100,000 patient-years.[6] The incidence of septic arthritis increases to 70 cases per 100,000 patient-years among patients that have rheumatoid arthritis.[7]

Neonates may have infectious arthritis because of a broad range of organisms, with *S. aureus*, group B Streptococcus, and Gram-negative organisms being most common. *S. aureus* and *Streptococcus pyogenes* are the most common pathogens in children younger than 5 years of age. *Hemophilus influenzae* type b (Hib) which used to be the most common pathogen in these children has essentially been eliminated by immunization with the conjugate Hib vaccine. Pneumococcal arthritis is also decreasing in incidence as a result of conjugate pneumococcal vaccine administration to infants. If the child has not been fully vaccinated or is immunocompromised, *H. influenzae* type b may be a cause.

Some organisms, such as *Neisseria gonorrhoeae*, are especially likely to infect a joint during bacteremia. Gonococcal arthritis is a common manifestation of disseminated gonococcal infection occurring in 42% to 85% of such patients.[8] Gonococcal arthritis is now uncommon in North America and Europe although it remains an important concern in developing countries.

Within the adult population, *S. aureus* is responsible for 37% to 65% of nongonococcal bacterial arthritis.[8] Streptococcal infections are the second most common followed by Gram-negative organisms. Among the latter, *E. coli* is the most common; however, *P. aeruginosa* is the most frequent organism in intravenous drug abusers.

Although rare, osteomyelitis and infectious arthritis can be caused by fungi and in the case of arthritis by viruses such as varicella-zoster, rubella or parvovirus.[9] Arthritis is rarely caused by Salmonella, Corynebacteria, Brucella, *Neisseria meningitidis*, *Mycoplasma pneumoniae* or *Ureaplasmaurealyticum*. Penetrating injury of the joint can result in an infection due to Pasteurella in dog bites, Capnocytophaga in human bites and Pantoea when the injury is induced by a thorn.

ETIOLOGY

Osteomyelitis

The most common method of classifying osteomyelitis is based on the mode of acquisition of the bone infection. Disease that results from spread through the bloodstream is termed *hematogeous osteomyelitis*, while that reaching the bone from an adjoining soft tissue infection is termed *contiguous osteomyelitis*. Patients with peripheral vascular disease are at risk for the development of contiguous osteomyelitis, and they present unique management features. Osteomyelitis that results from direct inoculation, such as from trauma, puncture wounds, or surgery, generally is also classified as inoculation osteomyelitis.

Osteomyelitis also can be classified based on the duration of the disease. Acute osteomyelitis describes infections of recent onset, usually several days to 1 week, whereas chronic infections are those of a longer duration. Some authors describe chronic infections as those with symptoms for more than 1 month before therapy, whereas other authors define chronic infections as relapse of an initial infection. *Hematogeous osteomyelitis* almost always involves one bone whereas contiguous osteomyelitis can present in multiple bones, especially when vascular insufficiency is an underlying risk factor.

Infectious Arthritis

Infectious arthritis can occur from many different types of microorganisms. Most infecting organisms produce an infection in a single joint, termed *monoarticular infection*; however, infections also can involve two or more joints. As with osteomyelitis, joint infections also can be classified according to the mechanisms by which the infecting organism reaches the joint. Infectious arthritis can result by spread from an adjacent bone infection, direct contamination of the joint space, or hematogenous dissemination. Hematogenous spread of the disease comprises the majority of infections; spread from osteomyelitis and direct inoculation is much less frequent. Septic arthritis is most prevalent in children and the elderly. Approximately, one-third of people with septic arthritis are children younger than 2 years of age.[8]

Unlike children, adults often have significant systemic diseases that predispose them to infectious arthritis, such as diabetes mellitus, immunosuppressive states (eg, cancer or liver disease), or preexisting arthritis. Risk factors associated with adult infectious arthritis (more than one factor may be present) are systemic corticosteroid use, preexisting arthritis, arthrocentesis, distant infection, diabetes mellitus, trauma, and other diseases. Intravenous drug abusers and individuals with intravascular infections such as endocarditis also are prone to develop septic arthritis.

PATHOPHYSIOLOGY

Osteomyelitis

Hematogenous Osteomyelitis

Hematogeous osteomyelitis is typically a disease of the growing bone and most cases occur in patients younger than 16 years of age. Less commonly, these infections occur in adults. Table 118-1 summarizes the primary characteristics of osteomyelitis.

Unique features of the anatomy and vascular supply of long bones appear to predispose them to become infected.[2] The hematogenous infections begin within the metaphyses (Fig. 118-1) as the

TABLE 118-1 Types of Osteomyelitis, Age Distribution, Common Sites, and Risk Factors

Type of Osteomyelitis	Typical Age (years)	Site(s) Involved	Risk Factors
Hematogenous	<1	Long bones and joints	Prematurity, umbilical or other central venous catheter or venous cut-down, respiratory distress syndrome, and perinatal asphyxia
	1-20	Long bones (femur, tibia, and humerus)	Infection (pharyngitis, cellulitis, and respiratory infections), trauma, and sickle cell disease
	Older than 50	Vertebrae	Diabetes mellitus, blunt trauma to spine, and urinary tract infection
Contiguous	Older than 50	Femur, tibia, and mandible	Hip fractures and open fractures
Puncture	<18	Foot	Puncture injury to foot
Vascular insufficiency	Older than 50	Feet and toes	Diabetes mellitus, peripheral vascular disease, and pressure sores

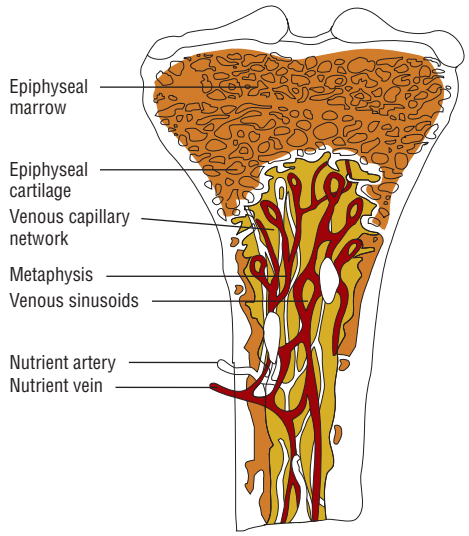

FIGURE 118-1 Cross-section of normal bone.

nutrient arteries of the long bones divide within the medullary canal of the bone into small arterioles. These end in hairpin turns near the growth plate and flow into veins, of much wider diameter, that drain the medullary cavity.[1] The infection is initiated within the bend of the arterioles where there is considerable slowing of blood flow in the hairpin capillary loops. This sludging of blood flow allows bacteria present within the bloodstream to settle and initiate an inflammatory response. They have access to the bone by gaps in the endothelium and the absence of a basement membrane. In addition to these structural features, phagocytosis is less active within the metaphysis. After the bacteria settle in the bone, avascular necrosis can occur from occlusion of the nutrient vessels and release of bacterial enzymes. Once the infection is initiated, exudate begins to form within the bone marrow and the fluid accumulates under increased pressure. The age of the patient largely determines the next stage in the pathophysiology.

Neonatal infections commonly involve multiple bones. The vascular supply of long bones in neonates has unique anatomic characteristics that affect their clinical presentation. Bridging blood vessels go across the epiphyseal plate from the metaphysis into the epiphysis thus enabling an infection that started within the metaphyseal area to spread easily to involve the epiphyses and then break into the joint. Therefore, in infants, not only can the infection spread under the periosteum or break through the periosteum and the shaft as in older children, but the infection also can spread directly through the bridging blood vessels to involve the joint.

In children older than 12 to 18 months, *hematogeous osteomyelitis* typically involves a single bone and has a predilection for involvement of the long bones, such as the femur, tibia, humerus, and fibula. The infection that started in the metaphysis of a long bone is prevented from spreading into the epiphysis and the adjacent joint space because of the epiphyseal growth plate which acts as a physical barrier; however, the exudate often dissects from the medulla through the soft cortex to the subperiosteal space as the periosteum in these children is loosely attached to the underlying cortex. The periosteum is thick and not easily ruptured thus containing the pus in the subperiosteal space, sometimes forming a subperiosteal abscess. If there is significant damage to the periosteum, the pus can decompress into a soft tissue abscess. The cortex obtains most of its blood supply from the periosteum and a subperiosteal abscess can impair the blood flow to the outer portion of the cortical bone resulting in a devitalized piece of dead bone termed a *sequestrum*. The elevated periosteum remains viable because its blood supply, derived from the overlying muscle, is unaffected. The raised periosteum will continue to produce bone; however, this new bone is now separated from the cortex because the periosteum has been raised from the infection. This new bone that is deposited under the periosteum is termed *involucrum*. In addition to these anatomic and functional features, there is some evidence that trauma is associated with developing an infection in specific bones. Children who develop *hematogeous osteomyelitis* may report some type of trauma before the onset of their symptoms and animal data indicate that traumatized bone is more likely to become infected than normal bone.

In adults, the periosteum is tightly bound to the cortex which is thick. These anatomic features generally cause the infections to remain intramedullary. As expected, subperiosteal abscess formation is less common in this population. The infection can spread to subperiosteal structures through the Haversian and Volkmann canals.

Osteomyelitis of the vertebrae is also acquired hematogenously and occurs most frequently in patients older than 50 years of age.[10,11] Vertebral disease in young children usually involve the disk space and the two vertebral facets adjoining it because of the nature of the vascular supply of the vertebrae at that age. This entity is known as diskitis. Vertebral osteomyelitis involving the body of the vertebra can be seen in children older than 8 years of age.

Chronic osteomyelitis is more likely to occur if large segments of bone become avascular and necrotic. This results in a piece of devitalized bone to which antimicrobial delivery is impaired. As a result, this infection is prone to exacerbations and may lead to weakening of that bone or to the formation of draining sinuses to the skin.

Direct Inoculation Osteomyelitis

This category of osteomyelitis includes infections caused by direct entrance of organisms from a source outside the body. Penetrating wounds (eg, trauma), open fractures, and various invasive orthopedic procedures can result in direct inoculation of organisms into the bone. More than 80% of cases of postoperative osteomyelitis are known to occur following open reduction of fractures. Specifically, these infections occur most commonly after internal fixation of a hip fracture or femoral or tibial shaft fracture. Inoculation osteomyelitis can also occur as a result of penetrating foreign bodies most commonly nail puncture injuries to the foot.

Contiguous Spread Osteomyelitis

Osteomyelitis secondary to spread from an adjacent soft tissue infection is called contiguous osteomyelitis. It can result from pressure ulcers or from adjacent soft tissue infections and most often involves the distal extremities. Less commonly, infections can spread from infected teeth to involve the mandible or occurs secondary to sinus infections by spreading through the mucosal lining of the sinuses into the vascular system surrounding the bone.

In contrast to *hematogeous osteomyelitis*, which occurs most commonly in children, contiguous-spread osteomyelitis occurs most commonly in patients older than age 50, most likely because of predisposing factors, such as hip fractures or vascular disease, are more common in this age group.

Patients with osteomyelitis in association with severe vascular insufficiency are extremely difficult to manage.[12] As anticipated, most of these patients have diabetes mellitus or severe atherosclerosis, and they develop their infections by contiguous spread. Generally, these patients are between the ages of 50 and 70 years. Frequently, patients with vascular disease develop osteomyelitis in their toes and fingers, and there is usually an adjacent area of infection, such as cellulitis or dermal ulcers. Importantly, infections in these patients are almost always polymicrobial and often include staphylococcus and streptococcus or the combination of staphylococcus, streptococcus, and Enterobacteriaceae. Enterococci and anaerobic organisms also can be involved.

TABLE 118-2 Characteristics of Acute Infectious Arthritis

Feature	Finding
Peak incidence	Children younger than 16 years Adults older than 50 years
Clinical findings	Fever of 38-40°C (100.4-104°F) in children; painful swollen joint in the absence of trauma Physical examination: Effusion, restriction of joint motion, tenderness, redness, and warmth of joint
Most commonly affected joints	Knee, hip, ankle, elbow, wrist, and shoulder
Laboratory findings	
Erythrocyte sedimentation rate	Elevated in 90% of cases
White blood cell count	Elevated in 30%-60% of cases
Left shift	Seen in two thirds of patients
Blood culture	Positive in 40% of cases
Needle aspiration of joint	Gram-stain diagnostic in 30%-50% of cases. Synovial fluid cultures are positive in 60%-80% of cases. Synovial fluid differential reveals 90% polymorphonuclear leukocytes. Synovial fluid glucose decreased relative to serum glucose. Lactic acid levels elevated in nongonococcal infectious arthritis, but not in gonococcal infectious arthritis

Infectious Arthritis

Infectious arthritis usually is acquired by hematogenous spread. The synovial tissue is highly vascular and does not have a basement membrane, so organisms in the blood can easily reach the synovial fluid. Table 118-2 summarizes the characteristics of acute infectious arthritis.

Preexisting abnormal joint architecture, joint trauma, and surgery are risk factors because chronic inflammation or trauma makes the joint more susceptible to infection. Individuals with rheumatoid arthritis can be prone to bacterial infection because of an inherent phagocytic defect, as well as concomitant corticosteroid therapy.

Organisms can gain access to the joint from a deep-penetrating wound injury, intra-articular steroid injections, arthroscopy, prosthetic joint surgery, and spread to the joint from a contiguous focus of osteomyelitis. After bacteria gain access to the joint, the organisms begin to multiply and produce a purulent exudate within the joint. If this joint effusion is present beyond 7 days, chronic, and sometimes irreversible, damage can occur to the bone and joint as a result of proteolytic enzymes and pressure necrosis. Purulent effusions can promote cartilage destruction by increasing leukocyte enzyme activity. In conjunction with the development of the effusion, almost all patients will develop a hot, swollen, painful joint.

CLINICAL PRESENTATION

Osteomyelitis

The clinical presentation of acute *hematogeous osteomyelitis* is summarized in Table 118-3. Although neonatal *hematogeous osteomyelitis* can spread rapidly to involve the joint, often there are few associated systemic symptoms.[13] A joint effusion is present in 60% to 70% of neonatal infections. Decreased limb motion or edema over the affected area may be the only signs from which to suspect the diagnosis. While it is sometimes acute in onset, the disease is often insidious in children.

Vertebral osteomyelitis produces nonspecific symptoms, such as constant back pain, fever or night sweats, and weight loss.[14] The pain typically is present at rest and increases in severity with movement. Serious neurologic complications can occur if the infection extends and compresses the spinal cord.

The presentation of osteomyelitis after surgery or trauma depends on the precipitating cause. If the infection follows surgery or bone trauma, the symptoms usually are noted within 1 month. The most frequent symptom is pain in the area of infection. Less commonly, patients also can develop a fever and elevated WBC count.

With contiguous-spread osteomyelitis there is often an area of localized tenderness, warmth, edema, and erythema over the infected site. Patients with significant vascular insufficiency usually have local symptoms, such as pain, swelling, and redness. Less commonly, they also can have fever and elevated WBC count.

TABLE 118-3 Clinical Presentation of Hematogenous Osteomyelitis

Signs and symptoms
Significant tenderness of the affected area, pain, swelling, fever, chills, decreased motion, and malaise

Laboratory tests
Elevated erythrocyte sedimentation rate, C-reactive protein, and white blood cell count
50% of patients will have positive blood cultures

Diagnostic studies
Bone changes observed on radiographs 10-14 days after the onset of infection. Magnetic resonance imaging and technetium scans positive as early as 1 day after the onset of infection

Infectious Arthritis

Patients with nongonococcal bacterial arthritis almost always present with a fever, and 50% of patients have an elevated WBC count (see Table 118-2). The average initial synovial WBC count is $10 \times 10^3/mm^3$ ($10 \times 10^9/L$) or greater in nongonococcal bacterial disease. Nongonococcal bacterial arthritis is almost always monoarticular. The knee is the most commonly involved joint, but infections also can occur in the shoulder, wrist, hip, ankle, interphalangeal joints, and elbow joints. Usually, the initial focus of infection that acted as the portal of entry can be identified. Common routes for bacterial entrance include infections of the respiratory tract, skin, and urinary tract or previous bacteremia; often no specific source can be identified. Blood cultures are important in these patients because they can be positive in 50% of patients.

The most frequent initial sign of disseminated gonococcal infections is the triad of dermatitis, tenosynovitis (inflammation and swelling of a tendon) and migratory polyarthralgia or polyarthritis. Women are more prone to develop disseminated gonococcal infections than men by a ratio of 4:1. The second and third trimesters of pregnancy and the time of menses appear to be the times of greatest risk for developing gonococcal bacteremia, hypothesized to be associated with mucosal vascularity. Common joints involved include the knee, wrist, elbow, and ankle. Presentation varies slightly depending on whether or not the woman is pregnant. In non-pregnant women, duration of symptoms are longer, presence of joint effusion is more likely, and white blood cells are more often present within the synovial fluid.[15]

Another type of infectious arthritis occurs following prosthetic joint surgery. The most common symptom is pain. Local signs of inflammation and fever are common in acute infections while chronic infections present in a more subtle fashion, typically with pain alone and often loosening of the prosthesis. With these infections, the C-reactive protein usually is elevated, although a leukocytosis often is absent. Infections that result from postoperative contamination usually become apparent within 1 year of surgery.

Radiologic and Laboratory Tests

Osteomyelitis

2 The evaluation of a patient who may have osteomyelitis has several unusual aspects. Radiographs of the involved area should be obtained to rule out other processes such as a fracture; bone changes

characteristic of osteomyelitis appear late and are not typically seen until at least 10 to 14 days after the onset of the infection as more than 50% of the bone matrix must be decalcified before the lesions can be detected radiologically. Magnetic resonance imaging (MRI) is the most sensitive and commonly used diagnostic imaging modality and offers the advantage of better anatomic definition, especially of abscesses or joint effusions. Radionuclide bone scanning (technetium/gallium) computed tomographic scanning or positive emission tomography scanning is useful in identifying the focus of osteomyelitis in patients unable to have an MRI.[16]

Despite the seriousness of osteomyelitis, often there are few laboratory abnormalities. The erythrocyte sedimentation rate (ESR), C-reactive protein, and WBC count may be the only laboratory abnormalities. The degree of abnormality of these laboratory findings does not correlate with the disease outcome; however, these inflammatory markers are useful for monitoring therapy. C-reactive protein is generally the more sensitive marker of response to therapy and often increases and decreases before the ESR.

When a clinical assessment of osteomyelitis is suspected, it is important to establish a bacteriologic diagnosis by culture of the infected bone and blood. Accurate culture information is especially important as a guide for treatment of osteomyelitis in this era of increasing antimicrobial resistance. Bone aspiration or bone biopsy are valuable in determining an accurate bacteriologic diagnosis. In addition, they help determine whether or not there is an abscess present. If an abscess is identified, it must be drained and the pus cultured, and a Gram stain performed. Aspirates of subperiosteal pus or metaphyseal fluid yield a pathogen in 70% of cases. Cultures should be done for both aerobic and anaerobic bacteria. A Gram stain of the aspirate can be useful in initiating appropriate empirical antibiotic therapy.

If a specimen is obtained from a previously undrained or unopened wound abscess, the pathogen usually can be identified. In chronic osteomyelitis, however, identification can be more difficult. Open wounds and draining sinuses frequently are contaminated with other organisms and thus provide inaccurate culture information.[17] They cannot be relied on to reflect the pathogen unless consecutive deep sinus tract cultures reveal the same pathogens.[18] Cultures of loculated pus aspirates in the area of orthopedic devices removed from infected bone can be trusted, however, to identify the infecting organism. The preferable time to obtain culture material in a patient with a chronic draining sinus is at the time of open surgical debridement.

In addition to performing cultures from the involved bone, it also is important to obtain cultures from any site believed to be the primary source of a bacteremia. Blood cultures should be obtained. Approximately 50% of patients with *hematogeous osteomyelitis* will have positive blood cultures and may obviate the need for bone aspiration in these patients.

Infectious Arthritis

3 Radiographs of infected joints often reveal distension of the joint capsule with soft tissue swelling in the adjacent space. Magnetic resonance imaging can be helpful in identifying an infected joint, especially the shoulder and hip. In patients who have developed an infected prosthetic joint, loosening of the prosthesis can be seen radiographically.

When evaluating the possibility of a patient having infectious arthritis, immediate joint aspiration with analysis of the synovial fluid is extremely important. The presence of purulent fluid usually indicates the presence of a septic joint. The synovial fluid WBC count is usually 50×10^3-$200 \times 10^3/mm^3$ (50×10^9-$200 \times 10^9/L$) when an infection is present. As with osteomyelitis, most patients will have an elevated C-reactive protein concentration and ESR. However, serum WBC, ESR, and C-reactive protein may not be useful acutely in septic arthritis.[19]Approximately half the patients with an infected joint have a low synovial glucose level, usually less than 40 mg/dL (2.2 mmol/L). Gram stains of joint fluid demonstrate bacteria in 50% of patients with septic arthritis; however, such stains are positive in only 25% of patients with gonococcal arthritis. Synovial fluid cultures usually are positive in patients with nongonococcal infections. Both blood and joint fluid should be cultured aerobically and anaerobically in a patient suspected of having an infected joint. Blood cultures are positive in one-half of patients with nongonococcal infections but in only 20% of those with gonococcal infections. Pharyngeal, rectal, cervical, or urethral smears and cultures, as well as cultures of cutaneous lesions, should be performed if a disseminated gonococcal infection is considered. Nucleic acid based assays should also be used for the diagnosis of genital gonococcal infection.

TREATMENT

Desired Outcome(s)

Osteomyelitis

The goals of treatment are resolution of the infection and prevention of long-term sequelae. The ultimate outcome of osteomyelitis depends on the acute or chronic nature of the disease and how rapidly appropriate therapy including surgical drainage where appropriate is initiated. Patients with acute osteomyelitis have the best prognosis. Cure rates exceeding 80% can be expected for patients with acute osteomyelitis who have surgery when indicated and receive appropriate antibiotics for 4 to 6 weeks. When the growth plate is involved in children, discrepancies in the growth of bones or angular bone deformities can result.

In contrast, patients with chronic osteomyelitis have a much poorer prognosis. Dead bone and other necrotic material from the infection act as a bacterial reservoir and make the infection very difficult to eliminate. Adequate surgical debridement to remove all the dead bone and necrotic material, combined with prolonged administration of antibiotics, provides the best chance to obtain a cure.[20] The inability to remove all the dead bone can allow residual infection and require suppressive antibiotics to control the infection.

Infectious Arthritis

While many patients who develop infectious arthritis recover with no long-term sequelae, 50% are left with decreased joint function or mobility. Gonococcal arthritis usually resolves rapidly with antibiotics and has fewer sequelae. Individuals at greatest risk for long-term sequelae are those who have symptoms present for more than 7 days before starting therapy and those with infections occurring within the hip joint and infections caused by Gram-negative organisms. Common long-term residual effects following infectious arthritis are limited joint motion and persistent pain.

During the initial phase of the infection, weight bearing, such as walking on the joint should be avoided. Passive range-of-motion exercises should be initiated when the pain begins to subside to maintain joint mobility. Approximately one-third of patients with bacterial arthritis have a poor joint outcome, such as severe functional deterioration. Poor joint outcomes are associated with older patients, those with preexisting joint disease, and patients with an infected joint containing synthetic material.

General Approach to Treatment

Osteomyelitis

4 Following completion of the steps needed to determine the infecting organism, the most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time. It is important to stress that early antibiotic therapy can mitigate the need for surgery, subsequent sepsis, chronic infection, disruption of longitudinal bone growth and angular deformity of the bone.[21] A delay in treatment can allow bone

TABLE 118-4 Empiric Treatment of Osteomyelitis

Patient Subtype	Likely Infecting Organism	Antibiotic[a]	Recommendation Grades[b]
Newborn	*Staphylococcus aureus*, group B *Streptococci*, *Escherichia coli*	Nafcillin or oxacillin 50-150 mg/kg/day IV plus cefotaxime 100-200 mg/kg/day IV	B-3
Children 5 years of age or younger	1. If vaccinated for *Haemophilus influenzae* type b: *S. aureus* or Streptococci 2. If not vaccinated against *H. influenzae* type b	1. Nafcillin or oxacillin 150-200 mg/kg/day IV orcefazolin 100 mg/kg/day IV 2. Cefuroxime 150 mg/kg/day IV	B-3 B-3
Children older than 5 years of age	*S. aureus*	Nafcillin or oxacillin 150-200 mg/kg/day IV or cefazolin 100 mg/kg/day IV	A-3
Adults	*S. aureus*	Nafcillin or oxacillin 2 g IV every 4 hours or cefazolin 2 g IV every 8 hours	A-3
IV drug abusers	*Pseudomonas*	Ciprofloxacin 750 mg orally twice daily or ceftazidime or cefepime 2 g IV every 8 hours	B-3
Postoperative or posttrauma patients	Gram-positive and Gram-negative organisms	Nafcillin or oxacillin 2 g IV every 4 hours plus ceftazidime or cefepime 2 g IV every 8 hours or ticarcillin–clavulanate 3.1 g IV every 4 hours	B-3
Patients with vascular insufficiency	Gram-positive and Gram-negative organisms	Nafcillin or oxacillin 2 g IV every 4 hours or cefazolin 2 g IV every 8 hours plus ceftazidime or cefepime 2 g IV every 8 hours	B-3
	If anaerobes suspected	Cefotetan 2 g IV every 12 hours or clindamycin 900 mg IV every 8 hours plus ceftazidime or cefepime 2 g IV every 8 hours	C-3

IV, intravenous.

[a]Dosage should be adjusted for some agents in patients with renal and/or hepatic dysfunction.

[b]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from more than one properly randomized, controlled studies or multiple time series; or dramatic results from uncontrolled experiments. 2 = Evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

necrosis to occur and make eradication of the infection much more difficult. In these patients with chronic osteomyelitis, exacerbations of the infection can result if all necrotic tissue is not removed surgically and all microorganisms eliminated. Chronic suppressive antimicrobial therapy and adjunctive treatment with hyperbaric oxygen or antibiotic-impregnated implants during surgery also has been used.

If a patient with *hematogeous osteomyelitis* does not respond by having a decrease in fever, local swelling, redness, and pain following the initiation of adequate antibiotic therapy, the patient should undergo surgical debridement of the infected area. It is important to emphasize the priority of starting antibiotics immediately after the cultures have been obtained.

Infectious Arthritis

Patients with infectious arthritis are typically admitted to the hospital to obtain synovial fluid and blood cultures and initiate antimicrobial therapy. Attempt to decrease bacterial burden in the joint space is obtained by performing either open or arthroscopic debridement. Empiric antibiotics are started as soon as culture specimens are collected. As with osteomyelitis, it is important to stress early initiation of antibiotic therapy to avoid complications such as avascular necrosis, limb-length discrepancy, and pathologic fractures.[22]

In patients with prosthetic joint devices, it is imperative that orthopedic surgeons work alongside infectious disease practitioners to determine the best course of action.[23] The gold standard treatment method includes resection of the implant, placement of temporary antibiotic-impregnated cement spacer, and delayed component re-implantation. Although it may be decided to retain the implant in certain cases for which patients will receive irrigation and debridement in addition to antibiotic therapy, or antibiotic therapy alone in patients unable to tolerate surgical procedures.[24]

Pharmacologic Therapy

Osteomyelitis

Antibiotic Selection A critical component in the management of osteomyelitis is the selection of appropriate antibiotics. Empiric therapy must be selected on the basis of the most likely infecting organism while the results of culture and susceptibility data are pending. Once culture and susceptibility results are obtained the antimicrobial therapy should be tailored. Table 118-4 summarizes empiric therapy recommendations.

With staphylococcus being the most common bacteria in osteomyelitis, resistance patterns must be considered when deciding on an empiric agent. For communities showing low evidence of resistant strains of *S. aureus*, nafcillin is the drug of choice.[25]Although cefazolin or cephalexin are often chosen to treat susceptible strains due to ease of dosing compared to nafcillin. Clindamycin can be used in less severe cases.[25,26] If 10% or more of the surrounding community *S. aureus* isolates are methicillin resistant, then an agent active against MRSA should be selected. Vancomycin is the drug of choice in this case.[25,26] If the patient is severely ill, then both vancomycin and nafcillin should be used for empiric treatment, as nafcillin is superior for the treatment of methicillin susceptible *S. aureus*.[25]

In the setting of vertebral osteomyelitis, empiric therapy should be initiated in conjunction with culture if the patient is hemodynamically unstable, septic or experiencing neurologic compromise; otherwise, it is recommended empiric therapy be held 1 to 2 weeks while awaiting culture results.[3]

Antibiotic Bone Concentration

5 Antibiotics used in the management of acute osteomyelitis generally are given in high doses (adjusted for weight, renal function, hepatic function, or both) so that adequate antimicrobial concentrations are reached within the infected bone and joint.[27] Table 118-5 summarizes antibiotics doses that have been successful in the treatment of osteomyelitis.

Oral Antibiotic Therapy

6 Criteria for the use of oral outpatient antibiotic therapy for osteomyelitis includes all of the following:

- Confirmed osteomyelitis
- Initial clinical response to parenteral antibiotics
- Suitable oral agent available
- Adherence ensured

TABLE 118-5 Antimicrobial Agents for the Treatment of Osteomyelitis

Antimicrobial	Dose[a]	Comments
Amoxicillin	Adult: 500-875 mg orally every 8 hours[21]	
Amoxicillin/Clavulanate	Adult: 875/125 mg orally every 8 hours[21]	
Ampicillin	Adult: 2 g IV every 4 hours[21] Children: 150-200 mg/kg/day in 4 equal doses (max 8-12 g daily)[29] VO:12 g IV every 24 hours, continuous, or in 6 divided doses[3]	May add IV aminoglycoside for treatment of *Enterococcus* spp[21] VO:For enterococcus, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis[3]
Ampicillin/Sulbactam	Adult: 1.5-3 g IV every 6 hours[21]	
Anti-staphylococcal (cloxacillin, flucloxacillin, dicloxacillin, nafcillin, oxacillin)	Adult: Nafcillin or oxacillin 1-2 g IV every 4-6 hours[21,28] Children: ≤200 mg/kg/day in 4 equal doses (max dose 8-12 g daily)[29] VO: Nafcillin or oxacillin 1.5-2 g IV every 4-6 hours or continuous infusion[3]	VO: 6 week duration[3]
Aztreonam	VO: 2g IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered. Use only for severe penicillin allergy and quinolone-resistant strains[3]
Cefepime	Adult: 2 g IV every 24 hours[21,28] VO: 2 g IV every 8-12 hours[3]	Add IV ciprofloxacin for treatment of *P. aeruginosa*[28] VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered. For Enterobacteriaceae, 2 g IV every 12 hours[3]
Cefotetan	Adult: 2 g IV every 12 hours[28]	
Ceftazidime	Adult: 2 g IV every 8-12 hours[21] VO: 2 g IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered[3]
Ceftriaxone	Adult:1-2 g IV every 24 hours[21,28] VO: 2 g IV every 24 hours[3]	VO: 6 week duration. For *Salmonella*, 6-8 week duration[3]
Chloramphenicol	Children: 75 mg/kg/day in 3 equal doses (max dose 2-4 g daily)[29]	To be used if safer agents are not available or affordable[29]
Ciprofloxacin	Adult: 400 IV every 8-12 hours[21,28] or 500-750 mg PO every 12 hours[21,23] VO: 500-750 mg orally every 12 hours, or 400 mg IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered. For *Salmonella*, 6-8 week duration[3]
Clindamycin	Adult: 600 mg IV every 6 hours[21,28] or 300-600 mg orally every 6 hours[21,23] Children: ≥40 mg/kg/day in 4 equal doses (max dose 3 g daily)[29] VO: 600-900 mg IV every 8 hours, or 300-450 mg orally twice daily[3]	VO: 6 week duration, not recommended for MRSA. Recommended as second line for sensitive staphylococcal infection[3]
Daptomycin	Adult: 4-6 mg/kg IV every 24 hours[21] VO: 6-8 mg/kg IV every 24 hours[3]	VO: 6 week duration. For enterococcus, 6 mg/kg IV every 24 hours plus 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis[3]
Doripenem	VO: 500 mg IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered[3]
Doxycycline	Adult: 100 mg orally twice daily[23]	VO: Can be used in addition to rifampin for brucellar infection
Ertapenem	VO: 1 g IV every 24 hours[3]	VO: 6 week duration[3]
First Generation Cephalosporin (Cefazolin, Cephalexin)	Adult: Cefazolin 1-1.5 g IV every 6 hours[28] or 1-2 g IV every 6-8 hours[21] Cephalexin 500 mg orally every 6 hours[21] Children: ≥150 mg/kg/day in 4 equal doses (max dose 2-4 g daily)[29] VO: Cefazolin 1-2 g IV every 8 hours[3]	VO: 6 week duration[3]
Fusidic acid	Adult: 500 mg orally three times daily[23]	
Imipenem/cilastatin	Adult: 1 g IV every 8 hours[28]	Add IV aminoglycoside for treatment of *P. aeruginosa*[28]
Levofloxacin	Adult: 500-750 mg IV once daily[21,28] or 750 mg PO once daily[23] or 500 mg orally twice daily[23] VO: 500-750 mg orally once daily[3]	Add IV rifampin for treatment of MRSA[28] VO: Add rifampin 600 mg orally daily for all staphylococcus strains, duration 6 weeks of combination therapy[3]
Linezolid	Adult: 600 mg IV or orally every 12 hours[21,23,28] Children: 30 mg/kg/day in 3 equal doses (max dose 1.2 g for no more than 28 days)[29] VO: 600 mg IV or orally every 12 hours[3]	VO: 6 week duration. For enterococcus, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis[3]
Meropenem	Adult: 1 g IV every 8 hours[21] VO: 1 g IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered[3]

(*continued*)

TABLE 118-5 Antimicrobial Agents for the Treatment of Osteomyelitis (*Continued*)

Antimicrobial	Dose	Comments
Metronidazole	Adult: 500 mg IV every 6-8 hours[21,28] or 500 mg orally three to four times a day[23] VO: 500 mg orally three to four times daily[3]	VO:F *Bacteroides* species and other susceptible anaerobes[3]
Minocycline	Adult: 200 mg orally initially, then 100 mg daily[28] or 100 mg PO twice daily[23]	
Moxifloxacin	Adult: 400 mg orally once daily[23] VO: 400 mg orally once daily[3]	VO: For Enterobacteriaceae and other susceptible aerobic Gram-negative organisms. Not recommended for staphylococcal infection[3]
Penicillin G	Adult: 2-4 million units IV every 4 hours[28] or 10-20 million units IV continuous every 24 hours[21] VO:20-24 million units IV every 24 hours, continuously, or in 6 divided doses[3]	VO: For enterococcus, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis[3]
Piperacillin/Tazobactam	Adult: 3.375 g IV every 6 hours[28]	Add IV ciprofloxacin for treatment of *P. aeruginosa*[28]
Rifampin	Adult: 600 mg IV every 12 hours[28] or 600-900 mg orally every 24 hours[21,23] or 300-450 mg orally twice daily[23]	Only to be used in combination with another antimicrobial
Ticarcillin/Clavulanate	Adult: 3.1 g IV every 4 hours[28]	
Trimethoprim-Sulfamethoxazole	Adult: 1 double-strength tablet orally every 12 hours[28] or 1 double-strength tablet orally three times a day[23] VO: 1-2 double-strength tablets orally twice daily[3]	VO: Second line agent for Enterobacteriaceae and other susceptible aerobic Gram-negative organisms. May need to monitor sulfamethoxazole levels[3]
Vancomycin	Adult: 1 g IV every 12 hours[28] or 15 mg/kg IV every 12 hours[21] Children: ≤40 mg/kg/day in 4 equal doses[29] VO: 15-20 mg/kg IV every 12 hours[3]	Adjust based on patient and pharmacokinetic parameters. Target trough of 15-20 mcg per milliliter[29] VO: Consider loading dose for MRSA and enterococcus, 6 week duration. For enterococcus, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis. For enterococcus, use only if patient is penicillin allergic or bacteria is penicillin resistant[3]

IV, intravenous;MRSA, methicillin susceptible *staphylococcus aureus*;VO, vertebral osteomyelitis.

[a]Dosage should be adjusted for some agents in patients with renal and/or hepatic dysfunction.

Suitable candidates are children with good clinical response to intravenous therapy and adults without diabetes mellitus or peripheral vascular disease.

The use of oral antibiotics is well studied in children.[30] Typically, injectable antibiotics are used initially and then switched to oral antibiotics when there was a decrease in the signs of inflammation and the ESR or when the patient was afebrile for 3 days. If pus was obtained on the initial needle aspirate, or if a reduction in fever, local swelling, and tenderness did not occur despite adequate rest, immobilization, and intensive antibiotic therapy, the patients underwent surgical drainage. The patients enrolled in oral antibiotic trials generally had disease of recent onset, identification of a specific infecting organism, enforced adherence, and surgery as indicated. In patients who meet these criteria, oral antibiotics appear to offer a great advantage in the treatment of osteomyelitis. Patients not meeting these criteria may have a higher risk of developing chronic osteomyelitis if oral therapy is inappropriate or not strictly adhered to. When oral antibiotics are used, the total duration of oral and injectable therapy is usually at least 4 weeks. Limited retrospective data in adults indicated that parenteral therapy for less than 4 weeks followed by oral therapy may be effective.[31]

Duration of Antibiotic Therapy

7 Following debridement, bone takes 3 to 4 weeks to revascularize thus the basis of treatment duration.[32] The specific duration of antibiotic therapy needed in the management of osteomyelitis is usually 4 to 6 weeks.[33] Failure rates approaching 20% have been observed in children treated with parenteral antibiotics for 3 weeks or less. One analysis in children with *hematogeous osteomyelitis* recommended 20 days of antibiotic therapy after initial parenteral therapy as long as the C-reactive protein level normalized within 7 to 10 days.[34] Although these data were largely evaluated in children, this duration of therapy recommendation is also used in adults. Treatment failures may be due to the presence of infected necrotic bone or infected hardware (wires, plates, screws, and rods) that could not be removed.[35]Improvement in the patient's clinical signs and symptoms and normalization of the C-reactive protein level or ESR are important parameters to assess therapy.[36] If signs or symptoms are still present at 6 weeks, therapy should be extended. In some cases of chronic osteomyelitis, lifelong suppressive therapy might be the most appropriate option.[37]

Duration of antibiotic administration for vertebral osteomyelitis may vary depending on the infecting organism. With Gram-negative bacteria a longer duration (greater than or equal to 8 weeks) is associated with less rates of recurrence compared to shorter durations (4-6 weeks).[5] One study compared 6 weeks versus 12 weeks duration in patients with pyogenic vertebral osteomyelitis and found the shorter duration to be non-inferior.[38] However, many factors remained left for questioning and it is uncertain whether or not it is safe to use a shorter duration for patients with extensive bone destruction or abscesses.[38,39] The IDSA guidelines recommend a minimum of 6 weeks of parenteral therapy or highly bioavailable oral therapy.[3]

Clinical **Controversy...**

Vertebral osteomyelitis—The exact duration of antimicrobial therapy for a patient with vertebral osteomyelitis is unknown. Many factors play a role in determining the severity of the infection and risk of recurrence. Longer courses might be needed in patients with Gram negative infections or infections complicated by abscesses.

Special Populations

Osteomyelitis in the intravenous drug user has unique features.[40] More than 50% of such infections involve the vertebral column and less than 20% of infections are located in either the sternoarticular or pelvic girdle. Infections are much less frequent within the extremities. They also have an unusual spectrum of organisms with Gram-negative organisms being responsible for 88% of infections. *P.aeruginosa*, either singly or in combination with other organisms, is cultured in 78% of all such infections. *Klebsiella, Enterobacter*, and *Serratia* species also can be found but less commonly. In addition, staphylococcal and streptococcal organisms are sometimes cultured.

Patients with sickle cell anemia and related hemoglobinopathies also represent a unique population in that two-thirds of bone infections in these patients are caused by *Salmonella* species, while the rest are usually caused by staphylococci and other Gram negative organisms.[41] Bowel infarctions from the sickle cell disease can facilitate the entry of salmonellae from the colon into the bloodstream with resultant hematogenous spread to the bone. Osteomyelitis in patients with sickle cell disease may occur in any bone, but it most commonly involves the medullary cavity of long or tubular bones. Because of the difficulty in separating bone pain during a sickle cell crisis from that of an infection, osteomyelitis can be relatively advanced in these patients by the time the diagnosis is made.

Infectious Arthritis

Antibiotic Selection

8 The three most important therapeutic maneuvers in the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest. Smears of the synovial fluid can be useful to select appropriate antibiotic therapy initially.[8] If bacteria are not observed on the Gram stain in a patient who has a purulent joint effusion, antibiotics still should be initiated because of the low sensitivity of the Gram stain. A delay in initiating antibiotics significantly increases the likelihood for long-term complications. The specific antibiotic selected depends on the most likely infecting organism. When staphylococcal infection is suspected, rifampin is often added to the anti-staphylococcal or anti-MRSA agent, especially in the setting of prosthetic hardware.[42]

Antibiotic Joint Space Concentration

The antibiotics selected usually are administered parenterally to achieve sufficient concentrations within the synovial fluid, and thus intra-articular antibiotic injections are unnecessary.

In prosthetic joint infections, antimicrobial cement spacers are often used to aide in delivery of the antimicrobial to the site of infection. The most common antimicrobials used include vancomycin and aminoglycosides, tobramycin and gentamicin.[43,44]However, the doses of each agent are widely variable and it is uncertain whether the placement of antimicrobial cement spacers adds outcome benefit to systemic therapy.[43] The thought of antimicrobial cement spacer providing local exposure of the antimicrobial agent without systemic consequences has been questioned.[45] Ameta-analysis reported the incidence of acute kidney injury in patients receiving treatment with antimicrobial cement spacers at 4.8%, incidence range varied from 2% to 17% based on the definition of acute kidney injury used.[43]

Clinical **Controversy...**

Antimicrobial cement spacers—The use of antimicrobial cement spacers is routine for patients with prosthetic joint infections. The antimicrobial agents used locally may place the patient at risk for systemic adverse reactions with little benefit added to systemic therapy. In addition, the exact dose of the antimicrobials used is unknown.

Similar to osteomyelitis, once the infection is confirmed if initial response to parenteral therapy is achieved, the culture susceptibilities have resulted, and adherence is ensured, then selected oral antibiotics can be used for the treatment of infectious arthritis. Shorter durations of antimicrobial therapy are needed to treat infectious arthritis compared to osteomyelitis. A randomized trial compared 10 days versus 30 days of antimicrobial therapy and found no difference between the groups.[34] The treatment duration may be extended to 20 days if the adjacent bone is affected.[46]

Home Antibiotic Therapy

Because the management of bone and joint infections frequently requires prolonged parenteral antibiotics, newer antibiotic regimens have been used. Administration of antibiotics in the home environment and the use of antibiotics with extended elimination half-lives are commonly used. Although acute osteomyelitis is one of the more common infectious diseases that can be treated with home intravenous antibiotics, not all patients are acceptable candidates for home administration. Patients must be screened to include only those who are receiving a stable treatment program, those who are interested and are motivated in participating, and those who have good venous access, as well as those who have support from family members or neighbors and have home facilities for storage and refrigeration. Patients with adequate vascular access may be able to use a peripheral intravenous catheter; however, a central intravenous catheter may be required if venous access difficulties occur. Certain exclusion criteria also must be considered. Complications of other preexisting diseases, such as diabetic retinopathy, intention tremor, disabling inflammation or degenerative joint disease, coagulopathies, or various neurologic disorders can prevent individuals from receiving home antibiotics. A history of alcoholism or of intravenous drug abuse also is important exclusion criteria. Patients who are fluent in only a foreign language and patients who are illiterate or hard of hearing may have to be excluded if a qualified guardian is unavailable. In addition to meeting these initial screening criteria, patients must successfully complete a thorough training program before hospital discharge. Aseptic technique, proper catheter care, and correct administration techniques must be documented. Once a patient is receiving therapy in the home environment, continued monitoring of their antimicrobial therapy and drug levels when indicated is important. It is vital to ensure compliance with the antimicrobial regimen. Catheter-related complications are common in patients receiving prolonged courses of parenteral antibiotics.

In addition, the specific antibiotic regimen characteristics must be considered when evaluating a patient for home antibiotics. Some important features are microbiologic culture and susceptibility data, the number of required daily antimicrobial doses, antibiotic stability data, and requirements for unique monitoring for the specific antimicrobial regimen, such as serum creatinine and drug level monitoring with aminoglycosides or vancomycin. Although an organism can be susceptible to several antimicrobial agents, one antibiotic can provide practical benefits over other agents.

PERSONALIZED PHARMACOTHERAPY

Individualized therapy is important in the treatment of osteomyelitis and infectious arthritis. Patient quality of life can be significantly diminished if long-term sequelae develop, such as impaired joint motion or draining sinus tracts, or if amputation is required. Patient demographics, infection characteristics (eg, infecting organism and its susceptibility patterns), treatment cost, and quality-of-life issues all play a major role in evaluating individualized treatment alternatives (oral therapy or home antibiotic treatment) rather than requiring patients to remain hospitalized to receive 4 to 6 weeks of parenteral antibiotics. In addition, adverse events commonly occur

with prolonged outpatient parenteral antibiotic therapy. One study in 45 children noted that 85.7% of patients receiving vancomycin had adverse drug events and 42.9% of patients required the drug be discontinued.[47] This analysis also noted that cefazolin had the lowest rate of adverse drug events in this population. Monitoring is important to ensure that personalized therapy is effective to both cure the infection as well as minimize the risk for complications.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

9 Patients with bone and joint infections must be monitored closely. Table 118-6 summarizes a pharmaceutical care monitoring protocol. An assessment of a therapy's success or failure is based on the patient's clinical findings and laboratory values. The clinical signs of inflammation, such as swelling, tenderness, pain, redness, and fever, should resolve with appropriate therapy. Initially, the clinical signs are assessed daily until improvement and then periodically thereafter. Elevations in WBC count also should decline gradually. The ESR usually is determined weekly. Elevations in the C-reactive protein or ESR may not return to normal until after several weeks of therapy. The WBC count usually is obtained once or twice per week until it returns to the normal range. If by the end of the 4- to 6-week antibiotic course the clinical findings of osteomyelitis are no longer present and the C-reactive protein and ESR are within normal limits, the patient can be considered a clinical cure. Patients can relapse, however, after initially appearing to be cured. No relapse for 1 year generally is considered a complete cure.

If a patient fails to resolve the clinical signs and symptoms of inflammation after appropriate empirical antibiotics, suspicion for an abscess should be raised and imaging by MRI and surgical debridement may be needed. In addition, the patient might have a resistant or an atypical infecting organism that may require a modification of the antibiotic therapy. It is especially important to identify the infecting organism and its susceptibility pattern. Follow-up cultures at subsequent debridements can be useful to assess the antibiotic therapy.

TABLE 118-6 Monitoring Protocol

Parameter	Frequency	Notes
Culture and susceptibility	At initiation of treatment	
White blood cell count	One time per week until within normal range	
C-reactive protein or erythrocyte sedimentation rate	Weekly	May not decrease to normal range until several weeks of therapy
Clinical signs of inflammation (redness, pain, swelling, tenderness, and fever)	Daily during initiation of therapy	
Adherence of outpatient therapy	Reinforce before starting oral therapy and with each healthcare visit	Adherence is critical if treatment is to be successful
Complete blood count	Weekly	Certain antimicrobial agents may cause blood dyscrasias when used for long term therapy (eg, linezolid, trimethoprim/sulfamethoxazole)

Despite apparently adequate surgery and antibiotics, some patients can fail therapy and have recurrent relapses in their infection.[39] This scenario is more common in those with chronic osteomyelitis. These patients can require long-term oral suppressive antimicrobial therapy to keep the infection under control.

ABBREVIATIONS

ESR	erythrocyte sedimentation rate
MRSA	methicillin-resistant *Staphylococcus aureus*
WBC	white blood cell
PO	orally
VO	vertebral osteomyelitis

119 Sepsis and Septic Shock

S. Lena Kang-Birken

KEY CONCEPTS

1. Gram-negative organisms are isolated in 50% to 62% of patients with severe sepsis or septic shock, followed by gram-positive bacteria in 37% to 47%, anaerobic organisms in 5%, and fungi in 8% to 19%.
2. Candidemia is a major cause of morbidity and mortality. *Candida albicans* remains the most common pathogen (45.6%); however, non–*albicans Candida* species collectively is more frequently isolated (54.4%).
3. Sepsis presents a complex pathophysiology, characterized by the activation of multiple overlapping and interacting cascades leading to systemic inflammation, a procoagulant state, and decreased fibrinolysis.
4. Mortality rates with sepsis are higher for older patients with preexisting disease, intensive care unit (ICU) care, and multiple organ failure.
5. Prompt initiation of one or more parenteral antibiotics within 1 hour of recognition of septic shock and severe sepsis without septic shock is required and the regimen should be assessed daily for potential de-escalation.
6. A significant volume of fluid leaks from the vasculature occurs with sepsis, and initial fluid resuscitation with large volumes of fluid is required. Crystalloid solutions are generally recommended for fluid resuscitation because of the absence of any clear benefit with colloids solutions in addition to the lower cost of crystalloids.
7. Norepinephrine is the preferred vasopressor to correct hypotension in septic shock, and epinephrine should be considered the first alternative to patients intolerant to norepinephrine.
8. Implementation of protocolized, quantitative resuscitation bundle within 6 hours of recognition of sepsis-induced hypoperfusion has been shown to decrease the mortality rates as well as the ICU length of stay.
9. A blood glucose level less than 180 mg/dL (10 mmol/L) is recommended for the majority of critically ill patients to reduce morbidity and mortality without the detrimental effects associated with hypoglycemia.
10. IV hydrocortisone is recommended for adult patients with septic shock whose blood pressure is unresponsive to fluids and vasopressors.

Sepsis and severe sepsis continue to pose major healthcare burden. The Nationwide Inpatient Sample years 2003 to 2009 reported hospitalizations with sepsis claims including septicemia sepsis, severe sepsis, and septic shock increased from 359 per 100,000 US residents to 535 per 100,000, a 49% increase.[1] Despite aggressive medical care and advances, overall in-hospital deaths remains at 15% to 40%, with over one-third of patients discharged to a long-term care facility.[2] Given the public health and financial burden, there is a vital need for clinicians to comprehend the pathophysiology and the optimal management approaches for acutely ill patients with severe sepsis or septic shock.

DEFINITIONS

Periods of bacteremia, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, septic shock, or multiple-organ dysfunction syndrome (MODS) often overlap, and they signify an important continuum of progressive physiologic decline (Fig. 119-1). *Severe sepsis* refers to patients with an acute organ dysfunction, such as acute renal failure or respiratory failure. Sepsis-induced hypotension is defined as a systolic blood pressure less than 90 mm Hg or mean arterial pressure (MAP) less than 70 mm Hg (<9.3 kPa) (Table 119-1).[3] *Septic shock* refers to sepsis patients with sepsis-induced hypotension that is refractory to adequate fluid resuscitation, thus requiring vasopressor administration. Sepsis-induced tissue hypoperfusion is defined as infection-induced hypotension, elevated lactate, or oliguria.[3,4]

INFECTION SITES AND PATHOGENS

Predisposing factors of septic shock include age, nonwhite ethnic origin in North Americans, comorbid diseases especially chronic obstructive pulmonary disease, malignancy, immunodeficiency or immunocompromised state, chronic organ failure, alcohol dependence, and genetic factors.[1,5,6] Male gender has been associated with higher incidence of sepsis and severe sepsis in the past. However, the difference between the genders appears to be diminishing.[1,2]

The primary sites of microbiologically documented infections that lead to sepsis are the respiratory tract (39%-50%), intra-abdominal space (8%-16%), and urinary tract (5%-37%).[1,2,7-9]

Gram-Positive Bacterial Sepsis

1 In international studies, gram-negative organisms were isolated in 50% to 62% of patients with severe sepsis or septic shock, gram-positive bacteria in 37% to 47%, anaerobic organisms in 5%, and fungi in 8% to 19%.[7,9] The most common gram-positive organisms are *Staphylococcus aureus, Streptococcus pneumoniae*, coagulase-negative staphylococci, and *Enterococcus* species.[8-11] *S. aureus* bacteremia is associated with an overall mortality rate ranging between 10% and 30%.[12] Factors related to a higher mortality include older age, shock, preexisting renal failure, and the presence of a rapidly fatal underlying disease. *Staphylococcus epidermidis* is most often related to infected intravascular devices, artificial heart valves and stents, and the use of IV and intra-arterial catheters. Enterococci are isolated most commonly isolated from blood cultures following a prolonged hospitalization and treatment with broad-spectrum cephalosporins.

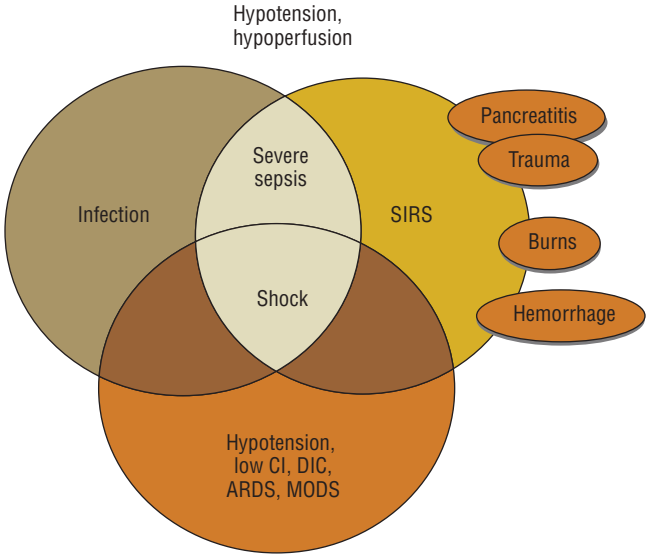

FIGURE 119-1 Relationship of infection, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock. (ARDS, acute respiratory distress syndrome; CI, cardiac index; DIC, disseminated intravascular coagulation; MODS, multiple-organ dysfunction syndrome.)

TABLE 119-1 Definitions Related to Sepsis

Condition	Definition
Bacteremia (fungemia)	Presence of viable bacteria (fungi) in the bloodstream
Infection	Inflammatory response to invasion of normally sterile host tissue by the microorganisms
SIRS	Systemic inflammatory response to a variety of clinical insults, which can be infectious or noninfectious. The response is manifested by two or more of the following conditions: temperature >38°C (>100.4°F) or <36°C (<96.8°F); HR >90 beats/min; RR >20 breaths/min or $PaCO_2$<32 mm Hg (<4.3 kPa); WBC >12,000 cells/mm^3 (>12 × 10^9/L), <4,000 cells/mm^3 (<4 × 10^9/L), or >10% (>0.10) immature (band) forms
Sepsis	SIRS secondary to suspected or documented infection Additional criteria include general variables (altered mental status, positive fluid balance of >20 mL/kg over 24 hours, hyperglycemia >120 mg/dL [>6.7 mmol/L]); inflammatory variables (plasma C-reactive protein/procalcitonin >2 SD above normal value); hemodynamic variables (arterial hypotension <90mm Hg (<12.0 kPa) or MAP <70 mm Hg (<9.3 kPa), elevated mixed venous oxygen saturation of >70% (>0.70); CI >3.5 L/min (>0.058 L/s); organ-dysfunction variables (arterial hypoxemia; acute oliguria of <0.5ml/kg/hr or 45 ml/hr for at least 2 hr, creatinine increase >0.5 mg/dL (>0.44 µmol/L), coagulation abnormalities, paralytic ileus, platelets <100,000 /mm^3 (<100 × 10^9/L), bilirubin >4 mg/dL (>68 µmol/L); tissue-perfusion variable (hyperlactatemia >1 mmol/L, decreased capillary refill)
Severe sepsis	Sepsis associated with one or more organ dysfunctions, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include but not limited to arterial hypoxemia (PaO_2/FiO_2<300) lactic acidosis, oliguria, increase in creatinine, coagulation abnormalities (INR>1.5), and elevated bilirubin
Septic shock	Sepsis with persistent hypotension despite fluid resuscitation (intravenous fluid of 30 mL/kg) or hyperlactatemia >1 mmol/L

CI, cardiac index; HR, heart rate; INR, international normalized ratio; RR, respiratory rate; SD, standard deviation; SIRS, systemic inflammatory response syndrome; T, temperature; WBC, white blood cell (count).

Gram-Negative Bacterial Sepsis

Escherichia coli (8%-30%), *Klebsiella* species (8%-23%), and *Pseudomonas aeruginosa* (7%-18%) are the most commonly isolated gram-negative microorganisms in sepsis.[8-11,13,14] Other common gram-negative pathogens include *Serratia* species, *Enterobacter* species, and *Proteus* species. *P. aeruginosa* and *Acinetobacter* species are more likely to be associated with prior antibiotic exposure.[13]

A greater proportion of patients with gram-negative bacteremia develop sepsis, and also more likely to produce septic shock in comparison to gram-positive organisms, 50% versus 25%, respectively.[8,9,11] Specifically, *P. aeruginosa* sepsis has been associated with a higher mortality rate.[9,13] Mortality increased significantly with increasing severity of sepsis (3.5% for sepsis, 9.9% in severe sepsis, and 28,6% in septic shock).[14] Furthermore, severity of any underlying conditions is another major factor associated with the outcome of gram-negative sepsis. Patients with rapidly fatal conditions, such as acute leukemia, aplastic anemia, cirrhosis, and human immunodeficiency virus (HIV) have a significantly worse prognosis than those patients with nonfatal underlying conditions such as diabetes mellitus and chronic renal insufficiency.[2]

Anaerobic and Miscellaneous Bacterial Sepsis

Anaerobic bacteria such as *Bacteroides fragilis* and *Clostridium* species are usually considered low-risk organisms for the development of sepsis. If present, anaerobes are often found together with other pathogenic bacteria that are commonly found in sepsis. Polymicrobial infections accounted for 5% to 39% of sepsis.[1,9-11,13] Mortality rates associated with polymicrobial infections are similar to sepsis caused by a single organism. Although some clinicians believe the particular combination of organisms present in polymicrobial sepsis can provide clues to the source of infection, no clear source for the infection can be identified in up to 25% of cases.

Fungal Sepsis

3 Candidemia is among the most common fungal etiologic agents of bloodstream infections. Although *Candida albicans* was the most commonly isolated fungus from blood cultures (45.6%), collectively, non-*albicans Candida* species were more frequently isolated (54.4%).[10-11,15-17] Non-*albicans Candida* species include *C. glabrata* (26%), *C. parapsilosis* (15.7%), *C. tropicalis* (8.1%), and *C. krusei* (2.5%). Other fungi identified as causes of sepsis are *Cryptococcus*, *Coccidioides*, *Fusarium*, and *Aspergillus*.[10] Traditionally, risk factors for fungal infection include abdominal surgery, poorly controlled diabetes mellitus, prolonged granulocytopenia, broad-spectrum antibiotic treatment, corticosteroid treatment, prolonged hospitalization, central venous catheter, total parenteral nutrition, hematologic malignancy, and chronic indwelling bladder (Foley) catheter. A large retrospective analysis also reported patients with candidemia and severe sepsis and septic shock were more likely to have been admitted from nursing homes or transferred from outside hospitals.[17] Recent exposure to azoles is an important risk factor for infection with fluconazole-resistant *Candida* spp.[18] There is a close correlation between antibacterial drug exposure and bloodstream infection with *C. glabrata* and fluconazole-resistant *Candida* isolates.[18]

A multicenter analysis of patients with septic shock due to candidemia between 2009 and 2011 reported overall 30-day mortality rate of 54%. A higher in-hospital mortality was reported (61%) among patients with healthcare-associated candidemia.[16] The highest mortality rate of 52.9% was observed in patients with *C. krusei* candidemia; *C. parapsilosis* candidemia was associated with the lowest 12-week mortality rate (23.7%).

PATHOPHYSIOLOGY

Sepsis is the result of complex interactions among the invading pathogen, the host immune system, and the inflammatory responses. The inflammatory response leads to damage to host tissue, and the anti-inflammatory response causes leukocytes to activate. Once the balance to control the local inflammatory process and to eradicate the invading pathogens is lost, systemic inflammatory response occurs, converting the infection to sepsis, severe sepsis, or septic shock.

Cellular Components for Initiating the Inflammatory Process

The pathophysiologic focus of gram-negative sepsis has been on the lipopolysaccharide component of the gram-negative bacterial cell wall. Commonly referred to as endotoxin, this substance is unique to the outer membrane of the gram-negative cell wall and is generally released with bacterial lysis. Lipid A, the innermost region of the lipopolysaccharide, is highly immunoreactive and is considered responsible for most of the toxic effects. Although lipid A can affect tissues directly, its predominant effect is to activate macrophages and trigger inflammatory cascades critical in the progression to sepsis and septic shock.[19] Endotoxin forms a complex with an endogenous protein called a lipopolysaccharide-binding protein, which then engages the CD14 receptor on the surface of a macrophage. Subsequently, cytokine mediators are activated and released by the macrophages.

In gram-positive sepsis, the exotoxin peptidoglycan on the cell wall surface appears to exhibit proinflammatory activity. Although it competes with lipid A for similar binding sites on CD14, the potency of peptidoglycan is less than that of endotoxin.[19] However, an important feature of gram-positive bacteria such as *S. aureus* and *Streptococcus pyogenes* is the production of potent exotoxins, some of which have been associated with septic shock.

Pro- and Anti-inflammatory Mediators

A complex interaction between proinflammatory and anti-inflammatory mediators plays a major role in the pathogenesis of sepsis. In general, proinflammatory reactions are directed at eliminating invading pathogens and the anti-inflammatory reactions are important for limiting local and systemic tissue injury. The key proinflammatory mediators are tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), and interleukin-6 (IL-6), which are released by activated macrophages.[19-21] Other mediators that may be important for the pathogenesis of sepsis are interleukin-8 (IL-8), platelet-activating factor (PAF), leukotrienes, and thromboxane A_2.

The TNF-α levels in plasma can be increased in patients with a variety of diseases and in many healthy people. However, there is a correlation of plasma TNF-α levels with the severity of sepsis. It is highly elevated early in the inflammatory response in most patients with sepsis.[20,21] The TNF-α release leads to activation of other cytokines (IL-1 and IL-6) associated with cellular damage. In addition, TNF-α stimulates the release of cyclooxygenase-derived arachidonic acid metabolites (thromboxane A_2 and prostaglandins) that contribute to vascular endothelial damage. Higher levels of IL-6 and IL-8 have been reported in patients with septic shock than those with SIRS.

The significant anti-inflammatory mediators include interleukin-1 receptor antagonist (IL-1RA), IL-4, and IL-10.[19,20,22] These anti-inflammatory cytokines inhibit the production of the proinflammatory cytokines and down regulate some inflammatory cells. Levels of IL-10 and IL-1RA are higher in septic shock than in sepsis, and higher levels are found among nonsurviving patients than in survivors.[20-22]

The activation and secretion of pro- and anti-inflammatory mediators in septic shock occur as a simultaneous immune response as early as the first 24 hours of diagnosis, but the balance between pro- and anti-inflammatory mechanisms determines the degree of inflammation, ranging from local antibacterial activity to systemic tissue toxicity, organ failure, or death.[20,21]

Cascade of Sepsis

3 The cascade leading to development of sepsis is complex and multifactorial, involving causative pathogen (virulence and organism load) and host characteristics (comorbidities and immunosuppression) triggering various mediators and cell lines. Endothelial cells produce a variety of cytokines that mediate a primary mechanism of injury in sepsis. When injured, endothelial cells allow circulating cells such as granulocytes and plasma constituents to enter inflamed tissues, which can result in organ damage.

The microcirculation is affected by sepsis-induced inflammation. The arterioles become less responsive to either vasoconstrictors or vasodilators. The capillaries are less perfused even at the early phases of septic shock, and there is neutrophil infiltration and protein leakage into the venules.[23]

The inflammatory process in sepsis is also directly linked to the coagulation system. Proinflammatory mechanisms that promote sepsis are also procoagulant and antifibrinolytic, whereas fibrinolytic mechanisms can be anti-inflammatory.[24] A key endogenous substance involved in inflammation of sepsis is activated protein C, which enhances fibrinolysis and inhibits inflammation. Levels of protein C are reduced in patients with sepsis.[24]

COMPLICATIONS

Septic shock is the most ominous complication associated with sepsis. Of the patients who presented to the emergency department with sepsis 3.6% progressed to septic shock within 4 hours, and 8.4% progressed to septic shock between 4 and 48 hours.[25] The predictors for progression to septic shock included female gender, nonpersistent hypotension, band neutrophils of at least 10% in blood, lactate of at least 4.0 mmol/L, and past medical of coronary artery disease.[25] Septic shock may lead to several complications including disseminated intravascular coagulation (DIC), acute respiratory distress syndrome (ARDS), and multiple organ failure. The organs that failed most frequently in patients with severe sepsis were kidneys (49%), lungs (48%), and heart (42%).[2] The less frequent complications are hematologic failure (18%), metabolic failure (17%), neurologic failure (11%), and hepatic failure (5%).[2] Mortality occurs in approximately half of the patients with septic shock.

Disseminated Intravascular Coagulation

DIC is the inappropriate activation of the clotting cascade that causes formation of microthrombi, resulting in consumption of coagulation factors, organ dysfunction, and bleeding. Sepsis remains the most common cause of DIC, and the incidence of DIC increases as the severity of sepsis increases. In sepsis alone, the incidence was 16% in comparison to 38% in septic shock.[26,27] DIC occurs in up to 50% of patients with gram-negative sepsis, but it is also common in patients with gram-positive sepsis.

DIC begins with the activation and production of the proinflammatory cytokines, such as TNF, IL-1, and IL-6, which appear to be the principal mediators, along with endotoxin. The combination of excessive fibrin formation, compromised fibrin removal from a depressed fibrinolytic system, and endothelial injury result in microvascular thrombosis and DIC.[27]

Complications of DIC vary and depend on the target organ affected and the severity of the coagulopathy. DIC can produce acute renal failure, hemorrhagic necrosis of the gastrointestinal (GI) mucosa, liver failure, acute pancreatitis, ARDS, and pulmonary failure. Furthermore, as the procoagulant state appears to be the key

in the pathogenesis of MODS, coagulation dysfunction and MODS often coexist in sepsis.

Acute Respiratory Distress Syndrome

Pulmonary dysfunction, the most common organ dysfunction in sepsis, usually precedes other organs, and it can even initiate the development of SIRS with resultant MODS. Activated neutrophils and platelets adhere to the pulmonary capillary endothelium, initiating multiple inflammatory cascades with a release of a variety of toxic substances. There is diffuse pulmonary endothelial cell injury, increased capillary permeability, and alveolar epithelial cell injury. Consequently, interstitial pulmonary edema occurs that gradually progresses to alveolar flooding and collapse. The end result is loss of functional alveolar volume, impaired pulmonary compliance, and profound hypoxemia.

Coagulation is locally upregulated in the injured lung, whereas fibrinolytic activity is depressed. These abnormalities occur concurrently and favor alveolar fibrin deposition, leading to local inflammation, macrophage migration, and increased vascular permeability. Anticoagulant interventions that block the extrinsic coagulation pathway can protect against the development of pulmonary fibrin deposition as well as lung dysfunction and acute inflammation.[27] Overall, fibrin deposition in the injured lung and abnormalities of coagulation and fibrinolysis are integral to the pathogenesis of ARDS.

Hemodynamic Effects

The hallmark of the hemodynamic effect of sepsis is the hyperdynamic state characterized by high cardiac output and an abnormally low systemic vascular resistance (SVR).[23,28] TNF-α and endotoxin directly depress cardiovascular function. Endotoxin depresses left ventricular (LV) function independent of changes in LV volume or vascular resistance. Myocardial dysfunction is common in severe sepsis and septic shock, affecting 64% of patients, and involves LV in more than half of the patients.[28]

Persistent hypotension raises concern for the balance of oxygen delivery (DO_2) to the tissues and oxygen consumption (VO_2) by the tissues. Sepsis results in a distributive shock characterized by inappropriately increased blood flow to particular tissues at the expense of other tissues, which is independent of specific tissue oxygen needs. This perfusion defect is accentuated by an increased precapillary atrioventricular shunt. If perfusion decreases, oxygen extraction increases, and the arteriovenous oxygen gradient widens. Cellular DO_2 is decreased, but VO_2 remains unaffected. When increased oxygen demand occurs without increased blood flow, the increased VO_2 is compensated by increased oxygen extraction. If perfusion decreases sufficiently in the face of high metabolic demands, then the reserve DO_2 can be exceeded, and tissue ischemia results. Significant tissue ischemia leads to organ dysfunction and failure. Therefore, systemic DO_2 relative to VO_2 should be optimized by increasing oxygen delivery or decreasing oxygen consumption in a hypermetabolic patient.

Acute Renal Failure

Early acute kidney injury occurs in 42% to 64% of adult patients with sepsis and septic shock.[29] Without normal urine output, fluid overload in extravascular space including the lungs develops, leading to impairment of pulmonary gas exchange and severe hypoxemia. Consequently, compromised oxygen delivery exacerbates peripheral ischemia and organ damage. Adequate renal perfusion and a trial of loop diuretics should be initiated promptly in oliguric or anuric patients with MODS along with dialysis to facilitate volume and electrolytes.

CLINICAL PRESENTATION

The clinical features of sepsis vary significantly depending on multiple factors including the patient's underlying health status, site and severity of infection, and time course of sepsis before therapy. Table 119-2 lists some of the common clinical features of sepsis. The initial clinical presentation can be referred to as signs and symptoms of early sepsis, defined as the first 6 hours. They are typically fever, chills, and change in mental status. Hypothermia can occur with a systemic infection, and this is often associated with a poor prognosis.[30] In patients with sepsis caused by gram-negative bacilli, hyperventilation can occur even before fever and chills, and it can lead to respiratory alkalosis as the earliest metabolic change.

Progression of uncontrolled sepsis leads to clinical evidence of organ system dysfunction as represented by the signs and symptoms attributed to late sepsis. With the exception of rapidly progressing cases as in meningococcemia, *P aeruginosa*, or *Aeromonas* infection, the onset of shock is somewhat delayed and usually follows a period of several hours of hemodynamic instability. Oliguria often follows hypotension. Increased glycolysis with impaired clearance of the resulting lactate by the liver and kidneys and tissue hypoxia because of hypoperfusion result in elevated lactate levels, contributing to metabolic acidosis. Altered glucose metabolism, including impaired gluconeogenesis and excessive insulin release, is evidenced by either hyperglycemia or hypoglycemia.

PROGNOSIS

4 As the patient progresses from SIRS to sepsis, severe sepsis, or septic shock, mortality increases in a stepwise fashion. Mortality rates are higher for patients with advanced age, preexisting disease, including chronic obstructive pulmonary disease, neoplasm, and HIV disease, intensive care unit (ICU) care, more failed organs, positive blood cultures, and *Pseudomonas* species infection.[1,2,12] The highest mortality was seen in patients with intra-abdominal infection secondary to ischemic bowel (75%) whereas the source associated with the lowest hospital mortality was obstructive uropathy-associated urinary tract infection (26%).[7] Mortality from severe sepsis and MODS is most closely related to the number of dysfunctioning organs. As the number of failing organs increased from two to five, mortality increased from 29% to 65% (Fig. 119-2).[2] Duration of organ dysfunction can also affect the overall mortality rate.

TABLE 119-2 Signs and Symptoms Associated with Sepsis

Early Sepsis	Late Sepsis
Fever or hypothermia	Lactic acidosis
Rigors, chills	Oliguria
Tachycardia	Leukopenia
Tachypnea	DIC
Nausea, vomiting	Myocardial depression
Hyperglycemia	Pulmonary edema
Myalgia	Hypotension (shock)
Lethargy, malaise	Hypoglycemia
Proteinuria	Azotemia
Hypoxia	Thrombocytopenia
Leukocytosis	ARDS
Hyperbilirubinemia	GI hemorrhage
Delirium	Coma

ARDS, acute respiratory distress syndrome; DIC, disseminated intravascular coagulation.

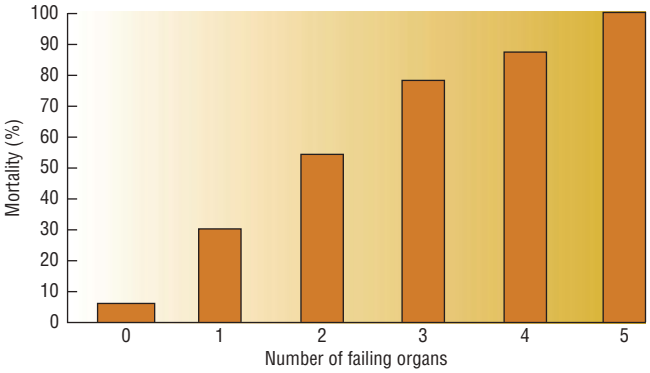

FIGURE 119-2 Mortality related to the number of failing organs.

An elevated lactate concentration of more than 4 mmol/L in the presence of SIRS significantly increases ICU admission rates, and persistent elevations in lactate for more than 24 hours are associated with an increased mortality rate. Furthermore, 28-day mortality rate was the highest (44.8%) among patients with septic shock and hyperlactatemia more than 2.5 mmol/L, followed by hyperlactatemia without vasopressor need (35.3%), and no hyperlactemia with vasopressor need (27.7%). Hyperlactemia increased the risk of 28-day mortality independent of vasopressor need (odds ratio 3.0, 95% confidence interval 2.1-4.1 for lactate of >4 mmol/L).[31]

Diagnosis and Identification of Pathogen

The presence of clinical features suggesting sepsis should prompt further evaluation of the patient. In addition to obtaining a careful history of any underlying conditions and recent travel, injury, animal exposure, infection, or use of antibiotics, a complete physical examination should be performed to determine the source of the infection.

A collection of specimens should be sent for culture prior to initiating any antimicrobial therapy. Minimally two sets of blood cultures (both aerobic and anaerobic bottles) should be collected without temporal separation between the sets.[3,32] With suspected catheter-related infection, a pair of blood cultures should be drawn through every lumen of each vascular access device.[32] In severe community-acquired pneumonia, blood cultures and respiratory secretions must be obtained. Urinary antigen detection of *Legionella* sero group 1 is recommended during outbreaks. To document a soft tissue infection, a Gram stain and bacterial culture of any obvious wound exudates should be performed. A needle aspiration of a closed infection such as cellulitis or abscess may be needed for stain and bacterial culture. In abdominal infections, fluid collections identified by imaging studies should be aspirated for Gram stains and aerobic and anaerobic cultures. Development of accurate and rapid identification tests has demonstrated positive impact on prescribing appropriate therapy in bloodstream infections such as methicillin-resistant *Staphylococcus aureus* (MRSA) and *Candida* spp.[3,33,34] The surviving sepsis guidelines recommend the use of 1,3 β-D-glucan assay in case of invasive candidiasis.[3]

A lumbar puncture is indicated with mental alteration, severe headache, or a seizure, assuming that there are no focal cranial lesions identified by computed tomography (CT) scan. Further tests may be indicated to assess any systemic organ dysfunction caused by severe sepsis. The laboratory tests should include hemoglobin, white blood cell (WBC) count with differential, platelet count, complete chemistry profile, coagulation parameters, serum lactate, and arterial blood gases. The potential role of biomarkers such as procalcitonin (PCT) levels or C-reactive protein for diagnosis of infection in patients with severe sepsis remain undefined as there is no definitive way to discriminate the acute inflammatory pattern of sepsis from other generalized inflammation.[3]

TREATMENT

In 2012, a "surviving sepsis" campaign guideline for management of severe sepsis and septic shock updated the earlier publication of an international effort to increase awareness and improve outcome in severe sepsis.[3,35] The primary goals of therapy for patients with sepsis are (a) timely diagnosis and identification of the pathogen, (b) rapid elimination of the source of infection medically and/or surgically, (c) early initiation of aggressive antimicrobial therapy, (d) interruption of pathogenic sequence leading to septic shock, and (e) avoidance of organ failure. Supportive care such as stress ulcer prophylaxis and nutritional support is important to prevent complications during the stay in the ICU. Table 119-3 describes the summary of the surviving sepsis campaign treatment recommendations.

Elimination of the Source of Infection

After the source of infection is identified, prompt efforts to eradicate that source should be made.[3] With an infected intravascular catheter, the catheter should be removed and cultured. Urinary tract catheters should be removed if association with sepsis is suspected. Suspicion of soft tissue (cellulitis or wound infection) or bone involvement should lead to aggressive debridement of the affected area. Evidence of an abscess or sepsis associated with any intraabdominal pathology should prompt surgical intervention.

Antimicrobial Therapy

5 The Surviving Sepsis Campaign guidelines recommended starting IV administration of one or more antibiotics within 1 hour of recognition of septic shock and severe sepsis without septic shock.[3] Early administration (within 1 hour vs 6 hours of diagnosis) of broad-spectrum antibiotics was independently associated with lower hospital mortality in patients with severe sepsis and septic shock, regardless of the number of organ failure.[36,37] Delays in the initiation of effective antimicrobial therapy especially after the onset of hypotension were significant predictors of mortality.[38] In addition to the timing of the empiric antibiotic, administration of appropriate antibiotic, especially for multidrug-resistant bacteria has a great impact in reducing mortality.[14,39,40] Inappropriate initial antimicrobial therapy occurred in about 20% of patients with septic shock, and was associated with a fivefold reduction in survival in comparison to those who received appropriate therapy (52.0% vs 10.3%, respectively).[11] Therefore, early administration of appropriate antimicrobial therapy is critical in the treatment of severe sepsis and septic shock.

Pharmacokinetics of Antimicrobial Agents in Critically Ill Patients

Pathophysiologic changes in sepsis can affect drug distribution, and adjusted dosing regimens are required in critically ill patients with sepsis.[41] Initially, high creatinine clearance can be seen in patients with normal serum creatinine because of increased renal preload. Volume of distribution can increase because of fluid accumulation from leaky capillaries and/or altered protein binding. Consequently, some antimicrobial agents, especially for hydrophilic antimicrobials including aminoglycosides, β-lactams, carbapenems, and vancomycin can result in lower peak serum concentrations with usual doses.[42] However, as sepsis progresses, organ perfusion decreases because of significant myocardial depression and leads to multiple organ dysfunction. Consequently, clearance of antimicrobial agents is decreased, prolonging the elimination half-life and accumulation of metabolites. Hence, in addition to selecting the most appropriate antimicrobial agents, a clinician must ensure effective antibiotic usage, such as proper dosing, interval of administration, optimal

TABLE 119-3 Evidence-Based Treatment Recommendations for Sepsis and Septic Shock

Recommendations	Recommendation Grades[a]
Initial Resuscitation (First 6 Hours)	
Quantitative resuscitation of patients with sepsis-induced tissue hypoperfusion, CVP 8-12 mm Hg (1.1-1.6 kPa), MAP ≥65 mm Hg (≥8.6 kPa), urine output > 0.5 mL/kg/hr, $SCVO_2$ ≥70% (≥0.70)	1C
Antibiotic Therapy	
IV broad-spectrum antibiotic within 1 hour of diagnosis of septic shock and severe sepsis against likely bacterial/fungal pathogens	1B
Reassess antibiotic therapy daily with microbiology and clinical data to narrow coverage (de-escalation)	1B
Combination empirical therapy for neutropenic patients with severe sepsis and patients with difficult-to-treat, multidrug-resistant bacterial pathogens such as *Acinetobacter* and *Pseudomonas* spp. for no more than 3-5 days and then de-escalate	2B
Fluid Therapy	
Crystalloids as the initial fluid of choice	1B
Minimum of 30 mL/kg of crystalloids for initial fluid challenge, but more rapid and greater amount may be needed	1C
Albumin when patients require substantial amounts of crystalloids	2C
Vasopressors	
Initiate vasopressor therapy to maintain MAP ≥65 mm Hg (≥8.6 kPa)	1C
Norepinephrine as the first choice vasopressor	1B
Epinephrine when an additional agent is needed to maintain adequate blood pressure	2B
Dopamine as an alternative vasopressor to norepinephrine in selective patients with low risk of tachyarrhythmia and bradycardia	2C
Inotropic Therapy	
Use dobutamine up to 20 mcg/kg/min or added to vasopressor when cardiac output remains low or ongoing signs of hypoperfusion despite adequate MAP	1C
Glucose Control	
Use insulin dosing protocol in ICU patients when 2 consecutive blood glucose levels are >180 mg/dL (>10 mmol/L), targeting an upper blood glucose <180 mg/dL (≤10 mmol/L)	1A
Steroids	
IV hydrocortisone 200 mg per day for septic shock only when hypotension remains poorly responsive to adequate fluid resuscitation and vasopressors	2C
Hydrocortisone should be tapered when vasopressors are no longer required	2D
Deep Vein Thrombosis Prophylaxis	
Use daily low-molecular-weight heparin and intermittent pneumatic compression device whenever possible	1B
If creatinine clearance is <30 mL/min (<0.5 mL/s), use unfractionated heparin or dalteparin	1A, 1A
If heparin is contraindicated, use mechanical prophylactic treatment	2C
Stress Ulcer Prophylaxis	
Stress ulcer prophylaxis should be given to patients who have bleeding risk factors	1B
Proton pump inhibitors are preferred over H2 receptor blockers	2C

CVP, central venous pressure; MAP, mean arterial pressure.

[a]Grades of Recommendation, Assessment, Development, and Evaluation (GRADE) system: a structured system for rating quality of evidence and grading strength of recommendation in clinical practice. Quality of evidence: high (grade A), moderate (grade B), low (grade C), or very low (grade D). Strength of recommendation: strong (grade 1) or weak (grade 2).

Adapted from Dellinger RP, Levy MM, Rhodes A, et al. Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. Crit Care Med 2013;41:580-637.

duration of treatment, monitoring of drug levels when appropriate, and avoidance of unwanted drug interactions. The lack of adherence to these requirements can lead to suboptimal or excessive tissue concentrations that can promote antibiotic resistance, toxicity, and inadequate efficacy despite appropriate antibiotic selection.

Selection of Antimicrobial Agents

The selection of an empiric regimen should be based on the suspected site of infection, the most likely pathogens, acquisition of the organism from the community or hospital, the patient's immune status, recent exposure to antibiotics within past 3 months, and the antibiotic susceptibility and resistance profile for the institution. All patients should be treated initially with parenteral antibiotics for optimal drug concentrations within the first hour of recognition of severe sepsis after appropriate cultures have been taken.[3] Empiric therapy for an immunocompromised patient should be broad enough to cover likely pathogens and penetrate adequately into the presumed infection site. Once the pathogen and its susceptibility pattern are known, the antimicrobial regimen should be modified accordingly.

Table 119-4 lists antimicrobial regimens that can be used empirically based on the possible source of infection. In the non-neutropenic patient with a urinary tract infection, ceftriaxone or a fluoroquinolone is generally recommended. When there is increased risk of *P. aeruginosa* in sepsis or hospital-acquired infections, an antipseudomonal antibiotic, such as ceftazidime is recommended.[43]

S. pneumoniae is the most common cause of community-acquired pneumonia, and it accounts for approximately 60% of all deaths. The steady prevalence of penicillin-resistant *S pneumoniae* requires empiric use of newer "respiratory" fluoroquinolones. Levofloxacin or moxifloxacin can be used as monotherapy, as they

TABLE 119-4 Empiric Antimicrobial Regimens in Sepsis

Infection (Site or Type)	Antimicrobial Regimen: Community-Acquired	Antimicrobial Regimen: Hospital-Acquired
Urinary tract	Ceftriaxone or ciprofloxacin/levofloxacin	Ciprofloxacin/levofloxacin or ceftriaxone or ceftazidime
Respiratory tract	Levofloxacin[a]/moxifloxacin or ceftriaxone + clarithromycin/azithromycin	Piperacillin/tazobactam or ceftazidime or cefipime + levofloxacin/ciprofloxacin or aminoglycoside carbapenem[b]
Intraabdominal	Ertapenem or ciprofloxacin/levofloxacin + metronidazole	Piperacillin/tazobactam or carbapenem[b]
Skin/soft tissue	Vancomycin or linezolid or daptomycin	Vancomycin + piperacillin/tazobactam
Catheter-related		Vancomycin
Unknown		Piperacillin/tazobactam or ceftazidime/cefipime or imipenem/meropenem ± vancomycin

[a]750 mg orally once daily.

[b]Imipenem, meropenem, and doripenem.

offer excellent coverage against penicillin-resistant pneumococci and aerobic gram-negative bacteria, as well as atypical pathogens, including *Legionella pneumophila, Mycoplasma pneumoniae*, and *Chlamydophila pneumoniae*.[44] Addition of a macrolide to a β-lactam empirical therapy improves outcome in severe pneumonia, and clarithromycin and azithromycin are effective against atypical pathogens and better tolerated than erythromycin.[45]

In nosocomial pneumonia, enteric gram-negative bacteria such as *Enterobacter* and *Klebsiella* species and *P. aeruginosa* are the major pathogens in addition to *S. aureus*. If *P. aeruginosa* infection is suspected, β-lactam antipseudomonal agents (ceftazidime or cefepime), antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin), or an aminoglycoside should be included in the regimen.[3,46] When *S. aureus* is likely to be methicillin-resistant, linezolid may be preferred to vancomycin because of the poor penetration of vancomycin into the lungs, as well as the worldwide emergence of glycopeptide intermediately resistant *S. aureus*.[47] Televancin, a bactericidal, lipoglycopeptide was evaluated in treatment of hospital-acquired pneumonia due to gram-positive organisms against vancomycin in two randomized trials.[48] MRSA was the most commonly isolated microorganism from both respiratory specimens and blood. Televancin was noninferior to vancomycin in terms of clinical responses. However, vancomycin dosing and the subsequent serum trough levels were slightly lower than the current practice. Further use in clinical settings will define its role.

Abdominal infections are frequent causes of sepsis and septic shock in the ICU and are associated with adverse outcomes. ICU mortality was higher in patients with abdominal infections than in those with other infections (29.4% vs 24.2%, p <0.001).[49] Microbiological cultures were positive in 67%, and polymicrobial infections were present in 40.1% of the patients. *E. coli* was isolated most frequently, followed by *Pseudomonas* spp. and *Klebsiella* spp. among gram-negative isolates. *Enterococcus* was the most common gram-positive isolate.[49] Because of widespread resistance of *E. coli* to ampicillin/sulbactam, it is no longer recommended.[50] Emerging fluoroquinolone-resistant *E. coli* and the local prevalence of extended-spectrum β-lactamase-producing strains of *Klebsiella* species and *E. coli* should be considered in choosing empiric therapy. *Bacteroides fragilis*, the major pathogen, has shown uniform susceptibility to metronidazole, carbapenems, and β-lactam/β-lactamase inhibitors.[51] High resistance rates were observed for clindamycin and moxifloxacin (as high as 60% for clindamycin and >80% for moxifloxacin), with relatively stable low resistance (5.4%) for tigecycline.

In addition to surgical intervention, broad-spectrum antibiotics, such as a β–lactam/β-lactamase inhibitor combination agent (piperacillin/tazobactam) is appropriate in treating intraabdominal infections.[50] Carbapenems such as imipenem, meropenem, and doripenem are indicated in the treatment of resistant pathogens, including Enterobacteriaceae and *P. aeruginosa* in critically ill patients.[50]

Skin and soft tissue infections (SSTIs) range from cellulitis to rapidly progressive necrotizing fasciitis, which may be associated with septic shock and toxic shock syndrome. Staphylococci and streptococci long have been the leading causes of SSTIs, but severe SSTIs can be caused also by indigenous aerobes and anaerobes such as *Clostridium* species.[52] Early initiation of appropriate empiric broad-spectrum antimicrobial therapy is essential and should include coverage against MRSA due to the high prevalence of community-associated MRSA strains.[47,52] Vancomycin, daptomycin, and linezolid have comparable clinical efficacy and safety data for complicated skin and skin-structure infections caused by MRSA.[47,53] Daptomycin resulted in a 70% success rate for septic patients bacteremic with MRSA, vancomycin-resistant *Enterococcus* (VRE) *faecium* or coagulase-negative staphylococci.[54]

Combination therapy does not appear to be more effective than monotherapy in reducing organ failure or mortality in low risk patients.[10,55] However, multidrug resistance in sepsis due to gram-negative bacteremia was strongly associated with the receipt of inappropriate empiric therapy and a three-fold increase in the risk of hospital mortality.[40] As such, the greatest benefit of combination therapy appeared to be in patients with *Pseudomonas* or multidrug-resistant gram-negative bacteremia and in neutropenic patients with severe sepsis or septic shock.[3,55-57]

Empiric combination therapy should not be administered for longer than 3 to 5 days.[3] The antimicrobial regimen should be reassessed daily based on the microbiological and clinical data. This creates a potential de-escalation opportunity as part of good antibiotic stewardship to narrow down the spectrum when possible to prevent drug toxicities and the development of nosocomial super infections with *Candida* species, *Clostridium difficile*, or VRE.[3,58] Furthermore, improved patient care outcomes have been demonstrated with such de-escalation of antibiotic therapy.[59] De-escalation of antimicrobial therapy in patients admitted to the ICU with severe sepsis or septic shock had a protective factor.[60] The hospital mortality rate was 27.4% in patients in whom therapy was de-escalated, 32.6% in the category of "no change", and 42.9% in the escalation group.[60]

Antifungal Therapy

Patients with candidemia are generally acutely sicker based on higher APACHE II scores, have presence of septic shock, and mechanical ventilation, and the mortality is significantly higher in comparison to patients with bacteremia (47% vs 28%, respectively).[17]

Septic shock caused by *C. albicans* demonstrated 24.6% survival with initial appropriate therapy but only 4.6% survival without (ninefold decrease).[11] Of the patients with candidemia, delayed appropriate antifungal treatment, especially in presence of septic shock and failure to achieve timely source control were independently associated with a greater risk of hospital mortality.[15,61,62] Hence, accurate and rapid identification of candida is critical in prompt initiation of appropriate therapy.[3,34]

Treatment of invasive candidiasis involves echinocandins, triazoles, or a formulation of amphotericin B. The choice depends on the clinical status of the patient, the fungal species and its susceptibility, relative drug toxicity, presence of organ dysfunction that would affect drug clearance, and the patient's prior exposure to antifungal agents.

Empirical fluconazole therapy for suspected nosocomial bloodstream infections can be appropriate for hospitalized patients at high risk for fungal infections, including those receiving total parenteral nutrition, with bowel perforation, *Candida* colonization, malignancy, emergency surgery, or with persistent or new signs and symptoms of infections despite receiving broad-spectrum antibacterial therapy.[63,64] However, recent exposure to antibiotics and fluconazole have been associated with fluconazole-resistant *Candida* species.[18,65] A global survey evaluating Candida bloodstream infections reported a low overall fluconazole resistance (5% of ICU isolates and 4.4% of non-ICU isolates).[66] *C. glabrata* was the only species to exhibit resistance to both azoles and echinocandins. Of 1,669 bloodstream infection isolates of *C. glabrata* reported resistance to fluconazole was 9.7%, of which 8% to 9.3% were resistant to enchinocandins.[67]

Echinocandins are potent against all *Candida* species, including *C. glabrata, C. krusei*, and *Candida lusitaniae*, as well as *Aspergillus* species. IV caspofungin was equally effective but better tolerated than amphotericin B deoxycholate for invasive candidiasis.[68] In an international, randomized, double-blind trial, micafungin 100-mg was noninferior to caspofungin for the treatment of candidemia and other forms of invasive candidiasis (76.4% vs 72.3%).[69] All three echinocandins appear to be comparable in terms of efficacy, pharmacology, and adverse effects, and the guidelines do not make a distinction or a preferred agent.[64,70]

In general, suspected systemic mycotic infection leading to sepsis in nonneutropenic patients should be treated empirically with parenteral fluconazole or an enchinocandin.[64] However, an echinocandin is preferred for a patient with recent azole exposure or if the patient is clinically unstable because of its greater activity against fluconazole-resistant *Candida* species and non-*albicans* species, including *C. glabrata* and *C. krusei*.[64] In neutropenic patients, an echinocandin, or voriconazole is recommended. Azoles should be avoided for empiric therapy in patients who have received an azole for prophylaxis.[64]

Antiviral Therapy

Early antiviral treatment of suspected or confirmed influenza is recommended among persons with severe influenza or at higher risk for influenza complications. A neuramidase inhibitor such as oseltamivir or zanamivir is generally effective but susceptibility among the seasonal influenza virus should be considered.[3] While cytomegalovirus in the bloodstream has been associated with poor prognosis, the role of cytomegalovirus and other herpesviruses in septic patients in mildly immunocompromised state remains unclear.

Duration of Therapy

The average duration of antimicrobial therapy in a patient with sepsis is 7 to 10 days, and fungal infections can require 10 to 14 days.[3,46,64] However, the duration can be longer in patients with a slow clinical response, undrainable focus of infection, bacteremia with *S. aureus*, or neutropenia. In a neutropenic patient, therapy is usually continued until the patient is no longer neutropenic and has been afebrile for at least 72 hours. After the patient is hemodynamically stable, afebrile for 48 to 72 hours, has a normalizing WBC count, and is able to take oral medications, then a "step-down" from parenteral to oral antibiotics can be considered for the remaining duration of therapy.

PCT is a biomarker that increases in response to endotoxins and inflammatory cytokines that are released during systemic bacterial infections. Hence, PCT has been studied as a marker to initiate and discontinue antibiotics in patients with severe sepsis or septic shock and surgical intensive care patients.[71] However, aside from the shortened length of antibiotic therapy, the survival benefit has not been clearly defined.

Clinical **Controversy...**

The biomarkers such as PCT rise early in severe sepsis by pneumonia and bloodstream infections, and a growing body of evidence supports the use of PCT to differentiate bacterial from viral diagnoses, to help risk stratify patients, and to guide antibiotic therapy decisions in terms of initiating and optimizing duration of therapy.[71,72]

A meta-analysis of randomized controlled clinical trials or cohort studies investigating PCT guided therapy in ICU patients with severe sepsis and septic shock found no significant difference in both hospital mortality and 28-day mortality between PCT-guided therapy and standard treatment groups.[73] Duration of antimicrobial therapy was significantly reduced in favor of PCT group. However, the length of stay in the ICU and in hospital did not differ between groups. The Procalcitonin and Survival Study Group in Demark found no significant difference in ICU mortality between the PCT arm and the standard of care arm with a strategy of escalation of broad-spectrum antimicrobials and intensified diagnostics based on daily PCT measurements.[74] PCT-guided antimicrobial escalation leads to increased use of broad-spectrum antimicrobials, organ-related harm, and prolonged admission to the ICU. Further trials are needed to determine the safety and efficacy of antibiotic sparing PCT strategies in critically ill patients.

Hemodynamic Support

A high cardiac output and a low SVR characterize septic shock. Patients can have hypotension as a result of low SVR and abnormal distribution of blood flow in the microcirculation, resulting in compromised tissue perfusion. Because approximately half of patients with septic shock die of multiple organ system failure, they should be monitored carefully, and aggressive hemodynamic support should be initiated. The Surviving Sepsis Guidelines recommend a MAP of at least 65 mm Hg (8.6 kPa) in patients with septic shock.[3] A large, controlled trial randomized patients to either a high (MAP of 80-85 mm Hg [10.6-11.3 kPa]) or low (MAP of 65-70 mm Hg [8.6-9.3 kPa]) target and found no significant difference in mortality at 28 days.[75] Among patients with chronic hypertension, those in the high-target group had less renal dysfunction and need for renal-replacement therapy. However, the high-target group had an increased risk of new atrial fibrillation in comparison to the low-target group. Hence, the question of an ideal MAP for septic shock still remains unanswered.

Hemodynamic support can be divided into three main categories: fluid therapy, vasopressor therapy, and inotropic therapy.

Fluid Therapy

6 Septic patients have enormous fluid requirements as a result of peripheral vasodilation and capillary leakage. In approximately 50% of septic patients who initially present with hypotension, fluids alone

will reverse hypotension and restore hemodynamic stability. Rapid fluid resuscitation improves the 28-day survival rate in patients with sepsis-induced hypoperfusion.[3] The goal of fluid therapy is to maximize cardiac output by increasing the LV preload, which will ultimately restore tissue perfusion. Fluid administration should be titrated to clinical end points such as heart rate, urine output, blood pressure, and mental status. Increased serum lactate, a by-product of cellular anaerobic metabolism, should normalize as tissue perfusion improves.

Isotonic crystalloids, such as 0.9% sodium chloride (normal saline) and lactated Ringer solution, are commonly used for fluid resuscitation. A patient in septic shock may require up to 10 L of crystalloid solution during the first 24-hour period. These solutions distribute into the extracellular compartment, and approximately 25% of the infused volume of crystalloid remains in the intravascular space, whereas the balance distributes to extravascular spaces. Although this could impair diffusion of oxygen to tissues, clinical impact is unproven.

The most commonly used colloids are 5% albumin, a naturally occurring plasma protein, and 6% hetastarch, a synthetic colloid formulation. These solutions offer more rapid restoration of intravascular volume because they produce greater intravascular volume expansion per quantity of volume infused. Colloids produce less peripheral edema than crystalloid, but there is no significant clinical impact. However, synthetic colloids cause dose-related acute kidney injury and increased bleeding.[3,76] The use of colloid solutions and blood products can be particularly important if there is significant blood loss associated with sepsis or if the patient had severe preexisting anemia.

There was no difference in 28-day mortality in critically ill patients given saline or albumin in the Saline versus Albumin Fluid Evaluation (SAFE) trial.[77] There was no significant difference in the mortality rate at 28 days for patients admitted to ICU with severe sepsis or septic shock given 20% albumin or crystalloid solution (31.8% vs 32.0%) and at 90 days (41.1% vs 43.6%).[78]

Crystalloid solutions are generally recommended for fluid resuscitation because of the absence of any clear benefit with colloids solutions in addition to the lower cost of crystalloids. For initial fluid challenge, a minimum of 30 mL/kg of normal saline is recommended. More rapid administration and greater amounts of fluid may be needed in some patients. The fluid administration should be continued as long as there is hemodynamic improvement either based on changes in pulse pressure, stroke volume, arterial pressure, and heart rate.[3]

Patients receiving fluid challenges require close monitoring of volume status to avoid pulmonary and systemic edema. Aggressive volume expansion can cause an increase in pulmonary capillary pressure, leading to an increase in lung water and associated hypoxemia. In a retrospective cohort of 405 patients with severe sepsis and septic shock, fluid overload was seen in 67% at day 1, and 48% had persistent fluid overload, exhibiting pulmonary vascular congestion and/or pleural effusions and requiring medical interventions including thoracentesis and diuretics.[79] Fluid overload was also associated with increased hospital mortality (odds ratio, 1.92; confidence interval, 1.16-3.22).

Vasopressor and Inotropic Therapy

When fluid resuscitation alone provides inadequate arterial pressure and organ perfusion, vasopressors and inotropic agents should be initiated. Inotropic agents such as dopamine and dobutamine have been effective in improving cardiac output by increasing cardiac contractility. Vasopressors such as norepinephrine should be considered when a systolic blood pressure is less than 90 mm Hg (12.0 kPa) or MAP is less than 65 mm Hg (<8.6 kPa) after adequate LV preload and inotrope therapy. Although inotropes and vasopressors are effective in life-threatening hypotension and in improving cardiac index (CI), there are significant complications such as tachycardia and myocardial ischemia and infarction as a result of the change in myocardial oxygen consumption in patients with coexisting coronary disease. Thus, a catecholamine infusion should be titrated gradually to restore MAP without impairing stroke volume.

Fluids and vasoactive agents have a strong influence on mortality. Mortality was lowest when vasoactive agents were started within 1 to 6 hours after onset of septic shock, with more than 1 L of fluid in the initial hour.[80]

7 Agents commonly considered for vasopressor or inotropic support include dopamine, dobutamine, norepinephrine, phenylephrine, and epinephrine (Table 119-5). Norepinephrine should generally be considered to be the first-choice vasopressor in septic shock after failure to restore adequate blood pressure and organ perfusion with appropriate fluid resuscitation.[3] Norepinephrine is a potent α-adrenergic agent with less pronounced β-adrenergic activity. It increases MAP and SVR because of its vasoconstrictive effects on peripheral vascular beds. Doses of 0.01 to 3 mcg/kg/min can reliably increase blood pressure with little changes in heart rate or CI. Despite the earlier concern of decreased renal blood flow associated with norepinephrine, data in humans and animals demonstrate a norepinephrine-induced renal blood flow as well as urine and cardiac output.[81] Norepinephrine is a more potent agent than dopamine in refractory septic shock. Norepinephrine resulted in greater increases in arterial blood pressure in comparison to patients with septic shock who were treated with dopamine (93% with norepinephrine vs 31% with dopamine).[81] In a meta-analysis evaluation the randomized trials comparing norepinephrine and dopamine, dopamine was associated with a higher risk of death and more frequently associated with arrythmias.[82]

Dopamine is a natural precursor of norepinephrine and epinephrine, and it exhibits dose-dependent pharmacologic effects. It is an α- and β-adrenergic agent with dopaminergic activity. Doses greater than 5 mcg/kg/min increase MAP and cardiac output, primarily because of the increase in heart rate and cardiac contractility through stimulation of β-adrenergic receptors. At higher doses, α-adrenergic effects predominate, resulting in arterial vasoconstriction. Because of combined vasopressor and inotropic effects, dopamine is more useful in patients with hypotension and compromised systolic function. However, it is also more arrhythmogenic and can cause more tachycardia.[3,81,82] It should be used with caution in patients who have underlying heart disease. Norepinephrine was more frequently used in 61,122 patients admitted with septic shock in US hospitals as initial vasopressor (77.6%) over dopamine, and

TABLE 119-5 Receptor Activity of Cardiovascular Agents Commonly Used in Septic Shock

Agent	α_1	α_2	β_1	β_2	Dopaminergic
Dopamine	++/+++	?	++++	++	++++
Dobutamine	+	+	++++	++	0
Norepinephrine	+++	+++	+++	+/++	0
Phenylephrine	++/+++	+	?	0	0
Epinephrine	++++	++++	++++	+++	0

α_1, α_1-adrenergic receptor; α_2, α_2-adrenergic receptor; β_1, β_1-adrenergic receptor; β_2, β_2-adrenergic receptor; 0, no activity; ++++, maximal activity; ?, unknown activity.

patients who received dopamine experienced greater hospital mortality (25% norepinephrine vs 23.7% dopamine).[83]

Epinephrine is a nonspecific α- and β-adrenergic agonist. Ranging from 0.1 to 0.5 mcg/kg/min, cardiac output is increased at lower doses, and vasoconstriction occurs predominantly at higher doses. Despite human and animal studies suggesting epinephrine impairing blood flow to the splanchnic system and increasing lactate level, clinical data demonstrating worse clinical outcomes as in mortality is lacking. The 2012 guidelines recommend epinephrine as the first alternative to patients intolerant to norepinephrine.[3]

Phenylephrine, a selective α-1-agonist, has rapid onset, short duration, and primary vascular effects, and it is least likely to produce tachycardia. Limited data suggest it can increase blood pressure modestly in fluid-resuscitated patients. Phenylephrine may decrease the stroke volume. Hence, it is only recommended when norepinephrine is associated with serious arrhythmias, cardiac output is known to be high, or as a salvage therapy when all other vasopressors have failed to achieve target MAP.[3,81]

During hypotension, endogenous vasopressin levels should increase and maintain arterial blood pressure, as vasopressin is a direct vasoconstrictor without inotropic or chronotropic effects. However, there is a vasopressin deficiency in septic shock most likely caused by inadequate production. Low doses of vasopressin produce a significant increase in MAP in septic shock, and it may be beneficial to add vasopressin in severe sepsis and septic shock that is refractory to other vasopressors.[77] Although vasopressin 0.03 units/min can be used to increase MAP or reduce norepinephrine requirements, this has not been shown to improve mortality rates.[3,84]

Dobutamine is a β-adrenergic inotropic agent that many clinicians consider to be the preferred drug for improvement of cardiac output and oxygen delivery, particularly in early sepsis before significant peripheral vasodilation has occurred. Doses of 2 to 20 mcg/kg/min increase the CI, ranging from 20% to 66%. However, heart rate often increases significantly.[81] Dobutamine should be considered in severely septic patients with low CI but adequate filling pressures and blood pressure.[3] A vasopressor such as norepinephrine and dobutamine can be used in combination to maintain both MAP and cardiac output.

In summary, for the septic patients with clinical signs of shock and significant hypotension unresponsive to aggressive fluid therapy, norepinephrine is the preferred agent for increasing MAP. In comparison to dopamine, it is less arrhythmogenic and studies have shown benefits in mortality. Epinephrine is an alternative to norepinephrine for refractory hypotension. Dopamine and epinephrine are more likely to induce or exacerbate tachycardia than norepinephrine. Phenylephrine is only recommended as a salvage therapy only if tachycardia or arrhythmia makes norepinephrine and epinephrine intolerable. In a septic patient with low CI after adequate fluid therapy and adequate MAP, dobutamine is the first-line agent for its strong inotropic effect, increasing cardiac output with minimal effect on SVR.

Initial Resuscitation

8 Initial resuscitation of patients in severe sepsis or sepsis-induced tissue hypoperfusion should begin within 6 hours of recognition of the syndrome. A randomized, controlled trial evaluated the timing of the goal-directed therapy involving adjustments of cardiac preload, afterload, and contractility to balance oxygen delivery with demand prior to admission to the ICU.[85] The goals during the first 6 hours included central venous pressure (CVP) of 8 to 12 mm Hg (1.1-1.6 kPa), MAP more than or equal to 65 mm Hg (≥8.6 kPa), urine output more than or equal to 0.5 mL/kg/h, and a central venous or mixed venous oxygen saturation ($Scvo_2$) more than or equal to 70% (≥0.70). During the first 6 hours of resuscitation, this early goal-directed therapy (EGDT) group had a central venous catheter placed and received more fluid than with traditional therapy (5 vs 3.5 L), dobutamine therapy to a maximum of 20 mcg/kg/min, and red blood cell transfusions. The 28-day mortality rate was 30% in the EGDT group, in comparison to 46.5% in the traditional therapy group consisting of fluid resuscitation, followed by vasopressor therapy if required. Increased oxygen delivery from the red blood cell transfusions to achieve a hematocrit of ≥30% (≥0.30) in the EGDT group appeared to be the primary difference between the two groups. However, a decade later, new data challenges the effect of EGDT on patient outcomes.[86-89]

Clinical **Controversy...**

The benefit of EGDT is controversial. EGDT emerged over a decade ago, as a novel approach for reducing mortality due to sepsis.[85] The impressive 15.9% absolute reduction in 28-day mortality rate is the result of invasive monitoring to guide resuscitation with aggressive IV fluids, vasopressors, red cell transfusions, and inotropes. Three large multicenter, randomized trials of 4,183 patients were conducted to validate the effect of EGDT on morbidity and mortality. The Protocolized Care for Early Septic Shock (ProCESS) trial was conducted in the United States at 31 academic hospitals. The patients with septic shock were randomly assigned to one of the three treatment groups: EGDT with continuous monitoring of CVP and Scvo2, protocolized standard therapy without continuous monitoring, and usual care. The EGDT group was most likely to receive vasopressors, inotropes, and red cell transfusions. However, there was no significant change in 60-day mortality (21.0% EGDT vs 18.9% usual care).[87] The Australasian Resuscitation in Sepsis Evaluation (ARISE) trial in Australia and New Zealand enrolled patients from 51 urban and rural hospitals who were diagnosed with septic shock.[88] No significant difference in 90-day mortality (18.6% EGDT vs 18.8% usual care) was noted. The Protocolised Management of Sepsis (ProMISe) trial in England showed similar findings as the ProCESS and ARISE.89. There was no significant difference in the 90-day mortality (29.5% EGDT vs 29.2% usual care), but the patients in the EGDT group had higher organ failure at 6 hours and longer stays in the ICU. Furthermore a meta-analysis of 11 published randomized clinical trials of EGDT did not show improved survival for patients in the EGDT group but rather had an increase admission to ICU from the emergency room for an invasive monitoring.[90]

The 2012 Surviving Sepsis Campaign recommends implementation of hospital-based performance improvement efforts such as a core set ("bundle") as they have been associated with improved patient outcomes. A 7.5-year study assessing the level of compliance with the 2004 Surviving Sepsis Campaign performance bundle and its effect on mortality in the United States, South America, and Europe reported lower mortality in high resuscitation compliance (29.0%) versus low compliance sites (38.6%).[91] In addition, hospital mortality rates dropped 0.7% per site for every three months of participation and the hospital and ICU length of stay decreased 4% for every 10% increase in site compliance. The 2012 guidelines have created the resuscitation bundle based on the time from of 3 hours and 6 hours with the recommended targets from the guidelines (Table 119-6).

Adjunctive Therapies

ARDS and hypoxia are common in septic patients, even in those without pulmonary infection. Oxygen therapy is indicated to

TABLE 119-6 Initial Resuscitation Bundle for Sepsis and Septic Shock

Within 3 hours
• Measure lactate level • Obtain blood cultures x 2 prior to antibiotic administration • Initiate empiric broad spectrum antibiotics • Fluid resuscitation with crystalloid for hypotension or lactate >4mmol/L
Within 6 hours
• Vasopressors if not responsive to initial fluid resuscitation to maintain MAP >65 mm Hg (≥8.6 kPa) • Measure for target CVP of ≥8 mm Hg (≥1.1 kPa), $SCVO_2$ of ≥70% (≥0.70) and normalization of lactate

CVP, central venous pressure; MAP, mean arterial pressure; $SCVO_2$, saturation of central venous oxygen.

Adapted from Dellinger RP, Levy MM, Rhodes A, et al. Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. Crit Care Med 2013;41:580-637.

maintain oxygen saturation greater than 90% (0.90), and with progressive pulmonary insufficiency, the patient may require assisted ventilation.

9 Hyperglycemia and insulin resistance are frequently associated with sepsis regardless of the presence of diabetes prior to sepsis, and more severe hyperglycemia is associated with higher morbidity and mortality.[3] However, intensive insulin therapy is no longer the standard of care in critically ill patients. Patients receiving intensive insulin therapy (target serum glucose of 81-108 mg/dL [4.5-6 mmol/L]) had a higher incidence of severe hypoglycemia and increased mortality at 90 days compared with patients receiving conventional insulin therapy (target ≤180 mg/dL [≤10.0 mmol/L]).[92] Further analysis of patients with moderate (41-70 mg/dL [2.3-3.9 mmol/L]) and severe hypoglycemia (≤40 mg/dL [≤2.2 mmol/L]) reported death rate of 23.5% with moderate hypoglycemia and 35.4% with severe hypoglycemia.[93] Severe hypoglycemia in the absence of insulin therapy was also associated with a higher risk of death. The 2012 guidelines recommend blood glucose levels more than 180 mg/dL (>10 mmol/L) to initiate an insulin protocol with an upper target blood glucose level than 180 mg/dL (10 mmol/L) for the majority of critically ill patients to improve the outcome while reducing the risk of hypoglycemia.[3]

10 Cortisol levels vary widely in patients with septic shock, and some studies have suggested increased mortality associated with both low and high serum cortisol levels. Corticosteroids have been studied as adjunct therapy in patients with severe sepsis and septic shock to decrease the duration of shock and to decrease mortality.

A significant reduction in 28-day all–cause mortality and hospital mortality was reported in patients unresponsive to vasopressor therapy and receiving prolonged courses (>5 days) of low-dose corticosteroid therapy (<300 mg hydrocorortisone or equivalent/day) compared to placebo (38% vs 44%; relative risk 0.84).[94] There was no benefit for those patients without adrenal insufficiency. However, the large multicenter trial, the Corticosteroid Therapy of Septic Shock (CORTICUS) found no survival benefit among patients who received prolonged courses of hydrocortisone, but reported a trend in shock reversal for patients who received hydrocortisone.[95] The use of adrenocorticotropic hormone (ACTH) stimulation test to identify those patients who have a relative adrenal insufficiency did not predict the faster resolution of shock. The differences between the studies appear to arise from the study design of considering the response of septic shock patients to fluid and vasopressor therapy prior to hydrocortisone therapy. The CORTICUS study included patients with septic shock regardless of their responsiveness to vasopressor therapy. The guidelines recommend using IV hydrocortisone only if hemodynamic stability is not achieved after adequate fluid resuscitation and vasopressor therapy, regardless of the state of adrenal insufficiency, negating the ACTH stimulation test.[3] The guidelines also suggest using continuous infusion of hydrocortisone rather than repetitive bolus injections to avoid increased hyperglycemia and hypernatremia. Data on optimal duration of hydrocortisone therapy and the comparative clinical trials comparing whether steroid should be abruptly discontinued or tapered are sparse. Patients should be tapered from steroid therapy when vasopressors are no longer required.[3]

Deep vein thrombosis prophylaxis with daily subcutaneous low-molecular weight heparin should be initiated in all patients admitted to the ICU with severe sepsis and septic shock.[3] There was no significant difference in asymptomatic venous thromboembolism (VTE) between the low-molecular heparin group versus unfractionated heparin twice daily group but the proportion of patients with pulmonary embolism on CT scan was much lower in the low-molecular weight heparin group.[3] In patients with creatinine clearance of less than 30 mL/min (0.5 mL/s), dalteparin did not accumulate while data on the low-molecular weight heparin products is lacking. Dalteparin or unfranctionated heparin is recommended for critically ill patients with acute renal injury.[3]

The systemic inflammatory events of sepsis may further predispose septic patients to VTE. A combination of pharmacologic therapy and intermittent pneumatic compression devices is recommended whenever possible. If heparin use is contraindicated, mechanical prophylactic treatment should be considered.[3] The incidence of venous thromboembolism (VTE) was 37.2% in patients admitted to the ICU with severe sepsis and septic shock despite thromboprophylaxis and resulted in increased ICU length of stay (18.2 vs 13.4 days).[96]

Stress ulcer prophylaxis should be initiated in all patients with severe sepsis and septic shock.[3] Proton pump inhibitors and H_2 receptor antagonists are equivalent in their ability to increase gastric pH. However, proton pump inhibitors may be more effective in GI bleeding protection over H_2 receptor antagonists.

PERSONALIZED PHARMACOTHERAPY

Patients presenting with severe sepsis and septic shock are critically ill and their management in an intensive care setting can be overwhelming. While it is critical to manage the complications involving multiple organ systems to ultimately sustain life during the initial hours, initial resuscitation of sepsis-induced tissue hypoperfusion and infection source identification are imperative as severe sepsis and subsequent multiorgan dysfunction arise from an uncontrolled infection and septic shock. Clinical presentation of each patient should be considered carefully and should prompt further evaluation of any underlying conditions, recent travel, injury, animal exposure, infection or use of antibiotics along with a complete physical examination to determine the possible source of infection. Based on the individual patients' findings and the most likely source of infection, the empiric regimen may be completely different from one patient to another. A patient presenting with sepsis secondary to a community-acquired pneumonia may receive ceftriaxone and azithromycin where another patient presenting with secondary peritonitis as a consequence of perforation of the GI tract may require a broad-spectrum regimen such as ertapenem or piperacillin/tazobactam.[44,45,50] Catheter-related sepsis may require a removal of the line as well as initiating vancomycin. There is abundant evidence in the literature demonstrating a correlation between the prompt and appropriate antibiotics and the overall survival rate.[36,37] Severe sepsis and complications such as shock, ARDS, and DIC result from an acute infection. As such, prompt identification of the source of infection in an individual patient and customizing the empiric antibiotic regimen while maintain hemodynamic stability may be the key to controlling the multiorgan dysfunctions and overall mortality rate.

ABBREVIATIONS

ACTH	adrenocorticotropic hormone
ARDS	acute respiratory distress syndrome
CI	cardiac index
CORTICUS	Corticosteroid Therapy of Septic Shock (trial)
CT	computed tomography
CVP	central venous pressure
DIC	disseminated intravascular coagulation
DO_2	oxygen delivery to tissues
EGDT	Early goal-directed therapy
GI	gastrointestinal
HIV	human immunodeficiency virus
ICU	intensive care unit
IL	interleukin
IL-1RA	interleukin-1 receptor antagonist
LV	left ventricular
MAP	mean arterial pressure
MODS	multiple-organ dysfunction syndrome
MRSA	methicillin-resistant *Staphylococcus aureus*
PAF	platelet activating factor
PCT	procalcitonin
$Scvo_2$	central venous oxygen saturation
SIRS	systemic inflammatory response syndrome
SSTIs	skin and soft tissue infections
SVR	systemic vascular resistance
TNF	tumor necrosis factor
VO_2	oxygen consumption
VRE	vancomycin-resistant enterococci
VTE	venous thromboembolism
WBC	white blood cell

Superficial Fungal Infections

120

Thomas E. R. Brown and Linda D. Dresser

KEY CONCEPTS

1. Vulvovaginal candidiasis (VVC) is a fungal infection of the vagina that can be classified as uncomplicated or complicated. This classification is useful in determining appropriate pharmacotherapy.
2. *Candida albicans* is the major pathogen responsible for VVC. The number of cases of non-*C. albicans* species appears to be increasing.
3. Signs and symptoms of VVC are not pathognomonic, and reliable diagnosis must be made with laboratory tests including vaginal pH, saline microscopy, and 10% potassium hydroxide (KOH) microscopy.
4. *C. albicans* is the predominant species causing all forms of mucosal candidiasis. Important host and exogenous risk factors have been identified that predispose an individual to the development of mucosal candidiasis. In oropharyngeal and esophageal candidiasis, the key risk factor is impaired host immune system.
5. Topical antimycotic agents such as nystatin or clotrimazole are the first choice for treating oropharyngeal candidiasis (OPC). Systemic therapy can be used in patients who are not responding to an adequate trial of topical treatment or are unable to tolerate topical agents and in those at high risk for systemic candidiasis. Fluconazole and itraconazole remain first line antimycotic agents.
6. For esophageal candidiasis, topical agents are not of proven benefit; fluconazole or itraconazole solution is the first choice.
7. Optimal antiretroviral therapy is important for the prevention of recurrent and refractory candidiasis in patients with human immunodeficiency virus (HIV) infection.
8. Primary or secondary prophylaxis of fungal infection is not recommended routinely for HIV-infected patients; use of secondary prophylaxis should be individualized for each patient.
9. Topical antimycotic agents are first-line treatment for fungal skin infections. Oral therapy is preferred for the treatment of extensive or severe infection and those with tinea capitis or onychomycosis.
10. New topical antifungal agents efinaconazole and tavaborole are recommended for mild-moderate toenail fungal infections.

Superficial mycoses are among the most common infections in the world and the second most common vaginal infections in North America. Mucocutaneous candidiasis can occur in three forms—oropharyngeal, esophageal, and vulvovaginal disease—with oropharyngeal and vulvovaginal disease being the most common. Over the past 15 to 20 years, the occurrence rates of some fungal infections have increased dramatically. The prevalence of fungal skin infections varies throughout different parts of the world, from the most common causes of skin infections in the tropics to relatively rare disorders in the United States. This chapter reviews the pharmacotherapy of vulvovaginal candidiasis (VVC), oropharyngeal and esophageal candidiasis, and common dermatophyte infections.

VULVOVAGINAL CANDIDIASIS

1 Vulvovaginal candidiasis refers to infections in individuals with or without symptoms who have positive vaginal cultures for *Candida* species. Depending on episodic frequency, VVC can be classified as either sporadic or recurrent.[1] This classification is essential to understand the pathophysiology, as well as the pharmacotherapy, of VVC. Furthermore, VVC may be defined as uncomplicated, which refers to sporadic infections that are susceptible to all forms of antifungal therapy regardless of the duration of treatment, or complicated, in which consideration of factors affecting the host, microorganism, and pharmacotherapy all have an essential role in successful treatment.[1] Complicated VVC includes recurrent VVC, severe disease, non-*Candida albicans* candidiasis, and host factors, including diabetes mellitus, immunosuppression, and pregnancy.[1]

Epidemiology

There is minimal information on the incidence and prevalence of VVC. Healthcare workers are not required to report cases of VVC; therefore, estimates are derived from self-reported histories. Epidemiologic data are limited because VVC usually is diagnosed without microscopy and/or cultures, and antifungal nonprescription preparations are available for self-treatment.[1] By 25 years of age, approximately 50% of college women will have had at least one episode of VVC.[1] It is rare before menarche and increases dramatically at about 20 years of age, with the peak incidence between age 30 and 40 years. It is associated with the initial act of sexual intercourse. As many as 75% of women experience one bout of symptomatic VVC in their lifetime. Between 40% and 50% of women who experience one episode of VVC experience a second episode, and 5% experience recurrent VVC.[2,3] Black women appear to be at higher risk than white women of developing VVC (62.8% vs 55%, respectively).[4] The incidence after menopause remains unknown. However, one study of 149 healthy postmenopausal women with vulvar conditions reported significantly more women taking hormone replacement therapy (HRT) were prone to developing VVC than those who were not taking HRT (culture-positive, clinical VVC in 49% on HRT versus 1% on those not on HRT).[5]

Costs from VVC can be direct (medical visits and self-treatment) and indirect (nonmedical expenses, eg, time losses from work, costs of travel, and time required in obtaining treatment). There are an estimated 6 million visits to healthcare providers each year, resulting in

more than $1 billion spent annually on these medical visits and self-treatment.[6] These costs could reach $3.1 billion by 2014.[7]

Pathophysiology

2 *C. albicans* is the major pathogen responsible for VVC, accounting for 80% to 92% of symptomatic episodes. The remainder are caused by non-*C. albicans* species, with *Candida glabrata* dominating.[8] The number of cases of non-*C. albicans* candidiasis appears to be increasing, possibly related to the use of nonprescription vaginal antifungal preparations and short-course therapy and/or the increased use of long-term maintenance therapy in preventing recurrent infections.[1]

Candida species can act as commensal members of the vaginal flora. Asymptomatic colonization with *Candida* species has been found in 10% to 20% of women of reproductive age.[8,9] *Candida* organisms are dimorphic; blastospores are responsible for colonization (transmission and spread), whereas germinated *Candida* forms are associated with tissue invasion and symptomatic infections.[10] To colonize the vagina, *Candida* species must be able to attach to the mucosa. The attachment process is complex. Not only are candidal surface structures important for attachment, but appropriate receptors for attachment must be present in the epithelial tissue. Not all women have the same range of receptors, which may explain variation in colonization.[9] Changes in the host's vaginal environment or response are necessary to induce a symptomatic infection. Unfortunately, in most cases of symptomatic VVC, no precipitating factor can be identified.[10]

Risk Factors

Several factors predispose a woman to VVC. VVC is not considered to be a sexually transmitted disease, although sexual factors can be important. There is a dramatic increase in the frequency of VVC when women become sexually active. In addition, oral-genital contact can increase the risk.[1] However, current guidelines do not recommend the treatment of asymptomatic partners.[8] Contraceptive agents, including the diaphragm with spermicide, the contraceptive sponge, and the intrauterine device, increase the risk of VVC. An in vitro study demonstrated that four different isolates of *Candida* species were capable of adhering to the contraceptive vaginal ring.[11] Oral contraceptive users demonstrated increased risk of candidiasis; however, these reports were with the higher-dose oral contraceptive pills, and the risk may not be as great with the lower-estrogen-dose oral contraceptives.[12]

Antibiotic use can increase the risk of VVC, but it is significant in only a small number of women. The mechanism by which antibiotics can increase the risk of VVC is unknown; colonization, however, is a prerequisite.[1] A small pilot study showed that 3 days of antibiotics increased the prevalence of asymptomatic vaginal colonization of *Candida* and the incidence of symptomatic VVC.[13] Diet (excess refined carbohydrates), douching, and tight-fitting clothing often are listed as important risk factors; however, no association has been established between these factors and increased risk of VVC.[1]

Clinical Presentation

3 These signs and symptoms of VVC (Table 120-1) are not pathognomonic, and a reliable diagnosis cannot be made without laboratory tests.[1,8] Self-diagnosis has a sensitivity of 35%, a specificity of 89%, and a positive predictive value of 62%.[4] More than 50% of women who had self-diagnosed VVC did not have yeast as the causative agent.[14] This limits the value of self-diagnosis and the success of self-treatment. The American College of Obstetricians and Gynecologists (ACOG) recommends that whenever possible women requesting treatment for VVC should be examined and evaluated. They only recommend self-diagnosis in compliant women with multiple confirmed prior cases of VVC who report the same symptoms. They further recommend that if these individuals fail to improve on a short course of therapy, they be evaluated for a further diagnosis.[15] Therefore, in most instances the diagnosis should be based on both clinical presentation and investigations, including vaginal pH, saline microscopy, and 10% potassium hydroxide (KOH) microscopy. The vaginal pH remains normal in VVC, and microscopic investigations should detect blastospores or pseudohyphae. *Candida* cultures usually are not required in the diagnosis of uncomplicated VVC; however, they are recommended when an individual presents with classic signs and symptoms of VVC, has a normal vaginal pH, but microscopy is inconclusive or recurrence is suspected.[8]

TABLE 120-1 Clinical Presentation of Vulvovaginal Candidiasis

General	Often involves both the vulva and the vagina
Symptoms	Intense vulvar itching, soreness, irritation, burning on urination, and dyspareunia
Signs	Erythema, fissuring, curdy "cheese"-like discharge, satellite lesions, edema
Laboratory tests	Vaginal pH—normal, saline and 10% KOH microscopy—blastospores or pseudohyphae
Other diagnostic tests	*Candida* cultures not recommended unless classic signs and symptoms with normal vaginal pH and microscopy are inconclusive or recurrence is suspected

KOH, potassium hydroxide.

TREATMENT

Goals of Therapy

The goal of therapy is complete resolution of symptoms in patients who have symptomatic VVC. A test of the cure is not necessary if symptoms resolve.[8] Antimycotic agents used in the treatment of VVC do not meet the definition of being fungicidal agents because of their slower killing rate. At the end of therapy, the number of viable organisms drops below the detectable range. However, by 6 weeks after a course of therapy, 25% to 40% of women will have positive yeast cultures and remain asymptomatic.[1] Asymptomatic colonization with *Candida* species does not require therapy.

General Approaches to Treatment

The approach to therapy is to remove or improve any predisposing factors if they can be identified. A pharmacologic antimycotic agent should have limited local and systemic side effects, a high cure rate, and easy administration. Additionally, it would be advantageous to use a therapy that is able to resolve symptoms within 24 hours, that has broad antimycotic activity (to cover increasing rates on non-*C. albicans* species), that prevents recurrence, and that can be used over a shortened period of time, such as 1 to 3 days. Many topical azoles medications (such clotrimazole, miconazole, etc.) are available without a prescription, and although this may increase public access to these medications, there is concern that having them available without a prescription may lead to inappropriate use. Patient actors who visited 60 pharmacies found that vaginal antimycotics were more likely to be supplied to appropriate individuals as more information was exchanged, if interactions involved a pharmacist, and if questions regarding specific symptoms were used.[16]

Patients should be advised to avoid harsh soaps and perfumes that can cause or worsen vulvar irritation. The genital area must be kept clean and dry by avoiding constrictive clothing and frequent or prolonged exposure to hot tub use.[3] Douching is not recommended

for either prevention or treatment.[14] Cool baths can soothe the skin.[3] The oral use of lactobacillus remains unclear. The addition of oral lactobacillus to single dose oral fluconazole VVC treatment augmented the cure rate compared to the use of fluconazole alone.[17] A mixture of oral consumption of bee-honey and yogurt showed some efficacy with mycotic cure rates of 76.9% compared to cure rates with antifungal agents of 91.5%.[18] Daily ingestion of 240 mL yogurt containing *Lactobacillus acidophilus* decreased colonization and symptomatic infections of VVC in women with recurrent infections.[19] However, a subsequent study showed that the addition of oral lactobacillus to itraconazole therapy in the treatment of recurrent VVC did not confer any additional benefit. Treatment using classic homeopathy was less effective than the use of itraconazole in recurrent VVC.[20] The use of probiotic remains controversial. A Cochrane Collaborative protocol has been developed to determine the role of probiotics in the treatment of VVC in nonpregnant women.[21]

Treatment of VVC will be considered to have positive outcomes if the symptoms of VVC are resolved within 24 to 48 hours and no adverse medication events are experienced. Self-assessment of symptom relief is appropriate for most cases of VVC. If symptoms remain unresolved or recur, then further testing and treatment can be required.

Pharmacologic Treatments

Uncomplicated Vulvovaginal Candidiasis

Cure rates for uncomplicated VVC are between 80% and 95% with topical or oral azoles and between 70% and 90% with nystatin preparations. Table 120-2 lists available topical and oral preparations for the treatment of uncomplicated VVC. There are many topical nonprescription preparations for the treatment of VVC. No significant differences in in vitro activity or clinical efficacy exist between the topical azole agents.[1,3,8,15] The selection of a topical azole antimycotic agent should be based primarily on an individual patient's preference as to product formulation. Some topical products can cause vaginal burning, stinging, or irritation; conversely, the vehicle used in topical creams or gels can provide initial symptomatic relief.[1] Of note, most topical preparations can decrease the efficacy of latex condoms and diaphragms.

TABLE 120-2 Treatment for Uncomplicated Vulvovaginal Candidiasis

Active Ingredient	Preparation	Regimen
Nonprescription/Topical Vaginal Products		
Butoconazole	2% cream	One applicator × 3 days
Clotrimazole	1% cream	One applicator × 7-14 days
	100 mg tablet	One 100 mg tablet × 7 days
	2% cream	One applicator × 3 day
Miconazole[a]	100 mg suppository	One 100 mg suppository × 7 days
	200 mg suppository	One 200 mg suppository × 3 days
	1,200 mg ovule	One ovule × 1 day
Ticonazole	6.5% cream	One applicator × 1 day
Prescription/Topical		
Nystatin	100,000 unit tablet	One tablet × 14 days
Butoconazole	2% cream	One applicator x 1 day
Terconazole	0.4% cream	One applicator × 7 days
	0.8% cream	One applicator × 3 days
	80 mg suppository	One suppository × 3 days
Oral Products		
Fluconazole	150 mg	One tablet × 1 day

[a]The FDA warns of the possible increase in the anticoagulant effects of warfarin with concomitant use.

Oral azoles (such as fluconazole or itraconazole) have been used in the treatment of VVC. Patients may prefer oral therapy because of its convenience.[22] A Cochrane review of 19 trials analyzing 22 oral versus topical antifungal comparisons concluded that there were no differences between the routes of administration in short-term mycologic cure rates. There was a significant difference between long-term cure rates in favor of long-term follow up; however, the authors stated that the clinical significance of this finding is uncertain.[1,23]

In the treatment of uncomplicated VVC, the duration of therapy is not critical. Cure rates with different lengths of treatment have not demonstrated that one duration of therapy is significantly better.[22-24] Shorter-duration therapies (eg, clotrimazole 1-day therapy) consist of higher concentrations of azoles that maintain the local therapeutic effect for up to 72 hours and allow for resolution of signs and symptoms.[25] A review of 14 trials that examined 1-day treatments showed less than 7% difference in short-term cure rates or improvement between any two treatments in any two studies and no significant differences in short- or long-term clinical cure rates among 1-day regimens.[24] Table 120-2 lists the therapeutic options recommended by the Centers for Disease Control and Prevention for the treatment of uncomplicated VVC.[26]

Clinical **Controversy...**

Although there are a few clinical trials evaluating the use of lactobacillus formulations. The use of probiotics alone or in combination with an anti-mycotic agent remains unclear.

Complicated Vulvovaginal Candidiasis

Complicated VVC occurs in patients who are immunocompromised or have uncontrolled diabetes mellitus.[1] These individuals need a more aggressive treatment plan.[15] Current recommendations are to lengthen therapy to 10 to 14 days regardless of the route of administration.[15] Therapeutic options include those listed in Table 120-2; however, regimens should be continued for 10 to 14 days. A study of oral fluconazole therapy in women with complicated VVC demonstrated that cure rates increased from 67% with single-dose therapy to 80% when the 150 mg dose of fluconazole was repeated 72 hours after the initial dose.[27]

VVC during pregnancy can be considered complicated because consideration of host factors such as hormonal changes that can affect normal flora are essential in selecting therapeutic regimens. Topical agents are considered to be safe throughout pregnancy. A systematic review of 10 trials demonstrated that imidazole topical agents (such as fluconazole) were more effective than nystatin. Two of the trials showed that treatment for 7 days was more effective than treatments of 4 days or less.[28] Oral agents are contraindicated in pregnancy because of the concern for fetal complications. A prospective assessment of pregnancy outcomes in 226 women exposed to fluconazole in the first trimester did not indicate increased risk of congenital abnormalities or other adverse outcomes.[29] A Danish registry based cohort found that oral fluconazole may increase the risk of tetratology of Fallot.[30] The ACOG recommends avoiding oral therapy, and recommends a topical imidazole therapy for 7 days.[14]

Recurrent Vulvovaginal Candidiasis

Recurrent vulvovaginal candidiasis (RVVC) is defined as having more than four episodes of VVC within a 12-month period.[1,7] The prevalence of RVVC is higher than once thought, as high as 7% to 8%.[31] A proper diagnosis should be obtained to rule out other infections or nonmycotic contact dermatitis. RVVC is best treated in two stages: an initial intensive stage followed by prolonged antifungal therapy to achieve mycologic remission. Ninety percent of women

randomly receiving 150 mg fluconazole daily for 10 days followed by 6 months of either fluconazole 150 mg weekly or placebo were symptom free for the 6 months following initial treatment (during the weekly fluconazole therapy), and there were 50% fewer symptomatic episodes in the 6 months following weekly suppressive therapy.[32] The Infectious Diseases Society of America recommends 10 to 14 days of induction therapy with a topical or oral azole, followed by 150 mg of fluconazole once weekly for 6 months for recurring *Candida* VVC.[33] Future directions in pharmacotherapy include the development of anti-Candida vaccines. Clinical investigations have begun to determine the effectiveness of these vaccines in preventing RVVC.[34]

ANTIFUNGAL-RESISTANT VULVOVAGINAL CANDIDIASIS

Resistance to azole antimycotics should be considered in individuals who have persistently positive yeast cultures and fail to respond to therapy despite adherence to prescribed regimens.[1] These infections can be treated with boric acid or 5-flucytosine.[35,36] Boric acid is administered as a 600 mg intravaginal capsule daily for 14 days of induction therapy, followed by a maintenance regimen of one capsule intravaginally twice weekly. Boric acid should not be administered orally, as it is toxic. 5-Flucytosine cream is administered vaginally, 1,000 mg inserted nightly for 7 days. The prevalence of *C. glabrata* with VVC is higher in those with diabetes, 68% had isolates for *C. glabrata* compared with 28.8% for *C. albicans*. Those with *C. glabrata* had significantly higher mycological cure rates with 600 mg of boric acid suppositories for 14 days compared with a single dose of fluconazole 150 mg.[37]

OROPHARYNGEAL AND ESOPHAGEAL CANDIDIASIS

Oropharyngeal candidiasis (OPC), or *thrush*, is a common and localized infection of the oral mucosa caused by the yeast *Candida*. *C. albicans*, a common oral commensal organism, is the most frequent infecting species. OPC is also referred to as *candidiasis* (or the more correct but less commonly used term *candidosis*). The infection may extend into the esophagus, causing esophageal candidiasis.

Epidemiology and Etiology

Candida is a commensal fungus found in the oral cavity in up to 65% of healthy individuals with higher prevalence in healthy children and young adults.[38,39] *Candida* carriage increases under immunocompromised conditions and also among hospitalized patients.[39] Even in the era of highly active antiretroviral therapy (HAART) up to 80% of human immunodeficiency virus (HIV)-infected persons may demonstrate oral yeast colonization.[40] The organism is capable of transition to a pathogen causing symptomatic mucosal infections in association with predisposing host factors.[39] *C. albicans* is the predominant colonizing *Candida* species (70%-80%), but any of the non-*C. albicans* species such as *C. glabrata* and *C. tropicalis* which may account for 5% to 8%, respectively, can be colonizers.[40] Colonization rates are influenced by the severity and nature of the underlying medical illness and the duration of hospitalization, as well as age (highest in infants younger than 18 months of age and in adults older than 60 years of age). A variety of host and exogenous factors (Table 120-3) can lead to the transformation of asymptomatic colonization to symptomatic disease, such as oropharyngeal and esophageal candidiasis. *C. albicans* is the most common species causing all forms of mucosal candidiasis in humans. Less frequently, non-*C. albicans* species can be pathogenic and cause disease. These include *C. glabrata*, *Candida tropicalis*, *Candida krusei*, and *Candida parapsilosis*.[41,42] *Candida krusei*, although relatively uncommon, generally is recovered from mucosal surfaces of neutropenic patients with hematologic malignancies.[42] Another species, *Candida dubliniensis*, has been identified in both HIV-infected and noninfected patients, and may cause ~15% of infections previously ascribed to *C. albicans*.[42] In patients with cancer, non-*C. albicans* species account for almost half of all *Candida* infections.

OPC is the most common opportunistic infection in patients with HIV disease, and it may be the first clinical manifestation of the HIV infection in the majority of untreated patients. OPC occurs in 50% to 90% of HIV-infected patients at some point during the progressive course of the disease to acquired immunodeficiency syndrome (AIDS),[38,41,42] although significant reductions in the incidence have been observed after the introduction of HAART. The absolute CD4 T-cell count is the primary risk factor for development of OPC with the greatest risk at CD4 T-cell levels less than 200 cells/mm^3 (less than 0.2×10^9/L). Also, the HIV viral load is a predictor of OPC development; OPC is thought to increase with HIV viral loads greater than 10,000 copies/mL (greater than 10×10^6/L). This finding correlates with the observation that initiation of antiretroviral therapy and subsequent increase in CD4 T-cell counts does not fully account for the decrease in OPC incidence.[41] Regardless of the CD4 T-cell count, or HIV viral load OPC is predictive for the development of AIDS-related illnesses if left untreated.[38,42]

In non-HIV diseases, such as cancer, the incidence of OPC varies depending on the type of malignant neoplastic disease, level of immune suppression, and type and duration of treatment, but it is less common than in HIV-infected patients. OPC was initially reported in ~25% of patients with solid tumors and up to 60% in those with hematologic malignancies or bone marrow transplant recipients.[43] Rates of OPC have decreased significantly in these patients because of widespread use of antifungal prophylaxis. Incidence in other patient populations predisposed to OPC such as the hospitalized patient administered broad-spectrum antibiotics or denture and other oral appliance users is not well quantified, however, do represent at-risk individuals where the clinical pharmacist has an important patient-care role.[39,43]

OPC can predispose patients to develop more invasive disease, including esophageal candidiasis.[43] The esophagus is the second most common site of GI candidiasis. The prevalence of esophageal candidiasis has increased mainly because of the number of individuals with AIDS, as well as the increased numbers of other severely immunocompromised patients, especially those with hematologic malignancies.[42] Esophageal candidiasis is the first opportunistic infection in 3% to 10% of HIV-infected patients and is the second most common AIDS-defining disease after *Pneumocystis jiroveci* pneumonia.[42] The mean incidence of esophageal candidiasis among HIV-infected patients is less than OPC and ranges from 15% to 20%.[42] The risk of esophageal candidiasis is increased in HIV-infected patients when the CD4 T-cell count has dropped below 100 to 200 cells/mm^3 (0.1×10^9 to 0.2×10^9/L), as well as in those with OPC.[43,44] However, the absence of OPC does not necessarily exclude the possibility of esophageal disease. Like OPC, the presence of esophageal candidiasis can help predict HIV disease progression and prognosis.[43] The incidence of esophageal candidiasis in non-HIV-infected immunocompromised patients is not well established. *C. albicans* is the most common cause of esophageal candidiasis, accounting for ~80% of cases, with the rest being caused by non-*C. albicans* species.[41]

The introduction of HAART appears to have resulted in a significant decline in the incidence of OPC and esophageal candidiasis.[41,42,45] In addition, the widespread use of the azole agents for treatment and prophylaxis has led to a decline in the prevalence of mucosal candidiasis while leading to the emergence of refractory infections that are more challenging to treat.

TABLE 120-3 Risk Factors for the Development of Oropharyngeal and/or Esophageal Candidiasis

Local Factors	Potential Mechanisms
Use of steroids and antibiotics	Suppression of cellular immunity and inhibition of phagocytosis by steroids, including chronic use of inhaled and topical steroids
	Alteration of endogenous oral flora by broad-spectrum antibiotics, especially when used with steroids, creates a milieu for proliferation of *Candida* species because of reduced environmental and nutritional competition
Dentures	Enhanced adherence of *Candida* species to the acrylic material of dentures, reduced saliva flow under surfaces of denture fittings, improperly fitted dentures, and poor oral hygiene provide a milieu conducive to the survival of microorganisms
Xerostomia caused by drugs (eg, tricyclic antidepressants and phenothiazine), chemotherapy, radiotherapy to the head/neck, and various diseases (eg, Sjögren's syndrome, HIV, and cancer of the head/neck), as well as bone marrow transplant recipients	Reduced dilutional and cleansing effect caused by low secretion rate and low pH in saliva: Saliva and mucosa secretions have defense factors, such as lactoferrin, sialoperoxidase, isozyme, histidine-rich polypeptide, secretory IgA antibodies, specific anti-*Candida* antibodies that help prevent adhesion and overgrowth of *Candida* species
Smoking	
Disruption of oral mucosa caused by chemotherapy and radiotherapy, ulcers, endotracheal intubation trauma, and burns	Oral mucositis induced by radiation and breaks in the physical barrier of the oral epithelium, which is protective against invasion by microorganisms; altered rate of mucosa regeneration by cancer chemotherapy, which increases vulnerability to infection
Systemic Factors	**Potential Mechanisms**
Drugs (eg, cytotoxic agents, corticosteroids, and immunosuppressants after organ transplant), omeprazole, and environmental chemicals (eg, benzene and pesticides)	Reduced immunity because of drug-induced neutropenia or cell-mediated immunity; potent inhibition of gastric acid by PPIs can facilitate the growth of *Candida* species; PPIs also can inhibit the cytotoxic effect of lymphocytes and reduce salivary secretion
Neonates or the elderly	Immature immune system of neonates who usually acquire infection during birth to a mother with vaginal candidiasis or from exposure to infected bottle nipples or to skin of adult caregiver
	Elderly—unclear if this is the direct effect of age per se or contribution from dentures or underlying comorbidity
HIV infection/AIDS	Depletion of CD4 T lymphocytes especially below 200-300 cells/mm^3 (0.2×10^9-0.3×10^9/L); anti-*Candida* protective mechanism of T lymphocytes at a mucosal level is unclear but can be caused by altered cytokines, especially interferon-γ, that inhibit transformation of *Candida* blastoconidia to the more invasive hyphal phase
Diabetes	Higher than normal numbers of *C. albicans* cultured from saliva of diabetic patients; can be related to the elevated glucose levels and reduced chemotactic factor in saliva, altered neutrophil function, and reduced saliva volume and flow
Malignancies (eg, leukemia and head/neck cancer)	Use of intensive radiotherapy and chemotherapy can disrupt oral mucosa and cause xerostomia; prolonged use of broad-spectrum antibiotics in neutropenic patients can alter the normal oral flora; because of the prolonged neutropenia, the principal immune defect, seen especially in leukemic patients, the initial oropharyngeal candidiasis can become systemic or invasive
Nutritional deficiencies (eg, iron, folate, and vitamins B1, B2, B6, B12, and C)	Can be related to dietary restriction or GI absorption problems; deficiencies can serve to enhance the pathogenic potential of the *Candida* inhabitants, alter host defense mechanisms, or change epithelial barrier integrity

AIDS, acquired immunodeficiency syndrome; GI, gastrointestinal; HIV, human immunodeficiency virus; IgA, immunoglobulin A; PPI, proton pump inhibitor.

Pathophysiology

The pathogenesis of OPC is most clearly elucidated in the setting of HIV infection. There appear to be several levels of immune defense against the development of OPC in HIV-infected persons, and they involve both systemic and local immunity. The primary line of host defense against *C. albicans* is cell-mediated immunity (CMI) at the mucosal surfaces, which is mediated by CD4 T cells.[38] The efficacy of the CD4 T cells is reduced when the number of cells drops below a protective threshold, and protection against infection becomes dependent on secondary or local immune mechanisms.[38,41] When the number of CD4 T cells drops too low, recruitment of these cells to the oral cavity is impaired. The CD4 T-cell count is the hallmark predictor for development of OPC. However, HIV viral load may have a stronger association with OPC than CD4 cell number.[41,46] The possibility that HIV plays a strong role in susceptibility to infection is supported clinically by the observation that OPC is more common in HIV-infected persons than in those with similar immunosuppression, such as lymphoma and bone marrow transplant. When the primary line of defense fails, the secondary host defenses become crucial. These include the CD8 T cells, salivary cytokines, and other innate immune cells, such as the neutrophils, macrophages, and epithelial cells (with anti-*Candida* activity). Deficiencies or dysfunction in any of these can result in increased susceptibility to OPC. The problem with the CD8 T cells is caused more by a dysfunction of the microenvironment, specifically, reduction in the E-cadherin adhesion molecule that promotes migration of the cells through mucosal tissues.[42] The role of humoral immunity by antibodies as a protective mechanism is unclear and controversial. The changeover of the role of *Candida* species from commensal to pathogenic in the human host usually occurs when breakdown in these host defenses occurs. The pathogenesis of OPC is still not completely understood. It is important to develop a better understanding of the pathogenesis and role of host defenses, including the mechanism of CD8 T-cell activity, reduced adhesion molecules, and whether other cofactors, such as HIV viral load, HAART, and injection drug use, play a role. Immunotherapeutic modalities can then be developed to eliminate the susceptibility factors and significantly reduce OPC in the at-risk populations.

TABLE 120-4 Clinical Classification of Oropharyngeal Candidiasis

Types	Population at Risk	Clinical Signs and Appearance
Pseudomembranous (thrush)	Neonates, patients with HIV or cancer, the debilitated elderly, patients on broad-spectrum antibiotics or steroid inhalers, patients with dry mouth from various causes, and smokers	Classic "cottage cheese" appearance, yellowish white, soft plaques (or milk curds) overlying areas of erythema on the buccal mucosa, tongue, gums, and throat; plaques are easily removed by vigorous rubbing but can leave red or bleeding sites when removed; lesions on the tongue dorsum give it a bald, depapillated appearance
Erythematous (atrophic)	Patients with HIV, patients on broad-spectrum antibiotics or steroid inhalers	Sensitive and painful erythematous mucosa with few, if any, white plaques; lesions are generally on the dorsal surface of the tongue or the hard palate, occasionally on the soft palate, but any part of the mucosa can be involved; appear as flat red patches on the palate or atrophic patches on the tongue dorsum with loss of papillae. Can be acute or chronic
Hyperplastic (candidal leukoplakia)	Smokers; uncommon in patients with HIV	Thick white and adherent keratotic plaques commonly seen on the buccal mucosa and lateral border of the tongue; can also be seen on the lips and the bottom of the mouth; plaques cannot be easily scraped off or only partially removed; this condition is distinct from oral hairy leukoplakia, and it can progress to severe dysplasia or malignancy
Angular cheilitis	Patients with HIV, denture wearers	Painful red, ulcerative, cracking, or fissuring lesion at one or both comers of the mouth because of an inflammatory reaction; usually lesions are small and rather punctate, but occasionally they can extend in a linear fashion from the angles onto the facial skin
Denture stomatitis (chronic atrophic)	Denture wearers who tend to be elderly and have poor oral hygiene	Red, flat lesions on the mucosa beneath the denture and extend right up to the denture border; more commonly located beneath a maxillary denture, although they can be encountered beneath a mandibular denture
Central papillary atrophy (median rhomboid glossitis)	Uncommon (<1% prevalence), men more commonly infected than women (3:1)	Rhomboid-shaped hypertrophic or atrophic plaque in the mid-doral tongue. Lesions may not resolve completely

HIV, human immunodeficiency virus.

Significant differences exist in the virulence among *Candida* species in mucosal candidiasis. One virulence factor is the ability of the organism to adapt and survive in response to changes in the host environment.[41] The genes required for virulence are regulated in response to the environmental signals indigenous to the host environment (eg, temperature, pH, osmotic pressure, iron and calcium ion concentrations, oxygenation, and carbon and nitrogen availability). The ability of *C. albicans* to undergo reversible morphologic transition between the budding pseudohyphal and the more invasive hyphal growth forms is also a determinant of virulence, and genes are recognized to play a role.[38] Other virulence factors are the adhesive ability of *C. albicans* to epithelial cells and proteins and its ability to invade host cells by means of phospholipase and proteinase enzymes. This may be one of the factors leading to OPC in non-HIV-infected individuals. Other components of the pathogenesis in the absence of HIV that have been postulated are the ability of the *Candida* species to adhere to buccal epithelial cells. A close correlation between adhesion of *Candida* species and their ability to cause infection has been demonstrated in animal model studies.[47] This is hypothesized to be a key element in the development of OPC in patients with altered microflora, including those receiving broad-spectrum antimicrobial therapy.

Risk Factors

4 Several host and exogenous factors contribute to the ability of *Candida* species to cause infection (see Table 120-3). Local and systemic factors, as well as characteristics of the organism itself, can increase the susceptibility of an individual to *Candida* infections.[38] Endocrine disorders besides diabetes mellitus, such as hypothyroidism, hypoparathyroidism, and hypoadrenalism, also can predispose patients to *Candida* species overgrowth. Patients with primary immune deficiencies such as lymphocytic abnormalities, phagocytic dysfunction, immunoglobulin A (IgA) deficiency, viral-induced immune paralysis, and severe congenital immunodeficiencies are also at risk for OPC as well as disseminated candidiasis. Oral mucosal disease, such as lichen planus, can be preexistent causes of candidiasis. Smoking may be a predisposing risk factor. In many cases, multiple concurrent predisposing factors to candidiasis can exist, for example, xerostomia with mucositis and a break in the epithelial surface or immunosuppression, such as might occur in a leukemic patient receiving radiation and chemotherapy. The severity and extent of *Candida* infections increase with the number and severity of predisposing risk factors.[39]

Clinical Presentation and Diagnosis

OPC can manifest in several major forms (Table 120-4).[38,39] The clinical signs and symptoms of OPC and the locations of the lesions can be quite diverse (Table 120-5). A presumptive diagnosis of OPC usually is made by the characteristic appearance on the oral mucosa, with resolution of signs and symptoms after antifungal therapy. Pseudomembranous candidiasis, commonly known as *oral thrush*, is the classic and most common form seen in immunosuppressed and immunocompetent hosts. Erythematous and hyperplastic candidiasis and angular cheilitis occur less commonly in the HIV-infected population. Dysphagia, odynophagia, and retrosternal chest pain are common complaints of esophageal candidiasis, which is usually, but not always, accompanied by the presence of OPC. Clinical symptomatology, along with a therapeutic trial of antifungal, can provide a reliable presumptive diagnosis of esophageal candidiasis. If antifungal therapy does not lead to resolution, more invasive tests such as upper GI endoscopy can be undertaken.

TREATMENT

Desired Outcomes

The primary desired outcome in the management of OPC is a clinical cure, that is, elimination of clinical signs and symptoms. Even when the patient is relatively asymptomatic, it is important to treat the initial episode of OPC to avoid progression to more extensive disease. In the most severe cases, the patient's quality of life can be impaired; this can result in decreased fluid and nutritional intake.

TABLE 120-5 Clinical Presentation of Oropharyngeal and Esophageal Candidiasis

Oropharyngeal Candidiasis	Esophageal Candidiasis
General	**General**
The clinical features can be quite diverse (see Table 98-4)	This usually occurs as an extension of OPC; however, the esophagus can be the only site involved; the distal two-thirds, rather than the proximal one-third, is the most common site
Symptoms	**Symptoms**
Symptoms are diverse and range from none to a sore, painful mouth, burning tongue, metallic taste, and dysphagia and odynophagia with involvement of the hypopharynx	Typically, the symptoms are dysphagia, odynophagia, and retrosternal chest pain but can be asymptomatic in some patients; although rare, epigastric pain can be the dominant symptom
Signs	**Signs**
Signs are variable and can include diffuse erythema and white patches on the surfaces of the buccal mucosa, throat, tongue, or gums; constitutional signs are absent	Constitutional signs, including fever, occasionally occur; physical findings can range from a few to numerous white or beige plaques of variable size Plaques can be hyperemic or edematous, with ulceration in more severe cases Most advanced cases can occur with increased mucosal friability and narrowing of lumen Uncommon complications include perforation and aortic–esophageal fistula formation
Laboratory tests	**Laboratory tests**
Scraping of an active lesion for microscopic examination can help confirm the diagnosis (presence of pseudohyphae and budding yeast) but is usually not necessary Cultures are not necessary because isolation of *Candida* species does not distinguish between colonization and true infection; cultures can be taken in patients responding poorly to therapy to determine the infecting species and to predict likely drug resistance	The best test is upper GI endoscopy (more useful than barium swallow); helps exclude other causes of esophagitis (eg, viral, aphthous ulcers); diagnosis is confirmed by the histologic presence of *Candida* species in biopsy lesions taken during endoscopy Cultures to look for drug-resistant *Candida* species are warranted in patients who require endoscopy

GI, gastrointestinal; OPC, oropharyngeal candidiasis.

Lack of appropriate treatment of OPC can lead to more extensive oral disease, especially in patients who are immunocompromised. The most serious complication of untreated OPC is extension of the infection to esophageal candidiasis. Because esophageal candidiasis is more debilitating, the patient's quality of life is more affected. It is important to initiate appropriate antifungal therapy for both OPC and esophageal candidiasis. Preventing or minimizing the number of future recurrences of both types of candidiasis is an equally important outcome. The approach depends largely on the underlying predisposing conditions. Mycologic cure is not a necessary treatment outcome because it may not be feasible or realistic, given that *Candida* species exist commonly as part of the normal mouth flora.

Minimizing toxicities and drug–drug interactions of systemic antifungal agents, as well as maximizing adherence by ensuring that the patient understands the importance of therapy and the directions to take the medication appropriately, are important secondary outcomes of therapy.

General Approach to Treatment

The management of OPC should be individualized for each patient, taking into consideration the underlying immune status, other concurrent mucosal and medical diseases, concomitant medications, and exogenous infectious sources. In HIV-infected patients with inadequately controlled disease, antifungal treatment produces only a transient clinical response, and the relapse rates are higher than in other patient populations. These patients usually require frequent courses of antifungal treatment. Therefore, in patients with HIV disease, treatment with effective HAART is paramount because this would provide the best prophylaxis against recolonization and recurrence of symptoms.[39,41,48]

Whenever feasible, it is desirable to minimize all predisposing factors, such as administration of corticosteroids, chemotherapeutic agents, and antimicrobials, as well as institute proper oral hygiene and resolve concurrent conditions, such as denture stomatitis. Selection of an appropriate antifungal agent for treatment of candidiasis requires consideration of several factors, including the patient's drug adherence, adequate saliva for dissolution of solid topical medications, risk of caries from sucrose- or dextrose-containing preparations, potential drug interactions, coexisting medical conditions (eg, liver disease), location and severity of the infection, and the need for long-term maintenance therapy. Another factor that could affect drug selection is overuse of fluconazole, leading to the emergence of fluconazole-resistant species of *C. albicans*, and in some cases to all azoles, and other intrinsically more resistant species, such as *C. krusei*, *C. glabrata*, and *C. tropicalis*.

5 Topical antimycotic therapies should be the first choice for milder forms of infections.[48] The efficacy of antimycotic agents for OPC varies in different patient populations. Until the polyene antimycotic agents became available in the 1950s, gentian violet, an aniline dye, was used to treat OPC. Problems with gentian violet include fungal resistance, skin irritation, and especially the unaesthetic staining of the oral mucosa. In resource limited areas gentian violet remains a therapeutic option. A 0.00165% gentian violet solution does not stain the oral mucosa and has potent antifungal activity.[49] Topical agents, such as nystatin and clotrimazole, have been the standard of treatment for uncomplicated OPC and generally are effective for treatment in otherwise healthy adults and infants with no underlying immunodeficiencies. Topical agents are available in an assortment of formulations, including oral rinses (suspension), troches, powder, vaginal tablets, creams and most recently as a mucoadhesive tablet[43,48,50] (Table 120-6).

Topical agents require frequent applications because of the short contact time with the oral mucosa; the ideal contact time is 20 to 30 minutes. Sufficient saliva is needed to dissolve clotrimazole troches, and this can be problematic for patients with xerostomia. Also, the rough surface of the tablet can become irritating to the oral soft tissue. Troches also contain dextrose, which has cariogenic potential. Nystatin suspension might be a better choice for patients with xerostomia, but it is difficult to maintain adequate contact time with the oral mucosa. Some patients complain of the unpleasant taste of nystatin, which can cause nausea and vomiting; this is especially problematic in cancer patients experiencing chemotherapy-induced nausea. The high sucrose content of nystatin suspension is

TABLE 120-6 Therapeutic Options for Mucosal Candidiasis

Initial Episodes of OPC:[a] Treat for 7-14 Days	Common/Significant Side Effects
Clotrimazole 10 mg troche: hold 1 troche in mouth for 15-20 minutes for slow dissolution 5 times daily (B-2)	Altered taste, mild nausea, vomiting
Nystatin 100,000 units/mL suspension: 5 mL swish and swallow 4 times daily (B-2)	Mild nausea, vomiting, diarrhea
Miconazole 50 mg mucoadhesive buccal tablets 50 mg daily (A-1)	Diarrhea, headache, nausea, dysgeusia, upper abdominal pain, and vomiting
Fluconazole 100 mg tablets:[b] 100-200 mg daily (A-1)	GI upset, hepatitis not common
Itraconazole 10 mg/mL solution:[c] 200 mg daily (A-2)	GI upset, not common: hepatotoxicity, CHF, pulmonary edema with long-term usee
Posaconazole 40 mg/mL suspension: 400 mg daily with a full meal (A-2)	GI upset, fever, headache, increased hepatic transaminases not common
Fluconazole-Refractory OPC: Treat for ≥14 Days	
Itraconazole 10 mg/mL solution: 200 mg daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg), taken on empty stomach (A-3)	GI upset, rash, reversible visual disturbance (altered light perception, photopsia, chromatopsia, photophobia), increased hepatic transaminases, hallucinations, or confusion
Posaconazole 40 mg/mL suspension: 400 mg twice daily × 3 days, then 400 mg daily × 28 days (A-2)	See above
Amphotericin B 100 mg/mL suspension:[d] 1-5 mL swish and swallow 4 times daily (B-2)	Oral: nausea, vomiting, diarrhea with higher dose
Amphotericin B deoxycholate 50 mg injection: 0.3-0.7 mg/kg/day IV daily (B-2)	IV: fever, chills, sweats, nephrotoxicity, electrolyte disturbances, bone marrow suppression
Caspofungin 50 mg IV daily (B-2)	Fever, headache, infusion-related reactions (<5%) (eg, rash, facial swelling, pruritus, vasodilation), hypokalemia, increased hepatic transaminases, anemia, neutropenia
Micafungin 150 mg IV daily (B-2)	Similar to caspofungin
Anidulafungin 200 mg IV daily (B-2)	Similar to caspofungin
Esophageal Candidiasis:[a] Treat for 14-21 Days	
Fluconazole 100 mg tablets: 200-400 mg (3-6 mg/kg) daily (A-1)	See above
Echinocandin: see above (B-2)	See above
Amphotericin B deoxycholate 50 mg injection: 0.3-0.7 mg/kg/day IV daily (B-2)	See above
Posaconazole 40 mg/mL suspension: 400 mg twice daily (A-3)	See above
Itraconazole 10 mg/mL solution:[c] 200 mg daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg) (A-3)	See above
Voriconazole and echinocandins (A-1): generally reserved for refractory cases	See above
Fluconazole-Refractory EC: Treat for 21-28 Days	
Itraconazole 10 mg/mL solution: 200 mg daily (A-2)	See above
Posaconazole 40 mg/mL suspension: 400 mg twice daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg), taken on empty stomach (A-3)	See above
Caspofungin 50 mg IV daily (B-2)	See above
Micafungin 150 mg IV daily (B-2)	Similar to caspofungin
Anidulafungin 100 mg IV on day 1, then 50 mg IV daily (B-2)	Similar to caspofungin
Amphotericin B deoxycholate: 0.3-0.7 mg/kg/day IV, or lipid-based amphotericin 3-5 mg/kg/day IV (B-2)	See above

CHF, congestive heart failure; GI, gastrointestinal; OPC, oropharyngeal candidiasis.

[a]Initial episodes of OPC can be adequately treated first with topical agents before resorting to systemic therapy (B-2), but systemic therapy is required for effective treatment of esophageal candidiasis. (A-2) Suppressive therapy is recommended for patients with frequent or severe recurrences (A-1).

[b]Fluconazole is more effective than ketoconazole (A-1).

[c]Solution is more effective than capsule (A-1); solution is better taken on an empty stomach.

[d]Suspension is not marketed; can be prepared extemporaneously by pharmacy.[50]

[e]See discussion under onychomycosis.

Recommendation grades:

Strength of recommendation: **A**—Both strong evidence for efficacy and substantial clinical benefit to support recommendation for use. *Should always be offered*. **B**—Moderate evidence for efficacy but only limited clinical benefit, to support recommendation for use. *Should generally be* offered. **C**—Evidence for efficacy is insufficient to support recommendation for or against use; or evidence for efficacy might not outweigh adverse consequences or cost of the treatment under consideration. *Optional*. **D**—Moderate evidence for lack of efficacy or adverse outcome supports a recommendation against use. *Should generally not be offered*.

Quality of evidence: **1**—Evidence from at least one properly designed randomized, controlled trial. **2**—Evidence from at least one well-designed trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), or from multiple time-series studies, or dramatic results from uncontrolled experiments. **3**—Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees. (UR) Evidence currently unrated.

cariogenic in dentate patients, and it should be used with caution in diabetic patients.[39,43] Miconazole 50 mg mucoadhesive tablets are the first buccal adherent miconazole product approved for the local treatment of OPC in adults and adolescents older than age 16 years.[51] This product offers the advantage of a once-daily formulation that is tasteless, odorless, and sugar free.[50] Topical creams, such as clotrimazole, ketoconazole, miconazole, and nystatin (usually mixed with a steroid), are more appropriate for application three times daily to the corners of the mouth in treating angular cheilitis, the inflammation, drying, and cracking of the corners of the mouth.[48]

Systemic therapy is necessary in patients with OPC that is refractory to topical treatment, those who cannot tolerate topical agents, moderate-to-severe disease, and those at high risk for disseminated systemic or invasive candidiasis. Effective treatment of esophageal candidiasis generally requires the use of systemic antifungal agents. However, these agents have the disadvantage of producing more side effects (see Table 120-6) and drug–drug interactions (see Chapter e99). Fluconazole is inexpensive and generally well tolerated, and its absorption is unaffected by food or gastric acidity. Ketoconazole requires gastric acidity for absorption, which can be problematic in AIDS patients with achlorhydria; hence, it is best given with an acidic beverage. Ketoconazole is not recommended today with the availability of more effective triazoles. Itraconazole capsules also have the same absorption problem and are no longer recommended. In contrast, itraconazole solution has enhanced absorption and is best taken in a fasting state; in addition, the solution provides the benefit of both topical effects to the oral mucosa and systemic effects and is beneficial to patients with mucositis or swallowing problems. Whenever possible, it is generally beneficial to limit the use of systemic azole agents to prevent unnecessary drug exposure and to minimize the potential for occurrence of drug-resistant candidiasis, particularly from fluconazole resistance.

When patients become unresponsive to topical agents or fluconazole and itraconazole, alternative agents are available.[43,44,48,52,53] These include amphotericin B and newer triazoles such as voriconazole and posaconazole and echinocandins (caspofungin, micafungin, and anidulafungin) (see discussion below). Although posaconazole is now available in three formulations; the original suspension as well as oral tablets and an intravenous product, only the suspension has an FDA indication for the treatment of OPC.[54]

Clinical **Controversy...**

The optimal strategy for the management of recurrent oral mucosal candidiasis is unclear. Primary and secondary prophylaxis is not routinely recommended in HIV infected patients. The decision to use secondary prophylaxis should be made on an individual case basis.

Oropharyngeal Candidiasis: Human Immunodeficiency Virus-Infected Patients

It is appropriate to start therapy with topical agents for initial or recurrent episodes of OPC, provided that clinical symptoms are not severe and that there is minimal risk of esophageal involvement.[42,48] Clinical responses with the resolution of signs and symptoms generally occur within 5 to 7 days of initiating treatment. Clotrimazole appears to be the most effective topical agent and demonstrates comparable clinical response rates with both fluconazole and itraconazole.[42,48] However, topical therapy is associated with more frequent relapses than with fluconazole.[44,48] This may be of limited clinical significance in patients receiving effective HAART because of their decreased susceptibility to opportunistic infection. In practice, nystatin suspension is still used frequently in initial episodes of OPC, although it is the least effective agent and is associated with frequent treatment failures and early relapses, especially in patients with advanced HIV disease or neutropenia.[39,43] Miconazole mucoadhesive tablets (MMT) 50 mg once daily was noninferior to clotrimazole troches 10 mg five times daily for the treatment of OPC in HIV infected patients (61% vs 65%, respectively for intention to treat cure rate), (68% vs 74%, respectively per protocol) populations at the test of cure visit. Safety and tolerability was also similar between treatment groups.[51]

Systemic oral azoles should be reserved for use in the more severe episodes of OPC unresponsive to topical agents or in patients with concurrent esophageal involvement.[43,48] In clinical practice, fluconazole usually is the systemic azole agent of choice because of its proven efficacy, favorable absorption, safety, and drug-interaction profiles, and it is relatively inexpensive. Fluconazole is superior to ketoconazole and itraconazole capsules.[42,48] A fluconazole regimen of 100 to 200 mg/day for 7 to 14 days is recommended.[48] A single dose of fluconazole 750 mg orally is as effective as fluconazole 150 mg orally for 14 days, which warrants further evaluation, given the potential advantages of adherence and cost-effectiveness.[52] Itraconazole oral solution with an improved absorption profile compared with the capsule formulation is as effective as fluconazole, with comparable clinical and mycologic response and relapse rates.[43,48] However, it carries a higher risk of drug interactions because it is a potent inhibitor of the cytochrome P450 (CYP) enzymes, and it is associated with more nausea than fluconazole. Posaconazole is an extended-spectrum triazole with potent in vitro activity against both *C. albicans* and non-*C. albicans* species. It is equivalent to fluconazole in terms of efficacy, safety, and tolerability.[53] Posaconazole has joined itraconazole solution and voriconazole as the azole alternatives to fluconazole in the management of moderate-to-severe OPC.[47] Other agents that are effective are amphotericin B and the echinocandins (caspofungin, micafungin, and anidulafungin). They are better reserved for refractory OPC, however, because of their greater toxicity. They are also more expensive and are less convenient to use.

Oropharyngeal Candidiasis: Non-Human Immunodeficiency Virus-Infected Patients

This patient population includes patients with hematologic malignancy (eg, leukemias) or blood and bone marrow transplantation (BMT) with a long duration of neutropenia and chronic graft-versus-host disease, patients with solid tumors, patients with solid-organ transplants who are receiving immunosuppressive therapy, and patients with diabetes mellitus, as well as patients on prolonged courses of antibiotics or corticosteroids and the debilitated elderly. Factors to consider in deciding whether to use topical or systemic antifungal therapy include the severity and extent of mucosal involvement (oropharyngeal vs esophageal), predisposing risk factors, and risk for dissemination. Patients who develop neutropenia (eg, leukemic and BMT patients) are usually at high risk for disseminated and invasive fungal disease, and treatment of oral candidiasis is more aggressive. Patients with cell-mediated immune deficits but normal or near-normal granulocyte function and number (eg, solid tumors, solid-organ transplants, or diabetic patients) are at low risk for dissemination of infection.

Specific antifungal therapy can be unnecessary for asymptomatic patients at relatively low risk for disseminated candidiasis, such as those who are not granulocytopenic or who are expected to have a short duration of granulocytopenia.[43] Many of these infections will clear spontaneously after recovery of the granulocytes or discontinuation of antibiotic and/or immunosuppressive therapy. However, antifungal therapy usually is required for patients who have persistent infection or significant symptoms, usually pain, or who are granulocytopenic with a relatively high risk of fungal dissemination. Topical agents can be given a first therapeutic trial depending on the severity of infection and the degree of immunosuppression.

Although both nystatin and clotrimazole can be effective in treating OPC, nystatin suspension does not effectively reduce the incidence of either oropharyngeal or systemic *Candida* infections in immunocompromised patients receiving chemotherapy or radiation; its use often is associated with treatment failures and early relapses.[48] Clotrimazole appears to be more effective in reducing colonization and treating acute episodes in cancer patients who are immunocompromised. MMTs were superior to miconazole oral gel in achieving a complete response in patients with head and neck cancer.[55] MMT has not been studied against clotrimazole in this patient population specifically but is approved for use in adults with OPC.

Systemic azole agents are used for treating OPC in patients who have failed or who are unable to take topical therapy.[43,48,53] The preceding discussion on the relative efficacy of fluconazole, itraconazole, and ketoconazole in HIV-infected patients can be extrapolated to the non-HIV-infected population. Oral fluconazole 100 to 200 mg daily is used more commonly because of more extensive experience with its use, and it is more effective and has a more favorable absorption and side-effect profile compared with other available azoles.[48] If the oral route is not feasible for reasons such as severe chemotherapy-induced mucositis, fluconazole can be administered IV. In patients unresponsive to azoles, IV amphotericin B in relatively low doses of 0.1 to 0.3 mg/kg/day can be tried.[48] Because of the higher risk for dissemination in patients who are severely neutropenic (less than 0.1×10^9 neutrophils/L) or clinically unstable (hypotensive or febrile), some clinicians prefer to initiate therapy with IV amphotericin B at 0.6 mg/kg/day, with therapy continued until the neutropenia has resolved or an echinocandin.[48] The echinocandins caspofungin, micafungin, and anidulafungin have all been found to be effective for treatment of OPC, thus offering another option, with fewer adverse effects in the patient with refractory disease.[48]

Topical therapy with clotrimazole or nystatin for 7 days is usually adequate for treating mucocutaneous candidiasis in most solid-organ transplant patients.[43] Use of topical therapy will reduce the number of systemic drugs that these patients receive and hence minimize the risk of drug–drug interactions. Failure to respond to topical agents warrants the use of fluconazole. Low-dose amphotericin B solution as "swish and swallow" (100 mg/mL, 1 mL four times daily) for 7 to 10 days is reserved for the unusual cases of treatment failure.

Patients who develop OPC because of prolonged antibiotic use or aerosolized corticosteroids use can be managed successfully by discontinuation of the offending agent, and the infection usually will resolve. If there is a strong desire to treat because of discomfort or need to hasten symptom resolution or an inability to stop the offending agent, therapy with a topical agent, either miconazole MT, clotrimazole or nystatin, is effective in most cases. The advantage of systemic azoles is the convenience of less frequent dosing. Symptoms usually improve in 3 or 4 days. Infants should be given smaller amounts more frequently (eg, nystatin 100,000 units every 2-3 hours) to ensure better contact time. For denture-related OPC, or candidal stomatitis, effective therapy requires treatment of both the mouth and the dentures to avoid relapse. The dentures must be brushed vigorously and disinfected every night by soaking in antiseptic solution, such as chlorhexidine gluconate 0.25% or a product such as Polident or Efferdent.[43,48] Topical antifungal therapy of the oral cavity is required. Consistent proper oral hygiene and care of the dentures can help prevent relapse.

Esophageal Candidiasis: Human Immunodeficiency Virus-Infected Patients

6 Treatment of esophageal candidiasis has not been as well studied as OPC. Because of the significant morbidity of esophageal candidiasis and the absence of evidence supporting the efficacy of topical antifungals, treatment requires systemic antifungal agents.[3] Fluconazole is superior to ketoconazole and itraconazole capsules with respect to endoscopic cure and clinical response and usually produces a more rapid onset of action and resolution of symptoms. Fluconazole is as effective as itraconazole solution, with reported response rates of greater than 80% to 90%.[39,43] However, itraconazole solution causes more nausea and drug interactions because of inhibition of the CYP enzymes. Amphotericin B, voriconazole, posaconazole, and the echinocandins are also effective in esophageal candidiasis, but they are generally reserved for patients with advanced or inadequately controlled HIV disease where the candidiasis tends to recur or becomes refractory to azole therapy.[56-59]

Esophageal Candidiasis: Non-Human Immunodeficiency Virus-Infected Patients

As in the case of HIV-infected patients, treatment of esophageal candidiasis requires systemic therapy. Patients can be started on fluconazole 200 to 400 mg/day for 14 to 21 days.[48] Higher fluconazole doses (up to 400 mg/day) have been suggested for patients with severe symptoms or those who are neutropenic.[60] Other agents currently recommended if fluconazole is not an option are an echinocandin or amphotericin B at 0.3 to 0.7 mg/kg. Itraconazole solution, posaconazole, and voriconazole are effective alternatives that may be considered for those not responding adequately to fluconazole. An echinocandin or IV amphotericin B may be selected over fluconazole for initial therapy in neutropenic patients who present with severe symptoms or who are at high risk for dissemination of *Candida* species, such as those receiving other aggressive immunosuppressive therapy (eg, corticosteroids, total-body irradiation, or antithymocyte globulin) and who have documented evidence of esophageal candidiasis or who have failed an initial empirical trial of oral nonabsorbable agents or systemic azoles.[48] Therapy should be continued at least until the neutropenia resolves. For patients whose symptoms have resolved and who are afebrile and clinically stable, therapy should be discontinued, and the patients should be monitored closely for infection recurrence. In high-risk patients, particularly those with persistent fever and neutropenia, the potential presence of clinically occult, diffuse GI or disseminated candidiasis should be considered. The echinocandins and newer azole agents (voriconazole and posaconazole) offer less toxic alternatives or oral agents and are preferred in patients who are intolerant of amphotericin B deoxycholate or who have preexisting renal impairment.[43,60,61] There are limited data on the clinical efficacy of anidulafungin compared with fluconazole, 95% versus 89% cure rates, respectively, in the non-HIV-infected patients.[60]

Antifungal-Refractory Oral Mucosal Candidiasis

Treatment failure is generally defined as persistence of signs and symptoms of OPC or esophageal candidiasis after an appropriate trial of antifungal therapy.[42] Treatment of refractory oral mucosal candidiasis is frequently unsatisfactory, and clinical response is usually short-lived, with rapid and periodic recurrences. The key risk factors for occurrence of refractory candidiasis are advanced stage of AIDS with low CD4 cell counts (less than 50 cells/mm^3 [less than 0.05×10^9/L]) and repeated or prolonged courses of various systemic antifungal agents, in particular systemic azoles.[43,48] Frequent or prolonged use of fluconazole can be associated with fluconazole-refractory candidiasis because of selection of more resistant non-*C. albicans* species. An important initial management strategy is to assess and optimize the antiretroviral therapy of the patient with refractory OPC to help improve the immune function. With the widespread use of HAART, fluconazole-refractory OPC is now less commonly encountered. It is also important to identify and rectify potentially correctable causes of clinical failures of mucosal candidiasis, such as poor drug adherence, adequate dosing, reduced drug absorption associated with hypochlorhydria, and drug–drug interactions.

There have been few controlled studies that assess the effectiveness of antifungal agents. Doubling of the fluconazole dosage to 400 or 800 mg/day can be effective in some patients with infection caused by *Candida* species of intermediate resistance, although the response may be only transient.[44] Fluconazole oral suspension can be beneficial in some patients because of increased salivary concentrations obtained when the suspension is taken with the swish and swallow technique.[48] Patients with fluconazole-refractory mucosal candidiasis can be treated with itraconazole oral suspension because it can be effective in 64% to 80% of patients; however, the benefit is short-lived if chronic suppressive therapy is not maintained.[42,48] Posaconazole suspension has been reported to be successful in ~74% of patients with refractory oral or esophageal candidiasis; voriconazole may also be efficacious in these patients. Amphotericin B oral suspension is another alternative for azole-refractory patients.[44,48] It has broad-spectrum activity against many fungal species and low likelihood of *Candida* species resistance. There are limited data and experience on its use in immunosuppressed patients, and results from small studies have yielded mixed results.[62] Amphotericin B suspension is no longer available commercially in the United States, but it can be prepared extemporaneously by the pharmacy.[62]

Clinical **Controversy...**

There are several alternatives to fluconazole refractory candidiasis, no drug of choice has been definitively identified, selection will depend on disease severity, route of administration effect on cytochrome P450 enzymes and side effect profile.

Until recently, IV amphotericin B deoxycholate has been the alternative for patients with endoscopically proven disease who have failed fluconazole or itraconazole therapy. Patients with severe disease unresponsive to other agents require IV amphotericin B 0.3 to 0.7 mg/kg/day for 7 to 10 days to achieve clinical response; higher dose or longer treatment duration can be needed in more severe disease.[44,48] After response, suppressive therapy with amphotericin B is required to increase disease-free intervals. Patients who fail to respond to amphotericin B and require greater than 1 mg/kg/day might be candidates for liposomal amphotericin B preparations because of renal and/or bone marrow toxicities, although at a markedly higher cost. Flucytosine usually is not used as monotherapy because of rapid development of resistance but can be used in combination with an azole or amphotericin B.[44] Less toxic agents that are also effective are voriconazole and the echinocandins.[60,61] Voriconazole, a triazole antifungal available in both oral and IV preparations, appears to be as effective as fluconazole for esophageal candidiasis, and it has shown success in treatment of fluconazole-refractory disease.[59] However, voriconazole has more side effects and multiple pharmacokinetic drug interactions compared to fluconazole.[59] Caspofungin, micafungin, and anidulafungin are approved for this indication. All three echinocandins have similar efficacy and tolerability profile as fluconazole, although caspofungin and anidulafungin have higher relapse rates compared with fluconazole.[48,61] Because the echinocandins require IV administration and are expensive, they are primarily used in patients who are refractory to the triazoles or have serious triazole-related adverse effects. As a class, the echinocandins have a favorable adverse effect profile. They are less toxic than amphotericin B (see Table 120-6) and have less impact on the CYP enzymes than either itraconazole or voriconazole. Immunomodulation with adjunctive granulocyte-macrophage colony-stimulating factor and interferon have been used for refractory oral candidiasis in very limited numbers of patients.[48]

Antifungal Prophylaxis

7 Ensuring that the HIV-infected patient is receiving appropriate antiretroviral therapy to enhance the immune system is perhaps the most important measure in preventing future episodes of mucosal candidiasis (oropharyngeal, esophageal, and vulvovaginal).[48] Initial success of treatment often is followed by symptomatic recurrences, especially in patients with advanced or poorly controlled HIV disease. Long-term suppressive therapy with fluconazole is effective in preventing recurrences or new infections of OPC in HIV disease and in patients with cancer.[48] However, the indications for antifungal prophylaxis and the best long-term management strategy still have not been well established. Fluconazole does not provide complete protection, and breakthrough infections can occur.[44] The reduced risk of recurrence of OPC also has not been demonstrated to improve survival. In addition, chronic exposure to azole therapy is a concern in that it might lead to the development of refractory disease or emergence of azole resistance.[48] However, in a randomized trial of continuous versus episodic fluconazole therapy, continuous therapy did not result in a higher rate of refractory OPC or esophageal disease.[63] HIV specialists do not recommend primary or secondary prophylaxis for OPC.[44] The rationale includes effectiveness of therapy for acute episodes of OPC, low incidence of serious invasive fungal disease, low mortality associated with mucosal candidiasis, potential for drug interactions, potential for emergence of drug resistance, and the prohibitive long-term cost of prophylaxis.

8 The decision to use secondary prophylaxis should be individualized for each patient. Secondary prophylaxis can be considered in patients with multiple recurrent episodes of symptomatic OPC or when the disease is sufficiently severe and affecting the quality of life.[44] Patients with a history of one or more episodes of documented esophageal candidiasis and a CD4 T-cell count still less than 200 cells/mm^3 (less than 0.2×10^9/L) despite being on HAART are candidates for secondary prophylaxis. Oral fluconazole 100 mg daily is the usual regimen recommended for OPC and esophageal candidiasis,[44,48] although 200 mg three times weekly also appears to be effective.[63] Once-weekly oral fluconazole (200 mg) is also effective for preventing OPC recurrences in those with less-advanced AIDS.[44] Itraconazole solution 200 mg daily orally is an alternative as suppressive therapy for OPC.[48]

Patients with malignant neoplastic diseases who are receiving irradiation, cytotoxic, and/or immunosuppressive therapy are at high risk for fungal infections in addition to bacterial and viral infections. Prophylaxis of *Candida* infection is controversial, and the results of studies have been conflicting and difficult to evaluate. In the hematopoietic stem cell transplant (HSCT) population, fluconazole prophylaxis is recommended prior to engraftment. Cross-resistance to other azoles may occur among *Candida* species; this should be a treatment consideration in a patient who develops a breakthrough fungal infection. Micafungin is an alternative to fluconazole prophylaxis of candidiasis.[64] The value of antifungal prophylaxis in these patients needs to be considered in the broader context of not only reducing colonization and the risk of superficial candidiasis but also, more importantly, reducing the risk for invasive candidiasis and improving survival. Management of these infections in this patient population is discussed further in Chapter 100.

Evaluation of Therapeutic Outcomes

Efficacy end points for oropharyngeal and esophageal candidiasis include rapid relief of symptoms and prevention of complications without early relapse after completion of the course of therapy.[44,48] Sterilization of the oral cavity is not a feasible end point because mycologic eradication is rarely achievable, especially in HIV-positive patients. Symptomatic relief of presenting signs and symptoms (see Table 120-5) generally occurs within 48 to 72 hours of starting therapy, with complete resolution by 7 to 10 days. Patients should be

TABLE 120-7 Patient Counseling Tips for Managing Oropharyngeal Candidiasis

1. Clean the oral cavity prior to administering the topical antifungal agent. Daily fluoride rinses can help reduce the risk of caries when using an agent containing sucrose or dextrose.
2. Use the topical antifungal agent after meals, as saliva flow and mouth movements can reduce the contact time.
3. Troches should be slowly dissolved in the mouth, not chewed or swallowed whole, over 15-20 minutes, and the saliva swallowed.
4. Suspension should be swished around the mouth in the oral cavity to cover all areas for as long as possible, ideally at least 1 minute, then gargled and swallowed.
5. Remove dentures while medication is being applied to the oral tissues.
6. Use a suspension or buccal mucoadhesive tablet instead of a troche if xerostomia is present; if a troche is preferred, the patient should rinse or drink water prior to dosing. For xerostomia, suggest nonpharmacologic measures for symptomatic relief (eg, ice chips, sugarless gum or hard candy, citrus beverages).
7. Dentures should be removed and disinfected overnight using an antiseptic solution (eg, chlorhexidine 0.12%-0.2%). Disinfect oral tissues in addition to dental prosthesis.
8. Complete treatment course even though symptomatic improvement can occur in 48-72 hours.
9. Maintain good oral hygiene. Brush teeth daily (twice daily) and floss, rinse mouth, or brush teeth after eating sweets.
10. Stop smoking; avoid alcohol.

Data from reference 52.

advised about the time course and told to return for reassessment when signs and symptoms recur. It is usually unnecessary for the patient to be reassessed soon after finishing the treatment course. However, HIV patients should be questioned and examined for the occurrence of mucosal candidiasis as part of their regular follow-up. The frequency of monitoring can be more often in neutropenic patients because of concern for dissemination of candidiasis. During the period of neutropenia, temperature should be monitored daily, as well as signs of dissemination.

Efficacy of the antifungal agent is partly influenced by patient adherence to the medication regimen. Patients must be counseled on proper administration and dosing, in particular for topical agents (Table 120-7).[60] Safety end points include monitoring for occurrence of the relevant drug side effects and drug interactions (see Table 120-6). Mild GI intolerance can occur with topical therapy, but serious adverse effects are rare. It is still prudent to monitor for hypersensitivity reactions, especially rash and pruritus that might occur with any medication. GI intolerance is more associated with the oral azoles. Hepatotoxicity can occur when azole therapy is prolonged beyond 7 to 10 days or high doses are used. Periodic monitoring of liver enzymes (alanine transaminase and aspartate amino-transferase) should be considered, especially if prolonged therapy (longer than 21 days) is anticipated. Patients who are receiving IV amphotericin B require daily monitoring by a pharmacist.

MYCOTIC INFECTIONS OF THE SKIN, HAIR, AND NAILS

Superficial cutaneous mycoses affect up to 20% to 25% of the global population.[65] The usual pathogens are the dermatophytes classified by genera: *Trichophyton*, *Epidermophyton*, and *Microsporum*. Less frequently infection is caused by nondermatophyte fungi (eg, *Malassezia furfur*) and Candida species. Dermatophytes have the ability to penetrate keratinous structures of the body and therefore infections are limited to hair, nails and skin. These infections affect both male and female genders and all races. Reservoirs of mycotic infections include humans, animals, and soil.[65,66] Individuals can develop an infection if they come in contact with a reservoir in addition to having a conducive environment for mycotic growth (ie, moist conditions).[67] Risk factors for the development of an infection include prolonged exposure to sweat or soaking in water, maceration, intertriginous folds, sharing personal belongings such as combs, close living quarters (dormitories, barracks).[66,67]

Mycotic infections of the skin have a classic appearance that consists of a central clearing surrounded by an advancing red, scaly, elevated border, also referred to as an "active" border.[67,68] The central clearing of the lesion may distinguish dermatophytoses from other skin eruptions such as psoriasis or lichen planus which have a more uniform inflammatory presentation.[68] Infections of the nail can appear chalky and dull yellow or white and become brittle and crumbly.

Diagnosis usually is based on patient history, as well as the physical examination.[69] Diagnostic tests include direct microscopic examination of a specimen after the addition of KOH or fungal cultures. The KOH test is quick, inexpensive, and easy to perform, whereas cultures are more expensive and take longer to obtain results. Diagnostic tests are recommended when systemic therapy is likely to be prescribed.[69]

9 A general approach to treatment of superficial mycotic infections includes keeping the infected area dry and clean and limiting exposure to the infected reservoir. Topical agents generally are considered to be first-line therapy for infections of the skin. Oral therapy is preferred when the infection is extensive or severe or when treating tinea capitis or onychomycosis. Table 120-8 lists specific treatments for each mycotic infection. Superficial mycotic infections are categorized by the pattern and site of infection.[66] The most commonly occurring infections in North America are detailed in the following sections.

Tinea Pedis

Tinea pedis is the most common dermatophytoses (affecting ~70% of adults). It is better known as "athlete's foot" and occurs in hot weather, with exposure to surface reservoirs (locker room floors), and with use of occlusive footwear.[67] Tinea pedis has three common presentations. The most common is the interdigital form which is characterized by fissuring, maceration and scaling of the spaces between the toes (most frequently the fourth and fifth toes). Patients often complain of itching and burning. The "moccasin-like" distribution presentation is usually caused by *Trichophyton* rubrum. In this form the plantar surface becomes chronically scaly and thickened with accompanying erythema of the soles, heels, and sides of the foot. The third presentation, vesiculobulous tinea pedis, is characterized by the formation of vesicles, pustules and occasionally bullae typically on the soles of the foot. Contact dermatitis, pustular psoriasis and eczema would be in the differential diagnosis. Disruption of skin integrity with tinea pedis is a risk factor for streptococcal cellulitis as a complication.[68] Treatment with topical therapy for 2 to 4 weeks often is adequate for mild infections; however, severe infections or involvement of the nails require oral therapy[67] (see Table 120-8). A new 2% gel formulation of naftifine has been approved by the FDA for the treatment of interdigital tinea pedis. In clinical trials of naftifine 2% gel for tinea pedis (interdigital and moccasin-type) found that there was continued improvement even after the therapy was completed with clinical and mycological cure rates increasing from 5.4% and 39.1%, respectively at the 2 weeks end of treatment time point to 21.5% and 62% at week 6.[70] This finding suggests a depot effect of naftifine gel which is supported by the results of studies demonstrating the epidermal level of naftifine at application site remains relatively constant over several weeks post-treatment.[71] Naftifine is not approved for moccasin-type tinea pedis but is the only agent formally studied for this indication in a randomized double-blind vehicle controlled trial. Naftifine 2% gel resulted in a complete cure rate at week 6 of 19.6% compared to 0.7% for vehicle treated patients. Treatment effectiveness at week 6 was 51% for the naftifine versus 6% for the vehicle group.[70] Luliconazole 1% cream once daily for 2 weeks was approved for the topical management of interdigital tinea pedis, tinea cruris and tinea corporis in patients 18 years or older. Similar to naftifine, luliconazole 1% cream

TABLE 120-8 Treatment of Mycoses of the Skin, Hair, and Nails

	Topical[a,b]	Oral[c]
Tinea pedis	Butenafine, daily Sertaconazole, twice daily Luliconazole daily Naftifine cream daily, gel daily	Fluconazole 150 mg 1 per week × 1-4 weeks
Tinea manuum	Ciclopirox, twice daily	Ketoconazole 200 mg daily × 4 weeks
Tinea cruris	Clotrimazole, twice daily Luliconazole, daily Naftifine cream daily,	Itraconazole 200-400 mg/day × 1 week
Tinea corporis	Econazole, daily Haloprogin, twice daily Ketoconazole cream, daily Luliconazole daily Miconazole, twice daily Naftifine cream, daily; Oxiconazole, twice daily Sulconazole, twice daily Terbinafine, twice daily Tolnaftate, twice daily Triacetin cream, solution, 3 times daily Undecylenic acid, various preparations: apply as directed	Terbinafine 250 mg/day × 2 weeks Fluconazole 150 mg once weekly × 4 weeks
Tinea capitis	Shampoo only in conjunction with oral therapy or for treatment of asymptomatic carriers	Terbinafine 250 mg/day × 4-8 weeks Fluconazole 150 mg/week × 4 weeks
Tinea barbae		Ketoconazole 200 mg daily × 4 weeks
	Ketoconazole twice weekly × 4 weeks Selenium sulfide daily × 2 weeks	Itraconazole 100-200 mg/day × 4-6 weeks Griseofulvin 500 mg/day × 4-6 weeks
Pityriasis versicolor	Clotrimazole, twice daily Econazole, daily Haloprogin, twice daily Ketoconazole, daily Miconazole, twice daily Oxiconazole cream only, twice daily Sulconazole, twice daily Tolnaftate, three times daily	Ketoconazole Fluconazole Itraconazole 200 mg daily × 3-7 days
Onychomycosis	Ciclopirox 8% nail lacquer: apply solution at night for up to 48 weeks (fingernails and toenails) Efinaconazole 10% topical solution daily for 48 weeks (toenails) Tavaborole 5% topical solution daily for 48 weeks (toenails)	Terbinafine 250 mg/day × 6 weeks (fingernail), 12 weeks (toenail) Itraconazole 200 mg twice daily × 1 week/month for 2 months (fingernail); 200 mg daily × 12 weeks (toenail) Fluconazole 50 mg daily or 300 mg once weekly for ≥6 months (fingernail) or 12 months (toenail)

[a]Other products are available, including combination products.

[b]Length of therapy depends on mycotic sensitivity and severity of infection.

[c]Only capsule formulation studied; give with food for increased absorption.

applied once daily for interdigital tinea pedis resulted in continued improvement even after therapy was completed.[72] Recurrence of infection occurs in up to 70% of individuals especially if there is concomitant onychomycosis. Prolonged treatment with either topical or systemic therapy may be required.[65,66] Other nonpharmacologic measures such as disinfecting footwear, avoidance of walking barefoot in public places, controlling hyperhidrosis, wearing absorbent socks and nonocclusive shoes should be advised.[67]

Tinea Manuum

Tinea manuum is a superficial fungal infection of one or infrequently both hands, and can involve the feet (tinea pedis). The infection presents with dry and hyperkeratotic palmar surface of the hand. The fingernails, when involved, may present with vesicles and scaling. Contact dermatitis, eczema, psoriasis and callus formation should be in the differential diagnosis.[68] Treatment of this infection is similar to tinea pedis (see Table 120-8). Emollients that contain lactic acid also can be useful.[65] Relapse or recurrence is frequent especially if tinea pedis or onychomycosis is present.[68]

Tinea Cruris

Tinea cruris is an infection of the proximal thighs and buttocks.[68] It is referred to as "jock itch" and is more common in males. Tinea cruris and tinea pedis often occur concurrently. High humidity and warm temperatures along with wet or tight-fitting clothes contribute to the development of tinea cruris. The scrotum and penis often are spared from infection. The lesions are red, scaling with raised borders. Pustules or vesicles and maceration are usually found along the active border. Itching and burning are the most common patient complaint. The differential diagnosis would include candida infection, erythrasma, mechanical intertrigo, psoriasis, and seborrheic dermatitis.[68] Treatment with topical therapy is recommended and should continue for 1 to 2 weeks after symptom resolution. Severe infections can require oral therapy (see Table 120-8). Relief of pruritus and burning can be facilitated by the use of short-term (2 or 3 days) topical steroids (2.5% hydrocortisone).[67] The feet of the patient should also be examined as a source of infection. Non-pharmacological measures such as keeping the area dry or avoiding prolonged exposure to moisture are important patient counselling points.[68]

Tinea Corporis

Tinea corporis, also known as ringworm, is an infection of the glabrous skin of the trunk, extremities, or face.[68] Lesions of tinea corporis may be singular or multiple and appear as round, scaly lesions with central clearing and a raised border with sharp margination.

The border may exhibit pustules. The degree of pruritis is variable. The differential diagnosis includes nummular eczema, contact dermatitis, psoriasis, pityriasis rosea, tinea versicolor, granuloma annulare and Lyme disease.[68] Prior use of topical corticosteroid preparations may alter the appearance such that the central clearing and raised borders are no longer apparent impacting diagnosis. Diagnosis should be confirmed with KOH examination of skin scrapings of the edge of the lesion. Therapy is similar to that for tinea pedis, tinea manuum, and tinea cruris (see Table 120-8). If the infection is very widespread systemic antifungal therapy may be necessary.[68]

Tinea Capitis

Tinea capitis is a mycotic infection involving the scalp, hair follicles, and adjacent skin that primarily affects children.[68,73] Approximately, 90% to 95% of tinea capitis cases are due to *Trichophyton tonsurans*. Inanimate objects such as hats, brushes, or pillowcases are often the source of transmission particularly in the setting of poor hygiene. Viable organisms can be recovered from shed hairs for up to a year.[68] The lesions are characterized by irregular, frequently well-demarcated areas of alopecia with scaling. The alopecia is a result of infected hairs breaking off a few millimeters from the scalp; sometimes called "black dot alopecia." A "kerion" is a sterile, inflammatory scalp mass, often accompanied with cervical and occipital lymphadenopathy, due to a cell-mediated immune response to the infecting pathogen and is another manifestation of tinea capitis. The differential diagnosis will be influenced by the appearance of the lesions. For lesions that are predominantly scaly in inflamed consider seborrheic dermatitis, atopic dermatitis or psoriasis. If alopecia is the primary presenting feature rule out alopecia areata, traction alopecia and trichotillomania (obsessive hair pulling). The diagnosis of tinea capitis can be made in children based on the presence of at least 3 clinical features: scalp scaling, scalp pruritis, occipital adenopathy and diffuse patchy or discrete alopecia.[74] However, given the broad differential diagnoses and the need for prolonged treatment required diagnosis should be confirmed with microscopic examination or fungal culture. Treatment should consist of oral therapy, as well as the cleaning of combs and brushes, which can be contaminated (see Table 120-8). Topical therapy will not penetrate into hair follicles. Daily shampooing is recommended for removal of scales. An antifungal shampoo (eg, selenium sulfide 1%, ketoconazole 2%) in addition to oral therapy is recommended to eliminate the shedding of viable spores.[75] Some children and adults can be asymptomatic carriers, thereby facilitating spread of the infection. Family members who culture positive for *T. tonsurans* should be treated with an antifungal shampoo (eg, ketoconazole, selenium sulfide, or povidone-iodine).[68]

Tinea Barbae

Tinea barbae affects the hairs and follicles of beards and mustaches of adult men and hirsute women.[68] Tinea barbae will present with scaling, follicular pustules and erythema. The differential diagnosis included bacterial folliculitis, contact dermatitis, perioral dermatitis, pseudofolliculitis barbae and herpes simplex. One clue to the diagnosis of tinea barbae is that hair removal with shaving is painless. Treatment is similar to that for tinea capitis (see Table 120-8). Removal of the beard or mustache is recommended.[67]

Pityriasis Versicolor

Hyper- and hypopigmented scaly patches characterize pityriasis versicolor, which is also known as *tinea versicolor*. It is caused by yeasts of the *Malassezia* genus which with the exception of *Malassezia pachydermatis*, are all lipophilic. The seborrheic areas (scalp, face, back and front of the trunk) of the human body are always colonized by one or more *Malassezia* spp., such as *M. globosa*, *M. sympodialis*, *M. sloffiae*, and *M. restricta* are the most common colonizers; *M. globosa* and *M. furfur* are most frequent clinical infection isolates. This is not considered a contagious infection given the source is normal flora. It is more common in adults and in areas with tropical ambient temperatures. The lesions are found on the trunk, face and extremities.[64] Lesions are described as well-demarcated and scaling thin plaques with various degrees of pigmentation. Most patients are asymptomatic or may complain of mild pruritis. Many are concerned about the cosmetic appearance and possible contagion.[76] Topical treatment usually is adequate unless there is extensive involvement, recurrent infections, or failure of topical therapy. Ketoconazole 2% shampoo was significantly more effective than selenium sulfide 2.5% shampoo (89% vs 35% cure rate).[77] Oral imidazole antifungal agents (ketoconazole, itraconazole, or fluconazole) are safe and effective options for oral therapy of extensive pityriasis versicolor. Recurrence of infection after cessation of treatment may be as high as 60% in the first year and 80% the second year. Suppressive maintenance therapy either orally or topically may be used in these cases although data is lacking to definitively identify the most optimal drug, dose or route.[76]

Onychomycosis (Tinea Unguium)

Onychomycosis is a fungal infection of the nail apparatus and is the most common single cause of nail dystrophy, affecting up to 8% of the general population and accounting for up to 50% of all nail problems.[78] Onychomycosis more commonly affects the toenails (2%-14% of adults), ~4 to 19 times more frequently than fingernails, with prevalence increasing with age.[78] This can be because of the slower growth of toenails (three times slower than fingernails), making it easier for fungi to establish infection. Onychomycosis has a significant impact on quality of life, both functional and psychosocial. In addition, the affected nails can disrupt the integrity of the surrounding skin, potentially increasing the risk of secondary bacterial infections.[78,79]

Onychomycosis is due to infection by dermatophytes (tinea unguium), yeasts and nondermatophyte fungi.[80] Dermatophytes are the most frequent causes of onychomycosis (~90% in toenail and ~50% in fingernail infections).[77] The dermatophytes responsible for causing >90% of cases of onychomycosis are *Trichophyton rubrum* (71%) and *Trichophyton mentagrophytes* (20%).[73] Less common fungi causing onychomycosis are the nondermatophytic molds (2.3%-11%) and yeasts (5.6%). *C. albicans* is the most commonly isolated yeast and typically affects fingernails rather than toenails.[77,81] Risk factors for dermatophytic onychomycosis are increasing age (especially older than 40 years), family history and genetic factors, immunodeficiency (eg, HIV, renal transplant, immunosuppressive therapy, and defective polymorphonuclear chemotaxis), diabetes mellitus, psoriasis, peripheral vascular disease, smoking, prevalence of tinea pedis, frequent nail trauma, and sporting activities such as swimming.[81,82] These risk factors also appear to apply to recurrence of onychomycosis. Mold onychomycosis does not seem to be associated with systemic or local predisposing factors, but there is a risk of systemic dissemination in immunosuppressed patients.[77] *Candida* onychomycosis seems to always occur in immunosuppressed patients.[81]

Onychomycosis can present in in a variety of clinical forms. The five major clinical patterns are i) lateral distal subungual onychomycosis (DLSO), ii) white superficial onychomycosis (WSO), iii) proximal subungual onychomycosis (PSO), iv) endonyx onychomycosis, and v) total dystrophic onychomycoisis (TDO).[78,79] In DSO, the most common type, the nail plate, the nail bed, and, in advanced cases, the matrix are all affected, and *T. rubrum* is the most common etiologic cause. The worst case of onychomycosis is progression of the infection to total dystrophic onychomycosis, characterized by almost complete destruction of the nail plate. WSO is usually caused by *T. mentagrophytes*, where the infection is localized to the surface of the nail plate. In PSO, the fungi

TABLE 120-9 Differential Diagnosis of Fungal Nail Infections

Diagnosis	Features Consistent with Diagnosis
Psoriasis	Nail pitting, rash elsewhere on body, family history of psoriasis
Lichen planus	Nail atrophy, scarring at proximal aspect of the nail
Periungual squamous cell carcinoma	Single nail affected, pain, warty nail fold change, or ooze from the edge of nail
Yellow nail syndrome	Multiple nails turn yellow, grow slowly, increased longitudinal and transverse curvature, intermittent pain and shedding, associated with chronic sinusitis, bronchiectasis, lymphedema
Trauma	Single nail affected, homogeneous alteration of nail color and altered shape of nail

Data from Reference 24.

TABLE 120-10 Factors That May Impact Treatment Decisions and Outcomes

- Type and severity of onychomycosis
- Causative organism—dermatophyte vs molds or yeast
- Infection of the finger vs toenail
- Extent of disease—involvement of matrix, one or two lateral edges, number of nails
- Thickness of nail plate
- Other sites of mycotic infection (palms, soles, toe webs)
- Other nail alterations affecting outcome (onycholysis, paronychia, dermatophytoma, etc.)
- Other nail diseases and symptoms
- Age and underlying medical conditions (diabetes, poor perfusion, immunocompromised)
- Drug interactions and adverse effects
- Cost of therapy

Data from references 67, 76, 78, and 79.

(usually *T. rubrum*) invade the nail through the proximal nail fold and spread to the nail plate and matrix. Although PSO is relatively uncommon in the general population, it occurs most frequently in severely immunocompromised patients and is often considered a marker for AIDS.[82,83] In endonyx onychomycosis the fungus directly invades the nail plate keratin instead of the nail plate margin.[78] Because of the multifactorial etiology of onychomycosis, it is important to differentiate onychomycosis from other causes of nail dystrophies (eg, psoriasis, lichen planus, chronic trauma, eczema, yellow nail syndrome, lamellar onychoschizia, periungual squamous cell carcinoma, malignant melanoma, and myxoid cyst) so that the patient receives appropriate therapy and is not subjected to prolonged treatment with unnecessary drugs.[79] Besides clinical history and physical examination, proper diagnosis of onychomycosis can include the combination of direct microscopy of scrapings from the appropriate nail area to look for fungal hyphae and fungal cultures, and, if necessary, histologic examination.[78,79,81] Table 120-9 provides a differential diagnosis for fungal nail diseases.[84]

TREATMENT

General Approach

Onychomycosis merits proper assessment and treatment consideration because it is a debilitating disease and can exert a negative impact on quality of life (eg, cosmetic and psychosocial effects, pain, discomfort, and decreased ambulation).[78,79] It is reasonable to not treat persons with minimal toenail involvement and no associated symptoms.[84] Although definitive data are lacking regarding the risk of progression of untreated disease, it can lead to complications such as cellulitis or reduced mobility, which can further compromise peripheral circulation in those with diabetes or peripheral vascular disease; additionally, infected nails can serve as a source of transmission of fungi to other areas of the body, as well as to other people, such as close household contacts, or in communal bathing places.[78,85] Treatment decisions should be made on an individual basis. The primary end point of treatment is eradication of the organism, with secondary end points being clinical cure and improvement. Assessment of clinical success (cure or improvement) requires follow-up for several months after the end of treatment because of the slow growth rate of nails, especially toenails (1 mm/mo).[78] Successful eradication of the fungus does not always result in normalization of the nails because they can have been dystrophic prior to infection. This can cause patient dissatisfaction, especially if this is not explained before starting treatment.[79] There are several factors that must be taken into account on a patient-by-patient basis to ensure appropriate treatment decisions (Table 120-10). The impact of patient adherence on the success of treatment cannot be overemphasized. Patients need to be educated about their disease, expectations of treatment, and prevention of recurrence, and various strategies have been suggested to improve treatment success.[79]

In general, onychomycosis of the toenail is more difficult to treat than fingernails, requires longer treatment duration, and is associated with a higher recurrence. The treatment options for onychomycosis include oral and topical therapies, mechanical or chemical nail avulsion, or a combination of these. Mechanical or chemical nail avulsion is used primarily as adjunct to oral therapy in patients with total dystrophic onychomycosis, in whom there is severe onycholysis and extensive nail thickening or longitudinal spikes. This is to enhance penetration of the antifungal agent to the entire nail plate and unit.[78,79,85]

Topical Therapy

Diffusion of topically applied drugs is impeded by the hard keratin and compact structure of the dorsal nail plate. The hydrophilic nature of the nail plate also inhibits absorption of most lipophilic molecules.[78]

10 Conventional topical antifungal products are available as creams, ointments, powders, and solutions. Because these formulations do not penetrate through the nail plate to the nail bed, they are most appropriately used when the nail plate has been removed.[80,85] Even then cure rates are still low and variable and are influenced by patient adherence.[80,81] Efinaconazole is a new triazole antifungal formulated as a topical solution with a novel applicator and tavaborole, a novel boron-based molecule that is the latest development in the management of onychomycosis.[85,86]

The most often recommended topical therapies for onychomycosis include amorolfine, ciclopirox, and the newer agents efinaconazole and tavaborole.[85] Amorolfine 5% and ciclopirox 8% solution (Penlac), are available as nail lacquers, the latter being the only one approved in the United States for the treatment of mild-to-moderate onychomycosis caused by *T. rubrum* without lunula involvement.[79,85] The volatile vehicle, used to deliver the drug, evaporates and leaves an occlusive film with a high drug concentration on the nail surface.[78,85] Ciclopirox, a hydroxypyridine, has a broad spectrum of antifungal activity (dermatophytes, *Candida* species, and some molds) and requires treatment for 1 year. Although ciclopirox was significantly better than vehicle alone, the mycologic cure rate was only 32% with ciclopirox versus 10% for vehicle alone after 48 weeks of treatment; the overall treatment cure (mycologic cure with 0%-10% involvement of the target nail) was 9% versus 0.9% for drug and vehicle, respectively.[85] Concomitant nail debridement accompanied treatment in most ciclopriox studies. Higher mycologic cure

rates of 45% to 65% have been reported in open-label trials involving 6 to 12 months of treatment.[86] Amorolfine appears to produce higher mycologic and treatment cure rates than ciclopirox but is not approved for use in the United States or Canada.[80,85] Efinaconazole is a triazole antifungal approved as a 10% topical solution for the treatment of DLSO. Efinaconazole was evaluated in two phase III randomized controlled trials enrolling adult patients with mild to moderate DLSO of the great toenail. Patients were treated with once daily administration for 48 weeks without concomitant nail debridement. At 4 weeks post-treatment there was significantly greater mycological cure rates in the eficonazole group (55.2%) versus the vehicle controls (16.8%).[86]

Tavaborole 5% solution is a novel boron-based antifungal agent approved for the treatment of toenail onychomycosis involving 20% to 60% of the nail without spikes and lunula involvement. Tavaborole 5% solution applied to the affected great toenail once daily for 48 weeks was compared to vehicle in two phase III trials. Complete cure was achieved in 6.5% of tavaborole treated patients versus 0.5% vehicle controls in trial 1 and 9.1% versus 1.5% respectively in trial 2. Mycologic cure rates were significantly higher with tavaborole compared to vehicle control at 31.1% and 35.9% versus 7.2% and 12.2% in trials 1 and 2, respectively.[87] Unfortunately no studies comparing any of the approved agents head to head have been conducted. Most experts consider topical therapy a feasible option when the infection is superficial involving the nail plate without matrix involvement, such as WSO, involves a partial area of the nail plate not exceeding 50% (owing to difficulty of applying treatment to the margin of the nail), is limited to a few (three or four) nails, is in the very early stages of DSO when infection is still confined to the distal edge of the nail, or when systemic therapy is contraindicated.[78,79] Combining topical therapy with debridement of the affected nail (thus diminishing the amount of nail requiring treatment) may increase the likelihood of successful treatment, although there is no strong supporting evidence and this practice has not been a consistent component of clinical trials.[84,85,86] Topical therapy is not associated with systemic adverse effects or drug interactions. Any adverse effect will be localized to the application site, such as mild erythema in the adjacent skin area.

Clinical **Controversy...**

Treatment of onychomycosis is associated with a high failure rate of 20% to 50%. There appears to be a sound pharmacologic rationale behind the use of topical therapy and concomitant nail debridement to improve overall efficacy. However, this approach had not been consistently employed in clinical trials making it unclear if nail debridement should be routinely performed nor is it possible to compare outcomes between studies that have included debridement to those that have not.

Systemic Therapy

Oral antifungal therapy is considered to be more effective than topical for treating onychomycosis. Terbinafine and itraconazole (capsule), the current first-line agents for treatment, have yielded higher efficacy rates using shorter treatment periods (generally 3 months or shorter) for toenail and fingernail onychomycosis compared with the traditional agents, such as griseofulvin and ketoconazole, which are rarely used nowadays. Terbinafine, an allylamine, exerts fungicidal activity and demonstrates the greatest in vitro activity against dermatophytes compared with the other oral antifungals; it has good activity against nondermatophyte molds and only marginal activity against *Candida* species.[78,85] Like other azoles, itraconazole is fungistatic, has a broad antifungal spectrum, and is very active against dermatophytes, nondermatophytes, and *Candida* species.[78] Both agents have lipophilic and keratinophilic properties, which explains their excellent penetration (appearing in the nail plate within days of treatment initiation) and accumulation in the nails, achieving concentrations far exceeding the minimal inhibitory concentration (MIC) of most dermatophytes. Nail terbinafine concentrations are detected within 1 week of starting therapy, whereas itraconazole can be detected 1 (fingernails) to 2 weeks (toenails) after starting therapy.[81] Both drugs are slowly eliminated from the nail, with effective drug concentrations persisting in nails for 30 to 36 weeks after completion of treatment with terbinafine and for 27 weeks with itraconazole.[83] The persistence of drug in the nails explains in part the long-term protection against relapses after the end of treatment and also permits use of intermittent (pulse) dosing.

The treatment of toenail onychomycosis requires a 12-week course, whereas a 6-week course is adequate for fingernail onychomycosis with either drug.[83,85] In general, cure rates of 80% to 90% for fingernail infection and 70% to 80% for toenail infection can be expected.[79] Terbinafine is approved for daily dosing (see Table 120-8).[79,83] Various terbinafine pulse regimens have been evaluated;[78] in some trials, pulse dosing was less effective than continuous dosing, and it did not provide clear safety advantages.[81] Pulse terbinafine had similar efficacy to continuous therapy had better outcomes compared with pulse itraconazole treatment.[88] Itraconazole pulse therapy is the preferred method over continuous dosing for fingernail infections, and it is licensed as twice-daily dosing for a 1-week cycle per month for 2 consecutive months (ie, two pulses), or as daily therapy for 6 weeks (see Table 120-8).[83] Although itraconazole pulse therapy is not approved by the U.S. Food and Drug Administration (FDA), three or four pulses are effective for toenail infections; otherwise, half the dose is taken daily for 3 months (see Table 120-8).[83] In addition to lower drug cost, the potential advantages of itraconazole pulse therapy compared with continuous therapy are a lower risk of adverse drug effects and improved patient adherence.

Terbinafine is generally considered by most experts as the first-line agent for onychomycosis; itraconazole is the alternative. It is more effective than itraconazole by continuous or pulse dosing.[78,79] Mycologic cure rates for terbinafine range from 77% to 100% depending on the study.[81,89,90] In a cumulative meta-analysis of randomized, controlled trials, mycologic cure rates for terbinafine, itraconazole pulse, itraconazole continuous, fluconazole, and griseofulvin were 76%, 63%, 59%, 60%, and 48%, respectively.[91] An earlier meta-analysis and systematic review also reported that continuous terbinafine was the most effective therapy for toenail onychomycosis.[91-93] In addition, terbinafine was reported to achieve high cure rates in high-risk immunosuppressed patients, such as diabetics and organ transplant recipients, comparable to the immunocompetent population, with no significant adverse effects or drug interactions. It also appears to be effective in HIV patients and nondermatophyte infections.[78,94] A pharmacoeconomic analysis of oral and topical (ciclopirox) therapies showed that from a managed-care perspective, terbinafine was the most cost-effective therapy in terms of highest success rate, lowest relapse rate, and highest number of disease-free days for both fingernail and toenail infections.[95] The cost per cure with the use of oral terbinafine (based on cure rates from clinical trials) ranged from $2,439 to $7,944, depending on disease severity.[96] Compared with the amount of money a patient would consider reasonable to spend on treatment, the current charges for a course of systemic therapy are considerably higher.[96,97]

Both terbinafine and itraconazole generally are well tolerated. The more common adverse effects reported with terbinafine are GI (eg, diarrhea, dyspepsia, nausea, and abdominal pain), dermatologic (eg, rash, urticaria, and pruritus), and headache; less common adverse effects are taste disturbances, fatigue, inability to concentrate, and asymptomatic liver enzyme abnormalities.[81,85] Terbinafine can cause transient decrease in absolute lymphocyte

counts; hence, monitoring of complete blood counts can be useful, especially in immunocompromised patients.[98] Although uncommon, severe adverse effects have been reported with terbinafine, including erythema multiforme, Stevens-Johnson's syndrome, toxic epidermal necrolysis, pancytopenia, lupus erythematosus, psoriasis, hair loss, and hepatotoxicity. Although the incidence of severe hepatotoxicity is considered rare, the FDA issued a public health advisory in 2001 regarding the association of terbinafine tablets with 16 possible cases of liver failure, including 2 liver transplants and 11 deaths.[99] Terbinafine thus is not recommended for patients with chronic or active liver disease, although hepatotoxicity can occur in patients with no preexisting liver disease or serious underlying medical condition. Prior to initiating terbinafine treatment, it is recommended to obtain appropriate nail specimens for laboratory testing to confirm the diagnosis of onychomycosis. Liver function parameters (serum transaminases) should be assessed at baseline and periodically during treatment with terbinafine.[98,99]

The common adverse effects of itraconazole are similar to those of terbinafine, such as GI disturbance, dermatologic disorders, and headache; less common adverse effects include dizziness, fatigue, fever, decreased libido, and asymptomatic liver enzyme abnormalities (1%-5% with continuous dosing and ~2% with pulse dosing).[83,100] Although still considered rare, 24 serious cases of liver failure, including transplantation and death, have been reported with the use of itraconazole, resulting in an FDA public health advisory warning.[99] Some of these patients did not have preexisting liver disease or serious underlying medical conditions, and some developed within the first week of treatment. Itraconazole should be avoided in patients with elevated liver enzymes or active liver disease or in those who have experienced other drug-induced liver toxicity. Liver function parameters (serum transaminases) should be assessed prior to and periodically during treatment. However, some experts have suggested that frequent monitoring is not as necessary if pulse therapy is used because symptomatic hepatotoxicity has not been reported with pulse therapy.[100] In addition, there is an FDA warning on the risk of developing congestive heart failure (CHF) associated with the use of itraconazole, possibly related to its potential negative inotropic effect.[78,89] Therefore, itraconazole should not be used in patients with evidence of ventricular dysfunction, such as CHF. Symptomatic assessment for the development of CHF also should be included as part of therapy monitoring. Before a patient is subjected to several months of itraconazole treatment, it is important to confirm the diagnosis of onychomycosis.

In contrast to the azoles, terbinafine does not inhibit the CYP 3A4 isoenzymes, but it is a potent inhibitor of the CYP2D6 isoenzymes, which are responsible for metabolism of tricyclic antidepressants and other psychotropic drugs.[78,83,98] The most significant drug interactions with terbinafine are decreased clearance of 33% by cimetidine and increased clearance of 100% by rifampin. Other drug interactions of variable clinical significance are tricyclic antidepressants, cyclosporine, caffeine, theophylline, and terfenadine. Itraconazole and its major metabolite can inhibit the CYP3A4 isoenzymes and result in numerous clinically significant drug interactions where coadministration with several drugs are contraindicated (eg, alprazolam, midazolam, triazolam, pimozide, lovastatin, simvastatin, cisapride, and terfenadine).[78,83,98]

Fluconazole is also active against dermatophytes, *Candida* species, and some nondermatophytes;[78,83] however, it does not have current FDA-approved indication for treatment of onychomycosis. The overall mycologic cure rate of fluconazole is 48%, which is lowest compared with all other oral agents.[91] The most effective dose and treatment duration have not been clearly established, with a variety of dosing regimens used, ranging from 50 mg daily to 300 mg once weekly for 6 to 12 months (see Table 120-8).[87,98] The advantages of fluconazole include a relatively good safety profile and fewer drug interactions compared with itraconazole.[83,98]

These three oral antifungal agents have superseded the use of griseofulvin and ketoconazole as treatments of choice for onychomycosis.[78,79] Griseofulvin has a narrow antifungal spectrum, low clinical efficacy, especially for toenail infections, high relapse rates, and the need for prolonged treatment duration (up to 12-18 months for toenails). Use of ketoconazole is also associated with high relapse rates, and the prolonged treatment duration carries an increased risk of hepatotoxicity.

Treatment Response and Recurrence

Treatment failures and recurrence rates of infection following initial cure are high, ranging from 20% to 50%.[78,79,84] Recurrence could be either a relapse (original infection not completely cured) or reinfection (new infection after achieving a cure of the original). Factors associated with poor response to systemic therapy include a compromised immune system (AIDS), reduced blood flow (diabetes, peripheral vascular disease, vasculitis, connective tissue disease, and CHF), coexisting nail disease (psoriasis), nail factors (slow growth, thick nails, and severe disease), drug-resistant organisms because of extensive prior drug exposure, and reduced bioavailability (absorption problems, poor compliance, and drug interactions).[83,84] To improve treatment outcomes and reduce recurrence, patients should be counseled on the importance of proper foot hygiene, for example, wearing breathable footwear and 100% cotton socks with frequent changes, keeping the nails short and clean, keeping the feet dry, protecting the feet in shared bathing areas, treating tinea pedis, and controlling other predisposing medical conditions.[84]

The use of combination therapy (topical–oral) has been suggested to provide antifungal synergy, broader antifungal spectrum, increased cure rates, suppression of resistant mutants and enhancement of tolerability and safety.[78] Combination therapy could shorten treatment duration of therapy, as this approach provides complementary mechanisms of attack.[78] Ciclopirox, amorolfine and topical imidazoles have all been studied in combination with systemic antifungal agents (eg, tioconazole 28% with griseofulvin 1 g for 1 year; amorolfine 5% with pulsed itraconazole; amorolfine 5% with oral terbiafine) and reported favorable results. Conversely, a study of combination amorolfine 5% or ciclopriox 8% nail lacquer with pulsed oral terbinafine did not offer any advantage over pulsed oral terbinafine monotherapy.[101] To date, no specific combination has been approved or endorsed for use.

Clinical **Controversy...**

The optimal dosing regimen of terbinafine therapy in onychomycosis remains unclear. Either continuous, or pulse therapy can be used, Selection should be based on cost and adherence to therapy.

121 Invasive Fungal Infections

Peggy L. Carver

KEY CONCEPTS

1. Systemic mycoses can be caused by pathogenic fungi and include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis, or infections by opportunistic fungi such as *Candida albicans*, *Aspergillus* species, *Trichosporon*, *Candida glabrata*, *Fusarium*, *Alternaria*, and *Mucor*.
2. The diagnosis of fungal infection generally is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens. Rapid, accurate diagnostic laboratory tests are currently under development.
3. Histoplasmosis is caused by *Histoplasma capsulatum* and is endemic in parts of the central United States along the Ohio and Mississippi River valleys. Although most patients experience asymptomatic infection, some can experience chronic, disseminated disease.
4. Asymptomatic patients with histoplasmosis are not treated, although patients who do not have acquired immune deficiency syndrome (AIDS) patients with evident disease are treated with either oral ketoconazole or IV amphotericin B; AIDS patients are treated with amphotericin B and then receive lifelong suppression.
5. Blastomycosis is caused by *Blastomyces dermatitidis*. In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment. However, consideration should be given to treating all infected individuals to prevent extrapulmonary dissemination. All persons with moderate to severe pneumonia, disseminated infection, or those who are immunocompromised require antifungal therapy.
6. Coccidioidomycosis is caused by *Coccidioides immitis* and is endemic in some parts of the southwestern United States. It can cause nonspecific symptoms, acute pneumonia, or chronic pulmonary or disseminated disease. Primary pulmonary disease (unless severe) frequently is not treated, whereas extrapulmonary disease is treated with amphotericin B, and meningitis is treated with fluconazole.
7. Cryptococcosis is caused by *Cryptococcus neoformans*, which occurs primarily in immunocompromised patients, and *Cryptococcus gattii*, which occurs primarily in nonimmunocompromised patients. Patients with acute meningitis are treated with amphotericin B with flucytosine. Patients infected with human immunodeficiency virus (HIV) often require long-term suppressive therapy with fluconazole or itraconazole.
8. A variety of *Candida* species (including *C. albicans*, *C. glabrata*, *Candida tropicalis*, *Candida parapsilosis*, and *Candida krusei*) can cause diseases such as mucocutaneous, oral, esophageal, vaginal, and hematogenous candidiasis, as well as candiduria. Candidemia can be treated with a variety of antifungal agents; the optimal choice depends on previous patient exposure to antifungal agents, potential drug interactions and toxicities of each agent, and local epidemiology of intensive care unit (ICU) or hematology–oncology centers.
9. Aspergillosis can be caused by a variety of *Aspergillus* species that can cause superficial infections, pneumonia, allergic bronchopulmonary aspergillosis (BPA), or invasive infection. Voriconazole has emerged as the drug of choice of most clinicians for primary therapy of most patients with invasive aspergillosis (IA). Combination therapy, while widely used, lacks clinical trial data to support its use.

1 Advances in medical technology including organ and bone marrow transplantation, cytotoxic chemotherapy, the widespread use of indwelling IV catheters, and the increased use of potent broad-spectrum antimicrobial agents all have contributed to the dramatic increase in the incidence of fungal infections worldwide.[1-3] Problems remain in the diagnosis, prevention, and treatment of fungal infections.[1,4-6] The Infectious Diseases Society of America (IDSA) publishes guidelines regarding the prophylaxis and treatment of many commonly encountered fungal infections.[7-12]

MYCOLOGY

Fungi are eukaryotic organisms with a defined nucleus enclosed by a nuclear membrane; a cytoplasmic membrane containing lipids, glycoproteins, and sterols, mitochondria, golgi apparatus, and ribosomes bound to endoplasmic reticulum; and a cytoskeleton with microtubules, microfilaments, and intermediate filaments. Fungi have rigid cell walls composed of chitin, cellulose, or both that stain with Gomori methenamine silver or periodic acid–Schiff reagent. Most fungi, except *Candida* species, are too weakly Gram-positive to be seen well on Gram stain. *Cryptococcus neoformans* has a polysaccharide capsule surrounding the cell wall.[1]

Morphologically, pathogenic fungi can be grouped as either filamentous molds or unicellular yeasts (Fig. 121-1). *Molds* grow as multicellular branching, threadlike filaments (hyphae) that are either septate (divided by transverse walls) or coenocytic (multinucleate without cross walls). Yeasts are oval or spherically shaped unicellular forms that generally produce pasty or mucoid colonies on agar medium similar to those observed with bacterial cultures. Yeasts have rigid cell walls and reproduce by budding, a process in which daughter cells arise from pinching off a portion of the parent cell.

Many pathogenic fungi, termed *dimorphic fungi*, exist as either a yeast or a mold, depending on pathogen, site of growth (in the host or in the laboratory setting), and temperature. Usually yeasts are the parasitic form that invades human or animal host tissue,

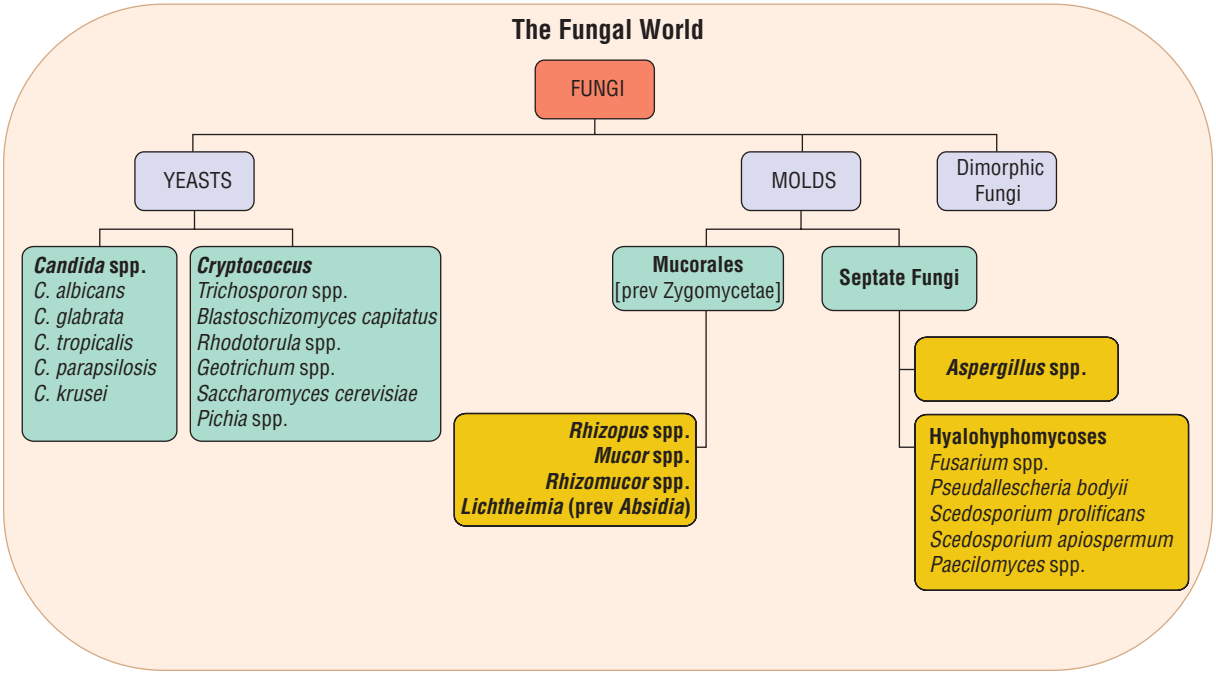

FIGURE 121-1 Morphologically, pathogenic fungi can be grouped as either filamentous molds or unicellular yeasts. *Molds* grow as multicellular branching, thread-like filaments (hyphae) that are either septate (divided by transverse walls) or coenocytic (multinucleate without cross walls).

whereas molds are the free-living form found in the environment. For example, *Histoplasma capsulatum* exists as a yeast in humans and as a mold in the laboratory.[1]

Clinical Versus Microbial Resistance

Host factors contribute greatly to clinical outcome. A patient may respond clinically to treatment with an antifungal agent despite resistance to that agent in vitro because the patient's own immune system may eradicate the infection, or the agent may reach the site of infection in high concentrations.[13] Thus, in vitro susceptibility does *not* necessarily equate with in vivo clinical success, and in vitro resistance might *not* always correlate with treatment failure.

It is important to distinguish between clinical resistance and microbial resistance. *Clinical resistance* refers to failure of an antifungal agent in the treatment of a fungal infection that arises from factors other than microbial resistance, such as failure of the antifungal agent to reach the site of infection or inability of a patient's immune system to eradicate a fungus whose growth is retarded by an antifungal agent.[13,14]

Microbial resistance can refer to *primary* or *secondary* resistance, as determined by in vitro susceptibility testing using standardized methodology. *Primary* or *intrinsic resistance* refers to resistance recorded prior to drug exposure in vitro or in vivo. *Secondary* or *acquired resistance* develops on exposure to an antifungal agent and can be either reversible, owing to transient adaptation, or acquired as a result of one or more genetic alterations. It is possible for a patient to respond clinically to treatment with an antifungal agent, despite resistance to that agent in vitro, because the patient's own immune system may eradicate the infection, or the agent reaches the site of infection in high concentrations.[6]

Susceptibility Testing of Antifungal Agents

Most laboratories do not routinely perform susceptibility tests on fungal isolates, but standardized methods for performing these tests are being developed and are now available for testing selected yeasts. As the prevalence of nosocomial and community-acquired fungal infections become more prominent, the need for in vitro susceptibility testing increases. Susceptibility testing occasionally is indicated, for example, in a patient with prolonged fungemia with a presumed susceptible isolate, and is most helpful in dealing with infections caused by non-*albicans* species of *Candida*.[5-7]

Clinical breakpoints (CBPs) are antimicrobial concentrations (MICs) obtained from susceptibility testing, which are used to define isolates as susceptible, intermediate, or resistant. No CBPs have been established for posaconazole or amphotericin B versus *Candida*, or for antifungal agents and filamentous fungi such as *Aspergillus*.[6] CBPs can be used to differentiate strains for which there is a high likelihood of treatment success (organisms which are clinically susceptible, or (S), from those for which treatment is more likely to fail (clinically resistant [R]). (Tables 121-1 and 121-2). A clinically intermediate (I) or susceptible dose-dependent (SDD) category can be assigned to pathogens for which the level of antimicrobial agent activity is associated with uncertain therapeutic effect, implying that infections due to the isolate may be appropriately treated in body sites where the drugs are physically concentrated or when a high dosage of drug can be used. Although CBPs are designed to guide therapy, they do not distinguish between fungal isolates with or without resistance mechanisms, nor do they always allow for early detection of resistant isolates. Table 121-3 shows the currently approved Interpretive CBPs for *Candida* species.

Resistance to Antifungal Agents

Understanding mechanisms of resistance is an important process in the optimization of antifungal therapy. The most exhaustive and definitive accounts of antifungal resistance have been described in *Candida* species, in particular *Candida albicans* and, to a lesser extent, *Candida glabrata*, *Candida tropicalis*, and *Candida krusei*, as well as in a few *C. neoformans* isolates.[13,14] *C. glabrata* isolates are increasingly resistant to both azole and echinocandin antifungal agents.

There are four different mechanisms that result in azole resistance: (a) mutations or upregulation of *ERG11* (an enzyme involved in the ergosterol biosynthesis pathway), (b) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation

TABLE 121-1 General Patterns of Susceptibility and Interpretive Breakpoints of *Candida* Species[a]

	Patterns of Susceptibility								
	Azoles			*Echinocandins*				*Amphotericin*	
***Candida* Species**	**Fluconazole**	**Itraconazole**	**Voriconazole**	**Posaconazole**	**Isavuconazole**	**Caspofungin**	**Micafungin**	**Anidulafungin**	**Amphotericin B**
C. albicans	+++ S	+++ S	+++ S	S	S	+++	+++	+++	+++
C. tropicalis	+++ S	+++ S	+++ S	+++ S	S	+++ S	+++ S	+++ S	+++ S
C. parapsilosis	S	S	S	S	S	S[d]	S[d]	S[d]	S
C. glabrata	++ S-DD to R[b]	++ S-DD to R[c]	++	S	S	S	S	S	S-I[e]
C. krusei	R	S-DD to R[c]	S	S	S	S	S	S	S-I[e]
C. lusitaniae	S	S	S	S	S	S	S	S	S to R[f]

For antifungal drugs and pathogens for which susceptibility breakpoints have been established (fluconazole, itraconazole, voriconazole): S, susceptible; S-DD, susceptible-dose dependent (see the text); I, intermediate; R, resistant; NA, not applicable (has not been established for this antifungal against this pathogen).

[a]Except for amphotericin B, interpretations are based on the use of a broth sensitivity test.

[b]Approximately 15% of C. glabrata isolates are resistant to fluconazole.

[c]Approximately 46% of C. glabrata isolates and 31% of C. krusei isolates are resistant to itraconazole.

[d]Most isolates of C. parapsilosis have reduced susceptibility to echinocandins.

[e]A significant proportion of C. glabrata and C. krusei isolates has reduced susceptibility to amphotericin B.

[f]Although frank resistance to amphotericin B is not observed in all isolates, it is well described for isolates of C. lusitaniae

within the fungal cell, (c) alteration of the structure or concentration of antifungal drug target proteins, and (d) alteration of membrane sterol proteins (Fig. 121-2). Although detailed analysis of each of the elucidated mechanism of resistance is beyond the scope this chapter, interested readers are referred to several recent publications which have comprehensively summarized this topic.[13,14]

The most commonly reported mechanisms of azole resistance among *C. albicans* isolates include reduced permeability of the fungal cell membrane to azoles, modification or overproduction of the target fungal enzymes (cytochrome P450, CYP) resulting in decreased binding of the azole to the target site, alterations in sterol synthesis, and activation of efflux pumps capable of actively pumping azoles from the target pathogen.

Fluconazole resistance is observed most frequently in *C. glabrata*, which may appear S-DD, or resistant, and in *C. krusei*, for which fluconazole resistance is universal.

Azole resistance among *Aspergillus* spp. (specifically *A. fumigatus*) is predominantly mediated by specific point mutations in TR/L98H in the CYP51A gene promoter region, causing amino acid changes and tandem repeats, and often results in cross-resistance with azole antifungals.

With the increase in echinocandin use, there has been an increase in the number of reports of echinocandin-resistant isolates from patients failing therapy. Echinocandin exposure and previous episodes of *C. glabrata* are predictors of FKS gene mutations in *Candida*.[15-17]

TABLE 121-2 General Patterns of In Vitro Susceptibility of Non-*Candida* Fungal Pathogens[a]

	Patterns of Susceptibility								
			Azoles			*Echinocandins*			*Amphotericin B*
Pathogen	**Fluconazole**	**Itraconazole**	**Voriconazole**	**Posaconazole**	**Isavuconazole**	**Caspofungin**	**Micafungin**	**Anidulafungin**	**Amphotericin B**
Aspergillus *A. fumigatus* *A. flavus* *A. terreus*	No No No	Yes Yes Yes	Yes Yes Yes	Yes Yes	Yes	Yes Yes Yes	Yes Yes	Yes Yes	Yes Yes No
Fusarium	No	No	Yes (but breakthrough infections are seen)	Conflicting data (species dependent)	Variable	No	No	No	Yes but occasional resistance
Scedosporium	No	No	Yes	Yes (apiospermum)	Variable	No	No	No	No
Zygomycetes[b]	No	No	No	Yes	Yes	No	No	No	Yes
Trichosporon	No	No	Yes	Yes	Yes	No	No	No	No
Cryptococcus	Yes	Yes	Yes	Yes	Yes	No	No	No	
Histoplasma	Yes	Yes	Yes	Yes	Yes	No[c]	No[c]	No[c]	Yes
Coccidioides	Yes	Yes	Yes	Yes	Yes	No[c]	No[c]	No[c]	Yes

[a]No = has minimal or no in vitro activity versus the pathogen; Yes = possesses adequate in vitro activity versus the pathogen.

[b]Includes *Rhizopus*, *Mucor*, and *Absidia* species.

[c]While the echinocandins display activity against the mycelial forms of endemic fungi such as *Histoplasma* spp., *Blastomyces* spp., and *Coccidioides* spp., they display significantly higher MIC values against the yeast forms of these organisms, and should not be used to treat these infections.

Data from references 6, 75, and 100.

TABLE 121-3 Clinical Breakpoints for Anole Antifungal Agents

	Interpretive Clinical Breakpoints[5,6]		
	Susceptible	**Susceptible-Dose Dependent**	**Resistant**
Fluconazole	***C. albicans*, *C. tropicalis*, and *C. parapsilosis***		
	≤2	4	≥8
	C. glabrata		
	—	≤32	≥64
	Susceptible	**Intermediate**	**Resistant**

	≤0.125	0.25-0.5	≥1
	C. krusei		
	≤0.5	1	≥2
Caspofungin Micafungin Anidulafungin	***C. albicans*, *C. tropicalis*, and *C. krusei***		
	≤0.25	0.5	≥1
	C. parapsilosis		
	≤2	4	≥8
Caspofungin Anidulafungin	***C. glabrata***		
	≤0.12	0.25	≥0.5
Micafungin	≤0.06	0.12	≥0.25
Posaconazole		Interpretive criteria have not been established	
Amphotericin B		Interpretive criteria have not been established	

Data from references 5 and 6.

Although, to date, the rate of amphotericin B resistance remains low, the exact incidence remains difficult to quantify and the response to antifungal agents difficult to characterize. As such, no consensus for therapy has been formulated at this time, although clinicians should keep in mind that *C. glabrata*, *Candida guilliermondii*, *C. krusei*, and *Candida lusitaniae* may have a higher propensity to developing resistance than other species.

Acquired resistance of *Aspergillus* species during long-term azole exposure to azoles, while still relatively uncommon, is emerging, and varies widely between geographic centers. Acquisition of primary-resistant isolates is also increasing, due to the agricultural use of azoles.[18,19] Cross-resistance of azole-resistant strains of *Aspergillus* to amphotericin B has not been described.

PATHOGENESIS AND EPIDEMIOLOGY

Systemic mycoses caused by primary or pathogenic fungi include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis. Primary pathogens can cause disease in both healthy and immunocompromised individuals, although disease generally is more severe or disseminated in the immunocompromised host. In contrast, mycoses caused by opportunistic fungi such as *C. albicans*, *Aspergillus* species, *Trichosporon*, *Torulopsis (Candida) glabrata*, *Fusarium*, *Alternaria*, and *Mucor* generally are found only in the immunocompromised host.[1]

Most fungal infections are acquired as a result of accidental inhalation of airborne conidia. For example, *H. capsulatum* is found in soil contaminated by bat, chicken, or starling excreta, and *C. neoformans* is associated with pigeon droppings. Although some fungi, including *C. albicans*, *C. neoformans*, and *Aspergillus* species, are ubiquitous pathogens with worldwide distribution, other fungi have regional distributions associated with specific geographic environments.[1]

IFIs are a major cause of morbidity and mortality in the immunocompromised patient.[20,21] In patients with hematologic malignancies and following hematopoietic stem cell transplantation (HSCT), there has been a shift in the most commonly encountered IFIs from *Candida* spp. to *Aspergillus* spp. *Candida* species (primarily *C. albicans*) are the fourth most commonly isolated bloodstream isolate and account for 78% of all nosocomial fungal infections.

Nosocomially acquired fungal infections can arise from either exogenous or endogenous flora. Endogenous flora can include normal commensal organisms of the skin, GI, genitourinary, or respiratory tract. *C. albicans* is found as a normal commensal of the GI tract in 20% to 30% of humans. A complex interplay of host and pathogen factors influences the acquisition and development of fungal infections. Intact skin or mucosal surfaces serve as primary barriers to infection. Alterations in the balance of normal flora caused by the use of antibiotics or alterations in nutritional status can allow the proliferation of fungi such as *Candida*, increasing the likelihood of systemic invasion and infection.[1]

Patients with decreased neutrophil counts or decreased neutrophil function are at higher risk of infections, particularly infections

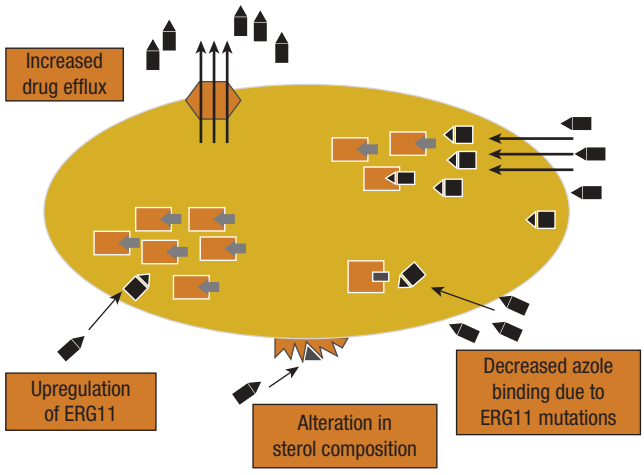

FIGURE 121-2 Mechanisms of azole resistance. Four different mechanisms result in azole resistance: (a) mutations or upregulation of *ERG11*, the target enzyme of azoles, (b) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation within the fungal cell, (c) alteration of the structure or concentration of antifungal drug target proteins, and (d) alteration of membrane sterol proteins.

caused by *Candida* and *Aspergillus* species. Fungal cells sometimes can persist within macrophages without being killed, perhaps because of resistance to the effects of lysosomal enzymes.[1]

Risk Factors for Fungal Infections

Increasing use of aggressive and intensive cancer chemotherapeutic regimens, immunosuppressive therapy for autoimmune disorders, and transplantation have led to an increase in the number of susceptible hosts, contributing to the changing epidemiology of fungal infections. Infection epidemiology can drastically vary depending on patients' underlying concomitant conditions, comorbidities, confounding risk factors and geographical area.

A clinical indicator for a patient's immunologic status is the quantitation of absolute neutrophil count (ANC). Neutropenia, defined as an ANC less than equal to 500/mm^3 (less than equal to 0.5×10^9/L), dramatically escalates the risk of acquiring and opportunistic infection. However, recent studies have demonstrated that the shift in fungemic pathogens occur in both neutropenic and nonneutropenic patients.

There is an increased prevalence of fungemia in the general in-patient setting and in critically-ill, neutropenic, and transplant patients.[22-26] Major risk factors for *Candida* blood stream infections (BSIs) in ICU patients include the use of central venous catheters (CVCs), receipt of multiple antibiotics or parenteral nutrition (PN), extensive surgery and burns, renal failure and hemodialysis, mechanical ventilation, and prior fungal colonization.[27]

Diagnosis and Rapid Diagnostic Tests

2 Traditionally, the diagnosis of invasive fungal infections (IFIs) is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens. While traditional direct microscopy, culture and histological techniques constitute the 'gold standard' for diagnosis, obtaining biopsies from sterile body sites for these studies is a highly invasive approach that may not be possible in severely ill patients. Also, histopathology lacks sensitivity and selectivity, as several filamentous fungi may exhibit undistinguishable morphologies. Further, the finding of a positive culture from a sterile site may indicate transient colonization and not true infection, especially for opportunistic fungi. Fungi may require special laboratory conditions, with additional time (up to 4 days) required in order to obtain species identification and the results of susceptibility testing. Some species, such as *C. glabrata*, tend to grow more slowly; initial identification of yeast from blood averages 100 hours (~4 days) in most institutions.[28] Several rapid, accurate diagnostic laboratory tests, including matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF), peptide nucleic acid (PNA) in situ hybridization (PNA-FISH), PCR, galactomannan, and T2 magnetic resonance assays, have been developed which have the potential to enhance sensitivity and speed of diagnosis of IFIs.[29,30]

New laboratory methods that allow for early differentiation of IFIs due to *Aspergillus* species versus zygomycetes and other moulds would be helpful in allowing clinicians in the earlier initiation of appropriate antifungal therapy. These underscore the need for rapid diagnosis and identification of clinically significant isolates to species level, and the need for susceptibility testing.[31]

TREATMENT
Invasive Mycoses

Strategies for the prevention or treatment of invasive mycoses can be classified broadly as prophylaxis, early empirical therapy, empirical therapy, and secondary prophylaxis or suppression.[1] In patients undergoing cytotoxic chemotherapy, antifungal therapy is directed primarily at the prevention or treatment of infections caused by *Candida* and *Aspergillus* species. Prophylactic therapy with topical, oral, or IV antifungal agents is administered prior to and throughout periods of granulocytopenia (absolute neutrophil count less than 1,000 cells/L [less than 1×10^9/L]). The potential benefits of prophylactic therapy must be weighed against the potential risks inherent in each regimen, including safety, efficacy, cost, the prevalence of infection, and the potential consequences (eg, resistance) of widespread use.

Early empirical therapy is the administration of systemic antifungal agents at the onset of fever and neutropenia. Empirical therapy with systemic antifungal agents is administered to granulocytopenic patients with persistent or recurrent fever despite the administration of appropriate antimicrobial therapy.

Secondary prophylaxis (or suppressive therapy) is the administration of systemic antifungal agents (generally prior to and throughout the period of granulocytopenia) to prevent relapse of a documented invasive fungal infection that was treated during a previous episode of granulocytopenia.

Although these treatment classifications also have been applied to the treatment of fungal infections in acquired immunodeficiency syndrome (AIDS), patients with AIDS rarely acquire systemic infections caused by *Candida* or *Aspergillus* species, unless they become granulocytopenic because of disease or drugs.

HISTOPLASMOSIS

In humans, histoplasmosis is caused by inhalation of dust-borne microconidia of the dimorphic fungus *H. capsulatum*. Although there exist two dimorphic varieties of *H. capsulatum*, the small-celled (2-5 microns) form (var. *capsulatum*) occurs globally, whereas the large-celled (8-15 microns) form (var. *duboisii*) is confined to the African continent and Madagascar. In tissues stained by conventional techniques, *H. capsulatum* appears as an oval or round, narrow-pore, budding, unencapsulated yeast.[32]

Epidemiology

3 Although histoplasmosis is found worldwide, certain areas of North and Central America are recognized as endemic areas. In the United States, most disease is localized along the Ohio and Mississippi River valleys, where more than 90% of residents may be affected. Precise reasons for this endemic distribution pattern are unknown but are thought to include moderate climate, humidity, and soil characteristics. *H. capsulatum* is found in nitrogen-enriched soils, particularly those heavily contaminated by avian or bat guano, which accelerates sporulation. Blackbird or pigeon roosts, chicken coops, and sites frequented by bats, such as caves, attics, or old buildings, serve as "microfoci" of infections; once contaminated, soils yield *Histoplasma* for many years. Although birds are not infected because of their high body temperature, bats (mammals) may be infected and can pass yeast forms in their feces, allowing the spread of *H. capsulatum* to new habitats. Air currents carry the spores for great distances, exposing individuals who were unaware of contact with the contaminated site.[32]

Pathophysiology

At ambient temperatures, *H. capsulatum* grows as a mold. The mycelial phase consists of septate branching hyphae with terminal micro- and macroconidia that range in size from 2 to 14 microns in diameter. When soil is disturbed, these conidia become aerosolized and reach the bronchioles or alveoli.[32]

Animal studies demonstrate that within 2 to 3 days after reaching lung tissue, the conidia germinate, releasing yeast forms that begin multiplying by binary fission. During the next 9 to 15 days, organisms are ingested but not destroyed by large numbers of

macrophages that are recruited to the infected site, resulting in small infiltrates. Infected macrophages migrate to the mediastinal lymph nodes and other sites within the mononuclear phagocyte system, particularly the spleen and liver. At this time, the onset of specific T-cell immunity in the nonimmune host activates the macrophages, rendering them capable of fungicidal activity. Tissue granulomas form, many of which develop central caseation and necrosis over the next 2 to 4 months. Over a period of several years, these foci become encapsulated and calcified, often with viable yeast trapped within the necrotic tissue.[32]

Cellular immunity, as measured by histoplasmin skin-test reactivity, wanes in the absence of occasional reexposure. Although exposure to heavy inocula can overcome these immune mechanisms, resulting in severe disease, reinfection occurs frequently in endemic areas. In the immune individual, the reactions of acquired immunity begin 24 to 48 hours after the appearance of yeast forms, resulting in milder forms of illness and little proliferation of organisms. Although viable organisms can be found within granulomas years after initial infection, the organisms appear to have little ability to proliferate within the fibrous capsules, except in immunocompromised patients.[32]

Clinical Presentation

The outcome of infection with *H. capsulatum* depends on a complex interplay of host, pathogen, and environmental factors.[10,32] Host factors include the degree of immunosuppression and the presence of immunity (from prior infection). Environmental factors include inoculum size, exposure within an enclosed area, and duration of exposure. Hematogenous dissemination from the lungs to other tissues probably occurs in all infected individuals during the first 2 weeks of infection before specific immunity has developed but is nonprogressive in most cases, which leads to the development of calcified granulomas of the liver and/or spleen. Progressive pulmonary infection is common in patients with underlying centrilobular emphysema.

Acute and chronic manifestations of histoplasmosis appear to result from unusual inflammatory or fibrotic responses to the pathogen, including pericarditis and rheumatologic syndromes during the first year after exposure, with chronic mediastinal inflammation or fibrosis, broncholithiasis, and enlarging parenchymal granulomas later in the course of disease.

Acute Pulmonary Histoplasmosis

In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in mild or asymptomatic pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Patients exposed to a higher inoculum during an acute primary infection or reinfection can experience an acute, self-limited illness with flu-like pulmonary symptoms, including fever, chills, headache, myalgia, and a nonproductive cough. Patients with diffuse pulmonary histoplasmosis can have diffuse radiographic involvement, become hypoxic, and require ventilatory support. A low percentage of patients present with arthritis, erythema nodosum, pericarditis, or mediastinal granuloma.

Chronic Pulmonary Histoplasmosis

Chronic pulmonary histoplasmosis generally presents as an opportunistic infection imposed on a preexisting structural abnormality, such as lesions resulting from emphysema. Patients demonstrate chronic pulmonary symptoms and apical lung lesions that progress with inflammation, calcified granulomas, and fibrosis. Patients with early, noncavitary disease often recover without treatment. Progression of disease over a period of years, seen in 25% to 30% of patients, is associated with cavitation, bronchopleural fistulas, extension to the other lung, pulmonary insufficiency, and often death.

Disseminated Histoplasmosis

In patients exposed to a large inoculum and in immunocompromised hosts, successful containment of the organism within macrophages may not occur, resulting in a progressive illness characterized by yeast-filled phagocytic cells and an inability to produce granulomas. This disease, termed *disseminated histoplasmosis*, is characterized by persistent parasitization of macrophages. The clinical severity of the diverse forms of disseminated histoplasmosis (**Table 121-4**) generally parallels the degree of macrophage parasitization observed.

Acute (infantile) disseminated histoplasmosis is characterized by massive involvement of the mononuclear phagocyte system by yeast-engorged macrophages. Classically, this severe type of infection is seen in infants and young children and (rarely) in adults with Hodgkin's disease or other lymphoproliferative disorders. In infants or children, acute disseminated histoplasmosis is characterized by unrelenting fever, anemia, leukopenia or thrombocytopenia, enlargement of the liver, spleen, and visceral lymph nodes, and GI symptoms, particularly nausea, vomiting, and diarrhea. The chest roentgenogram often demonstrates remnants of the initiating acute pulmonary lesion. Untreated disease is uniformly fatal in 1 to 2 months. A less severe "subacute" form of the disease, which occurs in both infants and immunocompetent adults, is characterized by focal destructive lesions in various organs, weight loss, weakness, fever, and malaise. Untreated disease generally is fatal in approximately 10 months.

Most adults with disseminated histoplasmosis demonstrate a mild, chronic form of the disease. Untreated patients often are ill for 10 to 20 years, demonstrating long asymptomatic periods interrupted by relapses of clinical illness characterized primarily by weight loss, weakness, and fatigue. Chronic disseminated histoplasmosis can be seen in patients with lymphoreticular neoplasms (Hodgkin's disease) and patients undergoing immunosuppressant chemotherapy for organ transplantation or for rheumatic diseases. Although CNS involvement occurs in 10% to 20% of patients with severe underlying immunosuppressive conditions, focal organ involvement is uncommon. The disease is characterized by the development of focal granulomatous lesions, often with bone marrow involvement resulting in thrombocytopenia, anemia, and leukemia. Fever, hepatosplenomegaly, and GI ulceration are common.

Histoplasmosis in HIV-Infected Patients

Adult patients with AIDS demonstrate an acute form of disseminated disease that resembles the syndrome seen in infants and children. Progressive disseminated histoplasmosis (PDH), which is defined as a clinical illness that does not improve after at least 3 weeks of observation and that is associated with physical or radiographic findings and/or laboratory evidence of involvement of extrapulmonary tissues, can occur as the direct result of initial infection or because of the reactivation of dormant foci. In endemic areas, 50% of AIDS patients demonstrate PDH as the first manifestation of their disease. PDH is characterized by fever (75% of patients), weight loss, chills, night sweats, enlargement of the spleen, liver, or lymph nodes, and anemia. Pulmonary symptoms occur in only one third of patients and do not always correlate with the presence of infiltrates on chest roentgenogram. A clinical syndrome resembling septicemia is seen in approximately 25% to 50% of patients.[10]

Diagnosis

The diagnosis of histoplasmosis is made on the basis of histopathology, cultures, antigen detection, and serologic tests for *Histoplasma*-specific antibodies. Detection of single, ovoid cells 2 to 5 microns in diameter with narrow-based budding by direct examination or by histologic study of blood smears or tissues should raise strong suspicion of infection with *H. capsulatum* because colonization does not occur as with

TABLE 121-4 Clinical Manifestations and Therapy of Histoplasmosis

Type of Disease and Common Clinical Manifestations	Approximate Frequency (%)[a]	Therapy/Comments
Nonimmunosuppressed Host		
Acute pulmonary histoplasmosis		
Asymptomatic or mild to moderate disease	50-99	*Asymptomatic, mild, or symptoms <4 weeks:* No therapy generally required. Itraconazole (200 mg three times daily for 3 days and then 200 mg once or twice daily for 6-12 weeks) is recommended for patients who continue to have symptoms for 11 months *Symptoms >4 weeks:* Itraconazole 200 mg once daily × 6-12 weeks[b]
Self-limited disease	1-50	*Self-limited disease:* Amphotericin B[c] 0.3-0.5 mg/kg/day × 2-4 weeks (total dose 500 mg) or ketoconazole 400 mg orally daily × 3-6 months can be beneficial in patients with severe hypoxia following inhalation of large inocula; antifungal therapy generally not useful for arthritis or pericarditis; NSAIDs or corticosteroids can be useful in some cases
Mediastinal granulomas	1-50	Most lesions resolve spontaneously; surgery or antifungal therapy with amphotericin B 40-50 mg/day × 2-3 weeks or itraconazole 400 mg/day orally × 6-12 months can be beneficial in some severe cases; mild to moderate disease can be treated with itraconazole for 6-12 months
Moderately severe to severe diffuse pulmonary disease		Lipid amphotericin B 3-5 mg/kg/day followed by itraconazole 200 mg twice daily for 3 days then twice daily for a total of 12 weeks of therapy; alternatively, in patients at low risk for nephrotoxicity, amphotericin B deoxycholate 0.7-1 mg/kg/day can be utilized; methylprednisolone (0.5-1 mg/kg daily IV) during the first 1-2 weeks of antifungal therapy is recommended for patients who develop respiratory complications, including hypoxemia or significant respiratory distress
Inflammatory/fibrotic disease	0.02	*Fibrosing mediastinitis:* The benefit of antifungal therapy (itraconazole 200 mg twice daily × 3 months) is controversial but should be considered, especially in patients with elevated ESR or CF titers ≤1:32; surgery can be of benefit if disease is detected early; late disease cannot respond to therapy *Sarcoid-like:* NSAIDs or corticosteroids[d] can be of benefit for some patients *Pericarditis:* Severe disease: corticosteroids 1 mg/kg/day or pericardial drainage procedure
Chronic cavitary pulmonary histoplasmosis	0.05	Antifungal therapy generally recommended for all patients to halt further lung destruction and reduce mortality *Mild–moderate disease:* Itraconazole 200 mg three times daily for 3 days and then one or two times daily for at least 1 year; some clinicians recommend therapy for 18-24 months due to the high rate of relapse; itraconazole plasma concentrations should be obtained after the patient has been receiving this agent for at least 2 weeks *Severe disease:* Amphotericin B 0.7 mg/kg/day for a minimum total dose of 25-35 mg/kg is effective in 59%-100% of cases and should be used in patients who require hospitalization or are unable to take itraconazole because of drug interactions, allergies, failure to absorb drug, or failure to improve clinically after a minimum of 12 weeks of itraconazole therapy
Histoplasma endocarditis		Amphotericin B (lipid formulations may be preferred, due to their lower rate of renal toxicity) plus a valve replacement is recommended; if the valve cannot be replaced, lifelong suppression with itraconazole is recommended
CNS histoplasmosis		Amphotericin B should be used as initial therapy (lipid formulations at 5 mg/kg/day, for a total dosage of 175 mg/kg may be preferred, due to their lower rate of renal toxicity) for 4-6 weeks, followed by an oral azole (fluconazole or itraconazole 200 mg two or three times daily) for at least a year; some patients may require lifelong therapy; response to therapy should be monitored by repeat lumbar punctures to assess *Histoplasma* antigen levels, WBC, and CF antibody titers; blood levels of itraconazole should be obtained to ensure adequate drug exposure
Immunosuppressed Host		
Disseminated histoplasmosis	0.02-0.05	*Disseminated histoplasmosis:* Untreated mortality 83%-93%; relapse 5%-23% in non-AIDS patients; therapy is recommended for all patients
Acute (Infantile)		*Nonimmunosuppressed patients:* Ketoconazole 400 mg/day orally × 6-12 months or amphotericin B 35 mg/kg IV
Subacute		*Immunosuppressed patients (non-AIDS) or endocarditis or CNS disease:* Amphotericin B >35 mg/kg × 3 months followed by fluconazole or itraconazole 200 mg orally twice daily × 12 months
Progressive histoplasmosis (immunocompetent patients and immunosuppressed patients without AIDS)		*Moderately severe to severe:* Liposomal amphotericin B (3 mg/kg daily), amphotericin B lipid complex (ABLC, 5 mg/kg daily), or deoxycholate amphotericin B (0.7-1 mg/kg daily) for 1-2 weeks, followed by itraconazole (200 mg twice daily for at least 12 months) *Mild to moderate:* Itraconazole (200 mg twice daily for at least 12 months)
Progressive disease of AIDS	25-50[e]	Amphotericin B 15-30 mg/kg (1-2 g over 4-10 weeks)[f] or itraconazole 200 mg three times daily for 3 days then twice daily for 12 weeks, followed by lifelong suppressive therapy with itraconazole 200-400 mg orally daily; although patients receiving secondary prophylaxis (chronic maintenance therapy) might be at low risk for recurrence of systemic mycosis when their $CD4^+$ T-lymphocyte counts increase to >100 cells/μL (>0.1 × 10^9/L) in response to HAART, the number of patients who have been evaluated is insufficient to warrant a recommendation to discontinue prophylaxis

AIDS, acquired immunodeficiency syndrome; CF, complement fixation; ESR, erythrocyte sedimentation rate; HAART, highly active antiretroviral therapy; NSAIDs, nonsteroidal antiinflammatory drugs; PO, orally.

[a]As a percentage of all patients presenting with histoplasmosis.

[b]Itraconazole plasma concentrations should be measured during the second week of therapy to ensure that detectable concentrations have been achieved. If the concentration is below 1 mcg/mL (mg/L; 1.4 μmol/L), the dose may be insufficient or drug interactions can be impairing absorption or accelerating metabolism, requiring a change in dosage. If plasma concentrations are greater than 10 mcg/mL (mg/L; 14 μmol/L), the dosage can be reduced.

[c]Deoxycholate amphotericin B.

[d]Effectiveness of corticosteroids is controversial.

[e]As a percentage of AIDS patients presenting with histoplasmosis as the initial manifestation of their disease.

[f]Liposomal amphotericin B (AmBisome) may be more appropriate for disseminated disease.

Data from references 10 and 32.

Aspergillus or *Candida* infection. In patients with acute self-limited histoplasmosis, extensive testing to verify the diagnosis may not be necessary.[32,33]

In most patients, serologic evidence (complement fixation test or immunodiffusion testing) remains the primary method in the diagnosis of histoplasmosis. Detection of *Histoplasma* antigen by enzyme immunoassay (EIA) in the urine, blood, or bronchoalveolar lavage fluid of infected patients provides rapid diagnostic information and is particularly useful in patients who are severely ill. The highest sensitivity is obtained by testing both urine and serum.[34] *Histoplasma* EIA has also been used to monitor the course of therapy and to detect relapses in patients with AIDS, and the clearance of antigen from serum and urine correlates with clinical efficacy during maintenance therapy.[35]

TREATMENT
Non-HIV-Infected Patient

4 Table 121-4 summarizes the recommended therapy for the treatment of histoplasmosis. In general, asymptomatic or mildly ill patients and patients with sarcoid-like disease do not benefit from antifungal therapy. In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in *mild* or *asymptomatic* pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Therapy can be helpful in symptomatic patients whose conditions have not improved during the first month of infection. Fever persisting more than 3 weeks can indicate that the patient is developing progressive disseminated disease, which can be aborted by antifungal therapy. Whether antifungal therapy hastens recovery or prevents complications is unknown because it has never been studied in prospective trials.

Fluconazole remains a second-line agent for the treatment of histoplasmosis. Clinical data regarding the use of newer azoles such as voriconazole and posaconazole are limited. While both have activity against *Histoplasma*, posaconazole appears to be more active than itraconazole in the immune compromised and nonimmune compromised mouse model of infection, while voriconazole has not been tested in animal models. Both agents have been used successfully in a few patients. Of note, the echinocandins have no activity against *Histoplasma*.

Patients with mild, self-limited disease, chronic disseminated disease, or chronic pulmonary histoplasmosis who have no underlying immunosuppression usually can be treated with either oral itraconazole or IV amphotericin B. The goals of therapy are resolution of clinical abnormalities, prevention of relapse, and eradication of infection whenever possible, although chronic suppression of infection can be adequate in immunosuppressed patients, including those with HIV disease.[10]

HIV-Infected Patient

In AIDS patients, intensive 12-week primary antifungal therapy (induction and consolidation therapy) is followed by lifelong suppressive (maintenance) therapy with itraconazole. Amphotericin B dosages of 50 mg/day (up to 1 mg/kg per day) should be administered IV to a cumulative dose of 15 to 35 mg/kg (1-2 g) in patients who require hospitalization. Amphotericin B can be replaced with itraconazole 200 mg orally twice daily when the patient no longer requires hospitalization or IV therapy to complete a 12-week total course of induction therapy. In patients who do not require hospitalization, itraconazole therapy for 12 weeks can be used.

Fluconazole 800 mg/day orally as induction, followed by 400 mg/day, was effective in 88% of patients, but relapses occurred in approximately one third of patients, and in vitro resistance developed in approximately 50% of patients who relapsed.

In regions experiencing high rates of histoplasmosis (greater than 5 cases/100 patient-years), itraconazole 200 mg/day is recommended as prophylactic therapy in HIV-infected patients. Fluconazole is not an acceptable alternative because of its inferior activity against *H. capsulatum* and its lower efficacy for the treatment of histoplasmosis.[10]

Although patients receiving secondary prophylaxis (chronic maintenance therapy) might be at low risk for recurrence of systemic mycosis when their $CD4^+$ T lymphocyte counts increase to greater than 100 cells/μL (greater than 0.1×10^9/L) in response to highly active antiretroviral therapy (HAART), the number of patients who have been evaluated is insufficient to warrant a recommendation to discontinue prophylaxis.

Evaluation of Therapeutic Outcomes

Response to therapy should be measured by resolution of radiologic, serologic, and microbiologic parameters and by improvement in signs and symptoms of infection. Although investigators are limited by the lack of standardized criteria to quantify the extent of infection, degree of immunosuppression, or treatment response, response rates (based on resolution or improvement in presenting signs and symptoms) of greater than 80% have been reported in case series in AIDS patients receiving varied dosages of amphotericin B. Rapid responses are reported, with the resolution of symptoms in 25% and 75% of patients by days 3 and 7 of therapy, respectively.

After the initial course of therapy for histoplasmosis is complete, lifelong suppressive therapy with oral azoles or amphotericin B (1-1.5 mg/kg weekly or biweekly) is recommended because of the frequent recurrence of infection. Relapse rates in AIDS patients not receiving maintenance therapy range from 50% to 90%.[10]

Antigen testing can be useful for monitoring therapy since concentrations decrease with therapy and increase with relapse.

BLASTOMYCOSIS

North American blastomycosis is a systemic fungal infection caused by *Blastomyces dermatitidis*, a dimorphic fungus that infects primarily the lungs. Patients, however, can present with a variety of pulmonary and extrapulmonary clinical manifestations. Pulmonary disease can be acute or chronic and can mimic infection with tuberculosis, pyogenic bacteria, other fungi, or malignancy. Blastomycosis can disseminate to virtually every other body organ, and approximately 40% of patients with blastomycosis present with skin, bone and joint, or genitourinary tract involvement without any evidence of pulmonary disease.[8,36]

Pulmonary infection probably occurs by inhalation of conidia, which convert to the yeast form in the lung. A vigorous inflammatory response ensues, with neutrophilic recruitment to the lungs followed by the development of cell-mediated immunity and the formation of noncaseating granulomas.

Epidemiology

Blastomycosis was renamed *North American blastomycosis* in 1942, when Conant and Howell named a similar fungus endemic to South America, *Blastomyces braziliensis*, and the disease it caused *South American blastomycosis*. Although the disease is now recognized to be endemic to the southeastern and south central states of the United States (especially those bordering on the Mississippi and Ohio River basins) and the midwestern states and Canadian provinces bordering the Great Lakes, numerous cases of North American blastomycosis have been diagnosed in Africa, northern parts of South America, India, and Europe. Endemic areas have been defined primarily by analysis of sporadic cases and epidemics or clusters

of disease because the lack of a dependable skin or laboratory test makes wide-scale epidemiologic testing to determine the incidence of infection unfeasible at present.[8,36] Although initial review of sporadic cases suggested that males with outdoor occupations that exposed them to soil were at greatest risk for blastomycosis, there is no sex, age, or occupational predilection for blastomycosis.[8,36]

Although *B. dermatitidis* generally is considered to be a soil inhabitant, attempts to isolate the organism in nature frequently have been unsuccessful. *B. dermatitidis* has been isolated from soil containing decayed vegetation, decomposed wood, and pigeon manure, frequently in association with warm, moist soil of wooded areas that is rich in organic debris.[8,36]

Pathophysiology and Clinical Presentation

Colonization does not occur with *Blastomyces*[8,36] *Acute pulmonary blastomycosis* generally is an asymptomatic or self-limited disease characterized by fever, shaking chills, and productive, purulent cough, with or without hemoptysis, in immunocompetent individuals. The clinical presentation can be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone.

Sporadic (nonepidemic) pulmonary blastomycosis can present as a more chronic or subacute disease, with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia. *Chronic pulmonary blastomycosis* is characterized by fever, malaise, weight loss, night sweats, chest pain, and productive cough. Patients often are thought to have tuberculosis and frequently have evidence of disseminated disease that can appear 1 to 3 years after the primary pneumonia has resolved. Reactivation of disease can occur in the lungs or as the focus of new infection in other organs.

In approximately 40% of patients, dissemination is not accompanied by reactivation of pulmonary disease. The most common sites for disseminated disease include the skin and bony skeleton, although less commonly the prostate, oropharyngeal mucosa, and abdominal viscera are involved. CNS disease, while exceedingly uncommon, is associated with the highest mortality rate.

Laboratory and Diagnostic Tests

The simplest and most successful method of diagnosing blastomycosis is by direct microscopic visualization of the large, multinucleated yeast with single, broad-based buds in sputum or other respiratory specimens following digestion of cells and debris with 10% potassium hydroxide.[8,36] Histopathologic examination of tissue biopsies and culture of secretions also should be used to identify *B. dermatitidis*, although it can require up to 30 days to isolate and identify a small inoculum.

No reliable skin test exists to determine the incidence and prevalence of disease in endemic populations, and reliable serologic diagnosis of blastomycosis has long been hampered by the lack of specific and standardized reagents. Serologic response does not always correlate with clinical improvement, although some investigators have noted that a decline in the number of precipitins or CF titers can offer evidence of a favorable prognosis in patients with established disease.

Acute pulmonary blastomycosis generally is an asymptomatic or self-limited disease characterized by fever, shaking chills, and productive, purulent cough, with or without hemoptysis, in immunocompetent individuals. The clinical presentation can be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone. Sporadic (nonepidemic) cases of pulmonary blastomycosis can present as a more chronic or subacute disease with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia.

TREATMENT

Non-HIV-Infected Patient

5 In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment. However, consideration should be given to treating all infected individuals to prevent extrapulmonary dissemination. All individuals with moderate to severe pneumonia, disseminated infection, or those who are immunocompromised require antifungal therapy.

In patients with mild to moderate pulmonary blastomycosis, itraconazole is effective; however, in patients with moderately severe to severe pulmonary disease, the clinical presentation of the patient, the immune competence of the patient, and the toxicity of the antifungal agents are the main determinants of the choice of antifungal therapy. All immunocompromised patients and patients with progressive pulmonary disease or with extrapulmonary disease should be treated (Table 121-5). In the case of disease limited to the lungs, cure might have occurred without treatment before the diagnosis is made. Regardless of whether or not the patient receives treatment, however, he or she must be followed carefully for many years for evidence of reactivation or progressive disease.[8,36]

Some authors recommend azole therapy for the treatment of self-limited pulmonary disease, with the hope of preventing late extrapulmonary disease; however, data supporting the efficacy of these regimens are lacking.[8,36] Itraconazole 200 to 400 mg/day demonstrated 90% efficacy as a first-line agent in the treatment of nonlife-threatening non-CNS blastomycosis, and for compliant patients who completed at least 2 months of therapy, a success rate of 95% was noted. No therapeutic advantage was noted with the higher (400 mg) dosage as compared with patients treated with 200 mg.

All patients with disseminated blastomycosis, as well as those with extrapulmonary disease, require therapy. Due to its adverse effects, variable oral absorption, and lack of CNS penetration, ketoconazole is now reserved as an alternative therapy for mild to moderate pulmonary and non-CNS disease. However, older studies demonstrate that ketoconazole 400 mg/day orally for 6 months cures more than 80% of patients with chronic pulmonary and nonmeningeal disseminated blastomycosis. Amphotericin B is more efficacious but more toxic and therefore is reserved for noncompliant patients and patients with overwhelming or life-threatening disease, CNS infection, and treatment failures.[8,36] Lipid preparations of amphotericin B have largely replaced conventional amphotericin B for treatment of blastomycosis, despite their higher cost, due to their decreased renal toxicity. Surgery has only a limited role in the treatment of blastomycosis.

HIV-Infected Patient

For unclear reasons, blastomycosis is an uncommon opportunistic disease among immunocompromised individuals, including AIDS patients; however, blastomycosis can occur as a late (CD4 lymphocytes less than 200 cells/mm^3 [less than 0.2×10^9/L]) and frequently fatal complication of HIV infection. In this population, overwhelming disseminated disease with frequent involvement of the CNS is common.[8,36] Following induction therapy with amphotericin B (total cumulative dose of 1 g), HIV-infected patients should receive chronic suppressive therapy with an oral azole antifungal.[8,36]

COCCIDIOIDOMYCOSIS

Epidemiology

Coccidioidomycosis is caused by infection with *Coccidioides immitis*, a dimorphic fungus found in the southwestern and western United States,

TABLE 121-5 Therapy of Blastomycosis

Type of Disease	Preferred Treatment
Pulmonary[a]	
Moderately severe to severe disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[b] 0.7-1 mg/kg IV daily (total dose 1.5-2.5 g) × 1-2 weeks or until improvement is noted, followed by itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily, × total of 6-12 months
Mild to moderate disease	Itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily, for a total of 6 months[c]
CNS disease	*Induction:* Lipid formulation of amphotericin B 5 mg/kg IV daily × 4-6 weeks, followed by an oral azole as consolidation therapy *Consolidation:* Fluconazole[d] 800 mg orally daily, or itraconazole[d] 200 mg two or three times orally daily, or voriconazole[d] 200-400 mg orally twice daily, for ≥12 months and until resolution of CSF abnormalities
Disseminated or Extrapulmonary Disease	
Moderately severe to severe disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[b] 0.7-1 mg/kg IV daily × 1-2 weeks or until improvement is noted, followed by itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily × 6-12 months. Treat osteoarticular disease with 12 months of antifungal therapy Most clinicians prefer to step-down to itraconazole[d] therapy once the patient's condition improves
Mild to moderate	Itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg once or twice daily × ≥12 months. Treat osteoarticular disease with 12 months of antifungal therapy
Immunocompromised Host (Including Patients with AIDS, Transplants, or Receiving Chronic Glucocorticoid Therapy)	
Acute disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[b] 0.7-1 mg/kg IV daily × 1-2 weeks or until improvement is noted, then give suppressive therapy for a total of at least 12 months of therapy
Suppressive therapy	Itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily for a total of at least 12 months of therapy; lifelong suppressive therapy with oral itraconazole[d] 200 mg daily may be required for immunosuppressed patients in whom immunosuppression cannot be reversed, and in patients who experience relapse despite appropriate therapy

AIDS, acquired immunodeficiency syndrome.

[a]In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment.

[b]Desoxycholate amphotericin B.

[c]Serum levels of itraconazole should be determined after the patient has received itraconazole for ≥2 weeks, to ensure adequate drug exposure.

[d]Azoles should not be used during pregnancy.

Data from reference 8.

as well as in parts of Mexico and South America. In North America, the endemic regions encompass the semiarid areas of the southwestern United States from California to Texas known as the Lower Sonoran Zone, where there is scant annual rainfall, hot summers, and sandy, alkaline soil. *C. immitis* grows in the soil as a mold, and mycelia proliferate during the rainy season. During the dry season, resistant arthroconidia form and become airborne when the soil is disturbed.

Although generally considered to be a regional disease, coccidioidomycosis has increased in importance in recent years because of the increased tourism and population in endemic areas, the increased use of immunosuppressive therapy in transplantation and oncology, and the AIDS epidemic. Although there is no racial, hormonal, or immunologic predisposition for acquiring primary disease, these factors affect the risk of subsequent dissemination of disease (Table 121-6).[37]

TABLE 121-6 Factors for Severe, Disseminated Infection with Coccidioidomycosis

Pathophysiology

When individuals come in contact with contaminated soil during ranching, dust storms, or proximity to construction sites or archaeologic excavations, arthroconidia are inhaled into the respiratory tree, where they transform into spherules, which reproduce by cleavage of the cytoplasm to produce endospores. The endospores are released when the spherules reach maturity. Similar to histoplasmosis, an acute inflammatory response in the tissue leads to infiltration of mononuclear cells, ultimately resulting in granuloma formation.[37]

Clinical Presentation of Coccidioidomycosis

Coccidioidomycosis encompasses a spectrum of illnesses ranging from primary uncomplicated respiratory tract infection that resolves spontaneously to progressive pulmonary or disseminated infection.[37] Initial or primary infection with *C. immitis* almost always involves the lungs. Although approximately one third of the population in endemic areas is infected, the average incidence of symptomatic disease is only approximately 0.43%.

Signs and Symptoms

Primary Coccidioidomycosis ("*Valley Fever*"): Approximately 60% of infected patients have an asymptomatic, self-limited infection without clinical or radiological manifestations. The remaining 40% of patients exhibit nonspecific symptoms that are often indistinguishable from ordinary upper respiratory infections, including fever, cough, headache, sore throat, myalgias, and fatigue that occur 1 to 3 weeks after exposure to the pathogen. More commonly, a diffuse, mild erythroderma or maculopapular rash is observed. Patients can have pleuritic chest pain and peripheral eosinophilia.

A fine, diffuse rash can appear during the first few days of the illness. Primary pneumonia can be the first manifestation of disease, characterized by a productive cough that can be blood-streaked, as well as single or multiple soft or dense homogeneous hilar or basal infiltrates on chest roentgenogram. *Chronic, persistent pneumonia or persistent pulmonary coccidioidomycosis* (primary disease lasting more than 6 weeks) is complicated by hemoptysis, pulmonary scarring, and the formation of cavities or bronchopleural fistulas.

Necrosis of pulmonary tissue with drainage and cavity formation occurs commonly. Most parenchymal cavities close spontaneously or form dense nodular scar tissue that can become superinfected with bacteria or spherules of *C. immitis*. These patients often have persistent cough, fevers, and weight loss.

Disseminated disease occurs in less than 1% of infected patients. The most common sites for dissemination are the skin, lymph nodes, bone, and meninges, although the spleen, liver, kidney, and adrenal gland also can be involved. Occasionally, miliary coccidioidomycosis occurs, with rapid, widespread dissemination, often in concert with positive blood cultures for *C. immitis*. Patients with AIDS frequently present with miliary disease. Coccidioidomycosis in AIDS patients appears to be caused by reactivation of disease in most patients. Dissemination also is more likely if infection occurs during pregnancy, especially during the third trimester or in the immediate postpartum period.[37]

CNS infection occurs in approximately 16% of patients with disseminated coccidioidomycosis. Patients can present with meningeal disease without previous symptoms of primary pulmonary infection, although disease usually occurs within 6 months of the primary infection. The signs and symptoms are often subtle and nonspecific, including headache, weakness, changes in mental status (lethargy and confusion), neck stiffness, low-grade fever, weight loss, and occasionally, hydrocephalus. Space-occupying lesions are rare, and the main areas of involvement are the basilar meninges.

Diagnosis

The diagnoses of coccidioidomycosis generally utilizes identification or recovery of *Coccidioides* spp. from clinical specimens and detection of specific anticoccidioidal antibodies in serum or other body fluids.

TREATMENT
General Guidelines

6 Therapy for coccidioidomycosis is difficult, and the results are unpredictable. Guidelines[11] are available for treatment of this disease; however, optimal treatment for many forms of this disease still generates debate. The efficacy of antifungal therapy for coccidioidomycosis often is less certain than that for other fungal etiologies, such as blastomycosis, histoplasmosis, or cryptococcus, even when in vitro susceptibilities and the sites of infections are similar. The refractoriness of coccidioidomycosis can relate to the ability of *C. immitis* spherules to release hundreds of endospores, maximally challenging host defenses.[37] Fortunately, only approximately 5% of infected patients require therapy.

Goals of Therapy

Desired outcomes of treatment are resolution of signs and symptoms of infection, reduction of serum concentrations of anticoccidioidal antibodies, and return of function of involved organs. It would also be desirable to prevent relapse of illness on discontinuation of therapy, although current therapy is often unable to achieve this goal.

Specific Agents Used for the Treatment of Coccidioidomycosis

Azole antifungals, primarily fluconazole and itraconazole, have replaced amphotericin B as initial therapy for most chronic pulmonary or disseminated infections. Amphotericin B is now usually reserved for patients with respiratory failure because of infection with *Coccidioides* species, those with rapidly progressive coccidioidal infections, or women during pregnancy. Therapy often ranges from many months to years in duration, and in some patients, lifelong suppressive therapy is needed to prevent relapses. Specific antifungals (and their usual dosages) for the treatment of coccidioidomycosis include IV amphotericin B (0.5-1.5 mg/kg per day), ketoconazole (400 mg/day orally), IV or oral fluconazole (usually 400-800 mg/day, although dosages as high as 1,200 mg/day have been used without complications), and itraconazole (200-300 mg orally twice daily or three times daily, as either capsules or solution).[37] If itraconazole is used, measurement of serum concentrations can be helpful to ascertain whether oral bioavailability is adequate.

Amphotericin B generally is preferred as initial therapy in patients with rapidly progressive disease, whereas azoles generally are preferred in patients with subacute or chronic presentations. The lipid formulations of amphotericin B have not been studied extensively in coccidioidal infection but can offer a means of giving more drugs with less toxicity. Fluconazole probably is the most frequently used medicine given its tolerability, although high relapse rates have been reported in some studies. Relapse rates with itraconazole therapy can be lower than those with fluconazole.[37]

The usefulness of newly available antifungal agents of possible benefit for the treatment of refractory coccidioidal infections has not been adequately assessed and they are not yet FDA approved for use in this population. Case reports have suggested that voriconazole can be effective in selected patients. Caspofungin has been effective in treating experimental murine coccidioidomycosis, but in vitro susceptibility of isolates varies widely, and there is only one report regarding its value. Posaconazole was shown to be an effective treatment in a small clinical trial and in patients with refractory infections. Its efficacy relative to other triazole antifungals is unknown.

Clinical **Controversy...**

Although there is continued disagreement among experts in endemic areas whether antifungal therapy in patients with uncomplicated early coccidioidal infection might shorten the course of illness or reduce the development of more serious complications, prospective randomized trials addressing this question are lacking. The excellent tolerability of oral azoles has lowered the threshold for deciding to treat primary infection, and clinicians should treat patients with significantly debilitating illness, those with extensive pulmonary disease, and with who are frail due to advanced age, concurrent diabetes or comorbidities.[11]

Combination therapy with members of different classes of antifungal agents has not been evaluated in patients, and there is a hypothetical risk of antagonism. However, some clinicians feel that outcome in severe cases is improved when amphotericin B is combined with an azole antifungal. If the patient improves, the dosage of amphotericin B can be slowly decreased while the dosage of azole is maintained.[37]

Primary Respiratory Infection

Although most patients with symptomatic primary pulmonary disease recover without therapy, management should include followup visits for 1 to 2 years to document resolution of disease or to identify as early as possible evidence of pulmonary or extrapulmonary complications.

Patients with a large inoculum, severe infection, or concurrent risk factors (eg, HIV infection, organ transplant, pregnancy, or high doses of corticosteroids) probably should be treated, particularly those with high CF titers, in whom incipient or occult dissemination is likely. Because some racial or ethnic populations have a higher risk of dissemination, some clinicians advocate their inclusion in the high-risk group. Common indicators used to judge the severity of infection include weight loss (greater than 10%), intense night sweats persisting more than 3 weeks, infiltrates involving more than one half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, CF antibody titers of greater than 1:16, failure to develop dermal sensitivity to coccidial antigens, inability to work, or symptoms that persist for more than 2 months.[37]

Commonly prescribed therapies include currently available oral azole antifungals at their recommended doses for courses of therapy ranging from 3 to 6 months.[37] In patients with diffuse pneumonia with bilateral reticulonodular or miliary infiltrates, therapy usually is initiated with amphotericin B; several weeks of therapy generally are required to produce clear evidence of improvement. Consolidation therapy with oral azoles can be considered at that time. The total duration of therapy should be at least 1 year, and in patients with underlying immunodeficiency, oral azole therapy should be continued as secondary prophylaxis.

Infections of the Pulmonary Cavity

Many pulmonary infections that are caused by *C. immitis* are benign in their course and do not require intervention. In the absence of controlled clinical trials, evidence of the benefit of antifungal therapy is lacking, and asymptomatic infections generally are left untreated. Symptomatic patients can benefit from oral azole therapy, although recurrence of symptoms can be seen in some patients once therapy is discontinued. Surgical resection of localized cavities provides resolution of the problem in patients in whom the risks of surgery are not too high.[37]

Extrapulmonary (Disseminated) Disease

Nonmeningeal Disease

Almost all patients with disease located outside the lungs should receive antifungal therapy; therapy usually is initiated with 400 mg/day of an oral azole. Amphotericin B is an alternative therapy and can be necessary in patients with worsening lesions or with disease in particularly critical locations such as the vertebral column. Approximately 50% to 75% of patients treated with amphotericin B for nonmeningeal disease achieve a sustained remission, and therapy usually is curative in patients with infections localized strictly to skin and soft tissues without extensive abscess formation or tissue damage. The efficacy of local injection into joints or the peritoneum, as well as intraarticular or intradermal administration, remains poorly studied. Amphotericin B appears to be most efficacious when cell-mediated immunity is intact (as evidenced by a positive coccidioidin or spherulin skin test or low CF antibody titer). Controlled trials that document these clinical impressions are lacking, however.[37]

Meningeal Disease

Fluconazole has become the drug of choice for the treatment of coccidioidal meningitis. A minimum dose of 400 mg/day orally leads to a clinical response in most patients and obviates the need for intrathecal amphotericin B. Some clinicians will initiate therapy with 800 or 1,000 mg/day, and itraconazole dosages of 400 to 600 mg/day are comparably effective. It is also clear, however, that fluconazole only leads to remission rather than cure of the infections; thus suppressive therapy must be continued for life. Ketoconazole cannot be recommended routinely for the treatment of coccidioidal meningitis because of its poor CNS penetration following oral administration. Patients who do not respond to fluconazole or itraconazole therapy are candidates for intrathecal amphotericin B therapy with or without continuation of azole therapy. The intrathecal dose of amphotericin B ranges from 0.01 to 1.5 mg given at intervals ranging from daily to weekly. Therapy is initiated with a low dosage and is titrated upward as patient tolerance develops.[37]

CRYPTOCOCCOSIS

Epidemiology

Cryptococcosis is a noncontagious, systemic mycotic infection caused by the ubiquitous encapsulated soil yeast *Cryptococcus*, which is found in soil, particularly in pigeon droppings, although disease occurs throughout the world, even in areas where pigeons are absent. Infections caused by *C. neoformans* var. *grubii* (serotype A) are seen worldwide among immunocompromised hosts, followed by *C. neoformans* var. *neoformans* (serotype D). On the other hand, *Cryptococcus gattii* (serotypes B and C) is geographically more restricted and in contrast to *C. neoformans*, rarely infects immunosuppressed patients, is not associated with HIV infection, and the infections are more difficult to treat. *C. gattii* is not associated with birds; its main reservoir was thought to be limited to certain species of eucalyptus tree. Until recently, it was most common in tropical and subtropical areas, such as Australia, South America, Southeast Asia, and central Africa, with the highest incidence in Papua New Guinea and Northern Australia, although infections occur in nontropical areas such as North America and Europe. *C. gattii* emerged on Vancouver Island, British Columbia, Canada, in 1999, and subsequently spread to the Vancouver lower mainland, Washington state, and Oregon.[38]

Infection is acquired by inhalation of the organism. The incidence of cryptococcosis has risen dramatically in recent years, reflecting the increased numbers of immunocompromised patients, including those with malignancies, diabetes mellitus, chronic renal failure, and organ transplants and those receiving immunosuppressive agents. In most developed countries, widespread use of HAART has significantly decreased the incidence of cryptococcosis; however, the incidence and mortality of this infection are still extremely high in areas with limited access to HAART and a high incidence of HIV.[39]

Disease can remain localized in the lungs or can disseminate to other tissues, particularly the CNS, although the skin also can be affected. Hematogenous spread generally occurs in the immunocompromised host, although it also has been seen in individuals with intact immune systems.

Clinical Presentation of Cryptococcosis

Primary cryptococcosis in humans almost always occurs in the lungs, although the pulmonary focus usually produces a subclinical infection.[38,39] Symptomatic infections usually are manifested by cough, rales, and shortness of breath that generally resolve spontaneously. Cryptococcus can present as part of an immune reconstitution inflammatory syndrome (IRIS), a paradoxical worsening of preexisting infectious processes following the initiation of HAART in HIV-infected individuals. In non-AIDS patients, the symptoms of cryptococcal meningitis are nonspecific. Headache, fever, nausea, vomiting, mental status changes, and neck stiffness generally are observed. Less common symptoms include visual disturbances (photophobia and blurred vision), papilledema, seizures, and aphasia. In AIDS patients, fever and headache are common, but meningismus and photophobia are much less common than in non-AIDS patients. Approximately 10% to 12% of AIDS patients have asymptomatic disease, similar to the rate observed in non-AIDS patients.[39,40] Intracerebral mass lesions (cryptococcomas) are more common in *C. gattii* than in *C. neoformans*, presumably due to their different host immune responses.[38]

Laboratory Tests

With cryptococcal meningitis, the CSF opening pressure generally is elevated. There is a CSF pleocytosis (usually lymphocytes), leukocytosis, a decreased glucose concentration, and an elevated CSF protein concentration. There is also a positive cryptococcal antigen (detected by LA). The test is rapid, specific, and extremely sensitive, but false-negative results can occur. False-positive tests can result from cross-reactivity with rheumatoid factor and *Trichosporon beigelii. C. neoformans* can be detected in approximately 60% of patients by India ink smear of CSF, and it can be cultured in more than 96% of patients. Occasionally, large volumes of CSF are required to confirm the diagnosis.

The CSF parameters in patients with AIDS are similar to those seen in non-AIDS patients, with the exception of a decreased inflammatory response to the pathogen, resulting in a strikingly low number of leukocytes in CSF and extraordinarily high cryptococcal antigen titers.

TREATMENT

The choice of treatment for disease caused by *C. neoformans* depends on both the anatomic sites of involvement and the host's immune status, and thus, treatment recommendations are divided into three specific risk groups: (a) HIV-infected individuals, (b) transplant recipients, and (c) non–HIV-infected and nontransplant hosts (Table 121-7).[9] The management of cryptococcosis includes systemic antifungal therapy, control of elevated intracranial pressure (ICP), and supportive care. When possible, immune defects should be addressed. Although no randomized clinical trials have been performed to address this, outcomes of treatment for CNS cryptococcosis (without mass lesions or hydrocephalus) appear to be similar for disease due to either *C. neoformans* or *C. gattii*.[38]

Nonimmunocompromised Patients

7 Prior to the introduction of amphotericin B, cryptococcal meningitis was an almost uniformly fatal disease; approximately 86% of patients died within 1 year. The use of large (1-1.5 mg/kg) daily doses of amphotericin B resulted in cure rates of approximately 64%. When amphotericin B is combined with flucytosine, a smaller dose of amphotericin B can be employed because of the in vitro and in vivo synergy between the two antifungal agents. Resistance develops to flucytosine in up to 30% of patients treated with flucytosine alone, limiting its usefulness as monotherapy.[41] Combination therapy with amphotericin B and flucytosine will sterilize the CSF within 2 weeks of treatment in 60% to 90% of patients, and most immunocompetent patients will be treated successfully with 6 weeks of combination therapy.[39] However, because of the need for prolonged IV therapy and the potential for renal and hematologic toxicity with this regimen, alternative regimens utilizing lipid formulations of amphotericin B and the use of shorter (2 weeks) courses of amphotericin B followed by consolidation therapy with fluconazole for 8 weeks, then maintenance therapy with a lower dosage of fluconazole for 6 to 12 months has been advocated.[9,40,42]

For asymptomatic, immunocompetent hosts with isolated mild to moderate pulmonary disease and no evidence of CNS disease, careful observation can be warranted; in the case of symptomatic infection, fluconazole for 6 to 12 months is warranted. In individuals with non-CNS cryptococcemia, a positive serum cryptococcal antigen titer (greater than 1:8), cutaneous infection, a positive urine culture, or prostatic disease, the clinician must decide whether to follow the regimen for isolated pulmonary disease or the more aggressive regimen for patients with CNS (disseminated) disease.[9]

Pilot studies evaluating combination therapy with fluconazole plus flucytosine as initial therapy yielded unsatisfactory results, and this approach is discouraged even in "low-risk" patients. Ketoconazole has been used successfully in the treatment of cutaneous cryptococcosis, but it is not useful in the treatment of CNS disease, probably because of its poor penetration into the CNS.[9]

Despite low CSF concentrations of amphotericin B (2%-3% of those observed in plasma), the use of intrathecal amphotericin B is not recommended for the treatment of cryptococcal meningitis except in very ill patients or in patients with recurrent or progressive disease despite aggressive therapy with IV amphotericin B. The dosage of amphotericin B employed is usually 0.5 mg administered through the lumbar, cisternal, or intraventricular (through an Ommaya reservoir) route two or three times weekly. Side effects of intrathecal amphotericin B include arachnoiditis and paresthesias. Intrathecal amphotericin B therapy should be administered in combination with IV amphotericin B.[42]

The recommended management of raised ICP in cryptococcal meningitis (without hydrocephalus, a mass lesion, or a shift on computed tomography [CT] scan) has been repeated CSF removal by spinal tap. Those who do not respond and have ongoing raised ICP should have ophthalmologic monitoring for possible vision loss, and should be considered for ventriculoperitoneal shunt surgery. Neither corticosteroids (in the absence of IRIS) nor acetazolamide is recommended for management of raised ICP. Symptomatic, medically refractory mass lesions that may be compressing vital structures should be considered for surgical therapy.[38]

Immunocompromised Patients

Immunocompromised hosts with isolated severe pulmonary and extrapulmonary disease (including cryptococcemia) without CNS disease should be treated similarly to nonimmunocompromised patients with CNS disease. Immunocompromised patients with CNS infection require more prolonged therapy; treatment regimens are based on those used in the HIV-infected population and follow induction therapy with amphotericin B and consolidation therapy with 6 to 12 months of suppressive therapy with fluconazole.[9]

Organ Transplant Recipients

Cryptococcosis has been documented in an average of 2.8% of solid-organ transplant recipients. The median time to disease onset is 21 months after transplantation; 68.5% of the cases occur greater than 1 year after transplantation.

Induction therapy for solid organ transplant recipients with cryptococcal meningoencephalitis consists of liposomal amphotericin B or amphotericin B lipid complex (ABLC) plus flucytosine for at least 2 weeks. Fluconazole maintenance therapy should be continued for at least 6 to 12 months. Immunosuppressive management should include sequential or stepwise reduction of immunosuppressants, with consideration of lowering the corticosteroid dose first.[43] Amphotericin B should be used with caution in transplant recipients and is not recommended as first-line therapy in this patient population due to the risk of nephrotoxicity in this population that frequently has reduced renal function. If used, the tolerated dosage of amphotericin B is uncertain, but 0.7 mg/kg daily is suggested with frequent renal function monitoring. Regardless of the agent utilized, all antifungal dosages need to be carefully monitored.[43]

HIV-Infected Patients

Primary antifungal prophylaxis for cryptococcosis is not routinely recommended in HIV-infected patients in the United States and Europe. However, in areas with limited HAART availability, high levels of antiretroviral drug resistance, and a high burden of disease, clinicians may wish to consider the use of either prophylactic therapy or a preemptive strategy with serum cryptococcal antigen testing for asymptomatic antigenemia.[9]

Early studies confirmed the benefit of early high-dose amphotericin B use, the usefulness of flucytosine added to amphotericin B for induction therapy, and the slight superiority of fluconazole over itraconazole for consolidation therapy.

Amphotericin B combined with flucytosine during the two-week induction phase of therapyis the initial treatment of choice. In patients who cannot tolerate flucytosine, amphotericin B alone is an acceptable alternative. After the initially successful 2-week induction period, consolidation therapy with fluconazole can be administered for 8 weeks or until CSF cultures are negative. In patients in whom fluconazole cannot be given, itraconazole is an acceptable, albeit less effective, alternative. Combination therapy with fluconazole plus flucytosine is effective; however, it is recommended as an alternative

TABLE 121-7 Therapy of Cryptococcosis[a,b]

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Nonimmunocompromised Patients (Non–HIV-Infected, Nontransplant)	
Meningoencephalitis *without* neurological complications, in patients in whom CSF yeast cultures are negative after 2 weeks of therapy	*Induction:* Amphotericin B[c] IV 0.7-1 mg/kg/day *plus* flucytosine 100 mg/kg/day orally in four divided doses × ≥4 weeks A lipid formulation of amphotericin B may be substituted for amphotericin B in the second 2 weeks
Follow all regimens with suppressive therapy	*Consolidation:* Fluconazole 400-800 mg orally daily × 8 weeks *Maintenance:* Fluconazole 200 mg orally daily × 6-12 months
Meningoencephalitis *with* neurological complications	*Induction:* Same as for patients without neurologic complications, but consider extending the induction therapy for a total of 6 weeks. A lipid formulation of amphotericin B may be given for the last 4 weeks of the prolonged induction period *Consolidation:* Fluconazole 400 mg orally daily × 8 weeks
Mild-to-moderate pulmonary disease (Nonmeningeal disease)	Fluconazole 400 mg orally daily × 6-12 months
Severe pulmonary cryptococcosis	*Same as CNS disease × 12 months*
Cryptococcemia (nonmeningeal, nonpulmonary disease)	*Same as CNS disease × 12 months*
Immunocompromised Patients	
Severe pulmonary cryptococcosis	*Same as CNS disease × 12 months*
HIV-infected Patients	
Primary therapy; induction and consolidation[g]	*Preferred regimen*: *Induction:* Amphotericin B[d] IV 0.7-1 mg/kg IV daily *plus* flucytosine 100 mg/kg/day orally in four divided doses for ≥2 weeks
Follow all regimens with suppressive therapy	*Consolidation:* Fluconazole 400 mg [6 mg/kg] orally daily × ≥8 weeks Liposomal amphotericin B 3-4 mg/kg IV daily, or amphotericin B lipid complex (ABLC) 5 mg/kg IV daily, for ≥2 weeks can be substituted for amphotericin B[d] in patients with or at risk for renal dysfunction *Alternative regimens, in order of preference:* Amphotericin B[d] IV 0.7-1 mg/kg IV daily × 4-6 weeks *or* liposomal amphotericin B 3-4 mg/kg IV daily[f] × 4-6 weeks *or* ABLC 5 mg/kg IV daily × 4-6 weeks *or* Amphotericin B[d] IV 0.7 mg/kg IV daily, *plus* fluconazole 800 mg (12 mg/kg) orally daily × 2 weeks, followed by fluconazole 800 mg (12 mg/kg) orally daily × ≥8weeks *or* Fluconazole ≥800 mg (1,200 mg/day is preferred) orally daily *plus* flucytosine 100 mg/kg/day orally in four divided doses × 6 weeks *or* Fluconazole 800-1,200 mg/day orally daily × 10-12 weeks (a dosage ≥1,200 mg/day is preferred when fluconazole is used alone)[e] *or* Itraconazole 200 mg orally twice daily × 10-12 weeks (use of itraconazole, which produces minimal concentrations of active drug in the CSF is discouraged)[i]
Suppressive/maintenance therapy[h]	Preferred: Fluconazole 200 mg orally daily × ≥1 year *or* Itraconazole[i] 200 mg orally twice daily × ≥1 year *or* Amphotericin B[j] IV 1 mg/kg weekly × ≥1 year
Organ Transplant Recipients	
Mild-moderate non-CNS disease or mild-to-moderate symptoms without diffuse pulmonary infiltrates	Fluconazole 400 mg (6 mg/kg) orally daily × 6-12 months
CNS disease, moderately severe or severe CNS disease or disseminated disease without CNS disease, or severe pulmonary disease without evidence of extrapulmonary or disseminated disease	*Induction:* Liposomal amphotericin B 3-4 mg/kg IV daily,[f] or ABLC 5 mg/kg IV daily *plus* flucytosine 100 mg/kg/day orally in four divided doses × ≥2 weeks If induction therapy does not include flucytosine, consider a lipid formulation of amphotericin B for ≥4-6 weeks of induction therapy. Consider the use of a lipid formulation of amphotericin B lipid formulation (6 mg/kg IV daily) in patients with a high-fungal burden disease or relapse of disease *Consolidation:* Fluconazole 400-800 mg (6-12 mg/kg) per day orally for 8 weeks *Maintenance:* Fluconazole 200-400 mg per day orally for 6-12 months

HIV, human immunodeficiency virus; IT, intrathecal.

[a]When more than one therapy is listed, they are listed in order of preference.

[b]See the text for definitions of induction, consolidation, suppressive/maintenance therapy, and prophylactic therapy.

[c]Deoxycholate amphotericin B.

[d]In patients with significant renal disease, lipid formulations of amphotericin B can be substituted for deoxycholate amphotericin B during the induction.

[e]Or until cerebrospinal fluid (CSF) cultures are negative.

[f]Liposomal amphotericin B has been given safely up to 6 mg/kg daily; could be considered in treatment failure or in patients with a high fungal burden.

[g]Initiate HAART therapy 2-10 weeks after commencement of initial antifungal treatment.

[h]Consider discontinuing suppressive therapy during HAART in patients with a CD4 cell count ≥100 cells/μL (≥0.1 × 10^9/L) and an undetectable or very low HIV RNA level sustained for ≥3months (with a minimum of 12 months of antifungal therapy). Consider reinstitution of maintenance therapy if the CD4 cell count decreases to <100 cells/μL (<0.1 × 10^9/L).

[i]Drug level monitoring is strongly advised.

[j]Use is discouraged except in azole intolerant patients, since it is less effective than azole therapy, and is associated with a risk of IV catheter-related infections.

Data from reference 9.

to the preceding therapies because of its potential for toxicity. Lipid formulations of amphotericin B are effective, but the optimal dosage is unknown.[9]

In HIV-infected patients, mortality is highly associated with elevated ICP (CSF opening pressure greater than 250 mm H_2O [greater than 2.5 kPa]). At the initiation of antifungal therapy, lumbar drainage should remove enough CSF to reduce the opening pressure by 50%. Patients initially should undergo daily lumbar punctures to maintain CSF opening pressure in the normal range. When the CSF pressure is normal for several days, the procedure can be suspended. Adjunctive steroid treatment is not recommended because therapy has resulted in mixed results and its impact on outcome is unclear. Similarly, neither mannitol nor acetazolamide therapy provides any clear benefit in the management of elevated ICP.[9]

Suppressive (Maintenance) Therapy for Cryptococcal Meningitis in the HIV-Infected Patient

Relapse of *C. neoformans* meningitis occurs in approximately 50% of AIDS patients after completion of primary therapy. Persistence of asymptomatic urinary *C. neoformans* has been documented in a high percentage of AIDS patients despite seemingly adequate courses of therapy for primary meningeal disease. The prostate appears to act as a sequestered reservoir of infection in these patients, resulting in systemic relapse.

Patients appear to be at low risk for recurrence of cryptococcosis when they have successfully completed a course of initial therapy for cryptococcosis, remain asymptomatic with regard to signs and symptoms of cryptococcosis, have received antifungal therapy for greater than 3 of the previous 6 months, have a serum cryptococcal antigen titer less than 1:512, or have a sustained increase (eg, greater than 6 months) in their $CD4^+$ T-lymphocyte counts to greater than 100 to 200 cells/μL (greater than 0.1×10^9-0.2×10^9/L) and an HIV viral load of less than 50 copies/mL (50×10^3/L).[9,40,42]

After the completion of induction/consolidation phases of therapy, long-term chronic suppression with fluconazole (200 mg orally daily) should be continued for a minimum of one year. Maintenance therapy can be discontinued after one year in patients who have successfully completed primary therapy, are free of symptoms and signs of active cryptococcosis, and have been receiving HAART with a sustained CD4 cell count greater than 100 cells/mL (greater than 0.100×10^6/L) and an undetectable viral load.[9]

Evaluation of Therapeutic Outcomes

Once the CNS is involved, the usual course is weeks to months of progressive deterioration, with 80% of untreated patients dying within the first year. The prognosis of cryptococcal meningitis depends largely on the underlying predisposing factors of the host. Although cryptococcal antigen is positive in 90% of patients with cryptococcal meningitis, fewer than one half of the patients with cryptococcal meningitis develop antibody to capsular polysaccharide. Those who produce antibody have a slightly improved prognosis. In contrast, the presence of headache is a favorable symptom, presumably because it leads to an earlier diagnosis. A favorable outcome is also associated with a normal mental status on diagnosis and a CSF white blood cell (WBC) count of less than 20 cells/mm^3 (20×10^6/L). A poor outcome is predicted, however, by the presence of one or more underlying diseases (including hematopoietic disorders and AIDS), corticosteroid or immunosuppressive therapy, pretreatment serum cryptococcal antigen titers of 1:32, and posttherapy serum antigen titers of 1:8. In non-AIDS patients, the cryptococcal antigen titer can be followed during therapy to assess response to antifungal therapy. In AIDS patients, decreasing titers are not necessarily predictive of success, and titers rarely become negative at the completion of therapy.

CANDIDA INFECTIONS

Candida species are yeasts that exist primarily as small (4-6 microns), unicellular, thin-walled, ovoid cells that reproduce by budding. On agar medium, they form smooth, white, creamy colonies resembling staphylococci. Although there are more than 150 species of *Candida*, eight species—*C. albicans*, *C. tropicalis*, *Candida parapsilosis*, *C. krusei*, *Candida stellatoidea*, *C. guilliermondii*, *C. lusitaniae*, and *C. glabrata*—are regarded as clinically important pathogens in human disease.[17] Yeast forms, hyphae, and pseudohyphae can be found in clinical specimens.

Pathophysiology

8 *C. albicans* is a normal commensal of the skin, female genital tract, and entire GI tract of humans. Therefore, the mere presence of hyphae or pseudohyphae in a clinical specimen is insufficient for the diagnosis of invasive disease. The majority of infections with *C. albicans* are acquired endogenously, although human-to-human transmission also can occur. Although the term *fungemia* refers to the presence of fungi in the blood, the most commonly isolated organism is *C. albicans*. Candidiasis can cause mucocutaneous or systemic infection, including endocarditis, peritonitis, arthritis, and infection of the CNS. (Mucocutaneous infections caused by *Candida* are discussed in further detail in Chapter 98.)

Adherence of *C. albicans* is important in the pathogenesis of oral candidiasis and subsequent colonization of the GI tract. Because evidence suggests that the GI tract is often the portal of entry for *Candida* in disseminated disease, factors that alter the adherence of *Candida* are crucial in the development of local and systemic infection. *C. tropicalis* adheres to intravascular catheters at a higher rate than *C. albicans*, a factor that may help to account for the increased incidence of systemic infections caused by this pathogen.

CANDIDEMIA AND ACUTE HEMATOGENOUSLY DISSEMINATED CANDIDIASIS

Epidemiology

Candidemia has increased substantially in the past 2 decades, and the fourth most common bloodstream infection (BSI) in US hospitals.[44] It is associated with high mortality, increased length of hospital stay, and significant economic burden.[44-54] Although patients with neutropenia are at high risk for IFIs, the use of antifungal prophylaxis and prompt initiation of antifungal therapy in persistently febrile patients with neutropenia who do not respond to antibioticshas resulted in a reduction in the frequency of *Candida* BSIs in this population.[7] In fact, most BSIs due to *Candida* species now occur in nonneutropenic patients who have been hospitalized in ICUs, especially adult ICUs and neonatal ICUs.

The most commonly encountered clinical species of *Candida* include *C. albicans*, *C. glabrata, C. tropicalis, C. parapsilosis*, *C. lusitaniae*, *C. krusei*, *and C. guilliermondii.* While *C. albicans* is still the most common species of *Candida* causing candidemia, its relative frequency is decreasing, while the frequency of the other, non-*albicans* species, including *C. glabrata*, *C. tropicalis*, *C. krusei*, and *C. parapsilosis*, have increased.[44,52,55-57] The change in species is of concern clinically, as certain pathogens, such as *C. krusei* and *C. glabrata*, are intrinsically more resistant to commonly used triazole drugs.[58,59] Although risk factors for the development of *Candida* BSIs in ICU patients can be identified, factors that lead to the acquisition of specific species are still unclear.[27]

Patients' characteristics influence the distribution of *Candida* species: *C. glabrata* infections are more common in the elderly,

C. krusei in immunocompromised patients, while *C. parapsilosis* is most common in children and neonates. *C. lusitaniae* infections are a cause of breakthrough fungemia in cancer patients; *C. parapsilosis* has emerged as the second most common pathogen, following *C. albicans*, in neonatal ICU patients, where it is often associated with central lines and PN, and fungemias in patients outside the United States, in particular in South America. Fungemia caused by *C. glabrata* is observed more commonly in adults older than 65 years of age.[32]

Pathophysiology

Candida generally is acquired via the GI tract, although organisms also can enter the bloodstream via indwelling IV catheters. Immunosuppressed patients, including those with lymphoreticular or hematologic malignancies, diabetes, and immunodeficiency diseases and those receiving immunosuppressive therapy with high-dose corticosteroids, immunosuppressants, antineoplastic agents, or broad-spectrum antimicrobial agents, are at high risk for IFIs (Table 121-8). Major risk factors include the use of CVCs, total PN, receipt of multiple antibiotics, extensive surgery and burns, renal failure and hemodialysis, mechanical ventilation, and prior fungal colonization. Patients who have undergone surgery (particularly surgery of the GI tract) are increasingly susceptible to disseminated candidal infections.[20,46]

TABLE 121-8 Risk Factors for Invasive Candidiasis

Colonization
Corrected colonization index (CCI) ≥0.4[a]
Colonization index (CI) ≥0.8[a]
Candida spp. cultured from sites other than blood
Candiduria
Antibiotic use
Number of antibiotics prior to infection (per additional antibiotics)
Use of two or more antibiotics
Use of broad-spectrum antibiotics in previous 10 days
Surgery
Surgery on ICU admission
Gastro-abdominal surgery
Abdominal drainage
Elective surgery
Cardiopulmonary bypass time >120 minutes
Hickman catheter
Foreign devices
Central venous catheter
Triple lumen catheter in patients who have undergone surgery
Bladder catheter
Renal failure and dialysis
Prior hemodialysis
Hemofiltration procedures
Increased serum creatinine[b]
New-onset hemodialysis within 3 days of admission to ICU
Acute renal failure
Underlying disease/baseline characteristics
Total PN
Diabetes mellitus
Apache II (per point)
Signs of severe sepsis
Diarrhea at any time
Mechanical ventilation ≥10 days
Hospital-acquired bacterial infection
Bacterial peritonitis by ICU day 11
GI disease
ICU length of stay
Transferred from other hospital
Use of corticosteroids
Profound neutropenia (ANC < 100/mm^3 [<0.100 ×10^9/L])

[a]CI = the ratio of number of nonblood distinct body sites (dbs) heavily colonized with identical strains to the total number of dbs; CCI = the product of the CI and the ratio of the number of dbs showing heavy growth (≥10^5 CFU/mL [≥10^8 CFU/L]) to the total of dbs growing *Candida* spp.

[b]Serum creatinine >1.2 mg/dL (>106 µmol/L) in females, >1.6 mg/dL (>141 µmol/L) in males.

Clinical Presentation of Hematogenous Candidiasis

Dissemination of *C. albicans* can result in infection in single or multiple organs, particularly the kidney, brain, myocardium, skin, eye, bone, and joints.[60] In most patients, multiple micro- and macroabscesses are formed. Infection of the liver and spleen is becoming recognized as a particularly common and difficult-to-treat site of infection that characteristically occurs in patients undergoing chemotherapy for acute leukemia or lymphoma.

Laboratory Tests

The interpretation of positive surveillance cultures of the skin, mouth, sputum, feces, or urine is hampered by their occurrence as commensal pathogens and in distinguishing colonization from invasive disease. A rapid presumptive identification of *C. albicans* can be made by incubation of *Candida* in serum; formation of a germ tube (the beginning of hyphae, which arise as perpendicular extensions from the yeast cell, with no constriction at their point of origin) within 1 to 2 hours offers a positive identification of *C. albicans*. Unfortunately, *C. dubliniensis* also can produce a germ tube, and a negative germ tube test does not rule out the possibility of *C. albicans*, but further biochemical tests must be performed to differentiate between other non-*albicans* species.

The PNA fluorescence in situ hybridization (FISH) method uses fluorescein-labeled PNA probes that target *C. albicans* 26S rRNA for the identification of *C. albicans*. The test has excellent sensitivity (99%-100%) and specificity (100%) in the direct identification of *C. albicans* from blood cultures.[61]

Matrix-assisted laser desorption/ionization time-of-flight intact cell mass spectrometry (MALDI-TOF-ICMS) and T2 Magnetic Resonance Assays, are promising tools for the rapid detection and identification of pathogenic *Candida* species.[29,30,61]

TREATMENT

The list of risk factors for invasive candidiasis in critically ill patients is extensive, and trying to decipher which patients may benefit from antifungal prophylaxis or empirical therapy based on risk factors in an ICU is exceedingly difficult. In addition, the number of risk factors present in ICU patients changes over time, and the majority of ICU patients will have more than one risk factor. Clinically useful, practical predictive algorithms and "scoring systems" to identify high-risk patients early during their ICU admission have not proved successful thus far. To maximize its clinical utility as a decision-making tool, the ideal algorithm would identify high-risk populations (ones with a rate of invasive candidiasis of 10%-15%), providing clinicians with a means of administering prophylaxis to a minimal number of patients, while preventing the maximal number of invasive candidiasis cases.[27]

Hematogenous Candidiasis

There is a high rate of mortality in nonneutropenic patients with fungal blood cultures. Delays in the initiation of antifungal therapy significantly increase mortality.[62,63] Treatment of candidiasis should be guided by knowledge of the infecting species, the clinical status of the patient, and when available, the antifungal susceptibility of the infecting isolate. Therapy should be continued for 2 weeks after

documented clearance of blood cultures, with resolution of all signs and symptoms of infection. All patients should undergo dilated fundiscopic exam within the 1st week of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach, since it can be used to identify isolates that are unlikely to respond to fluconazole or amphotericin B.[7] However, this is not currently available at many institutions.

Clinical **Controversy...**

Role of Catheter Removal

Although it is common practice in today's standard of care to place indwelling catheters in patients for the administration of medications and parenteral nutrition (TPN), catheter-related infections are a common complication. These foreign bodies (especially triple lumen catheters) double as entry ports for normal skin flora or other nosocomial pathogens, and they provide a readily available site for the binding of pathogens via microbiotic biofilms. Their subsequent role as a source of BSIs is facilitated by frequent use, TPN, and the potential for contamination of catheters by medical staff who are colonized with *Candida* species.

Most consensus recommendations urge removal of all existing tunneled CVCs and implantable devices, particularly in patients with fungemia caused by *C. parapsilosis*, which is very frequently associated with catheters, as it has been associated with reduced mortality in adults, and a shorter duration of candidemia.[7] Arguments against the removal of all catheters in patients with candidemia include the prominent role of the gut as a source for disseminated candidiasis, the significant cost and potential for complications, and the problems that can be encountered in patients with difficult vascular access.[7,64,65] However, in an individual patient it is often difficult to determine the relative contribution of gut versus catheter as the primary source of fungemia.[66-69] The evidence for this recommendation is weakest in cancer patients with severe neutropenia and mucositis (eg, acute leukemia, stem cell transplant), in whom candidemia is almost always primarily of gut origin, and removal of CVCs is least likely to have an impact on mortality.[66-69]

Nonimmunocompromised Patient

Prophylaxis

In ICUs, the use of fluconazole for prophylaxis or empirical therapy has increased exponentially in the past decade. However, studies that demonstrated benefit in the prevention of invasive candidal BSIs did so either by using highly selective criteria or by studying patients in an unusually high-risk ICU setting, and the role of antifungal prophylaxis in the surgical ICU remains extremely controversial. For a study to demonstrate efficacy in clinical trials, the baseline rate of invasive candidiasis must be greater than 10%, and that prophylaxis must result in greater than fourfold reduction of disease.[7] Although ICU-specific, a greater than 10% rate of invasive candidiasis is generally found only in the setting of high-risk transplant patients (eg, patients undergoing liver transplantation), or in patients with one or more of the following risk factors by day 3 of their ICU stay: new-onset dialysis, receipt of broad-spectrum antibiotics, the presence of diabetes, and in patients receiving PN.[70,71] Prophylactic antifungals are indicated in patients with recurrent intestinal perforations and/or anastomotic leak as these patients are at extremely high risk for invasive candidiasis (35%) and the use of empiric fluconazole has been shown to significantly decrease the incidence of infection to 4%.[27]

"Empirical" Therapy (Also Known as Preemptive Therapy)

The term "preemptive" antifungal therapy is often used to describe early antifungal therapy given to high-risk patients with persistent signs and symptoms and clinical, laboratory, or radiologic surrogate markers of infection but without mycological evidence of infection, or those heavily colonized with *Candida*. Few data are available for assessing the role of antifungals as empirical therapy for *suspected* fungemia in patients who do not yet exhibit a positive blood culture, or for isolates other than *C. albicans*. The empiric use of fluconazole did not significantly decrease the incidence of invasive candidiasis; thus, its use is not recommended at this time.[72]

Initial Antifungal Therapy in Non-neutropenic Patients with Documented Candidemia, in Whom the Species is Not Yet Identified and Results of Antifungal Susceptibility Testing are Not Known

Several large randomized studies in non-neutropenic patients have demonstrated that azoles (fluconazole or voriconazole), echinocandins, and deoxycholate amphotericin B (d-AmB) are similarly effective for the therapy of documented candidemia; however, fewer adverse effects are observed with azole therapy.[45] Similarly, echinocandins are at least as effective as amphotericin B or fluconazole in (primarily non-neutropenic) adult patients with candidemia with fewer drug-related adverse events. Although the use of combination therapy (high-dose fluconazole plus amphotericin B) was demonstrated to be superior to treatment with fluconazole alone, it was associated with a higher rate of nephrotoxicity, and the routine use of combination therapy in this patient population is not yet recommended.[7]

For empiric therapy in non-neutropenic adults, IDSA guidelines (Table 121-9) recommend use of an echinocandin or fluconazole as initial therapy. Echinocandins are recommended for patients with moderately severe to severe illness, and patients with recent azole exposure. Patients may be transitioned to fluconazole if their *Candida* isolates are known/likely to be susceptible to fluconazole (eg, *C. albicans*, *C. parapsilosis*) in patients who are clinically stable. Fluconazole may be used initially in patients who are less critically ill, with no recent azole exposure, who are not at high risk for *C. glabrata* or with central nervous system or endocardial disease.[7,45]

Among the lipid-associated formulations of amphotericin B, only liposomal amphotericin B (AmBisome) and ABLC (Abelcet) have been approved for use in proven cases of candidiasis; however, patients with invasive candidiasis also have been treated successfully with amphotericin B colloid dispersion (ABCD, Amphotec or Amphocil). The lipid-associated formulations are less toxic but as effective as amphotericin B deoxycholate.

Antifungal Therapy for Specific *Candida* Species

C. krusei infections should be treated with large doses of amphotericin B (greater than equal to 1 mg/kg per day) or with caspofungin. *C. tropicalis*, and *C. parapsilosis* can be treated with either amphotericin B at or fluconazole.[7] Amphotericin B resistance remains relatively rare despite more than 45 years of clinical use, although it has been reported in *C. lusitaniae* (now *Clavispora lusitaniae*) and *C. guilliermondii*. *Candida rugosa* often is considered to be "polyene tolerant," and these isolates are believed to be selected owing to the wide use of amphotericin B.

Immunocompromised Patients

In immunocompromised patients, the optimal agent, dose, and duration of therapy are unclear, and patients must be monitored carefully with serial blood cultures and careful physical examinations,

TABLE 121-9 Antifungal Therapy of Invasive Candidiasis[7,34]

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Prophylaxis of Candidemia	
Nonneutropenic patients[a]	Not recommended except for severely ill/high-risk patients in whom fluconazole IV/PO 400 mg daily should be used (see the text)
Neutropenic patients[a]	The optimal duration of therapy is unclear but at a minimum should include the period at risk for neutropenia: Fluconazole IV/PO 400 mg daily *or* itraconazole solution 2.5 mg/kg every 12 hours orally *or* micafungin 50 mg (1 mg/kg in patients under 50 kg) IV daily
Solid-organ transplantation, liver transplantation	*Patients with two or more key risk factors[b]:* Amphotericin B IV 10-20 mg daily *or* liposomal amphotericin B (AmBisome) 1 mg/kg/day *or* fluconazole 400 mg orally daily
Empirical (Preemptive) Antifungal Therapy	
Suspected disseminated candidiasis in febrile nonneutropenic patients	None recommended; data are lacking defining subsets of patients who are appropriate for therapy (see the text)
Initial Antifungal Therapy (Documented Candidemia with Unknown Candida Species)	
Febrile neutropenic patients with prolonged fever despite 4-6 days of empirical antibacterial therapy	*Treatment duration:* Until resolution of neutropenia An echinocandin[d] is a reasonable alternative; voriconazole can be used in selected situations (see the text)
Less critically ill patients with no recent azole exposure	An echinocandin[d] or fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily)
Additional mold coverage is desired	Voriconazole
Antifungal Therapy of Documented Candidemia and Acute Hematogenously Disseminated Candidiasis, Unknown Species	
Nonimmunocompromised host[c]	*Treatment duration:* 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection *Remove existing central venous catheters when feasible plus fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily) or an echinocandin[d]*
Patients with recent azole exposure, moderately severe or severe illness, or who are at high risk of infection due to *C. glabrata* or *C. krusei*	An echinocandin[d] Transition from an echinocandin to fluconazole is recommended for patients who are clinically stable and have isolates (eg, *C. albicans*) likely to be susceptible to fluconazole
Patients who are less critically ill and who have had no recent azole exposure	Fluconazole
Antifungal Therapy of Specific Pathogens	
C. albicans, C. tropicalis, and *C. parapsilosis*	Fluconazole IV/PO 6 mg/kg/day *or* an echinocandin[d] or amphotericin B IV 0.7 mg/kg/day *plus* fluconazole IV/orally 800 mg/day; amphotericin B deoxycholate 0.5-1 mg/kg daily or a lipid formulation of amphotericin B (3-5 mg/kg daily) are alternatives in patients who are intolerant to other antifungals; transition from amphotericin B deoxycholate or a lipid formulation of amphotericin B to fluconazole is recommended in patients who are clinically stable and whose isolates are likely to be susceptible to fluconazole (eg, *C. albicans*); voriconazole (400 mg [6 mg/kg] twice daily × two doses then 200 mg [3 mg/kg] twice daily thereafter) is efficacious, but offers little advantage over fluconazole; it may be utilized as step-down oral therapy for selected cases of candidiasis due to *C. krusei* or voriconazole-susceptible *C. glabrata* *Patients intolerant or refractory to other therapy[e]:* Amphotericin B lipid complex IV 5 mg/kg/day Liposomal amphotericin B IV 3-5 mg/kg/day Amphotericin B colloid dispersion IV 2-6 mg/kg/day
C. krusei	Amphotericin B IV ≤1 mg/kg/day *or* an echinocandin[d]
C. lusitaniae	Fluconazole IV/orally 6 mg/kg/day
C. glabrata	An echinocandin[d] (transition to fluconazole or voriconazole therapy is not recommended without confirmation of isolate susceptibility)
Neutropenic host[f]	*Treatment duration:* Until resolution of neutropenia *Remove existing central venous catheters when feasible, plus:* Amphotericin B IV 0.7-1 mg/kg/day (total dosages 0.5-1 g) *or patients failing therapy with traditional amphotericin B:* Lipid formulation of amphotericin B IV 3-5 mg/kg/day
Chronic disseminated candidiasis (hepatosplenic candidiasis)	*Treatment duration:* Until calcification or resolution of lesions *Stable patients:* Fluconazole IV/orally 6 mg/kg/day *Acutely ill or refractory patients:* Amphotericin B IV 0.6-0.7 mg/kg/day
Urinary candidiasis	*Asymptomatic disease:* Generally no therapy is required *Symptomatic or high-risk patients[g]*: Removal of urinary tract instruments, stents, and Foley catheters, +7-14 days therapy with fluconazole 200 mg orally daily *or* amphotericin B IV 0.3-1 mg/kg/day

PO, orally.

[a]Patients at significant risk for invasive candidiasis include those receiving standard chemotherapy for acute myelogenous leukemia, allogeneic bone marrow transplants, or high-risk autologous bone marrow transplants. However, among these populations, chemotherapy or bone marrow transplant protocols do not all produce equivalent risk, and local experience should be used to determine the relevance of prophylaxis.

[b]Risk factors include retransplantation, creatinine of more than 2 mg/dL (177 μmol/L), choledochojejunostomy, intraoperative use of 40 units or more of blood products, and fungal colonization detected within the first 3 days after transplantation.

[c]Therapy is generally the same for acquired immunodeficiency syndrome (AIDS)/non-AIDS patients except where indicated and should continued for 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection. All patients should receive an ophthalmologic examination. Amphotericin B can be switched to fluconazole (IV or oral) for the completion of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach because it can be used to identify isolates that are unlikely to respond to fluconazole or amphotericin B. However, this is not currently available at most institutions.

[d]Echinocandin = caspofungin 70 mg loading dose, then 50 mg IV daily maintenance dose, or micafungin 100 mg daily, or anidulafungin 200 mg loading dose, then 100 mg daily maintenance dose.

[e]Often defined as failure of ≥500 mg amphotericin B, initial renal insufficiency (creatinine ≥2.5 mg/dL [≥221 μmol/L] or creatinine clearance <25 mL/min [< 0.42 mL/s]), a significant increase in creatinine (to 2.5 mg/dL [221 μmol/L] for adults or 1.5 mg/dL [133 μmol/L] for children), or severe acute administration-related toxicity.

[f]Patients who are neutropenic at the time of developing candidemia should receive a recombinant cytokine (granulocyte colony-stimulating factor or granulocyte–monocyte colony-stimulating factor) that accelerates recovery from neutropenia.

[g]Patients at high risk for dissemination include neutropenic patients, low-birth-weight infants, patients with renal allografts, and patients who will undergo urologic manipulation.

Data from reference 7.

TABLE 121-10 Comparative Trials for Initial Antifungal Therapy in the Febrile Neutropenic Host

Year Published	Study Drugs	Study Design	Results and Comments
1982	Placebo versus amphotericin B	Randomized	Favored amphotericin B
1989	Placebo versus amphotericin B	Randomized	Favored amphotericin B
1996	Fluconazole versus amphotericin B	Randomized	Defervescence: equivalence; safety analysis favored fluconazole
1998	Fluconazole versus amphotericin B	Randomized	Composite: equivalence; secondary analysis favored fluconazole
2000	Fluconazole versus amphotericin B	Randomized	Composite: equivalence; safety analysis favored fluconazole
1999	Liposomal amphotericin B versus amphotericin B	Randomized, double blind	Composite: equivalence; secondary analysis favors liposomal amphotericin B
2000	Liposomal amphotericin B versus amphotericin B lipid complex	Randomized, double blind	Liposomal amphotericin B had superior safety versus amphotericin B lipid complex and a similar therapeutic success rate
2001	Itraconazole versus amphotericin B	Randomized, open label	Composite: equivalence; secondary analysis favors itraconazole
2002	Voriconazole versus liposomal amphotericin B	Randomized, open label	Composite: equivalence; secondary analysis variable (voriconazole failed to meet criteria for noninferiority); fewer breakthrough infections with voriconazole
2004	Caspofungin versus liposomal amphotericin B	Randomized, double blind	Composite: equivalence; secondary analysis favored caspofungin for treatment of baseline infections
2005	Liposomal amphotericin B loading regimen (10 mg/kg/day × 14 day) vs standard dosing (3 mg/kg/day)	Randomized, prospective, double blind	Loading regimen did not demonstrate any benefit in overall response or survival and was associated with higher rates of nephrotoxicity and hypokalemia

Data from reference 74.

particularly of the retina. Patients who are neutropenic at the time of developing candidemia should receive a recombinant cytokine (granulocyte colony-stimulating factor or granulocyte-monocyte colony-stimulating factor) that accelerates recovery from neutropenia.[7]

Prophylaxis

Recognition of the role of the GI tract in invasive *Candida* infections has led to efforts to decrease infections by prophylactic administration of topical or systemically absorbed antifungal agents in immunocompromised patients. The use of systemically absorbable agents such as azole antifungal agents appears to decrease the risk of IFIs.[7]

Several antifungal agents, including fluconazole (400 mg/day), posaconazole (200 mg three times daily), micafungin or caspofungin (50 mg daily) administered from the start of the conditioning regimen until day 75, can reduce the frequency of invasive *Candida* infections and decrease mortality in patients undergoing allogeneic bone marrow transplantation.[7,21,73]

Similarly, in less risk-selected patients with hematologic malignancies who are undergoing remission-induction chemotherapy, fluconazole, posaconazole, or caspofungin, during induction chemotherapy for the duration of neutropenia, are effective in preventing systemic infection and death caused by *Candida* species.[7]

For solid-organ transplant recipients, fluconazole or liposomal amphotericin B is recommended as postoperative antifungal prophylaxis for liver, pancreas, and small bowel transplant recipients at high risk of candidiasis.[7,20]

Widespread use of prophylactic fluconazole in all ICU patients is not warranted and may lead to an increase in resistance and adverse events. If utilized, prophylactic fluconazole should target high-risk patients with a presumed risk of invasive candidiasis of 10% to 15%.[7,27]

Empirical Therapy for Febrile Neutropenic Patients

Many clinicians advocate early institution of empirical IV amphotericin B in patients with neutropenia and persistent (greater than 5-7 days) fever.[21] However, the potential toxicities (particularly nephrotoxicity) of this agent preclude its routine use in all patients. Suggested criteria for the empirical use of amphotericin B include: (a) fever of 5 to 7 days' duration that is unresponsive to antibacterial agents, (b) neutropenia of more than 7 days' duration, (c) no other obvious cause for fever, (d) progressive debilitation, (e) chronic adrenal corticosteroid therapy, and (f) indwelling intravascular catheters. In patients who fail therapy with amphotericin B, lipid formulations of amphotericin B can be used. Lipid formulations of amphotericin B can be used as alternatives to amphotericin B deoxycholate for empirical therapy. Although they do not appear to be substantially more effective, there is less drug-related toxicity (Table 121-10).[74]

Itraconazole and fluconazole have demonstrated efficacy equivalent to that of d-AmB in patients with hematologic malignancy (not treated with allogeneic HSCT). However, as fluconazole is not active against filamentous fungi, its use in patients at high risk for these pathogens should be avoided. If itraconazole is used, the IV formulation should be used because the bioavailability of the oral formulations (including the solution) is unreliable; however, it is no longer available. Voriconazole and caspofungin were compared with liposomal amphotericin B in large randomized, multicenter trials of empirical antifungal therapy in febrile neutropenic patients. Voriconazole did not fulfill the protocol-defined criteria for noninferiority; however, it was superior in reducing documented breakthrough infections, infusion-related toxicity, and nephrotoxicity. Patients who received voriconazole had more frequent episodes of transient visual disturbances and hallucinations. Caspofungin demonstrated equivalent efficacy but was superior in the successful treatment of baseline IFIs.[74,75]

Specific Therapy

Amphotericin B, the azoles, and the echinocandins have roles in the treatment of hematogenous candidiasis, and the choice of therapy is guided by weighing the greater activity of amphotericin B for some non-*albicans* species (eg, *C. krusei*) against the lower toxicity and ease of administration of fluconazole and the echinocandins.[7]

Most clinicians recommend amphotericin B in total dosages of 0.5 to 1 g administered over approximately 1 to 2 weeks in patients with *Candida* endophthalmitis and in all neutropenic patients with candidemia. Longer courses of therapy can be needed in some patients.[17] Fluconazole and amphotericin B appear similarly effective for the treatment of *C. albicans* BSIs in the neutropenic patient; controlled data, however, are lacking. In patients with uncomplicated *C. albicans* fungemia who have not received systemic prophylaxis with antifungal azoles, therapy with fluconazole 400 to 800 mg/day IV

can be considered. However, in patients who have undergone allogeneic HSCT, the role of fluconazole is becoming more limited because of its widespread use for antifungal prophylaxis. In this setting, particularly if the patient has been treated previously with an azole antifungal agent, the possibility of microbiologic resistance must be considered. Infections with fluconazole-resistant *Candida* species, including *C. glabrata*, *C. krusei*, and fluconazole-resistant *C. albicans*, or with *Aspergillus* species are more likely.

Clinical **Controversy...**

Treatment of Candidemia in Non-Neutropenic Adults Once the *Candida* Species Is Identified

Expert opinion is divided regarding the optimal therapy of infections caused by *C. glabrata*.[76,77] Since *C. glabrata* often demonstrate reduced susceptibility to fluconazole, treatment with echinocandins, or amphotericin B at a dosage of 0.7 mg/kg/day is often recommended as initial therapy although there are successful treatment outcomes reported in response to fluconazole therapy of 6 to 12 mg/kg/day, and may be suitable in less critically ill patients.[76,77] The severity of illness and choice of antifungal predict response in patients with *C. glabrata* fungemia, and the choice of antifungal (fluconazole or an echinocandin) does not influence mortality. Failure is associated with admission to an intensive care unit. When fluconazole is dosed appropriately, (Table 121-9) *C. glabrata* fluconazole susceptibility breakpoints are predictive of clinical and microbiological response. Echinocandin therapy is independently associated with treatment success, but not survival, in invasive candidiasis due to *C. glabrata*.[77]

Amphotericin B, at a dosage of 1 mg/kg/day, is recommended for the management of systemic *C. krusei* infections. *C. tropicalis* and *C. parapsilosis* may be treated with either amphotericin B at 0.6 mg/kg/day or fluconazole at 6 mg/kg/day. Candidemia due to *C. parapsilosis* has increased in frequency among pediatric populations and appears to be associated with a lower mortality rate than other species of *Candida.* Since many, but not all isolates of *C. lusitaniae* are resistant to amphotericin B, fluconazole at 6 mg/kg/day is the preferred agent for treatment of this species.

In patients with *C. parapsilosis* candidemia, guidelines[7] recommend the use of fluconazole, since MICs of echinocandins tend to be higher for *C. parapsilosis*. However, a meta-analysis of 5 randomized, blinded, comparative trials for treatment of candidemia or invasive candidiasis concluded that the overall treatment success of echinocandins versus other agents was similar: 76.5% versus 73%.[78,79] In patients with *Candida glabrata* candidemia, guidelines recommend the use of an echinocandin.[7] Treatment should be continued for 2 weeks, in the absence of metastatic complications of disease. It is important to note when counting days of therapy that the days of treatment 'begin' on the first day of documented clearance of *Candida* species from bloodstream, with the use of an effective antifungal agent to which the species is susceptible.

Updated IDSA and European guidelines have recently been published.[7,31,80] In the European Guidelines, important recommendations include the recommendation for daily blood cultures until negative, and that patients can be switched to oral therapy after 10 days of IV therapy. They also recommend the use of amphotericin or echinocandins preferentially if catheters cannot be removed.[31,80,81]

CANDIDURIA

Within the urinary tract, most common lesions are either *Candida* cystitis or hematogenously disseminated renal abscesses. *Candida* cystitis often follows catheterization or therapy with broad-spectrum antimicrobial agents. The diagnosis of *Candida* cystitis can be problematic because of the frequent presence of *Candida* pseudohyphae and yeast cells in urine specimens secondary to urethral colonization. The usefulness of urine colony counts or antibody coating techniques is questionable. The recovery of 10,000 organisms or visualization of both yeast and pseudohyphae from fresh midstream urine or from bladder urine obtained by single catheterization (not indwelling) is suggestive of genitourinary candidiasis. In most patients, the infection is asymptomatic and clears spontaneously without specific antifungal therapy.

Initial therapy of candidal cystitis should focus on removal of urinary catheters whenever possible. Changing the catheter will eliminate candiduria in only 20% of patients, whereas discontinuation will eradicate *Candida* in 40% of patients. Asymptomatic candiduria rarely requires therapy. Therapy should be used in symptomatic patients and in neutropenic patients, as well as in patients with renal allografts and those who will undergo urologic manipulation, because of the risk of dissemination.[82,83]

Fluconazole 200 mg/day for 14 days hastens the time to a negative urine culture as compared with placebo treatment, but 2 weeks after the end of therapy, the frequency of a negative urine culture remains the same with both treatments.[83] Short courses of therapy are not recommended; treatment should include removal of catheters and stents whenever possible plus 7 to 14 days of therapy. Bladder irrigation with amphotericin B (50 mg in 500 mL sterile water instilled twice daily into the bladder via a three-way catheter) is only transiently effective. Minimal quantities (less than 3%) of amphotericin B are absorbed systemically from the bladder.[83,84]

ASPERGILLOSIS

Saprophytic molds belonging to the *Aspergillus* spp. can be found around the world, of which, *Aspergillus fumigatus* is the most commonly observed pathogen, followed by *Aspergillus flavus*. Guidelines for the prophylaxis and empiric treatment of IA in neutropenic hosts can be referred to for more comprehensive details.[85]

IA is the second most common IFI, with increasing incidence over the last 20 years along with the advances in the treatment of hematological malignancies. The infection most commonly affects immunocompromised patients and patients with acute myeloid leukemia (AML) and those who undergo allogeneic HSCT who have prolonged durations (more than 10 days) of neutropenia are at highest risk. In the highest risk group, IA rates can reach 25%. The frequency of IA and infections caused by other molds has increased over the past 2 decades. Despite heightened awareness of the profiles of patients at risk, for *Aspergillus* infections, and despite the advent of liposomal formulations of amphotericin B, IA continues to be associated with extremely high mortality rates.[12,86] The crude mortality approaches 80% to 90% in patients with AIDS and bone marrow transplant patients. Major target sites for primary invasive disease include the lungs and sinuses; frequently, secondary infections involve the central nervous system. The appropriate duration of treatment is based on the extent of the infection, response to therapy, and host factors.[12]

Epidemiology

Aspergillus is a ubiquitous mold that grows well on a variety of substrates, including soil, water, decaying vegetation, moldy hay or straw, and organic debris. Although more than 300 species of *Aspergillus* have been characterized, three species are most commonly

pathogenic: *A. fumigatus*, *A. flavus*, and *Aspergillus niger*. The varying degrees of pathogenicity of each species depend on their relative geographic prevalence, conidial size and shape, thermotolerance, and production of mycotoxins. For example, transport of *A. fumigatus* conidia into the lungs is facilitated by their smaller diameter in comparison with *A. flavus* and *A. niger*.

9 The term *aspergillosis* may be broadly defined as a spectrum of diseases attributed to allergy, colonization, or tissue invasion caused by members of the fungal genus *Aspergillus*. A single satisfactory classification system for these disease entities is difficult because different populations of patients can develop the same type of infection. For example, osteomyelitis can result from local trauma or hematogenous dissemination in an immunocompromised host. Colonization in normal hosts can lead to allergic diseases ranging from asthma to allergic BPA or, rarely, invasive disease.[87]

Pathophysiology

Aspergillosis generally is acquired by inhalation of airborne conidia that are small enough (2.5-3 microns) to reach alveoli or the paranasal sinuses. Each conidiophore releases 10^4 conidia that remain suspended for long periods and are viable for months in dry locations. Although some authors advocate monitoring of hospital air for *Aspergillus* conidia, guidelines for interpreting results do not exist. The use of high-efficiency particulate air (HEPA) filters in operating rooms and laminar flow rooms and removal of immunocompromised patients from hospital renovation sites can be helpful in preventing infection in this population.

Superficial or locally invasive infections of the ear, skin, or appendages often can be managed with topical antifungal therapy. Skin infections in patients with burn wounds, although uncommon, can progress to deep-tissue invasion despite the use of topical or parenteral antifungal agents. Risk factors for deep infection include extensive thermal injuries, malnutrition, cirrhosis, and previous infection with *Pseudomonas aeruginosa*.[88-90]

Allergic manifestations of *Aspergillus* range in severity from mild asthma to allergic BPA. BPA, which is almost always caused by *A. fumigatus*, is characterized by severe asthma with wheezing, fever, malaise, weight loss, chest pain, and a cough productive of blood-streaked sputum. Following recurrent episodes of severe asthma, the disease usually progresses to fibrosis and bronchiectasis with granuloma formation. When *Aspergillus* conidia become trapped in the viscous mucus of asthmatic patients, BPA develops. The fungus grows, releasing toxins and antigens. The resulting host sensitization results in a variety of immune reactions. Early in the course of disease, an immunoglobulin E (IgE)-mediated (type I) immune reaction results in bronchospasm, eosinophilia, and immediate skin reactivity. The ensuing fibrosis and pulmonary infiltrates appear to be mediated by circulating or precipitating antibody complexes of IgG antibody, followed by granuloma formation and mononuclear infiltration because of a type IV delayed hypersensitivity reaction. Therapy is aimed at minimizing the quantity of antigenic material released in the tracheobronchial tree. Management of acute asthma attacks minimizes trapping of *Aspergillus* by bronchial secretions, and administration of parenteral corticosteroids clears lung infiltrates.[88-90] Antifungal therapy generally is not indicated in the management of allergic manifestations of aspergillosis, although some patients have demonstrated a decrease in their corticosteroid dose following therapy with itraconazole.[91]

Aspergilloma

In the nonimmunocompromised host, *Aspergillus* infections of the sinuses most commonly occur as saprophytic colonization (aspergillomas or "fungus balls") of previously abnormal sinus tissue. An aspergilloma is composed of intertwined *Aspergillus* hyphae matted together with fibrin, mucus, and cellular debris. Infection usually is localized in the maxillary sinus and rarely is associated with local invasion of adjacent bone or brain tissue. Sinus aspergillosis also can present as allergic sinusitis with nasal drainage of brownish mucous plugs. Therapy with corticosteroids and surgery generally is successful. In the immunocompromised host, subacute, chronic, or fulminant invasive disease can be seen, and a combination of antifungal and surgical therapy generally is required.[85]

Pulmonary aspergillomas are fungus balls arising in preexisting cavities because of tuberculosis, histoplasmosis, lung tumors, or radiation fibrosis, although occasionally no previous pulmonary disease is present. The diagnosis of aspergilloma generally is made on the basis of chest radiographs, on which aspergillomas appear as a solid rounded mass, sometimes mobile, of water density within a spherical or ovoid cavity and separated from the wall of the cavity by an airspace of variable size and shape. Patients generally experience chest pain, dyspnea, and sputum production. Hemoptysis is observed in 50% to 80% of patients, probably because of ulceration of the epithelial lining of the cavity with formation of granulation tissue, and hemoptysis is the cause of death in up to 26% of patients with aspergilloma. A poor prognosis is associated with increasing size or number of aspergillomas, immunosuppression (including corticosteroids), increasing *Aspergillus*-specific titers, underlying sarcoidosis, and HIV infection. Although *Aspergillus* can be cultured in only 50% to 60% of patients, precipitating antibodies are positive in virtually 100% of patients.

Invasive disease occurs rarely, and therapy therefore is controversial. There are no controlled clinical trials with which to guide therapy, and recommendations for treatment have been generated from uncontrolled trials and case reports.[85] Concern regarding the risk of severe hemorrhage has led some clinicians to use aggressive surgical excision of aspergillomas or pulmonary resection in patients with hemoptysis. Complications, including bronchopulmonary fistulas, hemorrhage, empyema, and persistent airspace problems, have led to the recommendation that surgical intervention be reserved for patients with severe (greater than 500 mL/24 h) hemoptysis, however. Bronchial artery embolization has been used to occlude the vessel that supplies the bleeding site in patients experiencing hemoptysis. Unfortunately, bronchial artery embolization generally is unsuccessful or only temporarily effective. Collateral circulation eventually develops, supplying blood flow to the affected area, and hemoptysis often recurs; consequently, reembolization is often unsuccessful. Bronchial artery embolization should be used as a temporizing procedure in a patient with life-threatening disease who might respond to more definitive therapy if hemoptysis is stabilized. Mild to moderate hemoptysis should be managed conservatively. Although IV amphotericin B generally is not useful in eradicating aspergillomas, inhaled or intracavitary instillation of amphotericin B has been employed successfully in a limited number of patients. Itraconazole has been efficacious in uncontrolled studies; however, the dose and duration of therapy have not been standardized. Hemoptysis generally ceases when the aspergilloma is eradicated.[85]

Invasive Aspergillosis

IA remains a disease of very high mortality: for example, in HSCT recipients with a diagnosis of invasive aspergillosis, the 3-month post HSCT mortality rate is 53.8% for autologous transplant recipients but approaches 90% for allogeneic HSCT recipients. However, the overall 1-year survival rate is only about 20% for autologous and allogeneic HSCT recipients with proven or probable invasive mold infections.[92-94]

Although exposure to *Aspergillus* conidia is nearly universal, impaired host defenses are required for the development of invasive disease. Phagocytes (neutrophils, monocytes, and macrophages) rather than antibodies or lymphocytes constitute the primary host defense system against invasive disease with aspergillosis. Macrophages prevent germination of conidia and also eradicate conidia,

providing the first line of defense against invasive disease. Administration of corticosteroids appears to impair the killing of conidia by macrophages and to impair mobilization of neutrophils. Neutrophils halt hyphal growth and dissemination and kill mycelia, constituting a second line of defense. Prolonged neutropenia appears to be the most important predisposing factor to the development of IA, accounting for the high frequency of disease in patients with acute leukemia.[87]

Invasive disease with *Aspergillus* can arise de novo or from any of the allergic or colonizing forms of aspergillosis. Predisposing factors to the development of IA include glucocorticoid therapy, particularly following chronic administration or with higher dosages (30-200 mg/day of prednisone), cytotoxic agents, and recent or concurrent therapy with broad-spectrum antimicrobial agents. Patients with chronic hepatitis, alcoholism, diabetes mellitus, chronic granulomatous disease, leukopenia (less than 1,000 cells/mm^3 [less than 1×10^9/L]), leukemia (particularly acute lymphocytic or myelogenous leukemia), lymphoma, and acute rejection of an organ transplant are also at a higher risk of invasive disease. Although rare, IA has been reported in apparently normal hosts.[87] Aspergillosis is an uncommon fungal infection in patients with AIDS. AIDS patients may be at less risk for aspergillosis than other fungal infections because the primary cellular defect in AIDS patients is in the T-lymphocytes, whereas neutrophils and macrophages constitute the primary lines of defense to infection with aspergillosis.

Clinical Presentation

The lung is the most common site of invasive disease.[87] In the immunocompromised host, aspergillosis is characterized by vascular invasion leading to thrombosis, infarction, necrosis of tissue, and dissemination to other tissues and organs in the body. If bone marrow function returns, cavitation of the pulmonary lesion generally occurs, and the spread of infection can be halted. The progressive nature of the disease and its refractoriness to therapy are, in part, caused by the organism's rapid growth and its tendency to invade blood vessels.

Signs and Symptoms

Patients with IPA generally have blunted or non-specific signs and symptoms of infection due to impaired inflammatory responses.[95] Patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs. The CNS, liver, spleen, heart, GI tract, pericardium, and other body sites are involved in a substantial minority of cases. In neutropenic patients with *Aspergillus* pneumonia, hyphae invade the walls of bronchi and surrounding parenchyma, resulting in an acute necrotizing, pyogenic pneumonitis. As a result, patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs.

Diagnosis

The diagnosis of aspergillosis is complicated by the presence of *Aspergillus* as a normal commensal in the human GI tract and respiratory secretions, and establishment of a definitive diagnosis of disease is difficult. Demonstration of *Aspergillus* by repeated culture and microscopic examination of tissue provides the most firm diagnosis. A definitive diagnosis of invasive pulmonary aspergillosis (IPA) can be made by obtaining a biopsy of lung tissue; however, thrombocytopenia often limits clinicians' ability to perform this procedure. The appearance of *Aspergillus* in tissues varies with increasing host resistance from the normal vegetative hyphae found with necrotic tissue and exudate in the alveoli of immunocompromised hosts to the compact, tangled filaments (*granules*) observed in fungal balls. Identification of *Aspergillus* generally is based on the appearance of 2- to 4-micron-wide septate hyphae that are dichotomously branched at 45° angles. Sporulation is observed rarely in tissue. Although growth on Sabouraud dextrose or brain-heart infusion agar can be used for primary culture, bronchoscopy or bronchoalveolar lavage cultures are positive in only 40% of histopathologically identified specimens. Blood, CSF, and bone marrow cultures are rarely positive for *Aspergillus*.

Currently, the diagnosis is determined with the use of high resolution CT, in which IPA will manifest early on as "halo sign" (an area of low attenuation surrounding a nodular lung lesion, caused by edema or bleeding surrounding an ischemic area). In late IA nodular lesions, diffuse pulmonary infiltrates, consolidation, or ground glass opacities can be observed, and CT scans may demonstrate the crescent sign (an air crescent near the periphery of a lung nodule caused by contraction of infarcted tissue), while chest radiographs can demonstrate wedge-shaped, pleural-based infiltrates or cavities.[95] These signs are not specific to IPA, however, as bacteria and other fungal infections may produce similar findings. CT abnormalities are best documented in neutropenic marrow transplant recipients and commonly precede plain chest radiograph abnormalities.

Diagnostic Tests

New laboratory methods that allow for early differentiation of IFIs due to *Aspergillus* species versus zygomycetes and other moulds would be helpful in allowing clinicians in the earlier initiation of appropriate antifungal therapy. Although PCR-based testing is being performed in some centers, and appears promising, no FDA-approved method is commercially available.

The galactomannan test is an enzyme-linked immunosorbent assay (ELISA) (Platelia *Aspergillus* EIA test; Bio-Rad Laboratories) that detects galactomannan, an antigen released from *Aspergillus* hyphae upon invasion of host tissue. The clinical utility of this assay has been assessed in the clinical setting by sampling serum, BAL fluid, cerebrospinal fluid (CSF), and pleural fluid; however, the currently approved test is performed on serum. Additionally, while FDA-approved for use in the diagnosis of IA in HSCT recipients and in patients with leukemia; its usefulness in solid-organ transplant and pediatric populations needs to be established. In most patients, circulating antigen can be detected at a mean of 8 days before diagnosis by other means. The test has a sensitivity ranging from 30% to 100% and a specificity of approximately 85%; however, the sensitivity of the assay is decreased in patients receiving mold-active drugs on the day of sampling.[95] False positives can occur, particularly in patients receiving cyclophosphamide, piperacillin–tazobactam and amoxicillin–clavulanate, those with bifidobacteria infections, and in neonates.[96,97] And there are differences in the cutoff values for a positive result in the United States versus Europe. False negatives can occur during the concomitant use of antifungals, presumably because the level of galactomannan is related to the fungal burden.[95] In addition, it is important to note that the utility of galactomannan testing in the setting of prophylaxis has not been defined.[94]

1,3-β-D-glucan is a component of fungal cell walls that can be detected colorimetrically in clinical samples, including blood and bronchoalveolar lavage specimens, using a chromogenic variant of the limulus amoebocyte lysate assay. However, the current FDA-approved test (Fungitell; Associates of Cape Cod) is performed only on serum. The 1,3-β-D-glucan test can be used to detect most fungi, including *Fusarium*, *Trichosporon*, *Saccharomyces*, and *Acremonium*, which are less common but very important fungal pathogens, with a sensitivity of 55% to 100% and a specificity of 52% to 100%. However, the test does not detect the zygomycetes or cryptococci, and it can produce false positives in patients undergoing hemodialysis with cellulose membranes, and in other cases for unclear reasons.[95] Although a positive test result for the presence of (1,3)-β-D-glucan [BG] does not identify the infecting fungus, the practical application

of this test includes its use as a screening assay (presumptive marker) for invasive fungal infection to allow the earlier initiation of antifungal therapy. Other tests are necessary for the confirmation and identification of the fungal pathogen.

TREATMENT
Invasive Aspergillosis

Therapy for IA is far from optimal at this time in part because of the difficulties in establishing a diagnosis and in part because of a lack of truly effective antifungal agents. Administration of amphotericin B appears to decrease mortality from more than 90% to approximately 45%. These data, however, are difficult to interpret because many patients were diagnosed postmortem, or amphotericin B therapy was not administered until the patient had very advanced disease. Mortality from pulmonary aspergillosis in bone marrow transplant recipients exceeds 94% regardless of therapy.[87] Although early diagnosis and administration of antifungal therapy can result in higher response rates, correction of underlying immune deficits (in particular, return of neutrophil counts) is of paramount importance in eradication of infection.[87]

Until the diagnosis of aspergillosis can be determined more rapidly and definitively, empirical therapy must be instituted when invasive disease is suspected. In patients at highest risk for invasive disease (acute leukemia and bone marrow transplant recipients), the most important predisposing factors include prolonged severe neutropenia (less than 100 cell/μL [less than 0.1×10^9/L] for more than 1 week), graft rejection, chronic administration of corticosteroids, and tissue damage from preexisting infection.[87]

Non-HIV-Infected Patient

Prophylaxis

As noted above in the discussion of prophylaxis for *Candida* infections in immunocompromised hosts, prophylaxis with azoles or echinocandins can reduce the incidence of aspergillosis in select high-risk populations.

Specific Therapy

Even though older azole antifungal agents (miconazole and ketoconazole) possess poor in vitro activity against *Aspergillus* species, newer triazoles demonstrate improved activity both in vitro and in animal models of infection. Antifungal agents with in vitro activity against *Aspergillus* species include amphotericin B, the echinocandins, and the azoles itraconazole, voriconazole, posaconazole, and isavuconazole. Historically, high dosages (1-1.5 mg/kg/day) of d-AmB were utilized for the treatment of suspected or proven invasive aspergillosis. Lipid formulations of amphotericin B are overall less nephrotoxic and at least as effective as amphotericin B, and that they can be effective when amphotericin Bis not.[98] They are indicated when preexisting or arising nephrotoxicity or concomitant nephrotoxic agents preclude high-dose amphotericin B therapy or when treatment with amphotericin Bappears to fail. Use of the highest approved dosages of the lipid formulations for treatment of suspected or documented infections is strongly advocated. However, randomized data from clinical trials are limited for most agents. Thus, while open-label trials support the potential of posaconazole and the echinocandins for treatment of invasive aspergillosis in immunocompromised patients, current guidelines from the US and other countries, consider voriconazole as the agent of choice for the primary treatment of aspergillus.

Voriconazole has emerged as the drug of choice of most clinicians for primary therapy of most patients with IA, based on a pivotal study in which a randomized comparison of voriconazole and d-AmB followed by other licensed antifungal agents for primary therapy for invasive aspergillosis demonstrated superior antifungal efficacy and improved survival at week 12 in the voriconazole arm.[99]

Isavuconazole was recently approved for the primary treatment of aspergillosis, based upon the results of a double blind, randomized, multi-national trial in subjects with proven or probable invasive fungal disease caused by *Aspergillus* spp. or other filamentous fungi. Isavuconazole was well tolerated, with fewer drug-related adverse effects than voriconazole.[100,101]

In patients who are unable to tolerate voriconazole, amphotericin B can be used. Because *Aspergillus* is only moderately susceptible to amphotericin B, full doses (1-1.5 mg/kg/day) are generally recommended, with response measured by defervescence and radiographic clearing. To treat microfoci, therapy should be continued after resolution of clinical and radiographic abnormalities until cultures (if they can be obtained) are negative, and reversible underlying predispositions have abated.

Clinical response rather than any arbitrary total dose should guide duration of therapy. The optimal dosage or duration of treatment of invasive disease is unknown and dependent on the extent of disease, the response to therapy, and the patient's underlying disease(s) and immune status. Response to therapy is largely related to the extent of aspergillosis at the time of diagnosis, and host factors, such as resolution of neutropenia and the return of neutrophil function, lessening immunosuppression, and the return of graft function from a bone marrow or organ transplant.

Lipid formulations of amphotericin B can be indicated in patients with impaired renal function, and in those patients who develop nephrotoxicity while receiving d-AmB. The lipid-based formulations may be preferred as initial therapy in patients with marginal renal function or in patients receiving other nephrotoxic drugs. Although these preparations appear less toxic than standard preparations, only limited data regarding their relative efficacy for IA are available at this time, as the studies with the lipid preparations have been open-label or with historical conventional amphotericin B controls.[70,74]

Although caspofungin (and other echinocandins) have in vitro activity against *Aspergillus* species, echinocandins are unable to completely kill or inhibit *Aspergillus* species. Caspofungin is approved by the FDA for use as salvage therapy in patients who are refractory to or intolerant of other therapies such as conventional amphotericin B, lipid formulations of amphotericin B, and/or itraconazole.[18,75] However, for primary therapy of aspergillosis, response rates are lower with caspofungin than those obtained with voriconazole and amphotericin B.[102]

The role of azoles in the management of azole-resistant aspergillosis remains unclear. In patients infected with azole-resistant strains of *Aspergillus*, limited data suggests that combination therapy with liposomal amphotericin B or a combination of voriconazole or posaconazole with an echinocandin may be effective.

Clinical **Controversy...**

The Role of Combination Antifungal Therapy for the Treatment of Invasive Aspergillosis

The outcome of invasive aspergillosis (IA) continues to be associated with significant attributable mortality, especially in patients with hematological malignancies and in HSCT recipients. Based on extensive experience in the management of bacterial, and more recently, retroviral infections, the use of combination agents for synergistic or additive effects is now common practice, particularly for the treatment of IA. However, while the advantages of combination therapy include the possibility of more rapid, synergistic killing, disadvantages include the possibility of

antagonism, as well as increased cost and the increased risk of drug interactions and adverse effects.

A 'proof of principle' study demonstrated that combination antifungal therapy could provide superior outcomes versus single agent therapy in the treatment of candidemia. High-dose fluconazole, alone or in combination with amphotericin B, in non-immunocompromised patients with candidemia demonstrated no antagonism and a trend toward improved success and more rapid clearance of *Candida* from the bloodstream. However, renal toxicity (from amphotericin B) was higher in the combination therapy arm.[103] Whether these adverse effects would be similar, if lipid formulations were used instead of the deoxycholate formulation of amphotericin B, is not known.

In a recent large study, combination therapy with voriconazole plus anidulafungin, versus voriconazole alone in the subgroup of patients with invasive aspergillosis demonstrated only a trend toward increased 6 week survival.[104] Thus, there are as yet no firm recommendations regarding the use of such combinations in humans.[104,105]

Secondary Prophylaxis

The use of prophylactic antifungal therapy to prevent primary infection or reactivation of aspergillosis during subsequent courses of chemotherapy is controversial.[12] Studies assessing the utility of IV administration of amphotericin B in low doses (0.1 mg/kg per day) as prophylactic therapy or with higher dosages (0.5-0.6 mg/kg per day) as empirical therapy for IFIs in patients with granulocytopenia have not included sufficient numbers of patients to enable detection of differences in the number of *Aspergillus* infections.

In granulocytopenic patients who recover from an episode of IA, the risk of relapse of aspergillosis during subsequent courses of chemotherapy is greater than 50%. Secondary prophylaxis of aspergillosis with empirical administration of high-dose amphotericin B decreases the risk of relapse. Amphotericin B 1 mg/kg per day is started 24 to 48 hours prior to the start of chemotherapy and continued throughout the period of granulocytopenia.

TREATMENT OPTIONS FOR EMERGING PATHOGENS

The increased frequency of fungal pathogens that were once rare is gaining attention from the medical community. Mucormycosis, previously known zygomycosis, is a term describing infections caused by fungi belonging to the order Mucorales. Permissive environmental conditions, selective antifungal pressure, and increased numbers of immunosuppressed patients have led to increased numbers of infections caused by the Mucorales, which include *Rhizomucor* spp., *Absidia* spp. (now *Lichtheimia* spp.), *Rhizopus* spp., *Mucor* spp., and *Cunninghamella* spp. Prompt initiation of antifungal therapy is crucial, as treatment delays are associated with increased mortality.[106]

Of currently available systemic antifungals, only amphotericin B (including the lipid formulations) and posaconazole exhibit good in vitro activity against the Mucorales. Isavuconazole displays variable in vitro activity against the Mucorales, with wide MIC ranges. Prompt initiation of antifungal therapy is crucial, as treatment delays are associated with increased mortality.[106]

Mucor Infections

European guidelines recommend surgical debridement, in addition to therapy with a liposomal or lipid-complex formulation of amphotericin B at a dosage of greater than equal to 5 mg/kg/day. Isavuconazole was approved for the primary treatment of invasive mold infections, and as salvage therapy of patients who were intolerant of or failing prior antifungal therapy.[100,101] The approval was based upon the results of an open-label, noncomparative trial of patients with IFIs caused by rare molds, including members of the order Mucorales and patients with invasive aspergillosis and renal impairment.[101,107]

Fusarium and *Scedosporium*

Unfortunately, the early presentation of *Fusarium* and *Scedosporium* infections often mimics that of aspergillosis. On histopathology, *Scedosporium* species resembles *Aspergillus* species with dichotomously branching, septate hyphae and has a tendency for invasion of vascular structures.[106] These pathogens often demonstrate intrinsic resistance to amphotericin B and are associated with high mortality rates. Interpretive CBPs for antifungal MICs and *Scedosporium* spp. are not available, and the optimal choice and duration of therapy is unknown.[108] Voriconazole is FDA approved for the treatment of serious fungal infections caused by *S. apiospermum* and *Fusarium* species, including *Fusarium solani*, in patients intolerant of or refractory to other therapy.[58]

ANTIFUNGAL THERAPY

Pharmacists must have working knowledge of mechanism of action, spectrum of activity, dosing, and adverse effects of azole antifungals in order to provide appropriate recommendations for therapy. Dosing adjustments are needed for many antifungal agents in the setting of renal or hepatic dysfunction. A summary of the most common adverse effects of systemic antifungal agents are summarized in Fig. 121-3 and described in the text below.[58]

The antifungal armamentarium for the treatment of IFIs includes: (a) inhibitors of the fungal cell membrane such as polyenes (eg, amphotericin B) and azole antifungals, (b) inhibitors of DNA (5-flucytosine), and (c) inhibitors of cell wall biosynthesis (echinocandins).[58]

Antifungal therapy generally includes one or more antifungal agents, depending on the severity of infection and the patients' immune status. Rarely are the agents used in combination. Often therapy is initiated with an IV agent such as amphotericin B, and therapy is changed to an oral (azole) regimen as the patient's clinical status improves and oral therapy is tolerated.

Amphotericin B

Amphotericin B remains the therapy of choice for many systemic fungal infections despite a lack of controlled clinical trials documenting the optimal dosage, duration of therapy, or relative efficacy of this agent in comparison with newer azole antifungal agents. During pregnancy, amphotericin B remains the treatment of choice for most fungal infections because azole antifungals are teratogenic.[84,109] The side effects of amphotericin B generally are categorized as acute (infusion-related) or long term. Amphotericin B commonly causes renal functional impairment, including decreased glomerular filtration rate, hypokalemia, hypomagnesemia, metabolic acidosis due to distal (or type 1) renal tubular acidosis (RTA), and polyuria due to nephrogenic diabetes insipidus. The nephrotoxicity associated with amphotericin B is usually reversible with discontinuation of therapy. However, recurrent renal dysfunction can occur if treatment is reinstituted. The risk of amphotericin B nephrotoxicity is increased by higher daily doses and concurrent therapy with other nephrotoxins, such as an aminoglycoside or cyclosporine. The incidence and severity of nephrotoxicity can be minimized by administering amphotericin B in lipid-based formulations; liposomal amphotericin B may be less nephrotoxic than the ABLC.[58,110]

FIGURE 121-3 Adverse Effects of Systemic Antifungal Agents.

Lipid Formulations of Amphotericin B

The use of d-AmB frequently is associated with the development of induced nephrotoxicity. In an attempt to decrease the incidence of nephrotoxicity, three lipid formulations of amphotericin B have been developed and approved for use in humans: ABLC (Abelcet; Enzon Pharmaceuticals), ABCD (Amphotec; Intermune Pharmaceuticals), and liposomal amphotericin B (AmBisome; Gilead Pharmaceuticals). In these preparations, amphotericin B is incorporated into the phospholipid bilayer membrane rather than in the enclosed aqueous phase.

The various lipid formulations of amphotericin B exhibit markedly different pharmacokinetics; however, whether these differences result in different outcomes in the treatment of specific types of infections (eg, CNS infections) is unclear. Although larger doses of these preparations are required to achieve similar pharmacologic effects as the deoxycholate form of amphotericin B, the toxicity appears to be much lower. Although the FDA-approved dosages of these agents are 5 mg/kg per day (ABLC), 3 to 6 mg/kg per day (ABCD), and 3 to 5 mg/kg per day (liposomal amphotericin B), the agents appear generally equipotent. The optimal dose of these compounds for serious *Candida* infections is unknown; however, dosages of 3 to 5 mg/kg per day appear reasonable.[7]

Lipid formulations of amphotericin B are indicated for patients intolerant of, refractory to, or at high risk of being intolerant to conventional antifungal therapy.[7,110] Intolerance generally is defined as initial renal insufficiency (creatinine greater than 2.5 mg/dL [greater than 221 µmol/L] or creatinine clearance less than 25 mL/min [less than 0.42 mL/s]), a significant increase in creatinine (to 2.5 mg/dL [221 µmol/L] for adults or 1.5 mg/dL [133 µmol/L] for children), or severe acute administration-related toxicity, whereas refractory infections are defined as therapeutic failure of more than 500 mg amphotericin B.

Clinical **Controversy...**

Owing to the higher cost and paucity of randomized trials showing the efficacy of lipid-associated formulations of amphotericin B against proven invasive candidiasis, many clinicians limit their first-line use for the treatment of these infections to individuals who are intolerant to, at high risk of intolerance to, or refractory to amphotericin B deoxycholate. However, the data demonstrating up to a 6.6-fold increase in mortality in patients with amphotericin B-induced nephrotoxicity have convinced other clinicians that high-risk patients (eg, residence in an ICU care or intermediate care unit at the time of initiation of amphotericin B therapy) warrant first-line therapy with these agents.[7,110]

Flucytosine

Flucytosine (also known as 5-flucytosine) is a fluorinated pyrimidine analog that is highly water-soluble. Patients with creatinine clearances of less than 40 mL/min (0.67 mL/s) should receive careful dosage adjustments. Peak serum concentrations (2 hours after an oral dose) should be monitored in all patients (particularly those with a creatinine clearance of less than 10 mL/min [0.17 mL/s]) to maintain peak serum concentrations of more than 100 mg/L (775 µmol/L).[41]

Flucytosine generally is associated with few side effects in patients with normal renal, GI, and hematologic function, although rash, GI discomfort, diarrhea (5%-10%), and reversible elevations in hepatic enzymes are observed occasionally. In patients with renal dysfunction or concomitant amphotericin B therapy, leukopenia, thrombocytopenia, and (rarely) enterocolitis can occur. Although studies have suggested that little or no conversion of flucytosine to fluorouracil occurs in vitro, serum concentrations of greater than 1,000 ng/mL (1 mg/L; ~7.7 µmol/L) (therapeutic for the treatment of malignancies) have been documented in some patients. Investigators have theorized that flucytosine may be secreted into the GI tract, deaminated by intestinal bacteria, and reabsorbed as 5-fluorouracil.[41]

Flucytosine is used in combination with amphotericin B or fluconazole in the treatment of cryptococcosis or (less commonly) candidiasis. The rapid development of resistance to flucytosine, however, precludes its use as single-agent therapy. Mechanisms for drug resistance can include loss of deaminase and decreased permeability to the drug.[41]

Echinocandins

The echinocandins (caspofungin, micafungin, and anidulafungin) are a new class of antifungal agents that act as concentration-dependent,

noncompetitive inhibitors of BG synthase, an essential component of the cell wall of susceptible filamentous fungi that is absent in mammalian cells.[75,111]

All echinocandins display linear pharmacokinetics following administration of IV dosages, and are degraded primarily by the liver (also in the adrenals and spleen) by hydrolysis and *N*-acetylation. Following initial distribution, echinocandins are taken up by red blood cells (micafungin) and the liver (caspofungin and micafungin) where they undergo slow degradation to mainly inactive metabolites, although two uncommon metabolites of micafungin possess antifungal activity. Degradation products are excreted slowly over many days, primarily through the bile. Among the echinocandins, anidulafungin is unique in being eliminated almost exclusively by slow chemical degradation rather than undergoing hepatic metabolism.[75]

Echinocandins are available only as parenteral formulations, are not dialyzable, and do not require dosage adjustment in patients with renal insufficiency. They have minimal CSF penetration, largely because of their high protein binding and large molecular weights, although the clinical relevance of these findings can be disputed, given that several other antifungal agents (amphotericin B and itraconazole) are effective for the treatment of fungal meningitis despite low CSF concentrations.

Adverse effects of echinocandins include histamine release resulting in rash, facial swelling, and itchiness. Limited experience suggests that caspofungin and micafungin are safe to use in pediatric patients; the safety and effectiveness of anidulafungin in pediatric patients has not been established. At the time of FDA approval, there were concerns regarding the safety of caspofungin when combined with cyclosporine. However, three retrospective analyses of the use of caspofungin and cyclosporine in patients do not support a risk of clinically relevant hepatotoxicity.[75,111]

Azole Antifungal Agents

Adverse effects of azoles include GI disturbances (primarily nausea, vomiting, epigastric pain, and diarrhea), which appear to be more common in patients receiving ketoconazole and the solution formulation of itraconazole. Although cyclodextrin is not absorbed following oral administration, use of the IV formulations of itraconazole and voriconazole is limited to 2 weeks because of concerns for potential nephrotoxicity secondary to accumulation of the cyclodextrin vehicle, although recent studies suggest that this is of less concern than previously thought.[112] Fluconazole is well tolerated; intestinal complaints are the most frequently reported, followed by headaches and rash.[113] Unlike ketoconazole, fluconazole does not inhibit testicular or adrenal steroidogenesis in healthy volunteers or hospitalized patients. Reversible alopecia occurs not infrequently and usually appears after several months of treatment with higher doses of fluconazole.[114] Azoles are potentially teratogenic and should be avoided in pregnant women.[58,109]

Azole antifungals have been implicated in idiosyncratic drug induced liver injury with the incidence and pattern of injury varying between specific agents.[114-116] The exact mechanism of toxicity has not been elucidated and there is varying level of evidence with regards to the effect of dose on the development of the toxicity. It is recommended that baseline liver function tests (LFTs) be obtained for patients being started on therapy with these agents and periodically monitored. In general, hepatotoxicity can occur at any time after initiation of the antifungal with most cases occurring in the first month of therapy. The liver injury is usually reversible with discontinuation of the offending agent. Several reports support that substitution of the offending azole antifungal with a different azole antifungal can occur without impacting resolution of the toxicity.

Itraconazole

Itraconazole is triazole antifungal with a broad spectrum of antifungal activity. Despite its marked structural similarity to ketoconazole, itraconazole differs in several important respects. Itraconazole appears to have greater specificity against fungal versus mammalian CYP, resulting in greater potency and a decrease in CYP-mediated side effects. In addition, itraconazole possesses excellent in vitro activity against *Aspergillus* and *Sporothrix* species.[58,114]

Like ketoconazole, the capsule formulation of itraconazole depends on the availability of low gastric pH for dissolution and absorption. Administration with food appears to enhance significantly the bioavailability of itraconazole capsules, whereas it decreases the bioavailability of the oral solution. Because itraconazole exhibits pH-dependent dissolution and absorption, absorption of the capsule formulation is impaired in patients receiving antacids or H_2-receptor antagonists and in patients with achlorhydria.[112] Plasma concentrations of itraconazole following a single oral dose (capsules) in HIV-infected patients are approximately 50% lower than concentrations observed in healthy volunteers. The capsule formulation of itraconazole exhibits unpredictable oral bioavailability, particularly in subjects with hypochlorhydria and in patients with enteropathy caused by mucositis or graft versus host disease GVHD of the gut. An oral suspension formulation of itraconazole is available; that uses cyclodextrin as a solubilizing vehicle to increase the solubility of the drug. The oral bioavailability of the solution is unaffected by alterations in gastric pH or in patients with enteropathy.[58,112,114]

Fluconazole

Fluconazole is a triazole antifungal agent with markedly different pharmacologic features than other marketed azole antifungals. The small molecular weight, low protein binding, and increased water solubility of fluconazole result in rapid, essentially complete absorption of drug following oral administration. Because fluconazole is excreted primarily (greater than 80%) as unchanged drug in the urine, dosage adjustments are necessary in patients with renal dysfunction.[58]

Voriconazole

The hepatic biotransformation of voriconazole is fairly complex and involves CYP2C19, CYP3A4, and CYP2C9, with most metabolism mediated through CYP2C19. Two of the CYPs involved in voriconazole metabolism (CYP2C19 and CYP2C9) exhibit genetic polymorphism; variability in the CYP2C19 genotype accounts for approximately 30% of the overall between subject variability in voriconazole pharmacokinetics. About 3% to 5% of white and African human populations are poor metabolizers, while 15% to 20% of Asian populations are poor metabolizers. Drug levels can be as much as fourfold greater in poor metabolizers than in individuals who are homozygous extensive metabolizers. Coadministration of voriconazole with drugs that are potent CYP450 enzyme inducers can significantly reduce voriconazole levels. Voriconazole drug interactions are dose-dependent, as they exhibit unpredictable nonlinear pharmacokinetics; thus, drug interactions are more difficult to predict and manage.[117]

The most common side effect of voriconazole is a reversible disturbance of vision (photopsia), which occurs in approximately 30% of patients but rarely leads to discontinuation of the drug. Symptoms tend to occur during the first week of therapy and decrease or disappear despite continued therapy.

Patients experience altered color discrimination, blurred vision, the appearance of bright spots and wavy lines, and photophobia. Patients should be cautioned that driving can be hazardous because of the risk of visual disturbances. The visual effects are associated with changes in electroretinogram tracings, which revert to normal

when treatment with the drug is stopped; no permanent damage to the retina has been demonstrated.[58,118-120]

Clinical **Controversy...**

Controversy has arisen about whether single-drug therapy or combination therapy (eg, voriconazole plus an echinocandin or voriconazole plus a lipid formulation of amphotericin B) is optimum therapy. At present, the highest interest concerns combination therapy in the treatment of aspergillosis, given the continued high mortality of these infections.[83] However, in vitro and animal data have produced conflicting results. Several retrospective studies have suggested an improvement in mortality with combination therapy with two or three antifungal agents; however, prospective, controlled human studies are lacking. Thus, there are as yet no firm recommendations regarding the use of such combinations in humans.[12]

Posaconazole

Posaconazole has a broad spectrum of antifungal activity, including *Aspergillus* and *Candida* species and zygomycetes. In vitro studies demonstrate that posaconazole is an inhibitor but not a substrate of hepatic (but not total) CYP3A4, and both a substrate and an inhibitor of P-glycoprotein (Pgp), suggesting that it may exhibit a drug interaction profile similar to other azoles. In addition, posaconazole undergoes glucuronidation by uridine diphosphate (UDP)-glucuronosyltransferase enzymes.[117]

Posaconazole was initially developed as an oral suspension for the prevention of IFIs in immunocompromised patients, including hematologic malignancy patients with prolonged neutropenia from chemotherapy as well as HSCT patients with GVHD.[121] However, to ensure adequate absorption, the suspension formulation had to be administered 2 to 3 times daily, with a high fat meal or a nutritional supplement. Most patients with GVHD, and many with chemotherapy-associated nausea or vomiting, mucositis or diarrhea, were unable to comply with the requirement for a fatty meal, resulting in decreased plasma concentrations of posaconazole and an increased risk of breakthrough fungal infection.[121-124] More recently, the development of IV and delayed-release tablet formulations of posaconazole have circumvented these absorption issues. In addition, the tablet formulation allows once daily oral administration of posaconazole following administration of a twice daily loading dose on the first day of therapy.[125]

Isavuconazole

Isavuconazole, is available both orally and IV, has a broad spectrum of activity against a number of clinically important yeasts and molds, including *Candida* spp., *Aspergillus* spp., *C. neoformans*, *Trichosporon* spp., and variable activity against the Mucorales. The most commonly reported adverse events, which are mild and limited in nature, include nausea, diarrhea and elevated liver function tests. Its drug interaction potential appears similar to other azole antifungals, but less than those observed with voriconazole. The potential advantage of this agent over other currently available broad-spectrum azole antifungals is as a clinically useful alternative to voriconazole for the treatment of invasive aspergillosis, due to its lack of genetically determined variability in plasma levels, and more favorable and predictable drug interaction profile. Preliminary studies suggest that it may also prove useful for the treatment of invasive mold infections; however, these indications await the results of clinical trials.[100,101]

Drug Interactions with Antifungal Agents

Drug interactions with azole antifungals generally can be placed into three broad categories: (a) decreases in azole bioavailability because of chelation or secondary to increases in gastric pH, (b) interactions with other CYP-metabolized drugs, and (c) interactions caused by inhibition of Pgp. Drug interactions in the latter two categories can result in increases or decreases in the azole antifungal, in the interacting drug, or in both drugs.[117]

The interaction of azole antifungal agents with other CYP-metabolized drugs is well recognized. The azoles appear to be metabolized almost entirely via the CYP3A4 subfamily. As expected, they interact with other drugs metabolized partly or wholly through this enzyme pathway. In addition, fluconazole and voriconazole use the CYP2C19 pathway. Numerous clinically significant interactions have been documented with azole antifungals and a variety of other drugs. In most cases, the azole interferes with the metabolism of the other CYP-metabolized drug.[117]

Relative to ketoconazole and itraconazole, fluconazole appears to be intermediate in its ability to inhibit human cytochromes P450. The magnitude of fluconazole-induced inhibition of cyclosporine metabolism appears, however, to depend on the dosage of fluconazole.[117]

Predictably, drugs such as rifampin, rifabutin, isoniazid, phenytoin, and carbamazepine, which are known to induce the activity of cytochromes P450, result in increased metabolism of the azole antifungals and can result in therapeutic failures. Increased dosages of azole antifungals can be required in patients receiving these combinations of drugs.[117]

Itraconazole is an inhibitor of intestinal Pgp. Significant increases in digoxin (a Pgp substrate) have been observed in patients receiving both agents concurrently. Interactions with other substrates of Pgp would be expected to occur.[117]

Echinocandins are not inducers of CYP enzymes, nor do they interact with Pgp, and are considered poor substrates of CYP3A4. Nevertheless, drug interactions are noted with caspofungin and cyclosporine and tacrolimus; the mechanism for these interactions is not yet known. Rifampin both inhibits (acutely) and induces (after chronic administration) caspofungin metabolism, and a dosage increase is recommended in patients receiving other enzyme inducers, such as efavirenz, nevirapine, phenytoin, dexamethasone, and carbamazepine. Although micafungin does not significantly affect the clearance (or area under the plasma-concentration vs time curve [AUC]) of tacrolimus, it increases the AUCs of sirolimus and nifedipine and decreases the clearance of cyclosporine.[75,126]

Therapeutic Drug Monitoring (TDM) of Antifungal Agents

The available, good-quality, prospectively obtained data in the prophylactic or therapeutic setting are insufficient to justify the routine use of therapeutic drug monitoring. In addition, logistics, cost, and incorporation of therapeutic drug monitoring have yet to be worked out in modern prophylactic algorithms. However, under certain circumstances, serum or plasma concentration monitoring is warranted. Given the tremendous interpatient and intrapatient variability in voriconazole metabolism, TDM is warranted in most patients, Also, given the poor oral bioavailability of itraconazole capsules, and posaconazole solution, monitoring is recommended, particularly in patients with GVHD of the gut, mucositis, or diarrhea, or poor oral intake or those receiving concomitant therapy with proton-pump inhibitors.[127-131] Although the use of posaconazole tablets may result in a decreased need for TDM, recent data suggest that patients with a higher weight and those experiencing diarrhea are more likely to have lower levels.[65] Additional settings

TABLE 121-11 Plasma Concentration Monitoring of Antifungal Agents[127-132]

	Serum Concentration Monitoring Necessary?	Target Concentration Range	Timing of Sample
Echinocandins	No	NA	NA
Amphotericin B (including lipids)	No	NA	NA
Fluconazole	No	NA	NA
Itraconazole	Yes, to ensure absorption and efficacy	*Efficacy:* Prophylaxis: >0.5 mcg/mL (mg/L; >0.7 µmol/L) Treatment: >1 mcg/mL (mg/L; >1.4 µmol/L) *Toxicity:* <5 mcg/mL (mg/L; <7 µmol/L)	Trough 7 days after initiation of therapy
Voriconazole	Probably yes—in all patients treated for IFI, altered liver function, potential drug–drug interactions, lack of response *Low* concentrations are associated with poor outcome; *high* concentrations are associated with adverse effects Variable metabolism due to nonlinear PK and genetic variability in CYP2C19 → unpredictable dose–exposure relationship	*Efficacy:* Prophylaxis: trough >0.5-2 mcg/mL (mg/L; >1.4-5.7 µmol/L) Treatment: trough >1-2 mcg/mL (mg/L; >2.9-5.7 µmol/L) Concentrations >2.05 mcg/mL (mg/L; >5.7 µmol/L) are associated with improved outcome; 2-5.5 mcg/mL (mg/L; 5.7-15.7 µmol/L) is probably the best target *Toxicity:* concentrations >5.5 mcg/mL (mg/L; >15.7 µmol/L) are associated with ↑ risk of visual and hepatic adverse events	Trough after 5-7 days therapy if no loading dose administered; 48 hours after administration of loading dose in critically ill patient (time to steady state is unpredictable due to nonlinear metabolism)
Posaconazole	Maybe Outcomes (but not adverse events) correlate with higher plasma concentrations in prophylaxis and possibly treatment	*Efficacy:* Prophylaxis: >0.7 mcg/mL (mg/L; >1 µmol/L) Treatment: Not well studied; concentrations >1.25 mcg/mL (mg/L;1.78 µmol/L) needed ? *Toxicity:* Correlation with toxicity poorly defined	Random level at SS (>7 days therapy). The long $t_{1/2}$ ensures little fluctuation in peaks and troughs at SS
Flucytosine	Yes—High concentrations are associated with toxicity	*Toxicity:* "Peak" <80-100 mcg/mL (mg/L; <620-775 µmol/L) *Efficacy:* Trough >30 mcg/mL (mg/L; >232 µmol/L)	2 hours postdose "peak", 3-5 days after initiation of therapy

NA, not applicable.

include patients susceptible to flucytosine toxicity, to document adequate oral absorption of poorly bioavailable azoles in cases of suspected treatment failure or concern about compliance or absorption, solubility and finally, when drug interactions that might reduce or accelerate the metabolism of azoles is suspected.[127,132] Recommendations regarding plasma concentration monitoring of antifungals are summarized in Table 121-11.

ABBREVIATIONS

AIDS	acquired immunodeficiency syndrome
ABCD	amphotericin B colloid dispersion
ABLC	amphotericin B lipid complex
AUC	area under the plasma-concentration versus time curve
BG	(1,3)-β-D-glucan
BPA	bronchopulmonary aspergillosis
BSI	bloodstream infection
CBP	clinical breakpoint
CT	computed tomography
CVC	central venous catheter
CSF	cerebrospinal fluid
CYP	cytochrome P450
d-AmB	deoxycholate amphotericin B
ELISA	enzyme-linked immunosorbent assay
FISH	fluorescence in situ hybridization
GVHD	graft-versus-host disease
HEPA	high-efficiency particulate air
HAART	highly active antiretroviral therapy
HSCT	hematopoietic stem cell transplantation
ICP	intracranial pressure
ICUs	intensive care units
IDSA	Infectious Diseases Society of America
IPA	invasive pulmonary aspergillosis
IRIS	immune reconstitution inflammatory syndrome
MALDI-TOF-ICMS	matrix-assisted laser desorption ionization time-of-flight mass spectrometry
PDH	progressive disseminated histoplasmosis
PN	parenteral nutrition
PNA	peptide nucleic acid
SDD	susceptible dose-dependent
TDM	therapeutic plasma drug concentration monitoring
WBC	white blood cell

Infections in Immunocompromised Patients

122

Scott W. Mueller and Douglas N. Fish

KEY CONCEPTS

1. An *immunocompromised host* is a patient with defects in host defenses that predispose to infection. Risk factors include neutropenia, immune system defects (from disease or immunosuppressive drug therapy), compromise of natural host defenses, environmental contamination, and changes in normal flora of the host.
2. Immunocompromised patients are at high risk for a variety of bacterial, fungal, viral, and protozoal infections. Bacterial infections caused by gram-positive cocci (staphylococci and streptococci) occur most frequently, followed by gram-negative bacterial infections caused by Enterobacteriaceae and *Pseudomonas aeruginosa.* Fungal infections caused by *Candida* and *Aspergillus*, as well as certain viral infections (herpes simplex virus [HSV], cytomegalovirus [CMV]), are also important causes of morbidity and mortality.
3. Risk of infection in neutropenic patients is associated with both the severity and duration of neutropenia. Patients with severe neutropenia (absolute neutrophil count less than 500 cells/mm^3 [less than 0.5×10^9/L]) for greater than 7 to 10 days are considered to be at high risk of infection.
4. Fever (single oral temperature of greater than or equal to 38.3°C [greater than or equal to 101°F], or a temperature of greater than or equal to 38°C [greater than or equal to 100.4°F] for greater than or equal to 1 hour) is the most important clinical finding in neutropenic patients and is usually the stimulus for further diagnostic workup and initiation of antimicrobial treatment. Infection should be considered as the cause of fever until proven otherwise. Usual signs and symptoms of infection may be altered or absent in neutropenic patients. Appropriate empiric broad-spectrum antimicrobial therapy must be rapidly instituted to prevent excessive morbidity and mortality.
5. Empiric antimicrobial regimens for neutropenic infections should take into account patients' individual risk factors, as well as institutional infection and susceptibility patterns. The significant morbidity and mortality associated with gram-negative infections require that initial empiric regimens for treatment of febrile neutropenia have good activity against *P. aeruginosa* and Enterobacteriaceae. Parenteral regimens most commonly recommended for initial inpatient treatment include monotherapy with an antipseudomonal β-lactam, or a combination regimen consisting of an antipseudomonal β-lactam, plus an aminoglycoside. Low-risk patients may be successfully treated with oral antibiotics (ciprofloxacin plus amoxicillin-clavulanate), with the treatment setting determined by the patient's clinical status.
6. Neutropenic patients who remain febrile after 3 to 5 days of initial antimicrobial therapy should be reevaluated to determine whether treatment modifications are necessary. Common regimen modifications include addition of vancomycin (if not already administered) and antifungal therapy (amphotericin B, an echinocandin, or fluconazole). Therapy should be directed at causative organisms, if identified, but broad-spectrum regimens should be maintained during neutropenia.
7. The optimal duration of therapy for febrile neutropenia is controversial. The decision to discontinue antimicrobials is based on resolution of neutropenia, defervescence, culture results, and clinical stability of the patient.
8. Prophylactic antimicrobials are administered to cancer patients expected to experience prolonged neutropenia, as well as to hematopoietic stem cell and solid-organ transplant recipients. Prophylactic regimens may include antibacterial, antifungal, antiviral, or antiprotozoal agents, or a combination of these, selected according to risk of infection with specific pathogens. Optimal prophylactic regimens should take into account individual patient risk for infection and institutional infection and susceptibility patterns.
9. Patients undergoing hematopoietic stem cell transplantation are at an extremely high risk of infection because of prolonged neutropenia following intensive chemotherapy with or without irradiation, while solid-organ transplant recipients are at high risk because of prolonged administration of immunosuppressive drugs. Fungal (*Aspergillus*) and viral (CMV) infections are particularly troublesome in these populations, and prophylactic regimens directed against these pathogens are commonly used. When documented, these infections must be treated aggressively in order to optimize patient outcomes. Nevertheless, mortality rates are often high despite appropriate and aggressive antimicrobial therapy.
10. Immunocompromised patients must be continuously assessed for evidence of infection and response to antimicrobial therapy. Because a large number of antimicrobials may potentially be used, the occurrence of drug-related adverse effects must also be carefully assessed. Efforts should be directed at designing cost-effective treatment strategies that promote optimal patient outcomes.

An immunocompromised host is a patient with intrinsic or acquired defects in host immune defenses that predispose to infection. Advances in modern medicine have created more immunocompromised hosts than ever before. Historically, many of these patients died of their underlying diseases. Dramatic improvements in survival have been achieved by more aggressive therapy of underlying diseases and improved supportive care. However, because such aggressive therapy often renders patients profoundly immunosuppressed

for long periods, opportunistic infections remain important causes of morbidity and mortality. This chapter focuses on risk factors for infection, common pathogens and infection sites, and prevention and management of suspected or documented infections in cancer patients (including hematopoietic stem cell transplantation [HSCT] patients) and solid-organ transplant (SOT) recipients. Chapter e103 discusses infectious complications associated with human immunodeficiency virus (HIV) infection.

RISK FACTORS FOR INFECTION/ EPIDEMIOLOGY

Many factors influence the degree of immunosuppression and also influence the epidemiology of the associated infections.

Neutropenia

1 2 3 Neutropenia is defined as an abnormally reduced number of neutrophils circulating in peripheral blood. Although exact definitions of neutropenia can vary, an absolute neutrophil count (ANC) of less than 1,000 cells/mm^3 (1.0×10^9/L) indicates a reduction sufficient to predispose patients to infection.[1] ANC is the sum of the absolute numbers of both mature neutrophils (polymorphonuclear cells [PMNs], also called *polys* or *segs*) and immature neutrophils (*bands*). The absolute number of PMNs and bands is determined by dividing the total percentage of these cells (obtained from the white blood cell [WBC] differential) by 100 and then multiplying the quotient obtained by the total number of WBCs.

The degree or severity of neutropenia, rate of neutrophil decline, and duration of neutropenia are important risk factors for infection.[1-4] All neutropenic patients are considered to be at risk for infection, but those with ANC less than 500 cells/mm^3 (0.5×10^9/L) are at greater risk than those with ANCs of 500 to 1,000 cells/mm^3 (0.5×10^9 to 1.0×10^9/L). Most treatment guidelines use ANC less than 500 cells/mm^3 (0.5×10^9/L) as the critical value in making therapeutic decisions regarding the management of suspected or documented infections.[1-4] Risk of infection and death are greatest among patients with less than 100 neutrophils/mm^3 (0.1×10^9/L) ("profound neutropenia").[1-3,5] In patients with chemotherapy-induced neutropenia, the risk of infection is also increased according to both the rapidity of ANC decline and duration of neutropenia. Patients with severe neutropenia of more than 7 to 10 days' duration are considered to be at especially high risk for serious infections.[1-3,6] The duration of chemotherapy-induced neutropenia varies considerably among subsets of cancer patients according to the specific chemotherapeutic agents used and the intensity of treatment. Patients undergoing HSCT may have no detectable granulocytes in peripheral blood for up to 3 to 4 weeks and are at particular risk for severe infections with a variety of pathogens.[5]

Bacteria and fungi commonly cause infections in neutropenic patients. Gram-positive cocci (*Staphylococcus aureus*, *Staphylococcus epidermidis*, and other coagulase-negative staphylococci, streptococci, and enterococci) have emerged as the most common cause of acute bacterial infections among neutropenic patients. Gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*) traditionally were the most common causes of bacterial infection and remain frequent pathogens.[4,6-9] Although now not as common as gram-positive bacteria, the incidence of gram-negative infections may again be increasing and account for nearly half of bacterial infections.[2,6-9] Gram-negative infections are associated with significant morbidity and mortality, in large part due to increasing antibiotic resistance.[7-9] Patients who are neutropenic for extended periods and who receive broad-spectrum antibiotics are at high risk for fungal infections, usually due to *Candida* or *Aspergillus* spp.[1-3,6,10,11] Viral infections, although not as common as bacterial and fungal infections, also may cause severe infection in neutropenic patients.[1,2,5,6] Successful treatment of infections in neutropenic patients depends on resolution of neutropenia.[1,2]

Although not readily quantifiable, abnormalities may exist in granulocyte function as well as in cell numbers. Defects in phagocyte function may be caused by underlying disease (eg, leukemia) or its treatment (eg, corticosteroids, antineoplastic agents including monoclonal antibodies, and radiation).[2,6]

Immune System Defects

In addition to neutropenia, defects in T-lymphocyte and macrophage function (cell-mediated immunity), B-cell function (humoral immunity), or both predispose patients to infection. Cellular immune dysfunction is the result of underlying disease or immunosuppressive drug therapy; these defects result in a reduced ability of the host to defend against intracellular pathogens. Patients with malignancies and transplant patients receiving a wide variety of immunosuppressive drugs, such as cyclosporine, tacrolimus, sirolimus, mycophenolate, corticosteroids, azathioprine, and antineoplastic agents, are at risk for a variety of bacterial, fungal, viral, and protozoal infections (Table 122-1). Although some of these pathogens are associated with asymptomatic or mild disease in normal hosts, they may cause disseminated, life-threatening infections in immunocompromised hosts.

Underlying disease also frequently causes defects in humoral immune function. Patients with multiple myeloma and chronic lymphocytic leukemia have progressive hypogammaglobulinemia that results in defective humoral immunity. Splenectomy performed as a part of the staging process for Hodgkin's disease places patients at risk for infectious complications. Disease states with humoral immune dysfunction predispose the patient to serious, life-threatening infection with encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.

Destruction of Protective Barriers

Loss of protective barriers is a major factor predisposing immunocompromised patients to infection. Damage to skin and mucous membranes by surgery, venipuncture, IV and urinary catheters, radiation, and chemotherapy disrupts natural host defense systems, leaving patients at high risk for infection. Chemotherapy-induced mucositis may erode mucous membranes of the oropharynx and GI tract and establish a portal for subsequent infection by bacteria, HSV, and *Candida*.[1,2,5] Medical and surgical procedures, such as transplant surgery, indwelling IV catheter placement, bone marrow aspiration, biopsies, and endoscopy, further damage the integument and predispose patients to infection. Infections resulting from disruption of protective barriers usually are a result of skin flora, such as *S. aureus*, *S. epidermidis*, and various streptococci.[1,2,6]

Environmental Contamination/Alteration of Microbial Flora

Infections in immunocompromised patients are caused by organisms either colonizing the host or acquired from the environment. Microorganisms may be transferred easily from patient to patient on the hands of hospital personnel unless strict infection control guidelines are followed. Contaminated equipment, such as nebulizers or ventilators, and contaminated water supplies have been responsible for outbreaks of *P. aeruginosa* and *Legionella pneumophila* infections, respectively. Foods, such as fruits and green leafy vegetables, which often are colonized with gram-negative bacteria and fungi, are sources of microbial contamination in immunocompromised hosts.[1,5]

Most infections in cancer patients are caused by organisms colonizing body sites, such as the skin, oropharynx, and GI tract and are therefore caused by the patient's own endogenous flora.[1,2,5,6] The GI tract is a common site from which infections in immunocompromised hosts originate. Periodontitis, pharyngitis, esophagitis, colitis,

TABLE 122-1 Risk Factors and Common Pathogens in Immunocompromised Patients

Risk Factor	Patient Conditions	Common Pathogens
Neutropenia	Acute leukemia Chemotherapy	Bacteria: *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, streptococci, enterococci Fungi: *Candida*, *Aspergillus*, Mucorales (*Mucor*) Viruses: Herpes simplex

Alteration of normal microbial flora	Antimicrobial therapy Chemotherapy Hospital environment	Bacteria: Enterobacteriaceae, *P. aeruginosa*, *Legionella*, *S. aureus*, *S. epidermidis* Fungi: *Candida*, *Aspergillus*
Blood products, donor organs	Bone marrow transplantation Solid-organ transplantation	Fungi: *Candida* Viruses: Cytomegalovirus, Epstein–Barr virus, hepatitis B, hepatitis C Protozo: *Toxoplasma gondii*

perirectal cellulitis, and bacteremias are caused predominantly by normal flora of the gut; bloodstream infections are thought to arise from microbial translocation across injured GI mucosa.[1,5,6] Normal flora may be significantly disrupted and altered; oropharyngeal flora rapidly change to primarily gram-negative bacilli in hospitalized patients. Many cancer patients may already be colonized with gram-negative bacilli on admission as a result of frequent prior hospitalizations and clinic visits. In hospitalized cancer patients, however, many infections are caused by colonizing organisms acquired after admission.[1]

Although hospitalization and severity of illness are important risk factors for colonization by gram-negative bacilli, administration of broad-spectrum antimicrobial agents has the greatest impact on flora of immunocompromised hosts. Use of these agents disrupts GI tract flora and predisposes patients to infection with more virulent pathogens. Antineoplastic drugs (eg, cyclophosphamide, doxorubicin, and fluorouracil) and acid-suppressive therapy (eg, H_2-receptor antagonists, proton-pump inhibitors, and antacids) also may result in changes in GI flora and possibly predispose patients to infection.[1,2]

Numerous factors, such as underlying disease, immunosuppressive drug therapy, and antimicrobial administration, determine the immunocompromised host's risk of developing infection. Several risk factors are present concomitantly in many patients (see Table 122-1).

ETIOLOGY OF INFECTIONS IN NEUTROPENIC CANCER PATIENTS

2 Infection remains a significant cause of morbidity and mortality in neutropenic cancer patients. More than 50% of febrile neutropenic patients have an established or occult infection.[1,2] Patients with profound neutropenia are at greatest risk for systemic infection, with at least 20% of these individuals developing bacteremia.[1,2] Areas of impaired or damaged host defenses, such as the oropharynx, lungs, skin, sinuses, and GI tract, are common sites of infection. These local infections may progress to cause systemic infection and bacteremia.[2] Febrile episodes in neutropenic cancer patients can be attributed to microbiologically documented infection in approximately 30% to 40% of cases, about half of which are due to bacteremia. Further, infections can be documented clinically (but not microbiologically) in another 30% to 40% of patients, with the remaining 20% to 40% of patients manifesting infection only by fever.[2,4,6]

Table 122-1 lists organisms commonly infecting immunocompromised patients. Approximately 45% to 70% of bacteremic episodes in cancer patients are the result of gram-positive organisms compared with less than 30% of episodes documented during the 1970s and 1980s.[1,4,6-8] This shift is attributed to the frequent use of indwelling central and peripheral IV catheters, frequent use of broad-spectrum antibiotics with excellent gram-negative activity but relatively poor gram-positive coverage, higher rates of mucositis caused by aggressive cancer treatments, and prophylaxis with trimethoprim–sulfamethoxazole or quinolones.[1,4,6-8,12] Staphylococci (especially *S. epidermidis*) account for most infections, but *Bacillus* spp. and *Corynebacterium jeikeium* are also important pathogens.[1,2,6] Rates of infection due to methicillin-resistant *S. aureus* (MRSA) have increased in the hospital and community setting.[2,5,13] Viridans streptococci, which may be resistant to β-lactams, also have emerged as important pathogens, particularly in patients with chemotherapy-induced mucositis of the oropharynx.[2,4,5,12] Enterococci, including vancomycin-resistant strains, also may be problematic in many institutions.[2,5,12] Bacteremia caused by vancomycin-resistant enterococci (VRE) in neutropenic patients is associated with a mortality rate up to 30%.[4,14]

Gram-positive infections do not always cause immediately life-threatening infections and are associated with somewhat lower mortality rates (approximately 5%-10%) compared with gram-negative infections.[1,2,7] However, increasing rates of antibiotic resistance have made treatment of gram-positive infections in immunocompromised patients more challenging.[2,6,7] MRSA infections are associated with increased morbidity, mortality, and hospital costs compared with susceptible organisms.[15,16] Methicillin resistance among coagulase-negative staphylococci, which may cause 40% to 80% of infections in certain populations, is common (70%-90% of isolates).[1,2,5-7] Organisms that are resistant to vancomycin are increasing in importance.[1,2,4,7,14] Thus, prevention and timely diagnosis and treatment of gram-positive infections are clearly of great importance in the management of neutropenic cancer patients.

Gram-negative infections remain important causes of morbidity and mortality (approximately 20%-30%) in immunocompromised cancer patients.[7] However, the relative frequency of infection owing to specific pathogens has been shifting among gram-negative infections. *E. coli* and *Klebsiella* remain the most common isolates at many centers.[2,6] Strains of Enterobacteriaceae producing plasmid-mediated extended-spectrum β-lactamases that hydrolyze extended-spectrum cephalosporins, and carbapenemases that hydrolyze carbapenems have emerged and are cause for concern.[1,2,6,7,12] The global spread of carbapenem-resistant Enterobacteriaceae (CRE) is especially concerning. The frequency of infections resulting from other gram-negative organisms, such as *Enterobacter*, *Serratia*, and *Citrobacter*, has been increasing.[1,2] Infections with these particular organisms may be difficult to treat because of the ease of β-lactamase induction and the more frequent development of resistance to multiple antibiotics.[1,2,6,12]
