CHAPTER 11

Aromatic Electrophilic Substitution

Most substitutions at an aliphatic carbon are nucleophilic. In aromatic systems the situation is reversed, because the high electron density at the aromatic ring attracts positive species and not negative ones. In electrophilic substitutions, the attacking species is a positive ion or the positive end of a dipole or induced dipole. The leaving group (the electrofuge) must necessarily depart without its electron pair. In nucleophilic substitutions, the chief leaving groups are those best able to carry the unshared pair: Br^-, H_2O, OTs^-, and so on that is, the weakest bases. In electrophilic substitutions, the most important leaving groups are those that can best exist without the pair of electrons necessary to fill the outer shell, that is, the weakest Lewis acids. The most common leaving group in electrophilic aromatic substitutions is the proton.

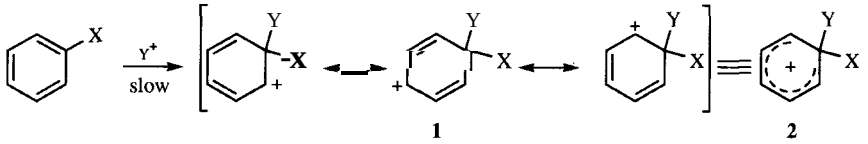
MECHANISMS

Electrophilic aromatic substitutions are unlike nucleophilic substitutions in that the large majority proceed by just one mechanism with respect to the substrate.[1] In this mechanism, which we call the *arenium ion mechanism*, the electrophile attacks in the first step, giving rise to a positively charged intermediate (the arenium ion), and the leaving group departs in the second step, so there is a resemblance to the tetrahedral mechanism of Chapter 10, but with the charges reversed. The IUPAC designation for this mechanism is $A_E + D_E$. Another mechanism, much less common, consists of the opposite behavior: The leaving group departs *before* the electrophile arrives. This mechanism, the S_E1 mechanism, corresponds to the S_N1 mechanism of nucleophilic substitution. Simultaneous attack and departure mechanisms (corresponding to S_N2) are not found at all. An addition-elimination mechanism has been postulated in one case (see 11-6).

The Arenium Ion Mechanism[2]

In the arenium ion mechamism the attacking species may be produced in various ways, but what happens to the aromatic ring is basically the same in all cases. For this reason most attention in the study of this mechanism centers around the identity

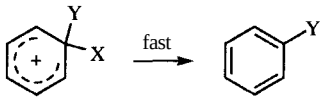
of the attacking entity and how it is produced.



1 2

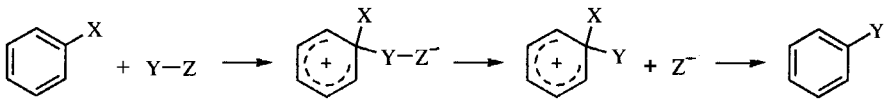
The electrophile may be a positive ion or a dipole. If it is a positive ion, it attacks the ring, removing a pair of electrons from the sextet to give a carbocation, which is a resonance hybrid, as shown in 1, and is frequently represented as in 2. Ions of this type are called[3] *Wheland intermediates, σ complexes,* or *arenium ions.*[4] In the case of benzenoid systems they are cyclohexadienyl cations. It is easily seen that the great stability associated with an aromatic sextet is no longer present in 1, though the ion is stabilized by resonance of its own. The arenium ion is generally a highly reactive intermediate and must stabilize itself by a further reaction, although it has been isolated (see p. 678).

Carbocations can stabilize themselves in various ways (see p. 227), but for this type of ion the most likely way[5] is by loss of either X^+ or Y^+. The aromatic sextet is then restored, and in fact this is the second step of the mechanism:



The second step is nearly always faster than the first, so the first is rate determining and the reaction is second order (unless the formation of the attacking species is slower still, in which case the aromatic compound does not take part in the rate expression at all). If Y^+ is lost, there is no net reaction, but if X^+ is lost, an aromatic substitution has taken place. If X^+ is a proton, a base is necessary to help remove it.

If the attacking species is not an ion but a dipole, the product must have a negative charge unless part of the dipole, with its pair of electrons, is broken off somewhere in the process, for example,



The attacking entity in each case and how it is formed are discussed for each reaction in the reactions section of this chapter.

The evidence for the arenium ion mechanism is mainly of two kinds:

1. *Isotope Effects.* If the hydrogen ion departs before the arrival of the electrophile (S_E1 mechanism) or if the arrival and departure are simultaneous, there should be a substantial isotope effect (i.e., deuterated substrates should undergo substitution more slowly than nondeuterated compounds) because, in each case, the C—H bond is broken in the rate-determining step. However, in the arenium ion mechanism, the C—H bond is not broken in the rate-

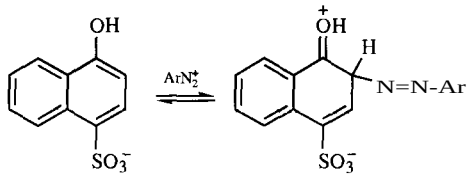
determining step, so no isotope effect should be found. Many such studies have been carried out and, in most cases, especially in the case of nitrations, there is no isotope effect.[6] This result is incompatible with either the S_E1 or the simultaneous mechanism.

However, in many instances, isotope effects have been found. Since the values are generally much lower than expected for either the S_E1 or the simultaneous mechanisms (e.g., 1-3 for k_H/k_D instead of 6-7), we must look elsewhere for the explanation. For the case where hydrogen is the leaving group, the arenium ion mechanism can be summarized:

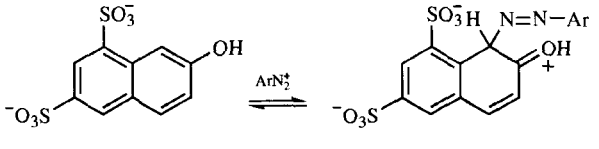
Step 1 $\mathrm{ArH} + \mathrm{Y}^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{Ar}\overset{+}{<}\begin{matrix}\mathrm{H}\\ \mathrm{Y}\end{matrix}$

Step 2 $\mathrm{Ar}\overset{\cdot}{<}_{\mathrm{Y}} \xrightarrow{k_2} \mathrm{ArY} + \mathrm{H}^+$

The small isotope effects found most likely arise from the reversibility of step 1 by a *partitioning effect*.[7] The rate at which ArHY^+ reverts to ArH should be essentially the same as that at which ArDY^+ (or ArTY^+) reverts to ArD (or ArT), since the Ar H bond is not cleaving. However, ArHY^+ should go to ArY faster than either ArDY^+ or ArTY^+, since the Ar–H bond is broken in this step. If $k_2 \gg k_{-1}$, this does not matter; since a large majority of the intermediates go to product, the rate is determined only by the slow step ($k_1[\mathrm{ArH}][\mathrm{Y}^+]$) and no isotope effect is predicted. However, if $k_2 \lesssim k_{-1}$, reversion to starting materials is important. If k_2 for ArDY^+ (or ArTY^+) is $< k_2$ for ArHY^+, but k_{-1} is the same, then a larger proportion of ArDY^+ reverts to starting compounds. That is, k_2/k_{-1} (the *partition factor)* for ArDY^+ is less than that for ArHY^+. Consequently, the reaction is slower for ArD than for ArH and an isotope effect is observed.



3 4



5 6

One circumstance that could affect the k_2/k_{-1} ratio is steric hindrance. Thus, diazonium coupling of 3 gave no isotope effect, while coupling of 5

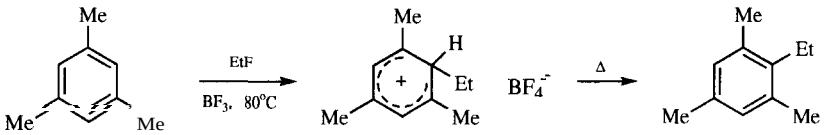
gave a k_H/k_D ratio of 6.55.[8] For steric reasons, it is much more difficult for 6 to lose a proton (it is harder for a base to approach) than it is for 4, so k_2 is greater for the latter. Since no base is necessary to remove ArN_2^+, k_{-1} does not depend on steric factors[9] and is about the same for each. Thus the partition factor k_2/k_{-1} is sufficiently different for 4 and 6 that 5 exhibits a large isotope effect and 3 exhibits none.[10] Base catalysis can also affect the partition factor, since an increase in base concentration increases the rate at which the intermediate goes to product without affecting the rate at which it reverts to starting materials. In some cases, isotope effects can be diminished or eliminated by a sufficiently high concentration of base.

Evidence for the arenium ion mechanism has also been obtained from other kinds of isotope-effect experiments, involving substitutions of the type

$$ArMR_3 + H_3O^+ \longrightarrow ArH + R_3MOH_2^+$$

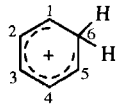
where M is Si, Ge, Sn, or Pb, and R is methyl or ethyl. In these reactions, the proton is the electrophile. If the arenium ion mechanism is operating, then the use of D_3O^+ should give rise to an isotope effect, since the D—O bond would be broken in the rate-determining step. Isotope effects of 1.55-3.05 were obtained,[11] in accord with the arenium ion mechanism.

2. *Isolation of Arenium Ion Intermediates.* Very strong evidence for the arenium ion mechanism comes from the isolation of arenium ions in a number of instances.[12] For example, 7 was isolated as a solid with melting point — 15°C



Mesitylene 7 8

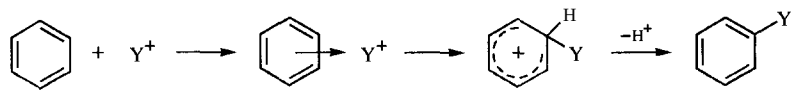
from treatment of mesitylene with ethyl fluoride and the catalyst BF_3 at —80°C. When 7 was heated, the normal substitution product 8 was obtained.[13] Even the simplest such ion, the benzenonium ion (9) has been prepared in $HF—SbF_5—SO_2ClF—SO_2F_2$ at -134°C, where it could be studied



9

spectrally.[14] The ^{13}C NMR spectra of the benzenonium ion[15] and the pentamethylbenzenonium ion[16] give graphic evidence for the charge distribution shown in 1. According to this, the 1, 3, and 5 carbons, each of which bears a charge of about $+\frac{1}{3}$, should have a greater chemical shift in the NMR than the 2 and 4 carbons, which are uncharged. The spectra bear this out. For example, ^{13}C NMR chemical shifts for 9 are C-3: 178.1; C-1 and C-5: 186.6; C-2 and C-4: 136.9, and C-6: 52.2.[15]

In Chapter 3, it was mentioned that positive ions can form addition complexes with *n* systems. Since the initial step of electrophilic substitution involves attack by a positive ion on an aromatic ring, it has been suggested[17] that such a complex, called a *n complex* (represented as 10), is formed first and then is converted to the arenium ion 11. Stable solutions of arenium ions or *n* complexes (e.g., with Br_2, I_2, picric



10 11

acid, Ag $^+$, or HC1) can be formed at will. For example, *n* complexes are formed when aromatic hydrocarbons are treated with HC1 alone, but the use of HC1 plus a Lewis acid (e.g., $AlCl_3$) gives arenium ions. The two types of solution have very different properties. For example, a solution of an arenium ion is colored and conducts electricity (showing positive and negative ions are present), while a *n* complex formed from HC1 and benzene is colorless and does not conduct a current. Furthermore, when DC1 is used to form a *n* complex, no deuterium exchange takes place (because there is no covalent bond between the electrophile and the ring), while formation of an arenium ion with DC1 and $AlCl_3$ gives deuterium exchange. The relative stabilities of some methylated arenium ions and *n* complexes are shown in Table 11.1. The arenium ion stabilities listed were determined by the relative basicity of the substrate toward HF.[18] The π complex stabilities are relative equilibrium constants for the reaction[19] between the aromatic hydrocarbon and HC1. As shown in Table 11.1, the relative stabilities of the two types of species are very different: The *n* complex stability changes very little with methyl substitution, but the arenium ion stability changes a great deal.

TABLE 11.1 Relative Stabilities of Arenium Ions and π Complexes and Relative Rates of Chlorination and Nitration[a]

Substituents	Relative Arenium Ion stability*	Relative π-Complex Stability[b]	Rate of Chlorination[c]	Rate of Nitration[d]
None (benzene)	0.09	0.61	0.0005	0.51
Me	0.63	0.92	0.157	0.85
p-Me_2	1.00	1.00	1.00	1.00

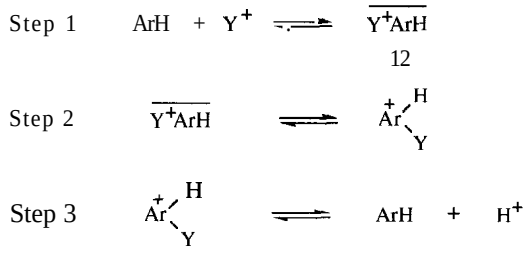
Me_5	29,900		360,000	

"In each case, *p*-xylene = 1.00
[fc]See Ref. 18.
'See Ref. 19.
[rf]See Ref. 23.

How can we tell if 10 is present on the reaction path? If it is present, there are two possibilities: (1) The formation of 10 is rate determining (the conversion of 10 to 11 is much faster), or (2) the formation of 10 is rapid, and the conversion 10 to 11 is rate determining. One way to ascertain which species is formed in the rate determining step in a given reaction is to use the stability information given in Table 11.1. We measure the relative rates of reaction of a given electrophile with the series of compounds listed in Table 11.1. If the relative rates resemble the arenium ion stabilities, we conclude that the arenium ion is formed in the slow step; but if they resemble the stabilities of the *n* complexes, the latter are formed in the slow step.[20] When such experiments are carried out, it is found in most cases that the relative rates are similar to the arenium ion and not to the *n* complex stabilities. For example, Table 11.1 lists chlorination rates.[19] Similar results were obtained in room temperature bromination with Br_2 in acetic acid[21] and in acetylation with CH_3CO^+-SbF_6^-[22]. It is clear that in these cases the *n* complex either does not form at all, or if it does, its formation is not rate determining (unfortunately, it is very difficult to distinguish between these two possibilities).

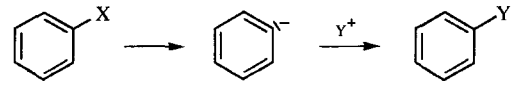
On the other hand, in nitration with the powerful electrophile NO_2^+ (in the form of NO_2^+ BF4), the relative rates resembled π complex stabilities much more than arenium ion stabilities (Table 11.1).[23] Similar results were obtained for bromination with Br_2 and $FeCl_3$ in nitromethane. These results were taken to mean[24] that in these cases *n* complex formation is rate determining. However, graphical analysis of the NO_2^+ data showed that a straight line could not be drawn when the nitration rate was plotted against *n* complex stability,[25] which casts doubt on the rate-determining formation of a *n* complex in this case.[26] There is other evidence, from positional selectivities (discussed on p. 694), that *some* intermediate is present before the arenium ion is formed, whose formation can be rate determining with powerful electrophiles. Not much is known about this intermediate, which is given the nondescriptive name *encounter complex* and generally depicted as 12. The arenium complex mechanism is therefore written as[27]



For the reason given above and for other reasons, it is unlikely that the encounter complex is a *n* complex, but just what kind of attraction exists between Y^+ and ArH is not known, other than the presumption that they are together within a solvent cage (see also p. 694). There is evidence (from isomerizations occurring in the alkyl group, as well as other observations) that *n* complexes are present on the pathway from substrate to arenium ion in the gas-phase protonation of alkylbenzenes.[28]

The S_E1 Mechanism

The S_E1 mechanism *(substitution electrophilic unimolecular*) is rare, being found only in certain cases in which carbon is the leaving atom (see **11-37**, **11-38**) or when a very strong base is present (see **11-1**, **11-11**, and **11-42**).[29] It consists of two steps with an intermediate carbanion. The IUPAC designation is $D_E + A_E$.



Reactions **12-39**, **12-43**, and **12-44** also take place by this mechanism when applied to aryl substrates.

ORIENTATION AND REACTIVITY

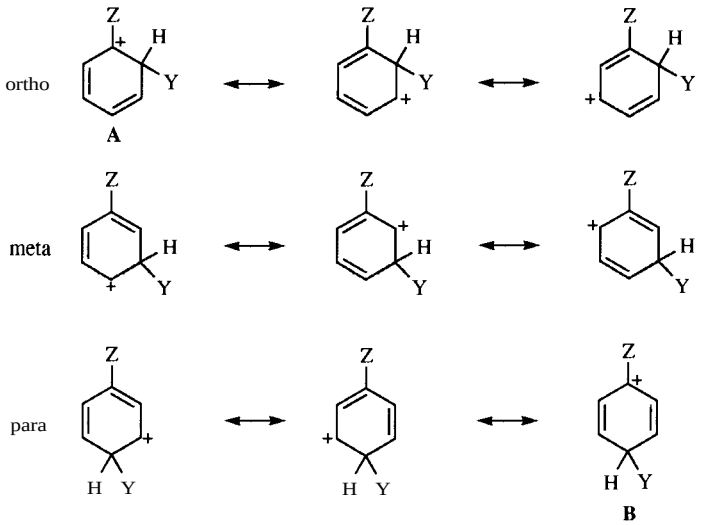
Orientation and Reactivity in Monosubstituted Benzene Rings[30]

When an electrophilic substitution reaction is performed on a monosubstituted benzene, the new group may be directed primarily to the ortho, meta, or para position and the substitution may be slower or faster than with benzene itself. The group already on the ring determines which position the new group will take and whether the reaction will be slower or faster than with benzene. Groups that increase the reaction rate are called *activating* and those that slow it *deactivating.* Some groups are predominantly meta directing; all of these are deactivating. Others are mostly ortho-para directing; some of these are deactivating too, but most are activating. Groups direct *predominantly,* but usually not *exclusively.* For example, nitration of nitrobenzene gave 93% *m*-dinitrobenzene, 6% of the ortho, and 1% of the para isomer.

The orientation and reactivity effects of each group are explained on the basis of resonance and field effects on the stability of the intermediate arenium ion. To understand why we can use this approach, it is necessary to know that in these reactions the product is usually kinetically and not thermodynamically controlled (see p. 284). Some of the reactions are irreversible and the others are usually stopped well before equilibrium is reached. Therefore, which of the three possible intermediates is formed is dependent not on the thermodynamic stability of the products but on the activation energy necessary to form each of the three intermediates. It is not easy to predict which of the three activation energies is lowest, but we make the assumption that the free energy profile resembles either Figure 6.2a or *b.* In either case, the transition state is closer in energy to the arenium ion intermediate than to the starting compounds. Invoking the Hammond postulate (p. 285), we can then assume that the geometry of the transition state also resembles that of the intermediate and that anything that increases the stability of the intermediate will also lower the activation energy necessary to attain it. Since the intermediate, once formed, is rapidly converted to products, we can use the relative stabilities of the three intermediates as guides to predict which products will

predominantly form. Of course, if reversible reactions are allowed to proceed to equilibrium, we may get product ratios that are quite different. For example, the sulfonation of naphthalene at 80°C, where the reaction does not reach equilibrium, gives mostly α-naphthalenesulfonic acid,[31] while at 160°C, where equilibrium is attained, the β isomer predominates (the a isomer is thermodynamically less stable because of steric interaction between the SO_3H group and the hydrogen at the 8 position).[32]

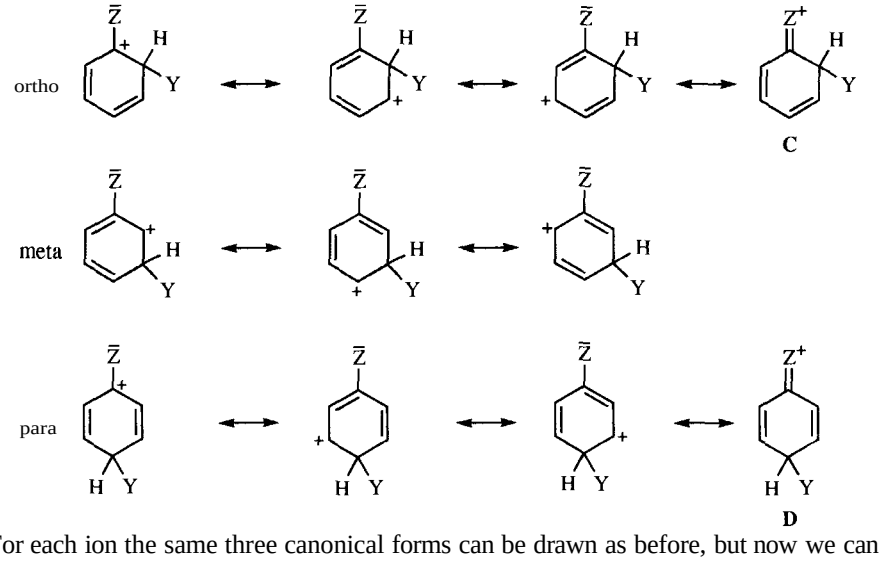
These are the three possible ions:



For each ion we see that the ring has a positive charge. We can therefore predict that any group Z that has an electron-donating field effect (+/) should stabilize all three ions (relative to 1), but that electron-withdrawing groups, which increase the positive charge on the ring, should destabilize them. We can also make a further prediction concerning field effects. These taper off with distance and are thus strongest at the carbon connected to the group Z. Of the three arenium ions, only the ortho and para have any positive charge at this carbon. None of the canonical forms of the meta ion has a positive charge there and so the hybrid has none either. Therefore, +/ groups should stabilize all three ions but mostly the ortho and para, so they should be not only activating but ortho-para directing as well. On the other hand, -/ groups, by removing electron density, should destabilize all three ions but mostly the ortho and para, and should be not only deactivating but also meta directing.

These conclusions are correct as far as they go, but they do not lead to the proper results in all cases. In many cases, there is *resonance interaction* between Z and the ring; this also affects the relative stability, in some cases in the same direction as the field effect, in others differently.

Some substituents have a pair of electrons (usually unshared) that may be contributed *toward* the ring. The three arenium ions would then look like this



For each ion the same three canonical forms can be drawn as before, but now we can draw an extra form for the ortho and para ions. The stability of these two ions is increased by the extra form not only because it is another canonical form, but because it is more stable than the others and makes a greater contribution to the hybrid. Every atom (except of course hydrogen) in these forms (C and D) has a complete octet, while all the other forms have one carbon atom with a sextet. No corresponding form can be drawn for the meta isomer. The inclusion of this form in the hybrid lowers the energy not only because of rule 6 (p. 41), but also because it spreads the positive charge over a larger area—out onto the group Z. Groups with a pair of electrons to contribute would be expected, then, in the absence of field effects, not only to direct ortho and para, but also to activate these positions for electrophilic attack.

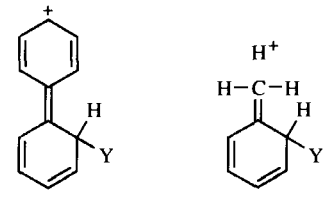
On the basis of these discussions, we can distinguish three types of groups.

1. Groups that contain an unshared pair of electrons on the atom connected to the ring. In this category are O^-, NR_2, NHR, NH_2,[33] OH, OR, NHCOR, OCOR, SR, and the four halogens.[34] The halogens deactivate the aromatic ring to substitution (the rate of reaction is slower than that of benzene), and this effect may arise from the unique energy level of the halogen lone-pair orbital, which is higher than the adjacent *n* MO of benzene (π_1).[35] The widely held explanation for this, however, is that the halogens have a $-$ / effect. The SH group would probably belong here too, except that in the case of thiophenols electrophiles usually attack the sulfur rather than the ring, and ring substitution is not feasible with these substrates.[36] The resonance explanation predicts that all these groups should be ortho–para directing, and they are, though all except O^- are electron withdrawing by the field effect

(p. 18). Therefore, for these groups, resonance is more important than the field effect. This is especially true for NR_2, NHR, NH_2, and OH, which are *strongly* activating, as is O^-. The other groups are mildly activating, except for the halogens, which are deactivating. Fluorine is the least deactivating, and fluorobenzenes usually show a reactivity approximating that of benzene itself. The other three halogens deactivate about equally. In order to explain why chlorine, bromine, and iodine deactivate the ring, even though they direct ortho-para, we must assume that the canonical forms C and D make such great contributions to the respective hybrids that they make the ortho and para arenium ions more stable than the meta, even though the -/ effect of the halogen is withdrawing sufficient electron density from the ring to deactivate it. The three halogens make the ortho and para ions more stable than the meta, but less stable than the unsubstituted arenium ion (1). For the other groups that contain an unshared pair, the ortho and para ions are more stable than either the meta ion or the unsubstituted ion. For most of the groups in this category, the meta ion is more stable than 1, so that groups such as NH_2, OH, and so on activate the meta positions too, but not as much as the ortho and para positions (see also the discussion on pp. 690-691).

2. Groups that lack an unshared pair on the atom connected to the ring and that are —/. In this category are, in approximate order of decreasing deactivating ability, NR_3^+, NO_2, CF_3, CN, SO_3H, CHO, COR, COOH, COOR, $CONH_2$, CCl_3, and NH_3^+. Also in this category are all other groups with a positive charge on the atom directly connected to the ring (SR_2^+, PR_3^+, etc.)[37] and many groups with positive charges on atoms farther away, since often these are still powerful — / groups. The field-effect explanation predicts that these should all be meta directing and deactivating, and (except for NH_3^+) this is the case. The NH_3^+ group is an anomaly, since this group directs para about as much as or a little more than it directs meta.[38] The NH_2Me^+, $NHMe_2^+$, and NMe_3^+ groups all give more meta than para substitution, the percentage of para product decreasing with the increasing number of methyl groups.[39]

3. Groups that lack an unshared pair on the atom connected to the ring and that are ortho-para directing. In this category are alkyl groups, aryl groups, and the COO^- group,[40] all of which activate the ring. We shall discuss them separately. Since aryl groups are -/ groups, they might seem to belong to category 2. They are nevertheless ortho-para directing and activating. This can be explained in a similar manner as in category 1, with a pair of electrons from the aromatic sextet playing the part played by the unshared pair, so that

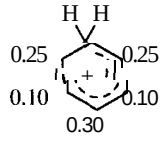


E F

we have forms like E. The effect of negatively charged groups like COO^- is easily explained by the field effect (negatively charged groups are of course electron donating), since there is no resonance interaction between the group and the ring. The effect of alkyl groups can be explained in the same way, but, in addition, we can also draw canonical forms, even though there is no unshared pair. These of course are hyperconjugation forms like F. This effect, like the field effect, predicts activation and ortho-para direction, so that it is not possible to say how much each effect contributes to the result. Another way of looking at the effect of alkyl groups, which sums up both field and hyperconjugation effects, is that (for Z = R) the ortho and para arenium ions are more stable because each contains a form (A and B) that is a tertiary carbocation, while all the canonical forms for the meta ion and for 1 are secondary carbocations. In activating ability, alkyl groups usually follow the Baker-Nathan order (p. 72), but not always.[41]

The Ortho/Para Ratio[42]

When an ortho-para directing group is on a ring, it is usually difficult to predict how much of the product will be the ortho isomer and how much the para isomer. Indeed, these proportions can depend greatly on the reaction conditions. For example, chlorination of toluene gives an ortho/para ratio anywhere from 62/38 to 34/66.[43] Nevertheless, certain points can be made. On a purely statistical basis there would be 67% ortho and 33% para, since there are two ortho positions and only one para. However, the phenonium ion (9), which arises from protonation of benzene, has the



9

approximate charge distribution shown.[44] If we accept this as a model for the arenium ion in aromatic substitution, a para substitutent would have a great stabilizing effect on the adjacent carbon than an ortho substituent. If other effects are absent, this would mean that >33% para and <67% ortho substitution would be found. In hydrogen exchange (Reaction 11-1), where other effects are absent, it has been found for a number of substitutents that the average ratio of the logarithsms of the partial rate factors for these positions (see p. 690 for a definition of partial rate factor) was close to 0.865,[45] which is not far from the value predicted from the ratio of charge densities in 9. This picture is further supported by the fact that meta-directing groups, which destabilize a positive charge, give ortho/para ratios >67:33 (of course the total amount of ortho and para substitution with these groups is small, but the *ratios* are generally >67:33).[46] Another important factor is the steric effect. If either the group on the ring or the attacking group is large, steric hindrance inhibits

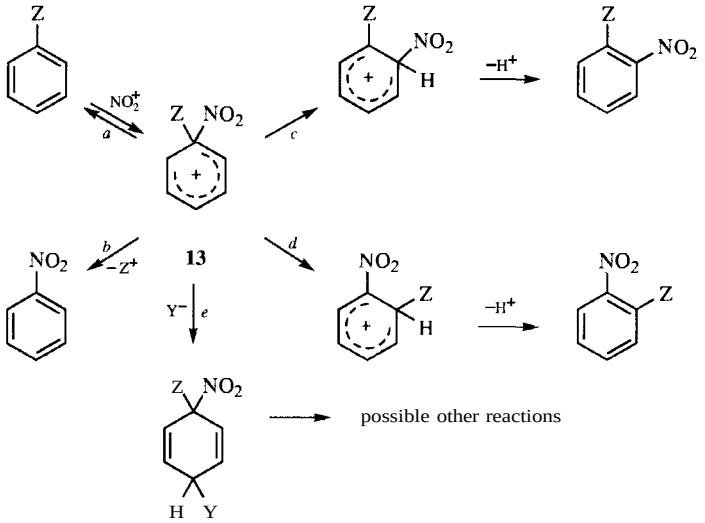
formation of the ortho product and increases the amount of the para isomer. An example may be seen in the nitration, under the same conditions, of toluene and *tert*-butylbenzene. The former gave 58% of the ortho compound and 37% of the para, while the more bulky *tert*-butyl group gave 16% of the ortho product and 73% of the para.[47] Some groups are so large that they direct almost entirely para.

When the ortho-para directing group is one with an unshared pair (this of course applies to most of them), there is another effect that increases the amount of para product at the expense of the ortho. A comparison of the intermediates involved (p. 683) shows that C is a canonical form with an ortho-quinoid structure, while D has a para-quinoid structure. Since we know that para-quinones are more stable than the ortho isomers, it seems reasonable to assume that D is more stable than C, and therefore contributes more to the hybrid and increases its stability compared to the ortho intermediate.

It has been shown that it is possible to compel regiospecific para substitution by enclosing the substrate molecules in a cavity from which only the para position projects. Anisole was chlorinated in solutions containing a cyclodextrin, a molecule in which the anisole is almost entirely enclosed (see Fig. 3.4). With a high enough concentration of cyclodextrin, it was possible to achieve a para/ortho ratio of 21.6 (in the absence of the cyclodextrin the ratio was only 1.48).[48] This behavior is a model for the regioselectivity found in the action of enzymes.

Ipso Attack

We have discussed orientation in the case of monosubstituted benzenes entirely in terms of attack at the ortho, meta, and para positions, but attack at the position bearing the substituent (called the *ipso position*[49]) can also be important. Ipso attack has mostly been studied for nitration.[50] When NO_2^+ attacks at the ipso position there are at least five possible fates for the resulting arenium ion (13).



Path a. The arenium ion can lose NO_2^+ and revert to the starting compounds. This results in no net reaction and is often undetectable.

Path b. The arenium ion can lose Z^+, in which case this is simply aromatic substitution with a leaving group other than H (see 11-36-11-44).

Path c. The electrophilic group (in this case NO_2^+) can undergo a 1,2 migration, followed by loss of the proton. The product in this case is the same as that obtained by direct attack of NO_2^+ at the ortho position of PhZ. It is not always easy to tell how much of the ortho product in any individual case arises from this pathway,[51] though there is evidence that it can be a considerable proportion. Because of this possibility, many of the reported conclusions about the relative reactivity of the ortho, meta, and para positions are cast into doubt, since some of the product may have arisen not from direct attack at the ortho position, but from attack at the ipso position followed by rearrangement.[52]

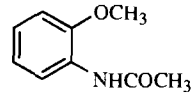
Path d. The ipso substituent (Z) can undergo 1,2 migration, which also produces the ortho product (though the rearrangement would become apparent if there were other substituents present). The evidence is that this pathway is very minor, at least when the electrophile is NO_2^+.[53]

Path e. Attack of a nucleophile on 13. In some cases, the products of such an attack (cyclohexadienes) have been isolated (this is 1,4 addition to the aromatic ring),[54] but further reactions are also possible.

Orientation in Benzene Rings With More Than One Substituent[55]

It is often possible in these cases to predict the correct isomer. In many cases, the groups already on the ring reinforce each other. Thus, 1,3-dimethylbenzene is substituted at the 4 position (ortho to one group and para to the other), but not at the 5 position (meta to both). Likewise the incoming group in *p*-chlorobenzoic acid goes to the position ortho to the chloro and meta to the carboxyl group.

When the groups oppose each other, predictions may be more difficult. In a case such as where two groups of about equal directing ability are in competing positions,

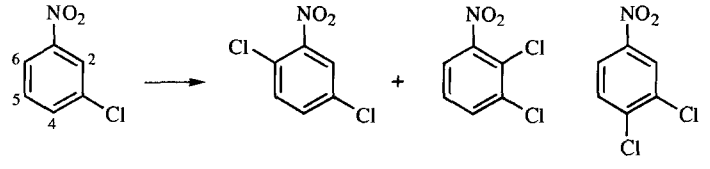


all four products can be expected, and it is not easy to predict the proportions, except that steric hindrance should probably reduce the yield of substitution ortho to the acetamido group, especially for large electrophiles. Mixtures of about equal proportions are frequent in such cases. Nevertheless, even when groups on a ring oppose each other, there are some regularities.

1. If a strong activating group competes with a weaker one or with a deactivating group, the former controls. Thus *o*-cresol gives substitution mainly ortho and para to the *hydroxyl* group and not to the methyl. For this purpose,

we can arrange the groups in the following order: NH_2, OH, NR_2, O^- > OR, OCOR, NHCOR > R, Ar > halogen > meta-directing groups.

2. All other things being equal, a third group is least likely to enter between two groups in the meta relationship. This is the result of steric hindrance and increases in importance with the size of the groups on the ring and with the size of the attacking species.[56]
3. When a meta-directing group is meta to an ortho-para directing group, the incoming group primarily goes ortho to the meta-directing group rather than para. For example, chlorination of 14 gives mostly 15. The importance of this



14 **15** **16** **17**

effect is underscored by the fact that 16, which is in violation of the preceding rule, is formed in smaller amounts, but 17 is not formed at all. This is called the *ortho effect*,[51] and many such examples are known.[58] Another is the nitration of *p*-bromotoluene, which gives 2,3-dinitro-4-bromotoluene. In this case, once the first nitro group came in, the second was directed ortho to it rather than para, even though this means that the group has to come in between two groups in the meta position. There is no good explanation yet for the ortho effect, though possibly there is intramolecular assistance from the meta-directing group.

It is interesting that chlorination of 14 illustrates all three rules. Of the four positions open to the electrophile, the 5 position violates rule 1, the 2 position rule 2, and the 4 position rule 3. The principal attack is therefore at position 6.

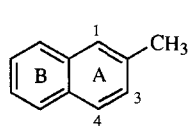
Orientation in Other Ring Systems[59]

In fused ring systems, the positions are not equivalent and there is usually a preferred orientation even in the unsubstituted hydrocarbon. The preferred positions may often by predicted as for benzene rings. Thus it is possible to draw more canonical forms for the arenium ion when naphthalene is attacked at the a position than when it is attacked at the β position, and the a position is the preferred site of attack,[60] though, as previously mentioned (p. 682), the isomer formed by substitution at the β position is thermodynamically more stable and is the product if the reaction is reversible and equilibrium is reached. Because of the more extensive delocalization of charges in the corresponding arenium ions, naphthalene is more reactive than benzene and substitution is faster at both positions. Similarly, anthracene, phenanthrene, and other fused polycyclic aromatic hydrocarbons are also substituted faster than benzene.

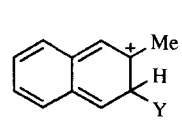
Heterocyclic compounds, too, have nonequivalent positions, and the principles are similar,[61] in terms of mechanism and rate data is available.[62] Furan, thiophene,

and pyrrole are chiefly substituted at the 2 position, and all are substituted faster than benzene.[63] Pyrrole is particularly reactive, with a reactivity approximating that of aniline or the phenoxide ion. For pyridine[64] it is not the free base that is attacked but the conjugate acid, pyridinium ion.[65] The 3 position is most reactive, but the reactivity in this case is much less than that of benzene, being similar to that of nitrobenzene. However, groups can be introduced into the 4 position of a pyridine ring indirectly, by performing the reaction on the corresponding pyridine N-oxide.[66]

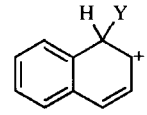
When fused ring systems contain substituents, successful predictions can often be made by using a combination of the above principles. Thus, ring A of 2-methylnaphthalene (18) is activated by the methyl group; ring B is not (though the presence



18

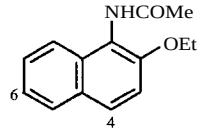


19

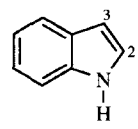


20

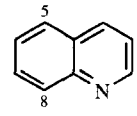
of a substituent in a fused ring system affects all the rings,[67] the effect is generally greatest on the ring to which it is attached). We therefore expect substitution in ring A. The methyl group activates positions 1 and 3, which are ortho to itself, but not position 4, which is meta to it. However, substitution at the 3 position gives rise to an arenium ion for which it is impossible to write a low-energy canonical form in which ring B has a complete sextet. All we can write are forms like 19, in which the sextet is no longer intact. In contrast, substitution at the 1 position gives rise to a more stable arenium ion, for which two canonical forms (one of them is 20) can be written in which ring B is benzenoid. We thus predict predominant substitution at C-1, and that is what is generally found.[68] However, in some cases predictions are much harder to make. For example, chlorination or nitration of 21 gives mainly the 4 derivative, but bromination yields chiefly the 6 compound.[69]



21

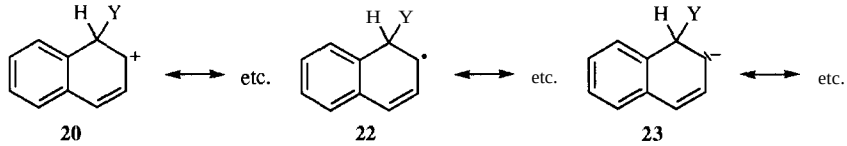


Indole



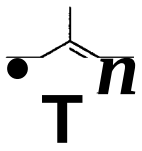
Quinoline

For fused heterocyclic systems too, we can often make predictions based on the above principles, though many exceptions are known. Thus, indole is chiefly substituted in the pyrrole ring (at position 3) and reacts faster than benzene, while quinoline generally reacts in the benzene ring, at the 5 and 8 positions, and slower than benzene, though faster than pyridine.



20 **22** **23**

In alternant hydrocarbons (p. 55), the reactivity at a given position is similar for electrophilic, nucleophilic, and free-radical substitution, because the same kind of resonance can be shown in all three types of intermediate (cf. **20**, **22**, and 23). Attack at the position that will best delocalize a positive charge will also best delocalize a negative charge or an unpaired electron. Most results are in accord with these predictions. For example, naphthalene is attacked primarily at the 1 position by NO_2^+, NH_2^-, and Ph•, and always more readily than benzene.



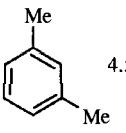
24

When strain due to a ring fused on an aromatic ring deforms that ring out of planarity, the molecule is more reactive to electrophilic aromatic substitution.[70] This has been explained by the presence of a shortened bond for the sp^2 hybridized carbon, increasing the strain at that position, and this is known as the *Mills-Nixon Effect*.[71] There is electron paramagnetic resonance (EPR) evidence for 3,6-dimethyl-1,2,4,5-tetrahydrobenzo-bis-cyclobutene (24) that supports the Mills-Nixon effect,[72] and a theoretical study supports this.[73] However, *ab initio* studies of triannelated benzene rings shows *no evidence* for the Mills-Nixon effect, and a new motif for bond-alternating benzenes was proposed.[74] Indeed, it is argued that the Mills-Nixon effect is not real.[75]

Quantitative Treatments of Reactivity in the Substrate

Quantitative rate studies of aromatic substitutions are complicated by the fact that there are usually several hydrogens that can leave, so that measurements of overall rate ratios do not give a complete picture as they do in nucleophilic substitutions, where it is easy to compare substrates that have only one possible leaving group in a molecule. What is needed is not, say, the overall rate ratio for acetylation of toluene versus that for benzene, but the *rate ratio at each position.* These can be calculated from the overall rates and a careful determination of the proportion of isomers formed, provided that the products are kinetically controlled, as is usually the case. We may thus define the *partial rate factor* for a given group and a given reaction as the rate of substitution at a single position relative to a single position in benzene. For example, for acetylation of toluene the partial rate factors are the following:

4.5x749 = 3375
4.8 x 4.8 x 23



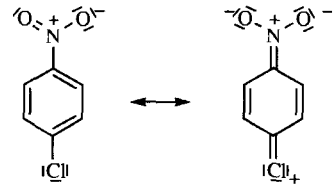
$4.5 \times 4.5 = 20$

for the ortho position $o_f^{Me} = 4.5$, for the meta $m_f^{Me} = 4.8$, and for the para $p_f^{Me} = 7.9$ [76] This means that toluene is acetylated at the ortho position 4.5 times as

fast as a single position in benzene, or 0.75 times as fast as the overall rate of acetylation of benzene. A partial rate factor > 1 for a given position indicates that the group in question activates that position for the given reaction. Partial rate factors differ from one reaction to another and are even different, though less so, for the same reaction under different conditions.

Once we know the partial rate factors, we can predict the proportions of isomers to be obtained when two or more groups are present on a ring, *if we make the assumption that the effect of substituents is independent.* For example, if the two methyl groups in m-xylene have the same effect as the methyl group in toluene, we can calculate the theoretical partial rate factors at each position by multiplying those from toluene, so they should be as indicated:

From this it is possible to calculate the overall theoretical rate ratio for acetylation of m-xylene relative to benzene, since this is one-sixth the sum of the partial rate factors (in this case 1130), and the isomer distribution if the reaction is kinetically controlled. The overall rate ratio actually is 347[77] and the calculated and observed isomer distributions are listed in Table 11.2.[76] In this case, and in many others, agreement is fairly good, but many cases are known where the effects are not additive.[78] For example,



25

this treatment predicts that for 1,2,3-trimethylbenzene there should be 35% 5 substitution and 65% 4 substitution, but acetylation gave 79% 5 substitution and 21% of the 4 isomer. The treatment is thrown off by steric effects, such as those mentioned earlier (p. 685), by products arising from ipso attack (p. 686) and by resonance interaction *between* groups (e.g., 25), which must make the results deviate from simple additivity of the effects of the groups.

Another approach that avoids the problem created by having competing leaving groups present in the same substrate is the use of substrates that contain only one leaving group. This is most easily accomplished by the use of a leaving group other

TABLE 11.2 Calculated and Experimental Isomer Distributions in the Acetylation of *m*-Xylene

	Isomer Distribution (%)	
Position	Calculated	Observed
2	0.30	0
4	9.36	97.5
5	0.34	2.5

than hydrogen. By this means, overall rate ratios can be measured for specific positions.[79] Results obtained in this way[80] give a reactivity order quite consistent with that for hydrogen as leaving group.

A quantitative scale of reactivity for aromatic substrates (fused, heterocyclic, and substituted rings) has been devised, based on the hard-soft concept (p. 338).[81] From MO theory, a quantity, called *activation hardness*, can be calculated for each position of an aromatic ring. The smaller the activation hardness, the faster the attack at that position; hence the treatment predicts the most likely orientations for incoming groups.

A Quantitative Treatment of Reactivity of the Electrophile: the Selectivity Relationship

Not all electrophiles are equally powerful. The nitronium ion attacks not only benzene but also aromatic rings that contain a strongly deactivating group. On the other hand, diazonium ions couple only with rings containing a powerful activating group. Attempts have been made to correlate the influence of substituents with the power of the attacking group. The most obvious way to do this is with the Hammett equation (p. 350):

$$\log \frac{k}{k_0} = \rho\sigma$$

For aromatic substitution, k_0 is divided by 6 and, for meta substitution, k is divided by 2, so that comparisons are made for only one position (consequently, k/k_0 for, say, the methyl group at a para position is identical to the partial rate factor p_f^{Me}). It was soon found that while this approach worked fairly well for electron-withdrawing groups, it failed for those that are electron donating. However, if the equation is modified by the insertion of the Brown σ^+ values instead of the Hammett σ values (because a positive charge develops during the transition state), more staisfactory correlations can be made, even for electron-donating groups (see Table 9.4 for a list of CT^+ values).[82] Groups with a negative value of CT_p^+ or CT_m^+ are activating for that position; groups with a positive value are deactivating. The p values correspond to the susceptibility of the reaction to stabilization or destabilization by the Z group and to the reactivity of the electrophile. The p values vary not only with the electrophile but also with conditions. A large negative value of p means an electrophile of relatively low reactivity. Of course, this approach is completely useless for ortho substitution, since the Hammett equation does not apply there.

A modification of the Hammett approach, suggested by Brown, called the *selectivity relationship*,[83] is based on the principle that reactivity of a species varies inversely with selectivity. Table 11.3[84] shows how electrophiles can be arranged in order of selectivity as measured by two indexes: (1) their selectivity in attacking toluene rather than benzene, and (2) their selectivity between the meta and para positions in toluene. As the table shows, an electrophile more selective in one respect is also more selective in the other. In many cases, electrophiles known to be more

TABLE 11.3 Relative Rates and Product Distributions in Some Electrophilic Substitutions on Toluene and Benzene

Reaction	Relative Rate $k_{toluene}/k_{benzene}$	Product Distribution (%)	
		m	p
Bromination	605	0.3	66.8
Chlorination	350	0.5	39.7
Benzoylation	110	1.5	89.3
Nitration	23	2.8	33.9
Mercuration	7.9	9.5	69.5
Isopropylation	1.8	25.9	46.2

stable (hence less reactive) than others show a higher selectivity, as would be expected. For example, the *tert*-butyl cation is more stable and more selective than the isopropyl (p. 219), and Br_2 is more selective than Br^+. However, deviations from the relationship are known.[85] Selectivity depends not only on the nature of the electrophile but also on the temperature. As expected, it normally decreases with increasing temperature.

Brown assumed that a good measurement of selectivity was the ratio of the para and meta partial rate factors in toluene. He defined the selectivity S_f of a reaction as

$$p_f^{Me}$$

That is, the more reactive an attacking species, the less preference it has for the para position compared to the meta. If we combine the Hammett-Brown $\sigma^+\rho$ relationship with the linearity between log S_f and log p_f^{Me} and between log S_f and log m_f^{Me}, it is possible to derive the following expressions:

$$\log m_f^{Me} = \frac{\sigma_m^+}{\sigma_p^+ - \sigma_m^+} S_f$$

S_f is related to p by

$$S_f = \rho(\sigma_p^+ - \sigma_m^+)$$

The general validity of these equations is supported by a great deal of experimental data on aromatic substitution reactions of toluene. Examples of values for some reactions obtained from these equations are given in Table 11.4.[86] For other substituents, the treatment works well with groups that, like methyl, are not very

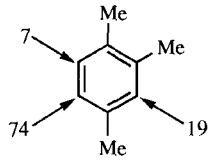
TABLE 11.4 Values of m_f^{Me}, p_f^{Me}, S_f, and p for Three Reactions of Toluene

Reaction	m_f^{Me}	p_f^{Me}	S_f	P
PhMe + EtBr $\xrightarrow[\text{benzene, 25°C}]{GaBr_3}$	1.56	6.02	0.587	-2.66
PhMe + HNO_3 $\xrightarrow[45°C]{90\%HOAc}$	2.5	58	1.366	-6.04
PhMe + BR_2 $\xrightarrow[25°C]{85\%HOAc}$	5.5	2420	2.644	-11.40

polarizable. For more polarizable groups the correlations are sometimes satisfactory and sometimes not, probably because each electrophile in the transition state makes a different demand on the electrons of the substituent group.

Not only are there substrates for which the treatment is poor, but it also fails with very powerful electrophiles; this is why it is necessary to postulate the encounter complex mentioned on page 680. For example, relative rates of nitration of *p*-xylene, 1,2,4-trimethylbenzene, and 1,2,3,5-tetramethylbenzene were 1.0, 3.7, and 6.4,[87] though the extra methyl groups should enhance the rates much more (*p*-xylene itself reacted 295 times faster than benzene). The explanation is that with powerful electrophiles the reaction rate is so rapid (reaction taking place at virtually every encounter[88] between an electrophile and substrate molecule)[89] that the presence of additional activating groups can no longer increase the rate.[90]

Given this behavior (little selectivity in distinguishing between different substrate molecules), the selectivity relationship would predict that positional selectivity should also be very small. However, it is not. For example, under conditions where nitration of *p*-xylene and 1,2,4-trimethylbenzene takes place at about equal rates, there was no corresponding lack of selectivity at positions *within* the latter.[91] Though



relative rate ratios

steric effects are about the same at both positions, more than 10 times as much 5-nitro product was formed as 6-nitro product. It is clear that the selectivity relationship has broken down and it becomes necessary to explain why such an extremely rapid reaction should occur with positional selectivity. The explanation offered is that the rate-determining step is formation of an encounter complex (12, p. 680).[92] Since the position of attack is not determined in the rate-determining step, the 5:6 ratio is not related to the reaction rate. Essentially the same idea was suggested earlier[93] and for the same reason (failure of the selectivity relationship in some cases), but the earlier explanation specifically pictured the complex as a *n* complex, and we have seen (p. 680) that there is evidence against this.

One interesting proposal[94] is that the encounter pair is a radical pair $\overline{NO_2^{\bullet}ArH^{\bullet+}}$ formed by an electron transfer (SET), which would explain why the

electrophile, once in the encounter complex, can acquire the selectivity that the free NO_2^+ lacked (it is not proposed that a radical pair is present in all aromatic substitutions; only in those that do not obey the selectivity relationship). The radical pair subsequently collapses to the arenium ion. There is evidence[95] both for and against this proposal.[96]

The Effect of the Leaving Group

In the vast majority of aromatic electrophilic substitutions, the leaving group is H^+ (it is certainly one of the best), and very little work has been done on the relative electrofugal ability of other leaving groups. However, the following orders of leaving-group ability have been suggested:[97] (1) for leaving groups that depart without assistance (S_N1 process with respect to the leaving group), NO_2^+ [98] < $i\text{-}Pr^+ \approx SO_3 < t\text{-}Bu^+ \approx ArN_2^+ < ArCHOH^+ < NO^+ < CO_2$; (2) for leaving groups that depart with assistance from an outside nucleophile (S_N2 process), $Me^+ < Cl^+ < Br^+ < D^+ \approx RCO^+ < H^+ \approx I^+ < Me_3Si^+$. We can use this kind of list to help predict which group, X or Y, will cleave from an arenium ion (1) once it has been formed, and so obtain an idea of which electrophilic substitutions are feasible. However, a potential leaving group can also affect a reaction in another way: by influencing the rate at which the original electrophile attacks directly at the ipso position. Partial rate factors for electrophilic attack at a position substituted by a group other than hydrogen are called ipso partial rate factors (i_f^X).[49] Such factors for the nitration of *p*-haloanisoles are 0.18, 0.08, and 0.06, for *p*-iodo, *p*-bromo-, and *p*-chloroanisole, respectively.[99] This means, for example, that the electrophile in this case attacks the 4 position of 4-iodoanisole 0.18 times as fast as a single position of benzene. Note that this is far slower than it attacks the 4 position of anisole itself so that the presence of the iodo group greatly slows the reaction at that position. A similar experiment on *p*-cresol showed that ipso attack at the methyl position was 6.8 times slower than attack at the para position of phenol.[100] Thus, in these cases, both an iodo and a methyl group deactivate the ipso position.[101]

REACTIONS

The reactions in this chapter are classified according to leaving group. Hydrogen replacements are treated first, then rearrangements in which the attacking entity is first cleaved from another part of the molecule (hydrogen is also the leaving group in these cases), and finally replacements of other leaving groups.

Hydrogen as the Leaving Group in Simple Substitution Reactions

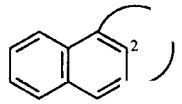
A. *Hydrogen as the Electrophile*

11-1 *Hydrogen Exchange*

DEUTERIO-DE-HYDROGENATION OR DEUTERIATION

$$ArH + D^+ \rightleftharpoons ArD + H^+$$

Aromatic compounds can exchange hydrogens when treated with acids. The reaction is used chiefly to study mechanistic questions (including substituent effects),[102] but can also be useful to deuterate (add ^2H) or tritiate (add ^3H) aromatic rings selectively. The usual directive effects apply and, for example, phenol treated with D_2O gives slow exchange on heating, with only ortho and para hydrogens being exchanged.[103] Strong acids, of course, exchange faster with aromatic substrates, and this exchange must be taken into account when studying the mechanism of any aromatic substitution catalyzed by acids. There is a great deal of evidence that exchange takes place by the ordinary arenium ion mechanism. Among the evidence are the orientation effects noted above and the finding that the reaction is general acid catalyzed, which means that a proton is transferred in the slow step (p. 337).[104] Furthermore, many examples have been reported of stable solutions of arenium ions formed by attack of a proton on an aromatic ring.[4] Simple aromatic compounds can be extensively deuterated in a convenient fashion by treatment with D_2O and BF3.[105] It has been shown that tritium exchange takes place readily at the 2 position of 26, despite the fact that this position is hindered by the bridge. The rates were not very different from the comparison compound 1,3-dimethylnaphthalene.[106]



n = 7, 8, 10

26

Hydrogen exchange can also be effected with strong bases,[107] such as NH_2^-. In these cases the slow step is the proton transfer:

$$ArH + B \longrightarrow Ar^- + BH^+$$

so the S_E1 mechanism and not the usual arenium ion mechanism is operating.[108] Aromatic rings can also be deuterated by treatment with D_2O and a rhodium(III) chloride[109] or platinum[110] catalyst or with C_6D_6 and an alkylaluminum dichloride catalyst,[111] though rearrangements may take place during the latter procedure. Tritium (^3H, abbreviated T) can be introduced by treatment with T_2O and an alkylaluminum dichloride catalyst.[111] Tritiation at specific sites (e.g., >90% para in toluene) has been achieved with T_2 gas and a microporous aluminophosphate catalyst.[112]

B. *Nitrogen Electrophiles*

11-2 *Nitration or Nitro-de-hydrogenation*

$$ArH + HNO_3 \xrightarrow{H_2SO_4} ArNO_2$$

Most aromatic compounds, whether of high or low reactivity, can be nitrated, because a wide variety of nitrating agents is available.[113] For benzene, the simple alkylbenzenes, and less reactive compounds, the most common reagent is a mixture of concentrated nitric and sulfuric acids, but for active substrates, the reaction can be

carried out with nitric acid alone, or in water, acetic acid, or acetic anhydride. In fact, these milder conditions are necessary for active compounds such as amines, phenols, and pyrroles, since reaction with mixed nitric and sulfuric acids would oxidize these substrates. A mixture of NO_2/O_2 Fe(acac)3, where acac = acetylacetonato, can also be used.[114] If anhydrous conditions are required, nitration can be effected with N_2O_5[115] in CCl_4 in the presence of P_2O_5, which removes the water formed in the reaction.[116] Nitration in alkaline media can be accomplished with esters of nitric acid such as ethyl nitrate ($EtONO_2$). These reagents can also be used with proton or Lewis acid catalysts. Other nitrating agents are $NaNO_2$ and trifluoroacetic acid,[117] N_2O_4 (which gives good yields with polycyclic hydrocarbons[118]), $VO(NO_3)_3$,[119] and nitronium salts[120] such as $NO_2^+ BF_4^-$, $NO_2^+ PF_6^-$, and $NO_2^+ CF_3SO_3^-$. The last-mentioned salt gives a very high yield of products at low temperatures.[121] A mixture of HNO_3/acetic anhydride on a H^+ beta-zeolite give high para selectivity for nitration.[122] Aromatic hydrocarbons and halobenzenes are nitrated in high yields with clay-supported cupric nitrate (Claycop),[123] with predominant para regioselectivity.[124] With active substrates such as amines and phenols, nitration can be accomplished by nitrosation under oxidizing conditions with a mixture of dilute nitrous and nitric acids.[125] Nitration of styrene poses a problem since addition occurs to the C=C unit to give a 1-nitroethyl aryl.[126] Heterocycles such as pyridine are nitrated with N_2O_5 and SO_2.[127] A mixture of NO_2/O_3 nitration electron deficient aromatics such as ethyl benzoate[128] as well as electron rich aryls such as *O*-acetylphenol.[129]

When amines are nitrated under strong-acid conditions, meta orientation is generally observed, because the species undergoing nitration is actually the conjugate acid of the amine. If the conditions are less acidic, the free amine is nitrated and the orientation is ortho-para. Although the free base may be present in much smaller amounts than the conjugate acid, it is far more susceptible to aromatic substitution (see also p. 684). Because of these factors and because they are vulnerable to oxidation by nitric acid, primary aromatic amines are often protected before nitration by treatment with acetyl chloride (10-55) or acetic anhydride (10-56). Nitration of the resulting acetanilide derivative avoids all these problems. There is evidence that when the reaction takes place on the free amine, it is the nitrogen that is attacked to give an N-nitro compound $Ar{-}NH{-}NO_2$ which rapidly undergoes rearrangement (see 11-31) to give the product.[130]

Since the nitro group is deactivating, it is usually easy to stop the reaction after one group has entered the ring, but a second and a third group can be introduced if desired, especially when an activating group is also present. Even *m*-dinitrobenzene can be nitrated if vigorous conditions are applied. This has been accomplished with $NO_2^+ BF_4^-$ in FSO_3H at 150°C.[131]

With most of the reagents mentioned, the attacking species is the nitronium ion NO_2^+. Among the ways in which this ion is formed are

1. In concentrated sulfuric acid, by an acid-base reaction in which nitric acid is the base:

$$HNO_3 + 2\,H_2SO_4 \rightleftharpoons NO_2^+ + H_3O^+ + 2\,HSO_4^-$$

This ionization is essentially complete.

2. In concentrated nitric acid alone,[132] by a similar acid-base reaction in which one molecule of nitric acid is the acid and another the base:

$$2\,HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O$$

This equilibrium lies to the left (about 4% ionization), but enough NO_2^+ is formed for nitration to occur.

3. The equilibrium just mentioned occurs to a small extent even in organic solvents.
4. With N_2O_5 in CCl_4, there is spontaneous dissociation:

$$N_2O_5 \rightleftharpoons NO_2^+ + NO_3^-$$

but in this case there is evidence that some nitration also takes place with undissociated N_2O_5 as the electrophile.

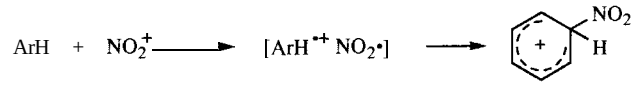
5. When nitronium salts are used, NO_2^+ is of course present to begin with. Esters and acyl halides of nitric acid ionize to form NO_2^+. Nitrocyclohexadienones are converted to NO_2^+ and the corresponding phenol.[115]

There is a great deal of evidence that NO_2^+ is present in most nitrations and that it is the attacking entity,[133] for example,

1. Nitric acid has a peak in the Raman spectrum. When nitric acid is dissolved in concentrated sulfuric acid, the peak disappears and two new peaks appear, one at $1400\,cm^{-1}$ attributable to NO_2^+ and one at $1050\,cm^{-1}$ due to HSO_4^-.[134]
2. On addition of nitric acid, the freezing point of sulfuric acid is lowered about four times the amount expected if no ionization has taken place.[135] This means that the addition of one molecule of nitric acid results in the production of four particles, which is strong evidence for the ionization reaction between nitric and sulfuric acids given above.
3. The fact that nitronium salts in which nitronium ion is known to be present (by X-ray studies) nitrate aromatic compounds shows that this ion does attack the ring.
4. The rate of the reaction with most reagents is proportional to the concentration of NO_2^+, not to that of other species.[136] When the reagent produces this ion in small amounts, the attack is slow and only active substrates can be nitrated. In concentrated and aqueous mineral acids the kinetics are second order: first order each in aromatic substrate and in nitric acid (unless pure nitric acid is used in which case there are pseudo-first-order kinetics). But in organic solvents, such as nitromethane, acetic acid, and CCl_4, the kinetics are first order in nitric acid alone and zero order in aromatic substrate, because the rate-determining step is formation of NO_2^+ and the substrate does not take part in this.

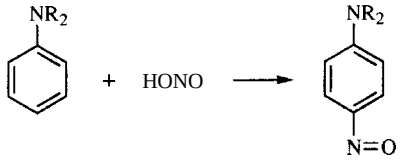
An interesting route to nitrobenzene begins with bromobenzene. Reaction with butyllithium gives phenyllithium, which reacts with an excess of N_2O_4 to give nitrobenzene.[137]

In a few cases, depending on the substrate and solvent, there is evidence that the arenium ion is not formed directly, but via the intermediacy of a radical pair (see p. 694):[138]



OS I, 372, 396, 408 (see also OS 53, 129); II, 254, 434, 438, 447, 449, 459, 466; ffl, 337, 644, 653, 658, 661, 837; IV, 42, 364, 654, 711, 722, 735; V, 346, 480, 829, 1029, 1067.

11-3 *Nitrosation or Nitroso-de-hydrogenation*



Ring nitrosation[139] with nitrous acid is normally carried out only with active substrates such as amines and phenols. However, primary aromatic amines give diazonium ions **(12-47)** when treated with nitrous acid,[140] and secondary amines tend to give N-nitroso rather than C-nitroso compounds **(12-49);** hence this reaction is normally limited to phenols and tertiary aromatic amines. Nevertheless secondary aromatic amines can be C-nitrosated in two ways. The N-nitroso compound first obtained can be isomerized to a C-nitroso compound **(11-32),** or it can be treated with another mole of nitrous acid to give an N,C-dinitroso compound. Also, a successful nitrosation of anisole has been reported, where the solvent was CF_3COOH–CH_2Cl_2.[141]

Much less work has been done on the mechanism of this reaction than on the preceding one.[142] In some cases the attacking entity is NO^+, but in others it is apparently NOCl, NOBr, N_2O_3, and so on, in each of which there is a carrier of NO^+. Both NOCl and NOBr are formed during the normal process of making nitrous acid the treatment of sodium nitrite with HC1 or HBr. Nitrosation requires active substrates because NO^+ is much less reactive than NO_2^+. Kinetic studies have shown that NO^+ is at least 10^{14} times less reactive than NO_2^+.[143] A consequence of the relatively high stability of NO^+ is that this species is easily cleaved from the arenium ion, so that k_{-1} competes with k_2 (p. 677) and isotope effects are found.[144] With phenols, there is evidence that nitrosation may first take place at the OH group, after which the nitrite ester thus formed rearranges to the C-nitroso product.[145] Tertiary aromatic amines substituted in the ortho position generally do not react with HONO, probably because the ortho substituent prevents planarity of the dialkylamino group, without which the ring is no longer activated. This is an example of steric inhibition of resonance (p. 42).

OS I, 214, 411, 511; II, 223; IV, 247.

11-4 *Diazonium Coupling*

ARYLAZO-DE-HYDROGENATION

$$ArH + Ar'N_2^+ \longrightarrow Ar{-}N{=}N{-}Ar'$$

Aromatic diazonium ions normally couple only with active substrates such as amines and phenols.[146] Many of the products of this reaction are used as dyes (*azo dyes*).[147] Presumably because of the size of the attacking species, substitution is mostly para to the activating group, unless that position is already occupied, in which case ortho substitution takes place. The pH of the solution is important both for phenols and amines. For amines, the solutions may be mildly acidic or neutral. The fact that amines give ortho and para products shows that even in mildly acidic solution they react in their un-ionized form. If the acidity is too high, the reaction does not occur, because the concentration of free amine becomes too small. Phenols must be coupled in slightly alkaline solution where they are converted to the more reactive phenoxide ions, because phenols themselves are not active enough for the reaction. However, neither phenols nor amines react in moderately alkaline solution, because the diazonium ion is converted to a diazo hydroxide Ar—N=N—OH. Primary and secondary amines face competition from attack at the nitrogen.[148] However, the resulting N-azo compounds (aryl triazenes) can be isomerized to C-azo compounds (11-33). In at least some cases, even when the C-azo compound is isolated, it is the result of initial N-azo compound formation followed by isomerization. It is therefore possible to synthesize the C-azo compound directly in one laboratory step.[149] Acylated amines and phenolic ethers and esters are ordinarily not active enough for this reaction, though it is sometimes possible to couple them (as well as such polyalkylated benzenes as mesitylene and pentamethylbenzene) to diazonium ions containing electron-withdrawing groups in the para position, since such groups increase the concentration of the positive charge and thus the electrophilicity of the ArN_2^+. Some coupling reactions which are otherwise very slow (in cases where the coupling site is crowded) are catalyzed by pyridine for reasons discussed on page 678. Phase transfer catalysis has also been used.[150] Coupling of a few aliphatic diazonium compounds to aromatic rings has been reported. All the examples reported so far involve cyclopropanediazonium ions and bridgehead diazonium ions, in which loss of N_2 would lead to very unstable carbocations.[151]

The mechanism of *(Z/E)* isomerization in Ar—N=N—Ar systems has been studied.[152]

OS I, 49, 374; II, 35, 39, 145.

11-5 *Direct Introduction of the Diazonium Group*

DIAZONIATION OR DIAZONIO-DE-HYDROGENATION

$$ArH \xrightarrow[HX]{2\ HONO} ArN_2^+\ X^-$$

Diazonium salts can be prepared directly by replacement of an aromatic hydrogen without the necessity of going through the amino group.[153] The reaction is essentially limited to active substrates (amines and phenols), since otherwise poor yields are obtained. Since the reagents and the substrate are the same as in reaction 11-3, the first species formed is the nitroso compound. In the presence of excess nitrous acid, this is converted to the diazonium ion.[154] The reagent (azidochloromethylene)dimethylammonium chloride $Me_2N{=}C(Cl)N_3$ Cl^- can also introduce the diazonium group directly into a phenol.[155] A synthesis of solid aryldiazonium chlorides is now available.[156]

11-6 *Amination or Amino-de-hydrogenation*[157]

$$ArH + HN_3 \xrightarrow{AlCl_3} ArNH_2$$

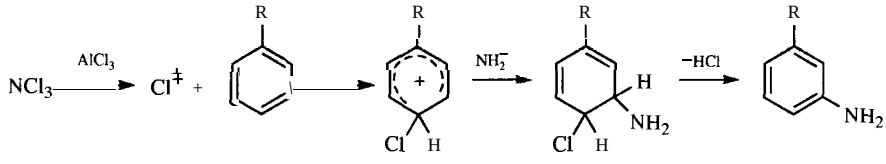
Aromatic compounds can be converted to primary aromatic amines, in 10-65% yields, by treatment with hydrazoic acid (HN_3) in the presence of $AlCl_3$ or H_2SO_4.[158] Higher yields (>90%) have been reported with trimethylsilyl azide (Me_3SiN_3) and triflic acid (F_3CSO_2OH).[159] Tertiary amines have been prepared in fairly good yields (~50-90%) by treatment of aromatic hydrocarbons with N-chlorodialkylamines, by heating in 96% sulfuric acid; or with $AlCl_3$ or $FeCl_3$ in nitroalkane solvents; or by irradiation.[160] Treatment of an aryl halide with an amine and a palladium catalyst leads to the aniline derivative.[161]

Tertiary (and to a lesser extent, secondary) aromatic amines can also be prepared in moderate to high yields by amination with an N-chlorodialkylamine (or an N-chloroalkylamine) and a metallic-ion catalyst (e.g., Fe^{2+}, Ti^{3+}, Cu^+, Cr^{2+}) in the presence of sulfuric acid.[162] The attacking species in this case is the aminium radical ion $R_2\dot{N}H$ formed by[163]

$$R_2\overset{+}{N}HCl + M^+ \longrightarrow R_2\overset{+}{N}H\cdot + M^{2+} + Cl^-$$

Because attack is by a positive species (even though it is a free radical), orientation is similar to that in other electrophilic substitutions (e.g., phenol and acetanilide give ortho and para substitution, mostly para). When an alkyl group is present, attack at the benzylic position competes with ring substitution. Aromatic rings containing only meta-directing groups do not give the reaction at all. Fused ring systems react well.[164]

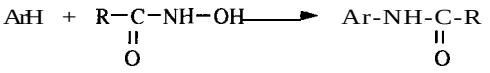
Unusual orientation has been reported for amination with halomines and with NCl_3 in the presence of $AlCl_3$. For example, toluene gave predominately meta amination.[165] It has been suggested that initial attack in this case is by Cl^+ and that a nitrogen nucleophile (whose structure is not known but is represented here as NH_2^- for simplicity) adds to the resulting arenium ion, so that the initial reaction is addition to a carbon-carbon double bond followed by elimination of HC1:[166]



According to this suggestion, the electrophilic attack is at the para position (or the ortho, which leads to the same product) and the meta orientation of the amino group arises indirectly. This mechanism is called the *σ-substitution mechanism.*

Aromatic compounds that do not contain meta-directing groups can be converted to diarylamines by treatment with aryl azides in the presence of phenol at − 60° C: ArH + $Ar'N_3$ → ArNHAr'.[167] Diarylamines are also obtained by the reaction of N-arylhydroxylamines with aromatic compounds (benzene, toluene, anisole) in the presence of F_3CCOOH: ArH + Ar'NHOH → ArNHAr'.[168]

Direct *amidation* can be carried out if an aromatic compound is heated with a hydroxamic acid in polyphosphoric acid, though the scope is essentially limited to phenolic ethers.[169]



Also see 13-16.

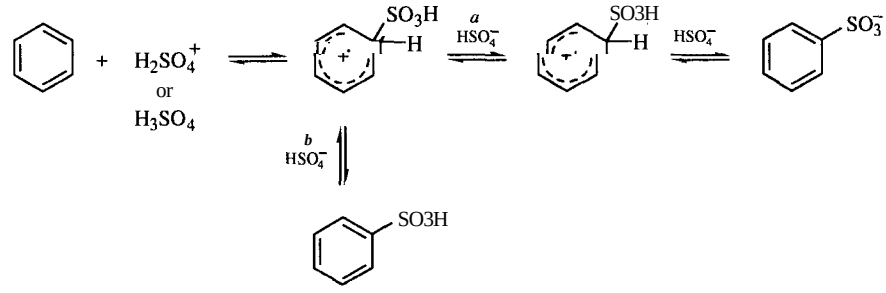
C. *Sulfur Electrophiles*

11-7 *Sulfonation or Sulfo-de-hydrogenation*

The sulfonation reaction is very broad in scope and many aromatic hydrocarbons (including fused ring systems), aryl halides, ethers, carboxylic acids, amines,[170] acylated amines, ketones, nitro compounds, and sulfonic acids have been sulfonated.[171] Phenols can also be successfully sulfonated, but attack at oxygen may compete.[172] Sulfonation is often accomplished with concentrated sulfuric acid, but it can also be done with fuming sulfuric acid, SO3, $ClSO_2OH$, or other reagents. As with nitration (11-2), reagents of a wide variety of activity are available to suit both highly active and highly inactive substrates. Since this is a reversible reaction (see 11-41), it may be necessary to drive the reaction to completion. However, at low temperatures the reverse reaction is very slow and the forward reaction is practically irreversible.[173] The SO3 reacts much more rapidly than sulfuric acid with benzene it is nearly instantaneous. Sulfones are often side products. When sulfonation is carried out on a benzene ring containing four or five alkyl and/or halogen groups, rearrangements usually occur (see 11-39).

A great deal of work has been done on the mechanism, chiefly by Cerfontain and co-workers.[174] Mechanistic study is made difficult by the complicated nature of the solutions. Indications are that the electrophile varies with the reagent, though SO_3 is involved in all cases, either free or combined with a carrier. In aqueous H_2SO_4 solutions, the electrophile is thought to be $H_3SO_4^+$ (or a combination of H_2SO_4 and H_3O^+) at concentrations below ~80-85% H_2SO_4, and $H_2S_2O_7$ (or a combination of H_2SO_4 and SO_3) at concentrations higher than this[175] (the changeover point varies with the substrate[176]). Evidence for a change in electrophile is that in the dilute and in the concentrated solutions the rate of the reaction was proportional to the activity

of $H_3SO_4^+$ and $H_2S_2O_7$, respectively. Further evidence is that with toluene as substrate the two types of solution gave very different ortho/para ratios. The mechanism is essentially the same for both electrophiles and may be shown as[175]



The other product of the first step is HSO_4^- or H_2O from $H_2S_2O_7$ or $H_3SO_4^+$, respectively. Path *a* is the principal route, except at very high H_2SO_4 concentrations, when path *b* becomes important. With $H_3SO_4^+$ the first step is rate determining under all conditions, but with $H_2S_2O_7$ the first step is the slow step only up to about 96% H_2SO_4, when a subsequent proton transfer becomes partially rate determining.[177] The compound $H_2S_2O_7$ is more reactive than $H_3SO_4^+$. In fuming sulfuric acid (H_2SO_4 containing excess SO_3), the electrophile is thought to be $H_3S_2O_7^+$ (protonated $H_2S_2O_7$) up to ~104% H_2SO_4 and $H_2S_4O_{13}$ (H_2SO_4 + 3 SO_3) beyond this concentration.[178] Finally, when pure SO_3 is the reagent in aprotic solvents, SO_3 itself is the actual electrophile.[179] Free SO_3 is the most reactive of all these species, so that attack here is generally fast and a subsequent step is usually rate determining, at least in some solvents.

OS II, 42, 97, 482, 539; III, 288, 824; IV, 364; VI, 976.

11-8 *Halosulfonation or Halosulfo-de-hydrogenation*

$$ArH + ClSO_2OH \longrightarrow ArSO_2Cl$$

Aromatic sulfonyl chlorides can be prepared directly, by treatment of aromatic rings with chlorosulfuric acid.[180] Since sulfonic acids can also be prepared by the same reagent (11-7), it is likely that they are intermediates, being converted to the halides by excess chlorosulfuric acid.[181] The reaction has also been effected with bromo- and fluorosulfuric acids.

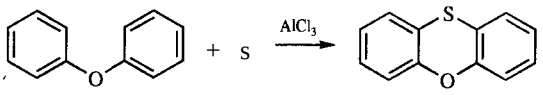
OS I, 8, 85.

11-9 *Sulfurization*

$$ArH + SCl_2 \xrightarrow{AlCl_3} ArSAr$$

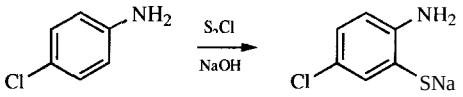
Diary 1 sulfides can be prepared by treating aromatic compounds with SCl_2 and a Friedel-Crafts catalyst. Other reagents that can bring about the same result are S_2Cl_2, thionyl chloride, and even sulfur itself. A catalyst is not always necessary.

The reaction has been used for ring closure:



When thionyl chloride is used, diaryl sulfoxides are usually the main products.[182] Unsymmetrical diaryl sulfides can be obtained by treatment of an aromatic compound with an aryl sulfenyl chloride (ArSCl) in the presence of a trace amount of iron powder.[183] Aromatic amines and phenols can be alkylthiolated (giving mostly ortho product) by treatment with an alkyl disulfide and a Lewis acid catalyst.[184]

With certain substrates (primary amines with a chloro group, or a group not replaceable by chloro, in the para position), treatment with S_2Cl_2 and NaOH gives thiophenolate salts:



This is called the *Herz reaction*.[185]

OS II, 242, 485. Also see OS I, 574; III, 76.

11-10 *Sulfonylation*

ALKYLSULFONYLATION OR ALKYLSULFO-DE-HYDROGENATION

$$ArH + Ar'SO_2Cl \xrightarrow{AlCl_3} ArSO_2Ar'$$

Diaryl sulfones can be formed by treatment of aromatic compounds with aryl sulfonyl chlorides and a Friedel–Crafts catalyst.[186] This reaction is analogous to Friedel–Crafts acylation with carboxylic acid halides (11-14). In a better procedure, the aromatic compound is treated with an aryl sulfonic acid and P_2O_5 in polyphosphoric acid.[187] Still another method uses an arylsulfonic trifluoromethanesulfonic anhydride ($ArSO_2OSO_2CF_3$) (generated *in situ* from $ArSO_2Br$ and CF_3SO_3Ag) without a catalyst.[188]

The reaction can be extended to the preparation of alkyl aryl sulfones by the use of a sulfonyl fluoride.[189]

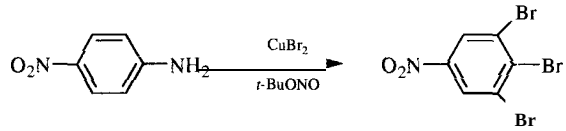
D. *Halogen Electrophiles*

11-11 *Halogenation*[190] *or Halo-de-hydrogenation*

$$ArH + Br_2 \xrightarrow{Fe} ArBr$$

1. *Chlorine and Bromine.* Aromatic compounds can be brominated or chlorinated by treatment with bromine or chlorine in the presence of a catalyst, most often iron. However, the real catalyst is not the iron itself, but the ferric bromide or ferric chloride formed in small amounts from the reaction

between iron and the reagent. Ferric chloride and other Lewis acids are often directly used as catalysts, as is iodine. Bromination of NaY zeolite brominates with high para selectivity.[191] When thallium(III) acetate is the catalyst, many substrates are brominated with high regioselectivity para to an ortho-para directing group.[192] For active substrates, including amines, phenols, naphthalene, and polyalkylbenzenes[193] such as mesitylene and isodurene, no catalyst is needed. A mixture of $Mn(OAc)_3$ and acetyl chloride, with ultrasound, chlorinates anisole with high selectivity.[194] *N*-Bromosuccinimide and HBF_4 can be used to brominate phenols with high para selectivity,[195] as can pyridinium bromide perbromide,[196] and NBS in acetic acid with ultrasound is effective.[197] Indeed, for amines and phenols the reaction is so rapid that it is carried out with a dilute solution of Br_2 or Cl_2 in water at room temperature, or with aqueous HBr in DMSO.[198] Sodium iodide in liquid NO_2 can be used to iodinate aniline derivatives,[199] and tert-butyl hypochlorite chlorinates aniline derivatives.[200] Even so, with amines it is not possible to stop the reaction before all the available ortho and para positions are substituted, because the initially formed haloamines are weaker bases than the original amines and are less likely to be protonated by the liberated HX.[201] For this reason, primary amines are often converted to the corresponding anilides if monosubstitution is desired. With phenols it is possible to stop after one group has entered.[202] The rapid room temperature reaction with amines and phenols is often used as a test for these compounds. Chlorine is a more active reagent than bromine. Phenols can be brominated exclusively in the ortho position (disubstitution of phenol gives 2,6-dibromophenol) by treatment about − 70° C with Br_2 in the presence of tert-butylamine or triethylenediamine, which precipitates out the liberated HBr.[203] Predominant ortho chlorination[204] of phenols has been achieved with chlorinated cyclohexadienes,[205] while para chlorination of phenols, phenolic ethers, and amines can be accomplished with N-chloroamines[206] and with *N*-chlorodimethylsulfonium chloride ($Me_2S^+Cl\ Cl^-$).[207] The last method is also successful for bromination. On the other hand, certain alkylated phenols can be brominated in the meta positions with Br_2 in the superacid solution SbF_5—HF.[208] It is likely that the meta orientation is the result of conversion by the superacid of the OH group to the OH_2^+ group, which should be meta directing because of its positive charge. Bromination and the Sandmeyer reaction (**14-25**) can be carried out in one laboratory step by treatment of an aromatic primary amine with $CuBr_2$ and *tert*-butyl nitrite, for example,[209]



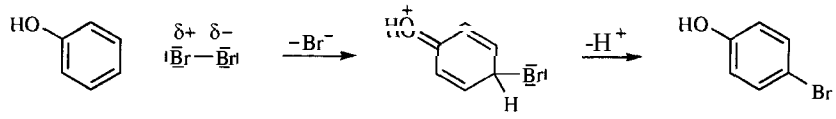
94%

Other reagents have been used, among them HOCl,[210] HOBr, and N-chloro and N-bromo amides (especially NBS and tetraalkylammonium polyha-

lides[211]). In all but the last of these cases the reaction is catalyzed by the addition of acids. Dibromoisocyanuric acid in H_2SO_4 is a very good brominating agent[212] for substrates with strongly deactivating substituents.[213] If the substrate contains alkyl groups, side-chain halogenation **(14-1)** is possible with most of the reagents mentioned, including chlorine and bromine. Since side-chain halogenation is catalyzed by light, the reactions should be run in the absence of light wherever possible.

With deactivated aromatic derivatives, such as nitrobenzene, BrF_3 and Br_2 is an effective reagent, gives the meta-brominated product.[214]

For reactions in the absence of a catalyst, the attacking entity is simply Br_2 or Cl_2 that has been polarized by the ring.[215]



27

Evidence for molecular chlorine or bromine as the attacking species in these cases is that acids, bases, and other ions, especially chloride ion, accelerate the rate about equally, though if chlorine dissociated into Cl^+ and Cl^-, the addition of chloride should decrease the rate and the addition of acids should increase it. Compound 27 has been detected spectrally in the aqueous bromination of phenol.[216]

When a Lewis acid catalyst is used with chlorine or bromine, the attacking entity may be Cl^+ or Br^+, formed by $FeCl_3 + Br_2 \rightarrow FeCl_3Br^- + Br^+$, or it may be Cl_2 or Br_2, polarized by the catalyst. With other reagents, the attacking entity in brominations may be Br^+ or a species such as H_2OBr^+ (the conjugate acid of HOBr), in which H_2O is a carrier of Br^+.[217] With HOCl in H_2O the electrophile may be Cl_2O, Cl_2, or H_2OCl^+; in acetic acid it is generally AcOCl. All these species are more reactive than HOCl itself.[218] It is extremely doubtful that Cl^+ is a significant electrophile in chlorinations by HOCl.[218] It has been demonstrated in the reaction between *N*-methylaniline and calcium hypochlorite that the chlorine attacking entity attacks the *nitrogen* to give *N*-chloro-*N*-methylaniline, which rearranges (as in **11-34)** to give a mixture of ring-chlorinated N-methylanilines in which the ortho isomer predominates.[219]

When chlorination or bromination is carried out at high temperatures (e.g., 300–400°C), ortho-para directing groups direct meta and vice versa.[220] A different mechanism operates here, which is not completely understood. It is also possible for bromination to take place by the S_E1 mechanism, (e.g., in the *t*-BuOK catalyzed bromination of 1,3,5-tribromobenzene).[221]

2. *Iodine.* Iodine is the least reactive of the halogens in aromatic substitution.[222] Except for active substrates, an oxidizing agent must normally be present to oxidize I_2 to a better electrophile.[223] Examples of such oxidizing agents are HNO_3, HIO_3, SO_3, peroxyacetic acid, and H_2O_2.[224] Note that IC1 is a better

iodinating agent than iodine itself.[225] Among other reagents used have been IF (prepared directly from the elements),[226] and benzyltrimethylammonium dichloroiodate (which iodinates phenols, aromatic amines, and N-acylated aromatic amines).[227] Iodination can also be accomplished by treatment of the substrate with I_2 in the presence of copper salts,[228] Al_2O_3,[229] and $PhI(OCOCF_3)_2$ with iodine.[230]

The actual attacking species is less clear than with bromine or chlorine. Iodine itself is too unreactive, except for active species such as phenols, where there is good evidence that I_2 is the attacking entity.[231] There is evidence that AcOI may be the attacking entity when peroxyacetic acid is the oxidizing agent,[232] and I_3^+ when SO_3 or HIO_3 is the oxidizing agent.[233] The I^+ ion has been implicated in several procedures.[234] For an indirect method for accomplishing aromatic iodination, see **12-28.**

3. *Fluorine.* Direct fluorination of aromatic rings with F_2 is not feasible at room temperature because of the extreme reactivity of F_2.[235] It has been accomplished at low temperatures (e.g., -70 to -20°C, depending on the substrate),[236] but the reaction is not yet of preparative significance. Fluorination has also been reported with acetyl hypofluorite (CH_3COOF, generated from F_2 and sodium acetate),[237] with XeF_2,[238] and with an *N*-fluoroperfluoroalkyl sulfonamide; for example, $(CF_3SO_2)2NF$.[239] However, none of these methods seems likely to displace the Schiemann reaction **(13-20)** as the most common method for introducing fluorine into aromatic rings.

The overall effectiveness of reagents in aromatic substitution is Cl_2 > BrCl > Br_2 > IC1 > I_2.

E. *Carbon Electrophiles*

In the reactions in this section, a new carbon-carbon bond is formed. With respect to the aromatic ring, they are electrophilic substitutions, because a positive species attacks the ring. We treat them in this manner because it is customary. However, with respect to the electrophile, most of these reactions are nucleophilic substitutions, and what was said in Chapter 10 is pertinent to them.

11-12 *Friedel-Crafts Alkylation*

ALKYLATION OR ALKYL-DE-HYDROGENATION

$$ArH + RC1 \xrightarrow{AlCl_3} ArCl$$

The alkylation of aromatic rings, called *Friedel-Crafts alkylation,* is a reaction of very broad scope.[240] The most important reagents are alkyl halides, alkenes, and

alcohols, but many other types of reagent have also been employed.[240] When alkyl halides are used, the reactivity order is F > Cl > Br > I[241]; for example, $FCH_2CH_2CH_2Cl$ reacts with benzene to give $PhCH_2CH_2CH_2Cl$[242] when the catalyst is BCl_3. By the use of this catalyst, it is therefore possible to place a haloalkyl group on a ring (see also **11-24**).[243] Di- and trihalides, when all the halogens are the same, usually react with more than one molecule of aromatic compound; it is usually not possible to stop the reaction earlier.[244] Thus, benzene with CH_2Cl_2 gives not $PhCH_2Cl$ but Ph_2CH_2; benzene with $CHCl_3$ gives Ph_3CH. With CCl_4, however, the reaction stops when only three rings have been substituted to give Ph_3CCl.

Alkenes are especially good alkylating agents. With respect to them the reaction is addition of ArH to a C=C double bond:

$$\text{Ar-H} + \text{—C=C—} \xrightarrow{AlCl_3} \text{—C–C—}$$

Acetylene reacts with 2 mol of aromatic compound to give 1,1-diarylethanes, but other alkynes react poorly, if at all. Alcohols are more active than alkyl halides, though if a Lewis acid catalyst is used, more catalyst is required, since the catalyst complexes with the OH group. However, proton acids, especially H_2SO_4, are often used to catalyze alkylation with alcohols. When carboxylic esters are the reagents, there is competition between alkylation and acylation (11-14). Though this competition can often be controlled by choice of catalyst, and alkylation is usually favored, carboxylic esters are not often employed in Friedel–Crafts reactions. Other alkylating agents are ethers, thiols, sulfates, sulfonates, alkyl nitro compounds,[245] and even alkanes and cycloalkanes, under conditions where these are converted to carbocations. Notable here are ethylene oxide, which puts the CH_2CH_2OH group onto the ring, and cyclopropyl[246] units. For all types of reagent the reactivity order is allylic $\approx$ benzylic > tertiary > secondary > primary.

Regardless of which reagent is used, a catalyst is nearly always required.[247] Aluminum chloride and boron trifluoride are the most common, but many other Lewis acids have been used, and also proton acids such as HF and H_2SO_4.[248] For active halides, a trace of a less active catalyst (e.g., $ZnCl_2$) may be enough. For an unreactive halide, such as chloromethane, a more powerful catalyst is needed (e.g., $AlCl_3$) and in larger amounts. In some cases, especially with alkenes, a Lewis acid catalyst causes reaction only if a small amount of proton-donating cocatalyst is present. Catalysts have been arranged in the following order of overall reactivity: $AlBr_3 > AlCl_3 > GaCl_3 > FeCl_3 > SbCl_5$[249] $> ZrCl_4, SnCl_4 > BCl_3, BF_3, SbCl_3$;[250] but the reactivity order in each case depends on the substrate, reagent, and conditions. Alkyl mesylates undergo alkylation reaction with benzene rings in the presence of $Sc(OTf)_3$.[251] Allylic acetates undergo alkylation with $Mo(CO)_6$,[252] and allylic chlorides react in the presence of $ZnCl_2/SiO_2$.[253] Montmorillonite clay (K10) is an effective medium for alkylation reactions.[254] Nafion-H, a superacidic perfluorinated resinsulfonic acid, is a very good catalyst for gas-phase alkylations with alkyl halides, alcohols,[255] or alkenes.[256] A benzene ring with a pendant epoxide unit gives a bicyclo compound baring a $-CH_2OH$ unit when treated with Nafion-H.[257]

Friedel–Crafts alkylation is unusual among the principal aromatic substitutions in that the entering group is activating so that di- and polyalkylation are frequently observed. However, the activating effect of simple alkyl groups (e.g., ethyl, isopropyl) is such that compounds with these groups as substituents are attacked in Friedel-Crafts alkylations only ~ 1.5-3 times as fast as benzene,[258] so it is often possible to obtain high yields of monoalkyl product.[259] Actually, the fact that di- and polyalkyl derivatives are frequently obtained is not due to the small difference in reactivity but to the circumstance that alkylbenzenes are preferentially soluble in the catalyst layer, where the reaction actually takes place.[260] This factor can be removed by the use of a suitable solvent, by high temperatures, or by high-speed stirring.

Also unusual is the fact that the OH, OR, NH_2, and so on, groups do not facilitate the reaction, since the catalyst coordinates with these basic groups. Although phenols give the usual Friedel-Crafts reactions, orienting ortho and para, the reaction is very poor for amines. However, amines can undergo the reaction if alkenes are used as reagents and aluminum anilides as catalysts.[261] In this method, the catalyst is prepared by treating the amine to be alkylated with 0.33 mol of $AlCl_3$. A similar reaction can be performed with phenols, though here the catalyst is $Al(OAr)_2$.[262] Primary aromatic amines (and phenols) can be methylated regioselectively in the ortho position by an indirect method (see **11-26).** For an indirect method for regioselective ortho methylation of phenols, see page 1089.

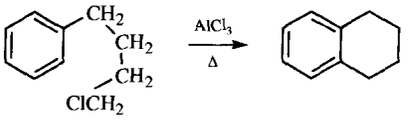
Naphthalene and other fused ring compounds are so reactive that they react with the catalyst, and therefore tend to give poor yields in Friedel-Crafts alkylation. Heterocyclic rings are also tend to be poor substrates for the reaction. Although some furans and thiophenes have been alkylated, a true alkylation of a pyridine or a quinoline has never been described.[263] However, alkylation of pyridine and other nitrogen heterocycles can be accomplished by a free radical **(14-23)** and by a nucleophilic method **(13-15).**

In most cases, meta-directing groups make the ring too inactive for alkylation. Nitrobenzene cannot be alkylated, and there are only a few reports of successful Friedel-Crafts alkylations when electron-withdrawing groups are present.[264] This is not because the attacking species is not powerful enough; indeed we have seen (p. 693) that alkyl cations are among the most powerful of electrophiles. The difficulty is caused by the fact that, with inactive substrates, degradation and polymerization of the electrophile occurs before it can attack the ring. However, if an activating and a deactivating group are both present on a ring, Friedel-Crafts alkylation can be accomplished.[265] Aromatic nitro compounds can be methylated by a nucleophilic mechanism **(13-15).**

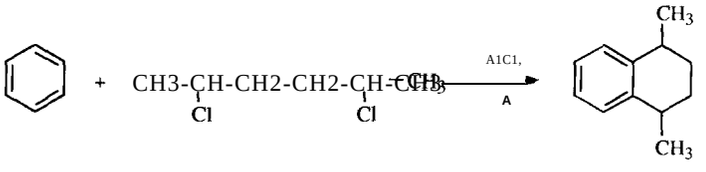
An important synthetic limitation of Friedel-Crafts alkylation is that rearrangement frequently takes place in the reagent. For example, benzene treated with *n*-propyl bromide gives mostly isopropylbenzene (cumene) and much less *n*-propylbenzene. Rearrangement is usually in the order primary → secondary → tertiary and occurs mostly by migration of H^- but also of R^- (see discussion of rearrangement mechanisms in Chapter 18). It is therefore not usually possible to put a primary alkyl group (other than methyl and ethyl) onto an aromatic ring by

Friedel-Crafts alkylation. Because of these rearrangements, *n*-alkylbenzenes are often prepared by *acylation* **(11-14),** followed by reduction **(19-33).**

An important use of the Friedel-Crafts alkylation reaction is to effect ring closure.[266] The most common method is to heat with aluminum chloride an aromatic compound having a halogen, hydroxy, or alkene group in the proper position, as, for example, in the preparation of tetralin:



Another way of effecting ring closure through Friedel-Crafts alkylation is to use a reagent containing two groups, for example,



These reactions are most successful for the preparation of six-membered rings,[267] though five- and seven-membered rings have also been closed in this manner. For other Friedel-Crafts ring-closure reactions, see **11-13, 11-14,** and **11-23.**

From what has been said thus far, it is evident that the electrophile in Friedel-Crafts alkylation is a carbocation, at least in most cases.[268] This is in accord with the knowledge that carbocations rearrange in the direction primary → secondary → tertiary (see Chapter 18). In each case, the cation is formed from the attacking reagent and the catalyst. For the three most important types of reagent these reactions are

From alkyl halides $RCl + AlCl_3 \longrightarrow R^+ + AlCl_4^-$

From alcohols[269] and Lewis acids $ROH + AlCl_3 \longrightarrow ROAlCl_2 \longrightarrow R^+ + {}^-OAlCl_2$

From alcohols and proton acids $ROH + H^+ \longrightarrow ROH_2^+ \longrightarrow R^+ + H_2O$

From alkenes (a supply of protons is usually required): $-C{=}C- + H^+ \longrightarrow H-\overset{|}{C}-\overset{+}{C}-$

There is direct evidence, from IR and NMR spectra, that the *tert*-butyl cation is quantitatively formed when *tert-butyl* chloride reacts with $AlCl_3$ in anhydrous liquid HC1.[270] In the case of alkenes, Markovnikov's rule (p. 984) is followed. Carbocation formation is particularly easy from some reagents, because of the stability of the cations. Triphenylmethyl chloride[271] and 1-chloroadamantane[272] alkylate activated

aromatic rings (e.g., phenols, amines) with no catalyst or solvent. Ions as stable as this are less reactive than other carbocations and often attack only active substrates. The tropylium ion, for example, alkylates anisole but not benzene.[273] It was noted on page 430 that relatively stable vinylic cations can be generated from certain vinylic compounds. These have been used to introduce vinylic groups into aryl substrates.[274] Lewis acids such as BF_3[275] or $AlEt_3$[276] can also be used to alkylation of aromatic rings with alkene units.

However, there is much evidence that many Friedel–Crafts alkylations, especially with primary reagents, do not go through a completely free carbocation. The ion may exist as a tight ion pair with, say, $AlCl_4^-$ as the counterion or as a complex. Among the evidence is that methylation of toluene by methyl bromide and methyl iodide gave different ortho/para/meta ratios,[277] though if the same species attacked in each case we would expect the same ratios. Other evidence is that, in some cases, the reaction kinetics are third order; first order each in aromatic substrate, attacking reagent, and catalyst.[278] In these instances, a mechanism in which the carbocation is slowly formed, and then rapidly attacks the ring is ruled out since, in such a mechanism, the substrate would not appear in the rate expression. Since it is known that free carbocations, once formed, rapidly attack the ring, there are no free carbocations here. Another possibility (with alkyl halides) is that some alkylations take place by an S_N2 mechanism (with respect to the halide), in which case no carbocations would be involved at all. However, a completely S_N2 mechanism requires inversion of configuration. Most investigations of Friedel–Crafts stereochemistry, even where an S_N2 mechanism might most be expected, have resulted in total racemization, or at best a few percent inversion. A few exceptions have been found,[279] most notably where the reagent was optically active propylene oxide, in which case 100% inversion was reported.[280]

Rearrangement is possible even with a non-carbocation mechanism. The rearrangement could occur *before* the attack on the ring takes place. It has been shown that treatment of $CH_3^{14}CH_2Br$ with $AlBr_3$ in the absence of any aromatic compound gave a mixture of the starting material and $^{14}CH_3CH_2Br$.[281] Similar results were obtained with $PhCH_2^{14}CH_2Br$, in which case the rearrangement was so fast that the rate could be measured only below $-70°C$.[282] Rearrangement could also occur *after* formation of the product, since alkylation is reversible (see **11-36**).[283]

See **14-21** and **14-23** for free-radical alkylation.

11-13 *Friedel-Crafts Arylation: The Scholl Reaction*

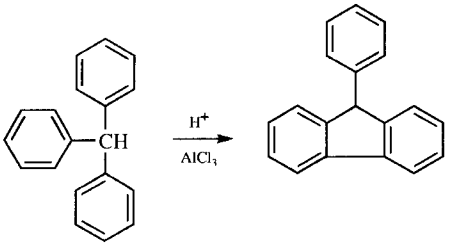
DE-HYDROGEN-COUPLING

$$2\ ArH \xrightarrow{AlCl_3} Ar{-}Ar + H_2$$

The coupling of two aromatic molecules by treatment with a Lewis acid and a proton acid is called the *Scholl reaction*.[284] Yields are low and the synthesis is seldom

useful. High temperatures and strong acid catalysts are required, and the reaction fails for substrates that are destroyed by these conditions. Because the reaction becomes important with large fused-ring systems, ordinary Friedel-Crafts reactions (**11-12**) on these systems are rare. For example, naphthalene gives binaphthyl under Friedel-Crafts conditions. Yields can be increased by the addition of a salt such as $CuCl_2$ or $FeCl_3$, which acts as an oxidant.[285] Rhodium catalysts have also been used.[286]

Intramolecular Scholl reactions, for example,



are much more successful than the intermolecular kind. The mechanism is not clear, but it may involve attack by a proton to give an arenium ion of the type 9 (p. 678), which would be the electrophile that attacks the other ring.[287] Sometimes arylations have been accomplished by treating aromatic substrates with particularly active aryl halides, especially fluorides. For free-radical arylations, see Reactions **14-17-14-22.**

OS **IV,** 482. Also see OS V, 102, 952.

11-14 *Friedel-Crafts Acylation*

ACYLATION OR ACYL-DE-HYDROGENATION

$$ArH + RCOCl \xrightarrow{AlCl_3} ArCOR$$

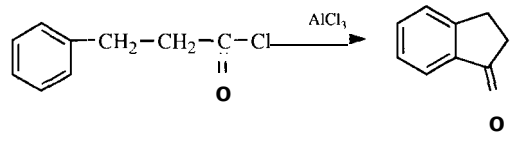
The most important method for the preparation of aryl ketones is known as *Friedel-Crafts acylation*.[288] The reaction is of wide scope. Reagents used[289] are not only acyl halides but also carboxylic acids,[290] anhydrides, and ketenes. Oxalyl chloride has been used to give diaryl 1,2-diketones.[291] Carboxylic esters usually give predominant alkylation (see **11-12).** The R group may be aryl as well as alkyl. The major disadvantages of Friedel-Crafts alkylation are not present here. Rearrangement of R is never found, and, because the RCO group is deactivating, the reaction stops cleanly after one group is introduced. All four acyl halides can be used, though chlorides are most commonly employed. The order of activity is usually, but not always, I > Br > Cl > F.[292] Catalysts are Lewis acids, similar to those in reaction **11-12,** but in acylation a little more than 1 mol of catalyst is required per mole of reagent, because the first mole coordinates with the oxygen of the reagent [as in $R(Cl)C{=}O^+{-}{}^-AlCl_3$].[293] A reusable catalyst, $Ln(OTf)_3{-}LiClO_4$, has been developed as well.[294] The HY-Zeolite compound has also been used to facilitate the reaction with acetic anhydride.[295] Proton acids can be used as catalysts when the

reagent is a carboxylic acid. The mixed carboxylic sulfonic anhydrides ($RCOOSO_2CF_3$) are extremely reactive acylating agents and can smoothly acylate benzene without a catalyst.[296] With active substrates (e.g., aryl ethers, fused-ring systems, thiophenes), Friedel-Crafts acylation can be carried out with very small amounts of catalyst, often just a trace, or even sometimes with no catalyst at all. Ferric chloride, iodine, zinc chloride, and iron are the most common catalysts when the reaction is carried out in this manner.[297]

The reaction is quite successful for many types of substrate, including fused ring systems, which give poor results in **11-12.** Compounds containing ortho-para directing groups, including alkyl, hydroxy, alkoxy, halogen, and acetamido groups, are easily acylated and give mainly or exclusively the para products, because of the relatively large size of the acyl group. However, aromatic amines give poor results. With amines and phenols there may be competition from N- or O-acylation; however, O-acylated phenols can be converted to C-acylated phenols by the Fries rearrangement **(11-30).** Friedel-Crafts acylation is usually prevented by meta-directing groups. Indeed, nitrobenzene is often used as a solvent for the reaction. Many heterocyclic systems, including furans, thiophenes, pyrans, and pyrroles but not pyridines or quinolines, can be acylated in good yield (however, pyridines and quinolines can be acylated by a free-radical mechanism, Reaction **14-23).** Gore, in Ref. 288 (pp. 36-100; with tables, pp. 105-321), presents an exhaustive summary of the substrates to which this reaction has been applied.

When a mixed anhydride RCOOCOR' is the reagent, two products are possible: ArCOR and ArCOR'. Which product predominates depends on two factors. If R contains electron-withdrawing groups, then ArCOR' is chiefly formed, but if this factor is approximately constant in R and R', the ketone with the larger R group predominantly forms.[298] This means that *formylations* of the ring do not occur with mixed anhydrides of formic acid HCOOCOR.

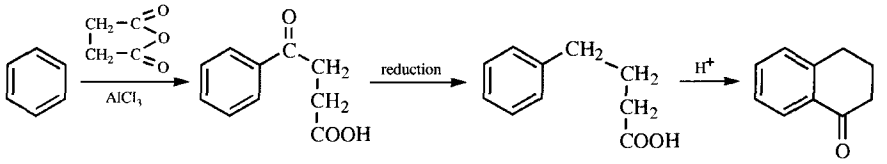
An important use of the Friedel-Crafts acylation is to effect ring closure.[299] This can be done if an acyl halide, anhydride, or acid group is in the proper position. An example is



The reaction is used mostly to close six-membered rings, but has also been done for five- and seven-membered rings, which close less readily. Even larger rings can be closed by high-dilution techniques.[300] Tricyclic and larger systems are often made by using substrates containing one of the acyl groups on a ring. Many fused ring systems are made in this manner. If the bridging group is CO, the product is a quinone.[301] One of the most common catalysts for intramolecular Friedel-Crafts acylation is polyphosphoric acid[302] (because of its high potency), but $AlCl_3$, H_2SO_4, and other Lewis and proton acids are also used, though acylations with acyl halides are not generally catalyzed by proton acids.

Friedel-Crafts acylation can be carried out with cyclic anhydrides,[303] in which case the product contains a carboxyl group in the side chain. When succinic

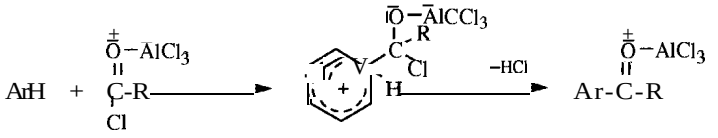
anhydride is used, the product is $ArCOCH_2CH_2COOH$. This can be reduced **(19-33)** to $ArCH_2CH_2CH_2COOH$, which can then be cyclized by an internal Friedel–Crafts acylation. The total process is called the *Haworth reaction:*[304]



The mechanism of Friedel–Crafts acylation is not completely understood,[305] but at least two mechanisms probably operate, depending on conditions.[306] In most cases the attacking species is the acyl cation, either free or as an ion pair, formed by[307]

$$RCOCl + AlCl_3 \longrightarrow RCH^+ + AlCl_4^-$$

If R is tertiary, RCO^+ may lose CO to give R^+, so that the alkylarene ArR is often a side product or even the main product. This kind of cleavage is much more likely with relatively unreactive substrates, where the acylium ion has time to break down. For example, pivaloyl chloride (Me_3CCOCl) gives the normal acyl product with anisole, but the alkyl product Me_3CPh with benzene. In the other mechanism an acyl cation is not involved, but the 1:1 complex attacks directly.[308]



Free-ion attack is more likely for sterically hindered R.[309] The ion CH_3CO^+ has been detected (by IR spectroscopy) in the liquid complex between acetyl chloride and aluminum chloride, and in polar solvents such as nitrobenzene; but in nonpolar solvents such as chloroform, only the complex and not the free ion is present.[310] In any event, 1 mol of catalyst certainly remains complexed to the product at the end of the reaction. When the reaction is performed with $RCO^+ SbF_6^-$, no catalyst is required and the free ion (or ion pair)[311] is undoubtedly the attacking entity.[312]

OS I, 109, 353, 476, 517; **II,** 3, 8, 15, 81, 156, 169, 304, 520, 569; **III,** 6, 14, 23, 53, 109, 183, 248, 272, 593, 637, 761, 798; IV, 8, 34, 88, 898, 900; V, 111; VI, 34, 618, 625.

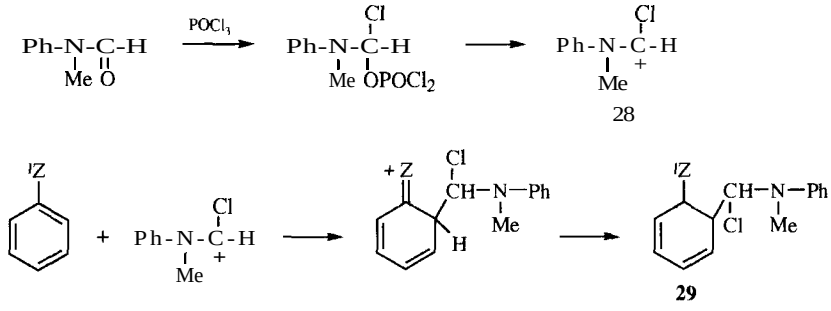
Reactions **11-15-11-18** are direct formylations of the ring.[313] Reaction **11-14** has not been used for formylation, since neither formic anhydride nor formyl chloride is stable at ordinary temperatures. Formyl chloride has been shown to be stable in chloroform solution for 1 h at $-60°$ C,[314] but it is not useful for formylating aromatic rings under these conditions. Formic anhydride has been prepared in solution, but has not been isolated.[315] Mixed anhydrides of formic and other acids are known[316] and can be used to formylate amines (see **10-56)** and alcohols, but no formylation takes place when they are applied to aromatic rings. See **13-15** for a nucleophilic method for the formylation of aromatic rings.

11-15 *Formylation With Disubstituted Formamides*

FORMYLATION OR FORMYL-DE-HYDROGENATION

$$ArH + Ph\text{-}N(Me)\text{-}C(=O)\text{-}H \xrightarrow{POCl_3} ArCHO + PhNHMe$$

The reaction with disubstituted formamides and phosphorus oxychloride, called the *Vilsmeier* or the *Vilsmeier–Haackreaction*,[317] is the most common method for the formylation of aromatic rings.[318] However, it is applicable only to active substrates, such as amines and phenols. An intramolecular version is also known.[319] Aromatic hydrocarbons and heterocycles can also be formylated, but only if they are much more active than benzene (e.g., azulenes, ferrocenes). Though *N*-phenyl-*N*-methylformamide is a common reagent, other arylalkyl amides and dialkyl amides are also used.[320] Phosgene ($COCl_2$) has been used in place of $POCl_3$. The reaction has also been carried out with other amides to give ketones (actually an example of **11-14),** but not often. The attacking species[321] is 28,[322] and the mechanism is probably:



Compound 29 is unstable and easily hydrolyzes to the product. Either formation of 28 or the reaction of 28 with the substrate can be rate determining, depending on the reactivity of the substrate.[323]

When $(CF_3SO_2)_2O$ was used instead of $POCl_3$, the reaction was extended to some less-active compounds, including naphthalene and phenanthrene.[324]

OS I, 217; **III,** 98, IV, 331, 539, 831, 915.

11-16 *Formylation with Zinc Cyanide and HCl:The Gatterman Reaction*

FORMYLATION OR FORMYL-DE-HYDROGENATION

$$ArH + Zn(CN)_2 \xrightarrow{HCl} ArCH{=}NH_2^+\,Cl^- \xrightarrow{H_2O} ArCHO$$

Formylation with $Zn(CN)_2$ and HCl is called the *Gatterman reaction.*[325] It can be applied to alkylbenzenes, phenols and their ethers, and many heterocyclic compounds. However, it cannot be applied to aromatic amines. In the original version of this reaction, the substrate was treated with HCN, HCl, and $ZnCl_2$, but the use of $Zn(CN)_2$ and HCl (HCN and $ZnCl_2$ are generated *in situ)* makes the reaction more

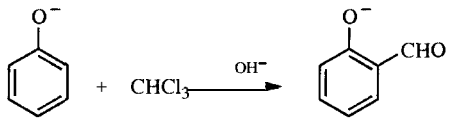
convenient to carry out and does not reduce yields. The mechanism of the Gatterman reaction has not been investigated very much, but there is an initial nitrogen-containing product that is normally not isolated but is hydrolyzed to aldehyde. The above structure is presumed for this product. When benzene was treated with NaCN under super acidic conditions (F_3CSO_2OH—SbF_5), a good yield of product was obtained, leading to the conclusion that the electrophile in this case was $H^+C{=}N^+H_2$.[326] The Gatterman reaction may be regarded as a special case of **11-27.**

Another method, formylation with CO and HC1 in the presence of $AlCl_3$ and CuCl (the *Gatterman–Kochreaction*),[327] is limited to benzene and alkylbenzenes.[328]

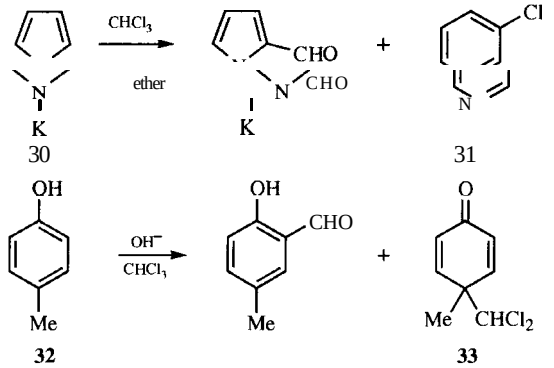
OS II, 583; HI, 549.

11-17 *Formylation with Chloroform: The Reimer–Tiemann Reaction*

FORMYLATION OR FORMYL-DE-HYDROGENATION

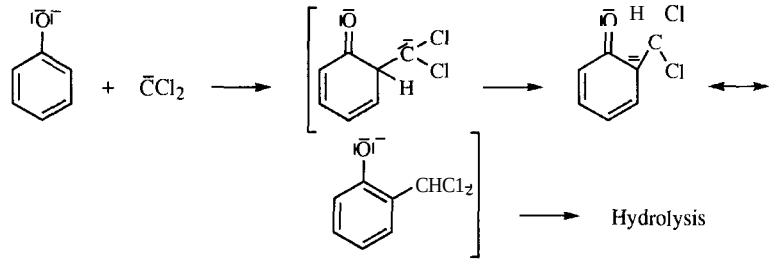


In the *Reimer-Tiemann reaction,* chloroform and hydroxide ion are used to formylate aromatic rings.[329] The method is useful only for phenols and certain heterocyclic compounds such as pyrroles and indoles. Unlike the previous formylation methods **(11-15** and **11-16),** this one is conducted in basic solution. Yields are generally low, seldom rising >50%.[330] The incoming group is directed ortho, unless both ortho positions are filled, in which case the attack is para.[331] Certain substrates have been shown to give abnormal products instead of or in addition to the normal ones. For example, 30 and 32 gave, respectively, 31 and 33 as well as the normal aldehyde products. From the nature of the reagents and from the



from the kind of abnormal products obtained, it is clear that the attacking entity in this reaction is dichlorocarbene CCl_2.[332] This in known to be produced by treatment of chloroform with bases (p. 464); it is an electrophilic reagent and is known to give

ring expansion of aromatic rings (see **15-62),** accounting for products like 30. The mechanism of the normal reaction is thus something like this.[333]



The formation of 33 in the case of 32 can be explained by attack of some of the CCl_2 ipso to the CH_3 group. Since this position does not contain a hydrogen, normal proton loss cannot take place and the reaction ends when the CCl_2^- moiety acquires a proton.

A method closely related to the Reimer–Tiemann reaction is the *Duff reaction,* in which hexamethylenetetramine, $(CH_2)_6N_4$, is used instead of chloroform. This reaction can be applied only to phenols and amines; ortho substitution is generally observed and yields are low. A mechanism[334] has been proposed that involves initial aminoalkylation **(11-25)** to give $ArCH_2NH_2$, followed by dehydrogenation to ArCH=NH and hydrolysis of this to the aldehyde product. When $(CH_2)_6N_4$ is used in conjunction with F_3CCOOH, the reaction can be applied to simple alkylbenzenes; yields are much higher and a high degree of regioselectively para substitution is found.[335] In this case too an imine seems to be an intermediate.

OS **III,** 463; IV, 866

11-18 *Other Formylations*

FORMYLATION OR FORMYL-DE-HYDROGENATION

$$ArH + Cl_2CHOMe \xrightarrow{AlCl_3} ArCHO$$

Besides **11-15-11-17,** several other formylation methods are known.[336] In one of these, dichloromethyl methyl ether formylates aromatic rings with Friedel–Crafts catalysts.[337] The Compound ArCHClOMe is probably an intermediate. Orthoformates have also been used.[338] In another method, aromatic rings are formylated with formyl fluoride HCOF and BF_3.[339] Unlike formyl chloride, formyl fluoride is stable enough for this purpose. This reaction was successful for benzene, alkylbenzenes, PhCl, PhBr, and naphthalene. Phenols can be regioselectively formylated in the ortho position in high yields by treatment with two equivalents of paraformaldehyde in aprotic solvents in the presence of $SnCl_4$ and a tertiary amine.[340] Phenols have also been formylated indirectly by conversion to the aryllithium reagent followed by treatment with *N*-formyl piperidine.[341] See also the indirect method mentioned at **11-26.**

OS **V,** 49; **VII,** 162.

Reactions **11-19** and **11-20** are direct carboxylations[342] of aromatic rings.[343]

11-19 *Carboxylation With Carbonyl Halides*

CARBOXYLATION OR CARBOXY-DE-HYDROGENATION

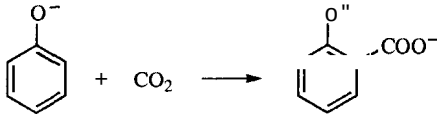
$$ArH + COCl_2 \xrightarrow{AlCl_3} ArCOOH$$

Phosgene, in the presence of Friedel–Crafts catalysts, can carboxylate the ring. This process is analogous to **11-14,** but the ArCOCl initially produced hydrolyzes to the carboxylic acid. However, in most cases the reaction does not take this course, but instead the ArCOCl attacks another ring to give a ketone ArCOAr. A number of other reagents have been used to get around this difficulty, among them oxalyl chloride, urea hydrochloride, chloral (Cl_3CCHO),[344] carbamoyl chloride (H_2NCOCl), and *N,N*-diethylcarbamoyl chloride.[345] With carbamoyl chloride the reaction is called the *Gatterman amide synthesis* and the product is an amide. Among compounds carboxylated by one or another of these reagents are benzene, alkylbenzenes, and fused ring systems.[346]

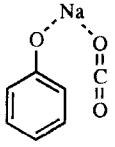
OS V, 706; **VII,** 420.

11-20 *Carboxylation with Carbon Dioxide: The Kolbe-Schmitt Reaction*

CARBOXYLATION OR CARBOXY-DE-HYDROGENATION



Sodium phenoxides can be carboxylated, mostly in the ortho position, by carbon dioxide (the *Kolbe-Schmitt reaction).* The mechanism is not clearly understood, but apparently some kind of a complex is formed between the reactants,[347] making the carbon of the CO_2 more positive and putting it in a good position to attack the ring.



Potassium phenoxide, which is less likely to form such a complex,[348] is chiefly attacked in the para position.[349] Carbon tetrachloride can be used instead of CO_2 under Reimer–Tiemann **(11-17)** conditions.

Sodium or potassium phenoxide can be carboxylated regioselectively in the para position in high yield by treatment with sodium or potassium carbonate and carbon monoxide.[350] Carbon-14 labeling showed that it is the carbonate carbon that appears in the *p*-hydroxybenzoic acid product.[351] The CO is converted to sodium or potassium formate. Carbon monoxide has also been used to carboxylate aromatic rings with palladium compounds as catalysts.[352] In addition, a palladium-catalyzed reaction has been used directly to prepare acyl fluorides ArH —> ArCOF.[353]

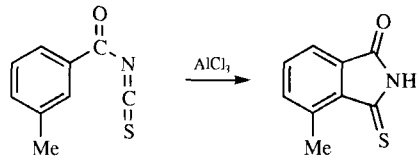
OS **II,** 557.

11-21 *Amidation With Isocyanates*

N-ALKYLCARBAMOYL-DE-HYDROGENATION

$$ArH + RNCO \xrightarrow{AlCl_3} ArCONHR$$

N-Substituted amides can be prepared by direct attack of isocyanates on aromatic rings.[354] The R group may be alkyl or aryl, but if the latter, dimers and trimers are also obtained. Isothiocyanates similarly give thioamides.[355] The reaction has been carried out intramolecularly both with aralkyl isothiocyanates and acyl isothiocyanates.[356] In the latter case, the product is easily hydrolyzable to a dicarboxylic acid; this is a way of putting a carboxyl group on a ring ortho to one already there (34 is



34

prepared by treatment of the acyl halide with lead thiocyanate). The reaction gives better yields with substrates of the type $ArCH_2CONCS$, where six-membered rings are formed.

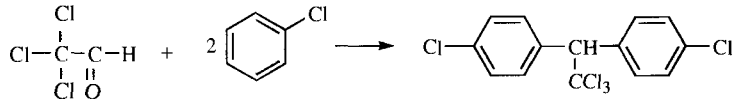
OS V, 1051; VI, 465.

Reactions **11-22-11-26** involve the introduction of a CH_2Z group, where Z is halogen, hydroxyl, amino, or alkylthio. They are all Friedel–Crafts reactions of aldehydes and ketones and, with respect to the carbonyl compound, additions to the C=O double bond. They follow mechanisms discussed in Chapter 16.

11-22 *Hydroxyalkylation or Hydroxyalkyl-de-hydrogenation*

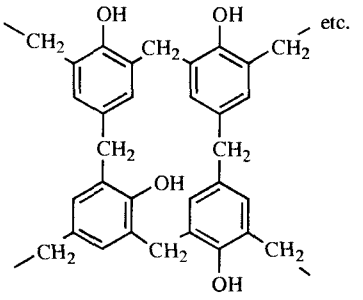
$$ArH + R\text{-}\underset{\underset{O}{\|}}{C}\text{-}R' \xrightarrow{H_2SO_4} Ar\text{-}\underset{\underset{R'}{|}}{\overset{\overset{R}{|}}{C}}\text{-}OH \text{ or } Ar\text{-}\underset{\underset{R'}{|}}{\overset{\overset{R}{|}}{C}}\text{-}Ar$$

The condensation of aromatic rings with aldehydes or ketones is called *hydroxyalkylation.*[357] The reaction can be used to prepare alcohols,[358] though more often the alcohol initially produced reacts with another molecule of aromatic compound (11-**12)** to give diarylation. For this the reaction is quite useful, an example being the preparation of l,l,l-trichloro-2, 2-bis (*p*-Chlorophenyl) ethane (DDT):



The diarylation reaction is especially common with phenols (the diaryl product here is called a *bisphenol).* The reaction is normally carried out in alkaline solution on the phenolate ion.[359] The hydroxymethylation of phenols with formaldehyde is called the *Lederer–Manasse reaction.* This reaction must be carefully controlled,[360] since it is possible for the para and both ortho positions to be substituted and for each of

these to be rearylated, so that a polymeric structure is produced:



However, such polymers, which are of the Bakelite type (phenol-formaldehyde resins), are of considerable commercial importance.

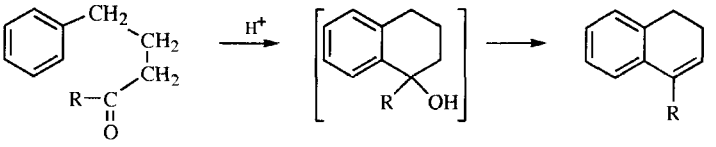
The attacking species is the carbocation, $R-\overset{+}{\underset{\displaystyle OH}{\underset{|}{C}}}-R$, formed from the aldehyde or ketone and the acid catalyst, except when the reaction is carried out in basic solution.

When an aromatic ring is treated with diethyl oxomalonate, $(EtOOC)_2C{=}O$, the product is an arylmalonic acid derivative, $ArC(OH)(COOEt)_2$, which can be converted to an arylmalonic acid, $ArCH(COOEt)_2$.[361] This is therefore a way of applying the malonic ester synthesis **(10-104)** to an aryl group (see also **13-12).** Of course, the opposite mechanism applies here: The aryl species is the nucleophile.

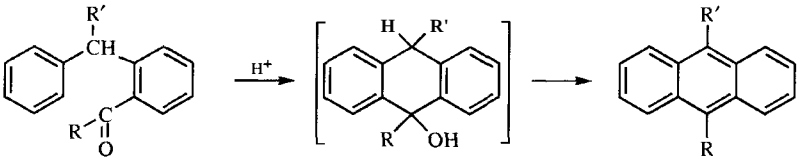
Two methods, both involving boron-containing reagents, have been devised for the regioselective ortho hydroxymethylation of phenols or aromatic amines.[362]

OS **III,** 326; **V,** 422; **VI,** 471, 856; **VIII,** 75, 77, 80. Also see OS I, 214.

11-23 *Cyclodehydration of Aldehydes and Ketones*

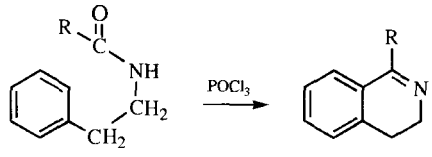


When an aromatic compound contains an aldehyde or ketone function in a position suitable for closing a six-membered ring, treatment with acid results in cyclodehydration. The reaction is a special case of **11-22,** but in this case dehydration almost always takes place to give a double bond conjugated with the aromatic ring.[363] The method is very general and is widely used to close both carbocyclic and heterocyclic rings.[364] Polyphosphoric acid is a common reagent, but other acids have also been used. In a variation known as the *Bradsher reaction*,[365] diarylmethanes containing a carbonyl group in the ortho position can be cyclized



to anthracene derivatives. In this case, 1,4-dehydration takes place, at least formally.

Among the many applications of cyclodehydration to the formation of heterocyclic systems is the *Bischler-Napieralski reaction*.[366] In this reaction, amides of the type 35 are cyclized with phosphorous oxychloride:



35

If the starting compound contains a hydroxyl group in the α position, an additional dehydration takes place and the product is an isoquinoline.[367] Higher yields can be obtained if the amide is treated with PCl_5 to give an imino chloride, $ArCH_2CH_2N{=}CR{-}Cl$, which is isolated and then cyclized by heating.[368] The nitrilium ion $ArCH_2CH_2^+N{\equiv}CR$ is an intermediate.

OS I, 360, 478; **II,** 62, 194; **III,** 281, 300, 329, 568, 580, 581; IV, 590; V, 550; VI, 1. Also see OS I, 54.

11-24 *Haloalkylation or Haloalkyl-de-hydrogenation*

$$ArH + HCHO + HC1 \xrightarrow{ZnCl_2} ArCH_2Cl$$

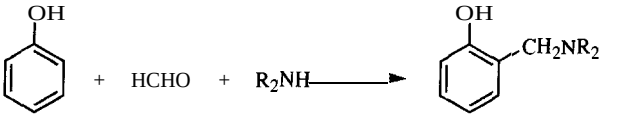
When certain aromatic compounds are treated with formaldehyde and HC1, the CH_2Cl group is introduced into the ring in a reaction called *chloromethylation.* The reaction has also been carried out with other aldehydes and with HBr and HI. The more general term *haloalkylation* covers these cases.[369] The reaction is successful for benzene, and alkyl-, alkoxy-, and halobenzenes. It is greatly hindered by meta-directing groups, which reduce yields or completely prevent the reactions. Amines and phenols are too reactive and usually give polymers unless deactivating groups are also present, but phenolic ethers and esters successfully undergo the reaction. Compounds of lesser reactivity can often be chloromethylated with chloromethyl methyl ether ($ClCH_2OMe$), or methoxyacetyl chloride ($MeOCH_2COCl$).[370] Zinc chloride is the most common catalyst, but other Friedel–Crafts catalysts are also employed. As with Reaction **11-22** and for the same reason, an important side product is the diaryl compound Ar_2CH_2 (from formaldehyde).

Apparently, the initial step involves reaction of the aromatic compound with the aldehyde to form the hydroxyalkyl compound, exactly as in **11-22,** and then the HC1 converts this to the chloroalkyl compound.[371] The acceleration of the reaction by $ZnCl_2$ has been attributed[372] to the raising of the acidity of the medium, causing an increase in the concentration of $HOCH_2^+$ ions.

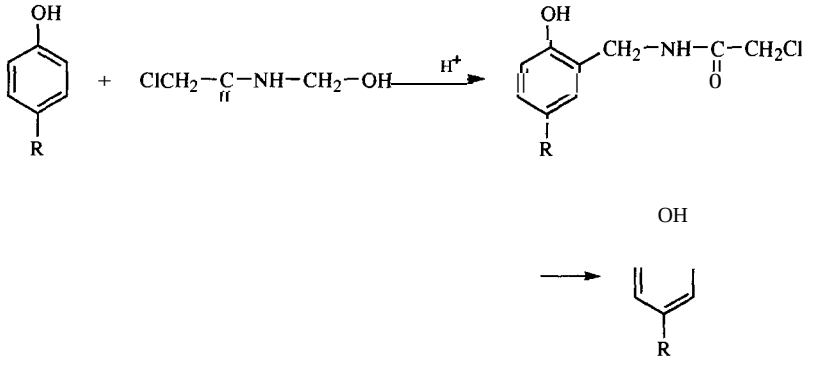
OS **III,** 195, 197, 468, 557; IV, 980.

11-25 *Aminoalkylation* and *Amidoalkylation*

DIALKYLAMINOALKYLATION OR DIALKYLAMINO-DE-HYDROGENATION



Phenols, secondary and tertiary aromatic amines,[373] pyrroles, and indoles can be aminomethylated by treatment with formaldehyde and a secondary amine. Other aldehydes have sometimes been employed. Aminoalkylation is a special case of the Mannich reaction **(16-15).** When phenols and other activated aromatic compounds are treated with *N*-hydroxymethylchloroacetamide, *amidomethylation* takes place[374]

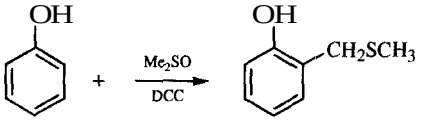


to give 36, which is often hydrolyzed *in situ* to the aminoalkylated product. Other N-hydroxyalkyl and N-chlorinated compounds have also been used.[374]

OS I, 381; IV, 626; V, 434; **VI,** 965; **VII,** 162.

11-26 *Thioalkylation*

ALKYLTHIOALKYLATION OR ALKYLTHIOALKYL-DE-HYDROGENATION



A methylthiomethyl group can be inserted into the ortho position of phenols by heating with DMSO and DCC.[375] Other reagents can be used instead of DCC, among them $SOCl_2$,[376] and acetic anhydride.[377] Alternatively, the phenol can be treated with dimethyl sulfide and NCS, followed by triethylamine.[378] The reaction can be applied to amines (to give *o*-$NH_2C_6H_4CH_2SMe$) by treatment with *t*-BuOCl, Me_2S, and NaOMe in CH_2Cl_2.[379] Aromatic hydrocarbons have been thioalkylated with ethyl α-(chloromethylthio)acetate ($ClCH_2SCH_2COOEt$) (to give $ArCH_2$-

SCH_2COOEt)[380] and with methyl methylsulfinylmethyl sulfide ($MeSCH_2SOMe$) or methylthiomethyl *p*-tolyl sulfone ($MeSCH_2SO_2C_6H_4Me$) (to give $ArCH_2$-SMe),[381] in each case with a Lewis acid catalyst.

OS VI, 581,601.

11-27 *Acylation with Nitrites: The Hoesch Reaction*

ACYLATION OR ACYL-DE-HYDROGENATION

$$ArH + RCN \xrightarrow[ZnCl_2]{} ArCOR$$

Friedel–Crafts acylation with nitriles and HC1 is called the *Hoesch* or the *Houben–Hoesch reaction*.[382] In most cases, a Lewis acid is necessary; zinc chloride is the most common. The reaction is generally useful only with phenols, phenolic ethers, and some reactive heterocyclic compounds (e.g., pyrrole), but it can be extended to aromatic amines by the use of BCl_3.[383] Acylation in the case of amines is regioselectively ortho. Monohydric phenols, however, generally do not give ketones[384] but are attacked at the oxygen to produce imino esters. Many nitriles

$$Ar-O-\overset{\overset{NH_2^+}{\|}}{C}-R \quad or$$

An imino ester

have been used. Even aryl nitriles give good yields if they are first treated with HC1 and $ZnCl_2$, and then the substrate added at 0°C.[385] In fact, this procedure increases yields with any nitrile. If thiocyanates (RSCN) are used, thiol esters (ArCOSR) can be obtained. The Gatterman reaction (11-16) is a special case of the Hoesch synthesis.

The reaction mechanism is complex and not completely settled.[386] The first stage consists of an attack on the substrate by a species containing the nitrile and HC1 (and the Lewis acid, if present) to give an imine salt (39). Among the possible attacking species are 37 and 38. In the second stage, the salts are hydrolyzed to the products:

$$ArH + R\text{-}\overset{+}{C}{=}NH \quad (37) \qquad or \qquad ArH + ZnCl_2(RCN)_2 + HCl \quad (38)$$

$$\xrightarrow{H^+} Ar\text{-}\overset{\overset{NH_2^+\ Cl^-}{\|}}{C}\text{-}R \longrightarrow Ar-\overset{\overset{O}{\|}}{C}-R$$

Ketones can also be obtained by treating phenols or phenolic ethers with a nitrile in the presence of F_3CSO_2OH.[387] The mechanism in this case is different.

OS II, 522.

11-28 *Cyanation or Cyano-de-hydrogenation*

$$ArH + Cl_3CCN \xrightarrow{HCl} Ar-\overset{\overset{NH_2^+\ Cl^-}{\|}}{C}-CCl_3 \xrightarrow{NaOH} ArCN$$

Aromatic hydrocarbons (including benzene), phenols, and phenolic ethers can be cyanated with trichloroacetonitrile, BrCN, or mercury fulminate, $Hg(ONC)_2$.[388] In the case of Cl_3CCN, the actual attacking entity is probably $Cl_3C-{}^+C{=}NH$, formed by addition of a proton to the cyano nitrogen. Secondary aromatic amines (ArNHR), as well as phenols, can be cyanated in the ortho position with Cl_3CCN and BCl_3.[389]

It is noted that aryl triflates are converted to the aryl nitrile by treatment with $Zn(CN)_2$ and a palladium catalyst.[390]

OS III, 293.

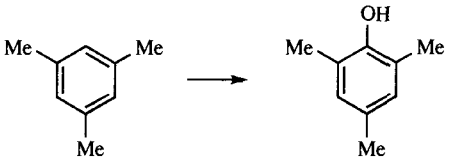
F. *Oxygen Electrophiles*

Oxygen electrophiles are very uncommon, since oxygen does not bear a positive charge very well. However, there is one reaction that can be mentioned.

11-29 *Hydroxylation or Hydroxy-de-hydrogenation*

$$ArH + F_3C-\overset{\overset{O}{\|}}{C}-O-OH \longrightarrow ArOH$$

There have been only a few reports of direct hydroxylation[391] by an electrophilic process (see, however, **14-5**).[392] In general, poor results are obtained, partly because the introduction of an OH group activates the ring to further attack. Quinone formation is common. However, alkyl-substituted benzenes such as mesitylene or durene can be hydroxylated in good yield with trifluoroperacetic acid and boron trifluoride.[393] In the case of mesitylene, the product is not subject to further attack:



In a related procedure, even benzene and substituted benzenes (e.g., PhMe, PhCl, xylenes) can be converted to phenols in good yields with sodium perborate: F3CSO2OH.[394] Aromatic amines, N-acyl amines, and phenols were hydroxylated with H_2O_2 in SbF_5—HF.[395] Pyridine and quinoline were converted to their 2-acetoxy derivatives in high yields with acetyl hypofluorite AcOF at $-75°C$.[396]

Another hydroxylation reaction is the *Elbs reaction?*[91] In this method, phenols can be oxidized to *p*-diphenols with $K_2S_2O_8$ in alkaline solution.[398] Primary, secondary, or tertiary aromatic amines give predominant or exclusive ortho substitution unless both ortho positions are blocked, in which case para substitution is found. The reaction with amines is called the *Boyland-Sims oxidation.* Yields are low with either phenols or amines, generally under 50%. The mechanisms are not clear,[399] but for the Boyland-Sims oxidation there is evidence that the $S_2O_8^{2-}$ ion attacks at the ipso position, and then a migration follows.[400]

Electrolysis of benzene, in the presence of trifluoroacetic acid and triethylamine, leads to a 73% yield of phenol.[401]

G. *Metal Electrophiles*

Reactions in which a metal replaces the hydrogen of an aromatic ring are considered along with their aliphatic counterparts in Chapter 12 (12-20 and 12-21).

Hydrogen as the Leaving Group in Rearrangement Reactions

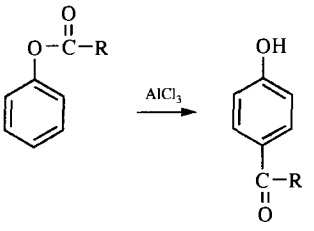
In these reactions, a group is detached from a *side chain,* and then attacks the ring, but in other aspects they resemble the reactions already treated in this chapter.[402] Since a group moves from one position to another in a molecule, these are rearrangements. In all these reactions, the question arises as to whether the group that cleaves from a given molecule attacks the same molecule or another one, that is, is the reaction intramolecular or intermolecular? For intermolecular reactions the mechanism is the same as ordinary aromatic substitution, but for intramolecular cases the migrating group could never be completely free, or else it would be able to attack another molecule. Since the migrating species in intramolecular rearrangements is thus likely to remain near the atom from which it cleaved, it has been suggested that intramolecular reactions are more likely to lead to ortho products than are the intermolecular type. This characteristic has been used, among others, to help decide whether a given rearrangement is inter- or intramolecular, though there is evidence that at least in some cases, an intermolecular mechanism can still result in a high degree of ortho migration.[403]

The Claisen (18-33) and benzidine (18-36) rearrangements, which superficially resemble those in this section, have different mechanisms and are treated in Chapter 18.

A. *Groups Cleaving from Oxygen*

11-30 *The Fries Rearrangement*

1/C-HYDRO, 5/O-ACYL-INTERCHANGE[404]



Phenolic esters can be rearranged by heating with Friedel-Crafts catalysts in a synthetically useful reaction known as the *Fries rearrangement.*[405] Both *o*- and *p*-acylphenols can be produced, and it is often possible to select conditions so that either one predominates. The ortho/para ratio is dependent on the temperature, solvent, and amount of catalyst used. Exceptions are known, but low temperatures generally favor the para product and high temperatures the ortho product. The R group may be aliphatic or aromatic. Any meta-directing substituent on the ring

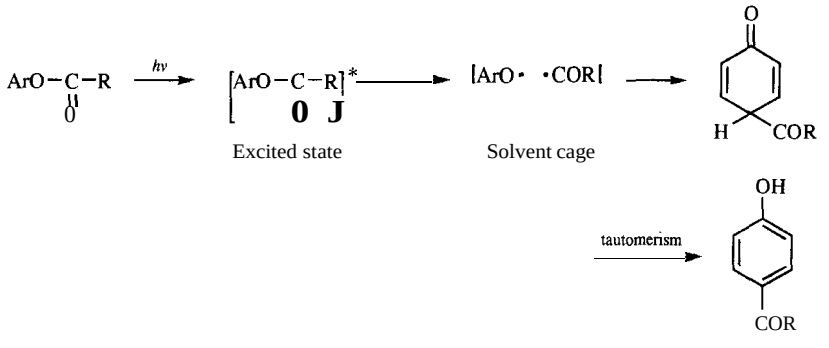
interferes with the reactions, as might be expected for a Friedel-Crafts process. In the case of aryl benzoates treated with F_3CSO_2OH, the Fries rearrangement was shown to be reversible and an equilibrium was established.[406] Transition metal catalyzed Fries rearrangements have been reported.[407]

The exact mechanism has still not been completely worked out.[408] Opinions have been expressed that it is completely intermolecular,[409] completely intramolecular,[410] and partially inter- and intramolecular.[411] One way to decide between inter- and intramolecular processes is to run the reaction of the phenolic ester in the presence of another aromatic compound, say, toluene. If some of the toluene is acylated, the reaction must be, at least in part, intermolecular. If the toluene is not acylated, the presumption is that the reaction is intramolecular, though this is not certain, for it may be that the toluene is not attacked because it is less active than the other. A number of such experiments (called *crossover experiments)* have been carried out; sometimes crossover products have been found and sometimes not. As in 11-14, an initial complex (40) is formed between the substrate and the catalyst, so that a catalyst/substrate molar ratio of at least 1:1 is required.

ArO-C(=O)-R
+0-AlC13

40

The Fries rearrangement can also be carried out with UV light, in the absence of a catalyst.[412] This reaction, called the *photo-Fries rearrangement*,[413] is predominantly an intramolecular free-radical process. Both ortho and para migration are observed.[414] Unlike the Lewis acid catalyzed Fries rearrangement, the photo-Fries reaction can be accomplished, though often in low yields, when meta-directing groups are on the ring. The available evidence strongly suggests the following mechanism[415] for the photo-Fries rearrangement[416] (illustrated for para attack):



The phenol ArOH is always a side product, resulting from some ArO· that leaks from the solvent cage and abstracts a hydrogen atom from a neighboring molecule. When the reaction was performed on phenyl acetate in the gas phase, where there are no solvent molecules to form a cage (but in the presence of isobutane as a source of abstractable hydrogens), phenol was the chief product and virtually no *o*- or *p*-hydroxyacetophenone was found.[417] Other evidence[418] for the mechanism is that

CIDNP has been observed during the course of the reaction[419] and that the ArO• radical has been detected by flash photolysis[420] and by nanosecond time-resolved Raman spectroscopy.[421]

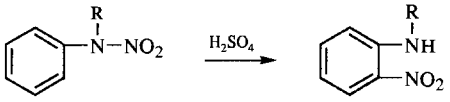
OS **II,** 543; **III,** 280, 282.

B. *Groups Cleaving from Nitrogen*[422]

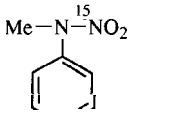
It has been shown that $PhNH_2D$ rearranges to *o*- and *p*-deuterioaniline.[423] The migration of OH, formally similar to reactions **11-31-11-35,** is a nucleophilic substitution and is treated in Chapter 13 **(13-23).**

11-31 *Migration of the Nitro Group*

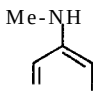
1/C-HYDRO, 3/N-NITRO-INTERCHANGE



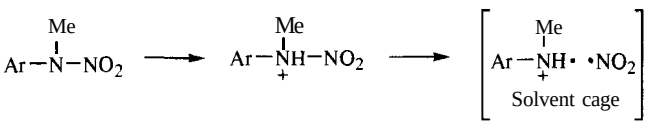
N-Nitro aromatic amines rearrange on treatment with acids to o- and p-nitroamines with the ortho compounds predominating.[424] Aside from this indication of an intramolecular process, there is also the fact that virtually no meta isomer is produced in this reaction,[425] though direct nitration of an aromatic amine generally gives a fair amount of meta product. Thus a mechanism in which NO_2^+ is dissociated from the ring, and then attacks another molecule must be ruled out. Further results indicating an intramolecular process are that rearrangement of several substrates in the presence of $K^{15}NO_3$ gave products containing no ^{15}N,[426] and that rearrangement of a mixture of $PhNH^{15}NO_2$ and unlabeled *p*-$MeC_6H_4NHNO_2$ gave 2-nitro-4-methylaniline containing no ^{15}N.[427] On the other hand, rearrangement of 41 in the presence of unlabeled $PhNMeNO_2$ gave labeled 42, which did not arise by displacement of F.[428] The R group may be hydrogen or alkyl. Two principal mechanisms have been suggested, one involving cyclic attack by the oxygen of the nitro group at the ortho position before the group cleaves,[429] and the other involving a cleavage into a radical and a radical ion held together in a solvent cage.[430] Among the evidence for the latter view[431] are



41



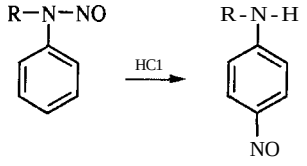
42



the effects of substituents on the rate of the reaction,[432] ^{15}N and ^{14}C kinetic isotope effects that show nonconcertedness,[433] and the fact that both *N*-methylaniline and nitrous acid are produced in sizable and comparable amounts in addition to the normal products *o*- and *p*-nitro-*N*-methylaniline.[434] These side products are formed when the radicals escape from the solvent cage.

11-32 *Migration of the Nitroso Group: The Fischer-Hepp Rearrangement*

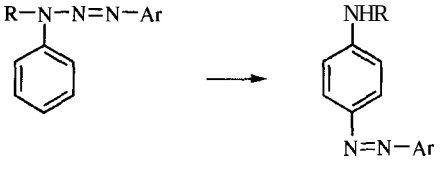
1/C-HYDRO-5/N-NITROSO-INTERCHANGE



The migration of a nitroso group, formally similar to 11-31, is important because p-nitroso secondary aromatic amines cannot generally be prepared by direct C-nitrosation of secondary aromatic amines (see 12-49). The reaction, known as the *Fischer-Hepp rearrangement*,[435] is brought about by treatment of N-nitroso secondary aromatic amines with HC1. Other acids give poor or no results. In benzene systems the para product is usually formed exclusively.[436] The mechanism of the rearrangement is not completely understood. The fact that the reaction takes place in a large excess of urea[437] shows that it is intramolecular[438] since, if NO^+, NOCl, or some similar species were free in the solution, it would be captured by the urea, preventing the rearrangement.

11-33 *Migration of an Arylazo Group*

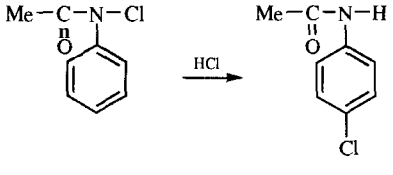
1/C-HYDRO-5/N-ARYLAZO-INTERCHANGE



Rearrangement of aryl triazenes can be used to prepare azo derivatives of primary and secondary aromatic amines.[439] These are first diazotized at the amino group (see 11-4) to give triazenes, which are then rearranged by treatment with acid. The rearrangement always gives the para isomer, unless that position is occupied.

11-34 *Migration of Halogen: The Orton Rearrangement*

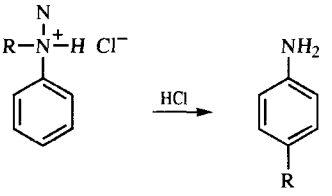
1/C-HYDRO-5/N-HALO-INTERCHANGE



Migration of a halogen from a nitrogen side chain to the ring by treatment with HC1 is called the *Orton rearrangement*.[440] The main product is the para isomer, though some ortho product may also be formed. The reaction has been carried out with N-chloro- and N-bromoamines and less often with N-iodo compounds. The amine must be acylated, except that $PhNCl_2$ gives 2,4-dichloroaniline. The reaction is usually performed in water or acetic acid. There is much evidence (cross-halogenation, labeling, etc.) that this is an intermolecular process.[441] First, the HC1 reacts with the starting material to give $ArNHCOCH_3$ and Cl_2; then, the chlorine halogenates the ring as in **11-11.** Among the evidence is that chlorine has been isolated from the reaction mixture. The Orton rearrangement can also be brought about photochemically[442] and by heating in the presence of benzoyl peroxide.[443] These are free radical processes.

11-35 *Migration of an Alkyl Group*[444]

1/C-HYDRO-5/N-ALKYL-INTERCHANGE



When HCl salts of arylalkylamines are heated at ~200-300°C, migration occurs. This is called the *Hofmann–Martius reaction.* It is an intermolecular reaction, since crossing is found. For example, methylanilinium bromide gave not only the normal products *o*- and *p*-toluidine but also aniline and di- and trimethylanilines.[445] As would be expected for an intermolecular process, there is isomerization when R is primary.

With primary R, the reaction probably goes through the alkyl halide formed initially in an S_N2 reaction:

$$R\overset{+}{N}H_2Ar + Cl^- \longrightarrow HCl + ArNH_2$$

Evidence for this view is that alkyl halides have been isolated from the reaction mixture and that Br^-, Cl^-, and I^- gave different ortho/para ratios, which indicates that the halogen is involved in the reaction.[445] Further evidence is that the alkyl halides isolated are not rearranged (as would be expected if they are formed by an S_N2 mechanism), even though the alkyl groups in the ring are rearranged. Once the alkyl halide is formed, it reacts with the substrate by a normal Friedel–Crafts alkylation process **(11-12),** accounting for the rearrangement. When R is secondary or tertiary, carbocations may be directly formed so that the reaction does not go through the alkyl halides.[446]

It is also possible to carry out the reaction by heating the amine (not the salt) at a temperature between 200 and 350°C with a metal halide such as $CoCl_2$, $CdCl_2$, or $ZnCl_2$. When this is done, the reaction is called the *Reilly–Hickinbottom rearrange-*

ment. Primary R groups larger than ethyl give both rearranged and unrearranged products.[447] The reaction is not generally useful for secondary and tertiary R groups, which are usually cleaved to alkenes under these conditions.

When acylated arylamines are photolyzed, migration of an acyl group takes place[448] in a process that resembles the photo-Fries reaction (11-30).

Other Leaving Groups

Three types of reactions are considered in this section.

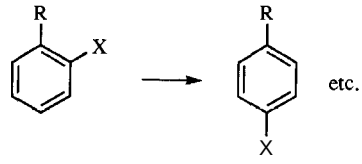
1. Reactions in which hydrogen replaces another leaving group:

$$ArX + H^+ \longrightarrow ArH$$

2. Reactions in which an electrophile other than hydrogen replaces another leaving group:

$$ArX + Y^+ \longrightarrow ArY$$

3. Reactions in which a group (other than hydrogen) migrates from one position in a ring to another. Such migrations can be either inter- or intramolecular:



The three types are not treated separately, but reactions are classified by leaving group.

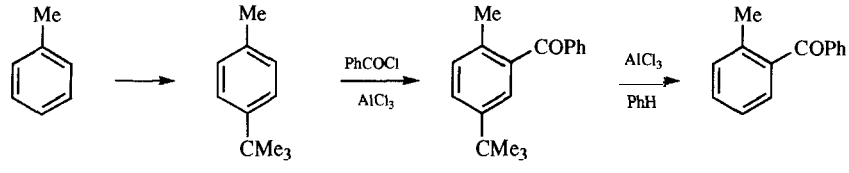
A. *Carbon Leaving Groups*

11-36 *Reversal of Friedel-Crafts Alkylation*

HYDRO-DE-ALKYLATION OR DEALKYLATION

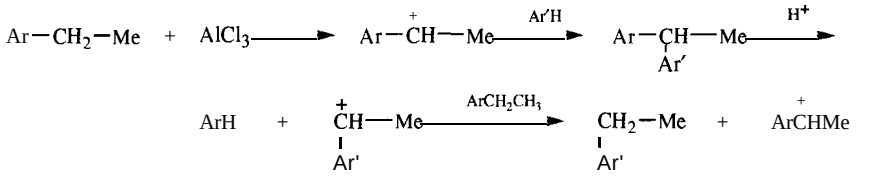
$$ArR + H^+ \xrightarrow{AlCl_3} ArH$$

Alkyl groups can be cleaved from aromatic rings by treatment with proton and/or Lewis acids. Tertiary R groups are the most easily cleaved; because this is true, the *tert*-butyl group is occasionally introduced into a ring, used to direct another group, and then removed.[449] For example,[450]

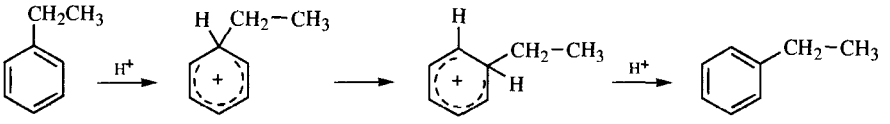


Secondary R groups are harder to cleave, and primary R harder still. Because of this reaction, care must be taken when using Friedel-Crafts catalysts (Lewis or proton acids) on aromatic compounds containing alkyl groups. True cleavage, in which the R becomes an alkene, occurs only at high temperatures—above 400°C.[451] At ordinary temperatures, the R group attacks another ring, so that the bulk of the product may be dealkylated, but there is a residue of heavily alkylated material. The isomerization reaction, in which a group migrates from one position in a ring to another or to a different ring, is therefore more important than true cleavage. In these reactions, the meta isomer is generally the most favored product among the dialkylbenzenes; and the 1,3,5 product the most favored among the trialkylbenzenes, because they have the highest thermodynamic stabilities. Alkyl migrations can be inter- or intramolecular, depending on the conditions and on the R group. The following experiments can be cited: ethylbenzene treated with HF and BF_3 gave, almost completely, benzene and diethylbenzenes (entirely intermolecular);[452] propylbenzene labeled in the (3 position gave benzene, propylbenzene, and di- and tripropylbenzenes, but the propylbenzene recovered was partly labeled in the a position and not at all in the *y* position (both intra- and intermolecular);[453] o-xylene treated with HBr and $AlBr_3$ gave a mixture of o- and *m*- but no *p*-xylene, while *p*-xylene gave *p*- and *m*- but no o-xylene, and no trimethyl compounds could be isolated in these experiments (exclusively intramolecular rearrangement).[454] Apparently, methyl groups migrate only intramolecularly, while other groups may follow either path.[455]

The mechanism[456] of intermolecular rearrangement can involve free alkyl cations, but there is much evidence to show that this is not necessarily the case. For example, many of them occur without rearrangement within the alkyl group. The following mechanism has been proposed for intermolecular rearrangement without the involvement of carbocations that are separated from the ring.[457]



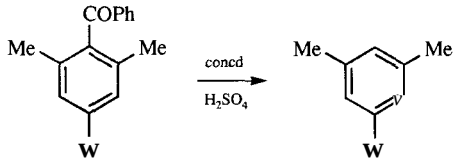
Evidence for this mechanism is that optically active $PhCHDCH_3$ labeled in the ring with ^{14}C and treated with $GaBr_3$ in the presence of benzene gave ethylbenzene containing no deuterium and two deuteriums and that the rate of loss of radioactivity was about equal to the rate of loss of optical activity.[457] The mechanism of intramolecular rearrangement is not very clear. The 1,2 shifts of this kind have been proposed:[458]



There is evidence from ^{14}C labeling that intramolecular migration occurs only through 1,2 shifts.[459] Any 1,3 or 1,4 migration takes place by a series of two or more 1,2 shifts.

Phenyl groups have also been found to migrate. Thus *o*-terphenyl, heated with $AlCl_3$–H_2O, gave a mixture containing 7% *o*-, 70% *m*-, and 23% *p*-terphenyl.[460] Alkyl groups have also been replaced by groups other than hydrogen, (e.g., nitro groups).

Unlike alkylation, *Friedel-Crafts acylation* has been generally considered to be irreversible, but a number of instances of electrofugal acyl groups have been reported,[461] especially where there are two ortho substituents, for example the hydro-de-benzoylation of 42.[462]



W = Me, Cl, OH, etc.

OS V, 332. Also see OS HI, 282, 653; V, 598.

11-37 *Decarbonylation of Aromatic Aldehydes*

HYDRO-DE-FORMYLATION OR DEFORMYLATION

$$ArCHO \xrightarrow{H_2SO_4} ArH + CO$$

The decarbonylation of aromatic aldehydes with sulfuric acid[463] is the reverse of the *Gatterman–Koch reaction* **(11-16).** It has been carried out with trialkyl- and trialkoxybenzaldehydes. The reaction takes place by the ordinary arenium ion mechanism: the attacking species is H^+ and the leaving group is HCO^+, which can lose a proton to give CO or combine with OH^- from the water solvent to give formic acid.[464] Aromatic aldehydes have also been decarbonylated with basic catalysts.[465] When basic catalysts are used, the mechanism is probably similar to the S_E1 process of **11-38.** See also **14-39.**

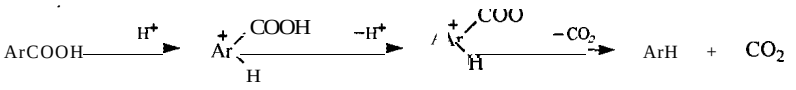
11-38 *Decarboxylation of Aromatic Acids*

HYDRO-DE-CARBOXYLATION OR DECARBOXYLATION

$$ArCOOH \xrightarrow[\text{quinoline}]{Cu} ArH + CO_2$$

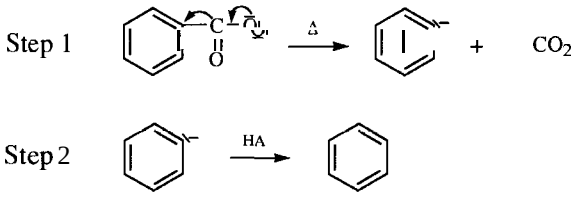
The decarboxylation of aromatic acids is most often carried out by heating with copper and quinoline. However, two other methods can be used with certain substrates. In one method, the salt of the acid ($ArCOO^-$) is heated, and in the other the carboxylic acid is heated with a strong acid, often sulfuric. The latter method is accelerated by the presence of electron-donating groups in ortho and para positions and by the steric effect of groups in the ortho positions; in benzene systems it is

generally limited to substrates that contain such groups. In this method, decarboxylation takes place by the arenium ion mechanism,[466] with H^+ as the electrophile and



CO_2 as the leaving group.[467] Evidently, the order of electrofugal ability is $CO_2 > H^+ > COOH^+$, so that it is necessary, at least in most cases, for the COOH to lose a proton before it can cleave.

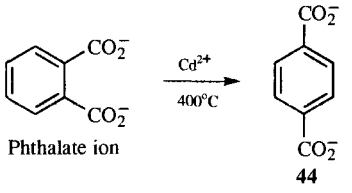
When carboxylate *ions are* decarboxylated, the mechanism is entirely different, being of the S_E1 type. Evidence for this mechanism is that the reaction is first order and that electron-withdrawing groups, which would stabilize a carbanion, facilitate the reaction.[468]



Despite its synthetic importance, the mechanism of the copper-quinoline method has been studied very little, but it has been shown that the actual catalyst is cuprous ion.[469] In fact, the reaction proceeds much faster if the acid is heated in quinoline with cuprous oxide instead of copper, provided that atmospheric oxygen is rigorously excluded. A mechanism has been suggested in which it is the cuprous salt of the acid that actually undergoes the decarboxylation.[469] It has been shown that cuprous salts of aromatic acids are easily decarboxylated by heating in quinoline[470] and that arylcopper compounds are intermediates that can be isolated in some cases.[471] Metallic silver has been used in place of copper, with higher yields.[472]

In certain cases, the carboxyl group can be replaced by electrophiles other than hydrogen, (e.g., NO,[472] I,[473] Br,[474] or Hg).[475]

Rearrangements are also known to take place. For example, when the phthalate ion is heated with a catalytic amount of cadmium, the terphthalate ion (44) is produced:[476]



Phthalate ion

44

In a similar process, potassium benzoate heated with cadmium salts disproportionates to benzene and 44. The term *Henkel reaction* (named for the company that patented the process) is used for these rearrangements.[477] An S_E1 mechanism has

been suggested.[478] The terphthalate is the main product because it crystallizes from the reaction mixture, driving the equilibrium in that direction.[479]

For aliphatic decarboxylation, see **12-38.**

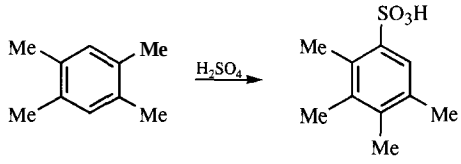
11-39 *The Jacobsen Reaction*



When polyalkyl- or polyhalobenzenes are treated with sulfuric acid, the ring is sulfonated, but rearrangement also takes place. The reaction, known as the *Jacobsen reaction,* is limited to benzene rings that have at least four substituents, which can be any combination of alkyl and halogen groups, where the alkyl groups can be ethyl or methyl and the halogen iodo, chloro, or bromo. When isopropyl or *tert*-butyl groups are on the ring, these groups are cleaved to give alkenes. Since a sulfo group can later be removed **(11-41),** the Jacobsen reaction can be used as a means of rearranging polyalkylbenzenes. The rearrangement always brings the alkyl or halo groups closer together than they were originally. Side products in the case illustrated above are pentamethylbenzenesulfonic acid, 2,4,5-trimethylbenzenesulfonic acid, and so on, indicating an intermolecular process, at least partially.

The mechanism of the Jacobsen reaction is not established,[480] but there is evidence, at least for polymethylbenzenes, that the rearrangement is intermolecular, and that the species to which the methyl group migrates is a polymethylbenzene, not a sulfonic acid. Sulfonation takes place after the migration.[481] It has been shown by labeling that ethyl groups migrate without internal rearrangement.[482]

B. *Oxygen Leaving Groups*

11-40 *Deoxygenation*

$$\mathrm{ArOR} \longrightarrow \mathrm{ArH}$$

In a few cases, it is possible to remove an oxygen substituent directly from the aromatic ring. Treatment of an aryl mesylate (ArOMs) with a nickel catalyst in DMF, for example, leads to the deoxygenated product, Ar–H.[483]

C. *Sulfur Leaving Groups*

11-41 *Desulfonation or Hydro-de-sulfonation*

$$\mathrm{ArSO_3H} \xrightarrow[\text{dil. } \mathrm{H_2SO_4}]{135\text{–}200^\circ\mathrm{C}} \mathrm{ArH} + \mathrm{H_2SO_4}$$

The cleavage of sulfo groups from aromatic rings is the reverse of 11-7.[484] By the principle of microscopic reversibility, the mechanism is also the reverse.[485] Dilute H_2SO_4 is generally used, as the reversibility of sulfonation decreases with increasing H_2SO_4 concentration. The reaction permits the sulfo group to be used as a blocking group to direct meta, and then to be removed. The sulfo group has also been replaced by nitro and halogen groups. Sulfo groups have also been removed from the ring by heating with an alkaline solution of Raney nickel.[486] In another catalytic process, aromatic sulfonyl bromides or chlorides are converted to aryl bromides or chlorides, respectively, on heating with chlorotris(triphenylphosphine)rhodium(I).[487] This reaction is similar to the decarbonylation of aromatic acyl halides mentioned in **14-39.**

$$ArSO_2Br \xrightarrow{RhCl(PPh_3)_3} ArBr$$

OS I, 388; **II,** 97; **III,** 262; IV, 364. Also see OS I, 519; **II,** 128; V, 1070.

D. *Halogen Leaving Groups*

11-42 *Dehalogenation or Hydro-de-halogenation*

$$ArX \xrightarrow{AlCl_3} ArH$$

Aryl halides can be dehalogenated by Friedel–Crafts catalysts. Iodine is the most easily cleaved. Dechlorination is seldom performed and defluorination apparently never. The reaction is most successful when a reducing agent, say, Br^- or I^- is present to combine with the I^+ or Br^+ coming off.[488] Except for deiodination, the reaction is seldom used for preparative purposes. Migration of halogen is also found,[489] both intramolecular[490] and intermolecular.[491] The mechanism is probably the reverse of that of **11–11**.[492]

Rearrangement of polyhalobenzenes can also be catalyzed by very strong bases; for example, 1,2,4-tribromobenzene is converted to 1,3,5-tribromobenzene by treatment with PhNHK.[493] This reaction, which involves aryl carbanion intermediates (S_E1 mechanism), has been called the *halogen dance.*[494]

Removal of halogen from aromatic rings can also be accomplished by various reducing agents, among them Bu_3SnH,[495] catalytic hydrogenolysis,[496] catalytic transfer hydrogenolysis,[497] $Fe(CO)_5$,[498] Na-Hg in liquid NH_3,[499] $LiAlH_4$,[500] $LiAlH_4$ irradiated with light[501] or with ultrasound,[502] $NaBH_4$ and a catalyst,[503] NaH,[504] HCOOH with Pd/C,[505] and Raney nickel in alkaline solution,[506] the last method being effective for fluorine as well as for the other halogens. Carbon monoxide, with potassium tetracarbonylhydridoferrate, $KHFe(CO)_4$, as a catalyst, specifically reduces aryl iodides.[507] Not all these reagents operate by electrophilic substitution mechanisms. Some are nucleophilic substitutions and some are free-radical processes. Photochemical[508] and electrochemical[509] reduction are also known. Halogen can also be removed from aromatic rings indirectly by conversion to Grignard reagents (12-36)followed by hydrolysis **(11-44).**

OS **III,** 132, 475, 519; V, 149, 346, 998; **VI,** 82, 821.

11-43 *Formation of Organometallic Compounds*

$$ArBr + M \longrightarrow ArM$$

$$ArBr + RM \longrightarrow ArM + RBr$$

These reactions are considered along with their aliphatic counterparts at Reactions 12-36 and 12-37.

E. *Metal Leaving Groups*

11-44 *Hydrolysis of Organometallic Compounds*

HYDRO-DE-METALLATION OR DEMETALATION

$$ArM + H^+ \longrightarrow ArH + M^+$$

Organometallic compounds can be hydrolyzed by acid treatment. For active metals such as Mg, Li, and so on, water is sufficiently acidic. The most important example of this reaction is hydrolysis of Grignard reagents, but M may be many other metals or metalloids. Examples are SiR_3, HgR, Na, and $B(OH)_2$. Since aryl Grignard and aryllithium compounds are fairly easy to prepare, they are often used to prepare salts of weak acids, for example,

$$PhMgBr + H{-}C{\equiv}C{-}H \longrightarrow H{-}C{\equiv}C^- + {}^+MgBr + PhH$$

Where the bond between the metal and the ring is covalent, the usual arenium ion mechanism operates.[510] Where the bonding is essentially ionic, this is a simple acid-base reaction. For the aliphatic counterpart of this reaction, see Reaction 12-23.

Other reactions of aryl organometallic compounds are treated with their aliphatic analogs: Reactions 12-24-12-34.

[33] It must be remembered that in acid solution amines are converted to their conjugate acids, which for the most part are meta directing (type 2). Therefore in acid (which is the most common medium for electrophilic substitutions) amino groups may direct meta. However, unless the solution is highly acidic, there will be a small amount of free amine present, and since amino groups are activating and the conjugate acids deactivating, ortho-para direction is often found even under acidic conditions.

[34] For a review of the directing and orienting effects of amino groups, see Chuchani, G. in Patai *The Chemistry of the Amino Group;* Wiley: NY, **1968,** p. 250; for ether groups see Kohnstam, G.; Williams, D.L.H. in Patai *The Chemistry of the Ether Linkage;* Wiley: NY, **1967,** p. 132.

CHAPTER 12

Aliphatic Electrophilic Substitution

In Chapter 11, it was pointed out that the most important leaving groups in electrophilic substitution are those that can best exist with an outer shell that is deficient in a pair of electrons. For aromatic systems, the most common leaving group is the proton. The proton is also a leaving group in aliphatic systems, but the reactivity depends on the acidity. Protons in saturated alkanes are very unreactive, but electrophilic substitutions are often easily carried out at more acidic positions, for example, a to a carbonyl group, or at an alkynyl position ($RC{\equiv}CH$). Since metallic ions are easily able to bear positive charges, we might expect that organometallic compounds would be especially susceptible to electrophilic substitution, and this is indeed the case.[1] Another important type of electrophilic substitution, known as *anionic cleavage*, involves the breaking of C–C bonds; in these reactions there are carbon leaving groups (**12-38**–**12-44**). A number of electrophilic substitutions at a nitrogen atom are treated at the end of the chapter.

Since a carbanion is what remains when a positive species is removed from a carbon atom, the subject of carbanion structure and stability (Chapter 5) is inevitably related to the material in this chapter. So is the subject of very weak acids and very strong bases (Chapter 8), because the weakest acids are those in which the hydrogen is bonded to carbon.

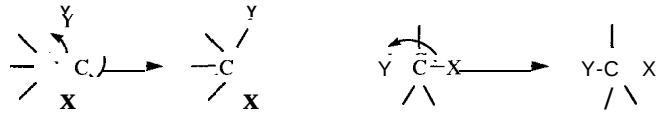
MECHANISMS

For aliphatic electrophilic substitution, we can distinguish at least four possible major mechanisms,[2] which we call S_E1, S_E2 (front), S_E2 (back), and S_Ei. The S_E1 is unimolecular; the other three are bimolecular.

Bimolecular Mechanisms: S_E2 and S_Ei

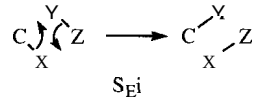
The bimolecular mechanisms for electrophilic aliphatic substitution are analogous to the S_N2 mechanism in that the new bond forms as the old one breaks. However, in the S_N2 mechanism the incoming group brings with it a pair of electrons, and this orbital can overlap with the central carbon only to the extent that the leaving group takes away *its* electrons; otherwise the carbon would have more than eight electrons at once in its outer shell. Since electron clouds repel, this means also that the incoming group attacks backside, at a position 180° from the leaving group,

resulting in inversion of configuration. When the attacking species is an electrophile, which brings to the substrate only a vacant orbital, it is obvious that this consideration does not apply and we cannot *a priori* predict from which direction the attack must come. We can imagine two main possibilities: Attack from the front, which we call S_E2 (front), and attack from the rear, which we call S_E2 (back). The possibilities can be pictured (charges not shown):



S_E2 (front) S_E2 (back)

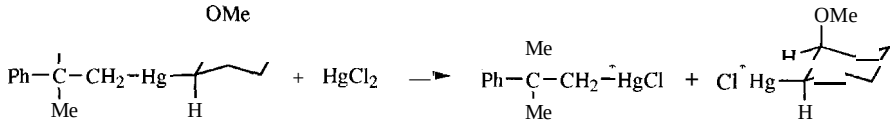
Both the S_E2 (front) and S_E2 (back) mechanisms are designated D_EA_E in the IUPAC system. With substrates in which we can distinguish the possibility, the former mechanism should result in retention of configuration and the latter in inversion. The reaction of allylsilanes with adamantyl chloride and $TiCl_4$, for example, gives primarily the antiproduct via a S_E2' reaction.[3] When the electrophile attacks from the front, there is a third possibility. A portion of the electrophile may assist in the removal of the leaving group, forming a bond with it at the same time that the new C–Y bond is formed



S_Ei

This mechanism, which we call the S_Ei mechanism (IUPAC designation: cyclo-$D_EA_ED_nA_n$),[4] also results in retention of configuration.[5] Plainly, where a second-order mechanism involves this kind of internal assistance, backside attack is impossible.

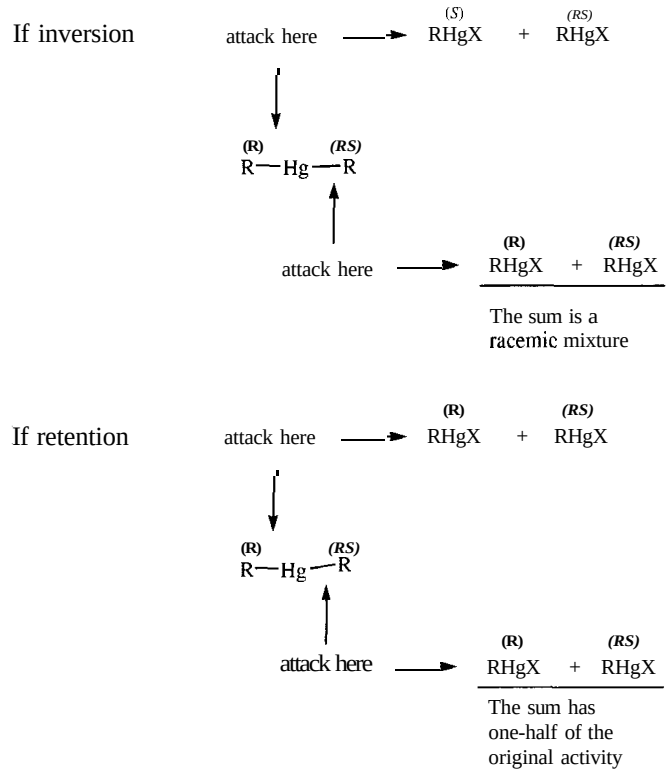
It is evident that these three mechanisms are not easy to distinguish. All three give second-order kinetics, and two result in retention of configuration.[6] In fact, although much work has been done on this question, there are few cases in which we can unequivocally say that one of these three and not another is actually taking place.



1 **2**

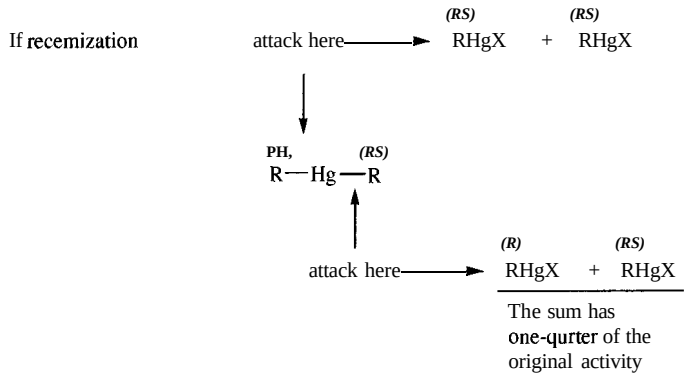
Clearly, a study of the stereochemistry can distinguish between S_E2 (back) on the one hand and S_E2 (front) or S_Ei on the other. Many such investigations have been made. In the overwhelming majority of second-order electrophilic substitutions, the result has been retention of configuration or some other indication of frontside attack, indicating an S_E2 (front) or S_Ei mechanism. For example, when *cis*-**1** was treated with labeled mercuric chloride, the 2 produced was 100% cis. The bond between the mercury and the ring must have been broken (as well as the other Hg–C

bond), since each of the products contained about one-half of the labeled mercury.[7] Another indication of frontside attack is that second-order electrophilic substitutions proceed very easily at *bridgehead* carbons (see p. 392).[8] Still another indication is the behavior of neopentyl as a substrate. The S_N2 reactions at neopentyl are extremely slow (p. 431), because attack from the rear is blocked. The fact that neopentyl systems undergo electrophilic substitution only slightly more slowly than ethyl[9] is further evidence for frontside attack. One final elegant experiment may be noted.



The compound di-*sec*-butylmercury was prepared with one sec-butyl group optically active and the other racemic.[10] This was accomplished by treatment of optically active *sec*-butylmercuric bromide with racemic *sec*-butylmagnesium bromide. The di-*sec*-butyl compound was then treated with mercuric bromide to give 2 mol of *sec*-butylmercuric bromide. The steric course of the reaction could then be predicted by the following analysis, assuming that the bonds between the mercury and each carbon have a 50% chance of breaking. The original activity referred to is the activity of the optically active *sec*-butylmercuric bromide used to make the dialkyl compound. The actual result was that, under several different sets of conditions, the product had one-half of the original activity, demonstrating retention of configuration.

However, inversion of configuration has been found in certain cases, demonstrating that the S_E2 (back) mechanism can take place. For example, the reaction of optically active *sec*-butyltrineopentyltin with bromine (12-28) gives inverted



sec-butyl bromide.[11] A number of other organometallic compounds have also been shown to give inversion when treated with halogens,[12] although others do not.[13] So far, no inversion has been found with an organomercury substrate. It may be that still other examples of backside attack exist[14] but have escaped detection because

$$s\text{-BuSnR}_3 + Br_2 \longrightarrow s\text{-BuBr} \qquad R = \text{neopentyl}$$

of the difficulty in preparing compounds with a configurationally stable carbon-metal bond. Compounds that are chiral because of an asymmetric carbon at which a carbon-metal bond is located[15] are often difficult to resolve and once resolved are often easily racemized. The resolution has been accomplished most often with organomercury compounds,[16] and most stereochemical investigations have therefore been made with these substrates. Only a few optically active Grignard reagents have been prepared (i.e., in which the only asymmetric center is the carbon bonded to the magnesium).[17] Because of this, the steric course of electrophilic substitutions at the C–Mg bond has not often been determined. However, in one such case, the reaction of both the exo and endo isomers of the 2-norbornyl Grignard reagent with $HgBr_2$ (to give 2-norbornylmercuric bromide) has been shown to proceed with retention of configuration.[18] It is likely that inversion takes place only when steric hindrance prevents frontside attack and when the electrophile does not carry a Z group (p. 760).

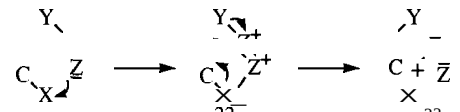
The S_E2 (back) mechanism can therefore be identified in certain cases (if inversion of configuration is found), but it is plain that stereochemical investigations cannot distinguish between the S_E2 (front) and the S_Ei mechanisms and that, in the many cases where configurationally stable substrates cannot be prepared, such investigations are of no help at all in distinguishing among all three of the second-order mechanisms. Unfortunately, there are not many other methods that lead to unequivocal conclusions. One method that has been used in an attempt to distinguish between the S_Ei mechanism on the one hand and the S_E2 pathways on the other

involves the study of salt effects on the rate. It may be recalled (p. 450) that reactions in which neutral starting molecules acquire charges in the transition state are aided by an increasing concentration of added ions. Thus the S_Ei mechanism would be less influenced by salt effects than would either of the S_E2 mechanisms. On this basis Abraham and Johnston[19] concluded that the reactions $R_4Sn + HgX_2 \rightarrow RHgX + R_3SnX$ (X = Cl or I) take place by S_E2 and not by S_Ei mechanisms. Similar investigations involve changes in solvent polarity (see also p. 769).[20] In the case of the reaction (where R = R' = *i*-Pr and R = *i*-Pr, R' = neopentyl), the use of polar

$$s\text{-BuSnR}_2\text{R}' + \text{Br}_2 \longrightarrow s\text{-BuBr}$$

solvents gave predominant inversion, while nonpolar solvents gave predominant retention.[21]

On the basis of evidence from reactivity studies, it has been suggested[22] that a variation of the S_Ei mechanism is possible in which the group Z becomes attached to X before the latter becomes detached:



This process has been called the S_EC[22] or S_E2 (co-ord)[23] mechanism (IUPAC designation A_n + cyclo-$D_EA_ED_n$).

It has been shown that in certain cases (e.g., $Me_4Sn + I_2$) the reactants in an S_E2 reaction, when mixed, give rise to an immediate charge-transfer spectrum (p. 102), showing that an electron donor–acceptor (EDA) complex has been formed.[24] In these cases it is likely that the EDA complex is an intermediate in the reaction.

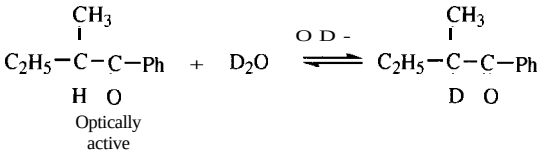
The S_E1 Mechanism

The S_E1 mechanism is analogous to the S_N1. It involves two steps: a slow ionization and a fast combination.

Step 1 $\text{R–X} \xrightarrow{\text{slow}} \text{R}^{=} + \text{X}^{+}$

Step 2 $\bar{\text{R}} + \text{Y}^{+} \longrightarrow \text{R-Y}$

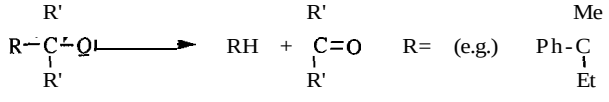
The IUPAC designation is $D_E + A_E$. First-order kinetics are predicted and many such examples have been found. Other evidence for the S_E1 mechanism was obtained in a study of base-catalyzed tautomerization. In the reaction the rate of



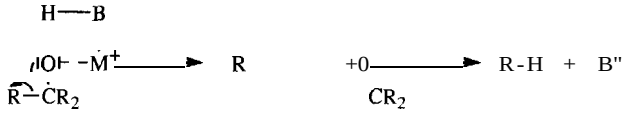
deuterium exchange was the same as the rate of racemization[25] and there was an isotope effect.[26]

The S_N1 reactions do not proceed at bridgehead carbons in [2.2.1] bicyclic systems (p. 397) because planar carbocations cannot form at these carbons. However, carbanions not stabilized by resonance are probably not planar; S_E1 reactions should readily occur with this type of substrate. This is the case. Indeed, the question of carbanion structure is intimately tied into the problem of the stereochemistry of the S_E1 reaction. If a carbanion is planar, racemization should occur. If it is pyramidal and *can hold its structure*, the result should be retention of configuration. On the other hand, even a pyramidal carbanion will give racemization if it cannot hold its structure, that is, if there is pyramidal inversion as with amines (p. 129). Unfortunately, the only carbanions that can be studied easily are those stabilized by resonance, which makes them planar, as expected (p. 233). For simple alkyl carbanions, the main approach to determining structure has been to study the stereochemistry of S_E1 reactions rather than the other way around. What is found is almost always racemization. Whether this is caused by planar carbanions or by oscillating pyramidal carbanions is not known. In either case, racemization occurs whenever a carbanion is completely free or is symmetrically solvated.

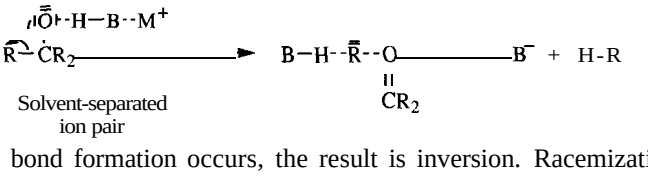
However, even planar carbanions need not give racemization. Cram[27] found that retention and even inversion can occur in the alkoxide cleavage reaction **(12-39):**



which is a first-order S_E1 reaction involving resonance-stabilized planar carbanions (here designated R^-).[27] By changing the solvent, Cram was able to produce products ranging from 99% retention to 60% inversion and including complete racemization. These results are explained by a carbanion that is not completely free but is solvated. In nondissociating, nonpolar solvents such as benzene or dioxane, the alkoxide ion exists as an ion pair, solvated by the solvent BH



In the course of the cleavage, the proton of the solvent moves in to solvate the newly forming carbanion. As is easily seen, this solvation is asymmetrical since the solvent molecule is already on the front side of the carbanion. When the carbanion actually bonds with the proton, the result is retention of the original configuration. In protic solvents, such as diethylene glycol, a good deal of inversion is found. In these solvents, the *leaving group* solvates the carbanion, so the solvent can solvate it only from the opposite side:



When C–H bond formation occurs, the result is inversion. Racemization results in polar aprotic solvents such as DMSO. In these solvents the carbanions are rela-

tively long-lived (because the solvent has no proton to donate) and symmetrically solvated.

Similar behavior was found for carbanions generated by base-catalyzed hydrogen exchange (Reaction 12-1):[28]

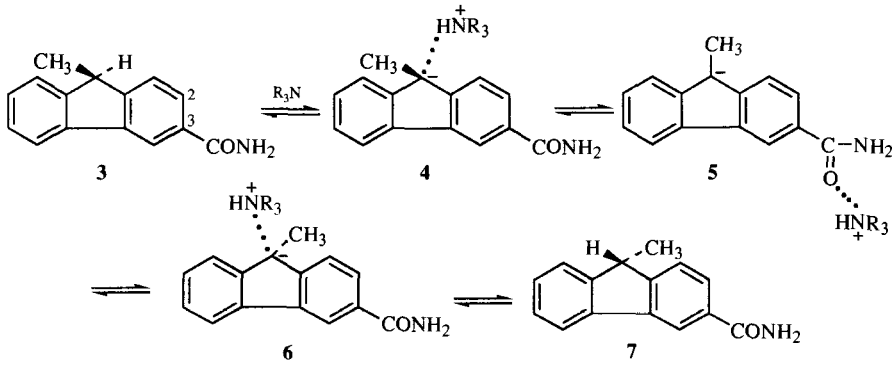
$$\text{R-H} + \text{B-D} \underset{}{\overset{B^-}{\rightleftharpoons}} \text{R-D} + \text{B-H} \qquad B^- = \text{base}$$

R = (e.g.) Ph—C(CN)—Et

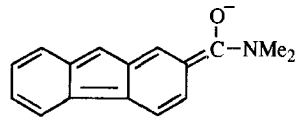
In this case, information was obtained from measurement of the ratio of k_c (rate constant for isotopic exchange) to k_a (rate constant for racemization). A k_e/k_a ratio substantially > 1 means retention of configuration, since many individual isotopic exchanges are not producing a change in configuration. A k_e/k_a ratio of ~ 1 indicates racemization and a ratio of $\frac{1}{2}$ corresponds to inversion (see p. 392). All three types of steric behavior were found, depending on R, the base, and the solvent. As with the alkoxide cleavage reaction, retention was generally found in solvents of low dielectric constant, racemization in polar aprotic solvents, and inversion in protic solvents. However, in the proton exchange reactions, a fourth type of behavior was encountered. In aprotic solvents, with aprotic bases like tertiary amines, the k_e/k_a ratio was found to be < 0.5, indicating that racemization took place *faster* than isotopic exchange (this process is known as *isoracemization*). Under these conditions, the conjugate acid of the amine remains associated with the carbanion as an ion pair. Occasionally, the ion pair dissociates long enough for the carbanion to turn over and recapture the proton:

Thus, inversion (and hence racemization, which is produced by repeated acts of inversion) occurs without exchange. A single act of inversion without exchange is called *isoinversion.*

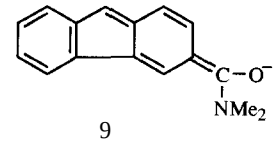
The isoinversion process can take place by a pathway in which a positive species migrates in a stepwise fashion around a molecule from one nucleophilic position to another. For example, in the exchange reaction of 3-carboxamido-9-methylfluorene (3) with Pr_3N in r-BuOH, it has been proposed that the amine removes a proton from



the 9 position of 3 and conducts the proton out to the C=O oxygen (5), around the molecule, and back to C-9 on the opposite face of the anion. Collapse of 6 gives the inverted product 7. Of course, 5 could also go back to 3, but a molecule that undergoes the total process **3** → 4 → 5 → 6 → 7 has experienced an inversion without an exchange. Evidence for this pathway, called the *conducted tour mechanism,*[29] is that the 12-carboxamido isomer of 3 does not give isoracemization. In this case, the negative charge on the oxygen atom in the anion corresponding to 5 is less, because a canonical form in which oxygen acquires a full negative charge (8) results in disruption of the aromatic sextet in both benzene rings (cf. 9 where one



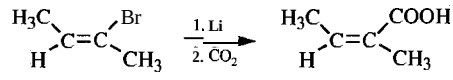
8



9

benzene ring is intact). Whether the isoracemization process takes place by the conducted tour mechanism or a simple nonstructured contact ion-pair mechanism depends on the nature of the substrate (e.g., a proper functional group is necessary for the conducted tour mechanism) and of the base.[30]

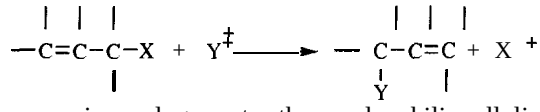
It is known that vinylic carbanions *can* maintain configuration, so that S_E1 mechanisms should produce retention there. This has been found to be the case. For example, *trans*-2-bromo-2-butene was converted to 64-74% angelic acid:[31]



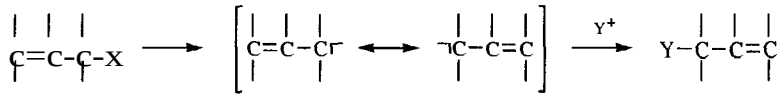
Only ~5% of the cis isomer, tiglic acid, was produced. In addition, certain carbanions in which the negative charge is stabilized by *d*-orbital overlap can maintain configuration (p. 233) and S_E1 reactions involving them proceed with retention of configuration.

Electrophilic Substitution Accompanied by Double-Bond Shifts

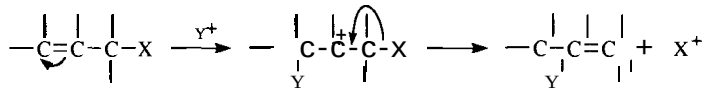
When electrophilic substitution is carried out at an allylic substrate, the product may be rearranged:



This type of process is analogous to the nucleophilic allylic rearrangements discussed in Chapter 10 (p. 420). There are two principal pathways. The first of these is analogous to the S_E1 mechanism in that the leaving group is first removed, giving a resonance-stabilized allylic carbanion, and then the electrophile attacks.

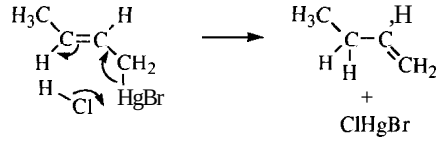


In the other pathway, the Y group first attacks, giving a carbocation, which then loses X.

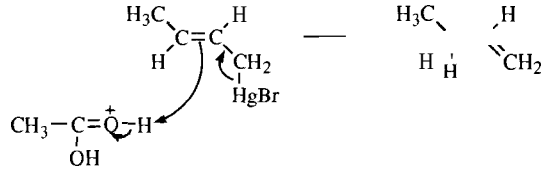


These mechanisms are more fully discussed under Reaction **12-2.**

Most electrophilic allylic rearrangements involve hydrogen as the leaving group, but they have also been observed with metallic leaving groups.[32] Sleezer et al.[33] found that crotylmercuric bromide reacted with HCl $\sim 10^7$ times faster than *n*-butylmercuric bromide and the product was > 99% 1-butene.[33] These facts point to an S_Ei' mechanism (IUPAC designation cyclo-$\frac{1}{3}/D_EA_ED_nA_n$):



The reaction of the same compound with acetic acid-perchloric acid seems to proceed by an S_E2' mechanism (IUPAC designation $\frac{1}{3}/D_EA_E$):[33]



The geometry of electrophilic allylic rearrangement has not been studied very much (cf. the nucleophilic case, p. 422), but in most cases the rearrangement takes place with anti stereoselectivity,[34] though syn stereoselectivity has also been demonstrated.[35] In one case, use of the electrophile H^+ and the leaving group $SnMe_3$ gave both syn and anti stereoselectivity, depending on whether the substrate was cis or trans.[36]

Other Mechanisms

Addition-elimination **(12-14)** and cyclic mechanisms **(12-38)** are also known.

Much less work has been done on electrophilic aliphatic substitution mechanisms than on nucleophilic substitutions, and the exact mechanisms of many of the reactions in this chapter are in doubt. For many of them, not enough work has been done to permit us to decide which of the mechanisms described in this chapter is operating, if indeed any is. There may be other electrophilic substitution mechanisms, and some of the reactions in this chapter may not even be electrophilic substitutions at all.

REACTIVITY

Only a small amount of work has been done in this area compared to the vast amount done for aliphatic nucleophilic substitution and aromatic electrophilic substitution. Only a few conclusions, most of them sketchy or tentative, can be drawn.[37]

1. *Effect of Substrate.* For S_E1 reactions electron-donating groups decrease rates and electron-withdrawing groups increase them. This result is as would be expected from a reaction in which the rate-determining step is analogous to the cleavage of a proton from an acid. For the S_E2 (back) mechanism, Jensen and Davis[11] showed that the reactivity of alkyl groups is similar to that for the S_N2 mechanism (i.e., Me > Et > Pr > /-Pr > neopentyl), as would be expected, since both involve backside attack and both are equally affected by steric hindrance. In fact, this pattern of reactivity can be regarded as evidence for the occurrence of the S_E2 (back) mechanism in cases where stereochemical investigation is not feasible.[38] For S_E2 reactions that proceed with retention, several studies have been made with varying results, depending on the reaction.[39] One such study, which examined the reaction RHgBr + Br_2 → RBr catalyzed by Br^-, gave the results shown in Table 12.1.[40] As can be seen, a branching increased the rates, while β branching decreased them. Sayre and Jensen[40] attributed the decreased rates to steric hindrance, though attack here was definitely frontside, and the increased rates to the electron-donating effect of the alkyl groups, which stabilized the electron-deficient transition state.[41] Of course, steric hindrance should also be present with the a branched groups, so these workers concluded that if it were not, the rates would be even greater. The Br electrophile is a rather large one and it is likely that smaller steric effects are present with smaller electrophiles. The rates of certain second-order substitutions of organotin compounds have been found to increase with increasing electron withdrawal by substituents. This behavior has been ascribed[42] to an S_E2 mechanism involving ion pairs, analogous to Sneen's ion-pair mechanism for nucleophilic substitution (p. 400). Solvolysis of 2-bromo-1,1,1-trifluoro-2-(*p*-methoxyphenyl)ethane in water proceeds via a free carbocation intermediate, but ion pairing influences the reaction in the presence of bromide ion.[43]

2. *Effect of Leaving Group.* For both S_E1 and second-order mechanisms, the more polar the C–X bond, the easier it is for the electrofuge to cleave. For

TABLE 12.1 Relative Rates of the Reaction of RHgBr with Br_2 and Br^-[a]

R	Relative Rate	R	Relative Rate
Me	1	Et	10.8
Et	10.8	*i*-Bu	1.24
i-Pr	780	Neopentyl	0.173
t-Bu	3370		

metallic leaving groups in which the metal has a valence > 1, the nature of the other group or groups attached to the metal thus has an effect on the reaction. For example, consider a series of organomercurials RHgY. Because a more electronegative Y decreases the polarity of the C—Hg bond and furthermore results in a less stable HgY^+, the electrofugal ability of HgY decreases with increasing electronegativity of Y Thus, HgR′ (from RHgR') is a better leaving group than HgCl (from RHgCl). Also in accord with this is the leaving-group order Hg-*t*-Bu > Hg-*i*-Pr > HgEt > HgMe, reported for acetolysis of R_2Hg,[41] since the more highly branched alkyl groups better help to spread the positive charge. It might be expected that, when metals are the leaving groups, S_E1 mechanisms would be favored, while with carbon leaving groups, second-order mechanisms would be found. However, the results so far reported have been just about the reverse of this. For carbon leaving groups, the mechanism is usually S_E1, while for metallic leaving groups the mechanism is almost always S_E2 or S_Ei. A number of reports of S_E1 reactions with metallic leaving groups have appeared,[44] but the mechanism is not easy to prove and many of these reports have been challenged.[45] Reutov and co-workers[44] expressed the view that in such reactions a nucleophile, which may be the solvent, must assist in the removal of the electrofuge and refer to such processes as $S_E1(N)$ reactions.

3. *Effect of Solvent.*[46] In addition to the solvent effects on certain S_E1 reactions, mentioned earlier (p. 764), solvents can influence the mechanism that is preferred. As with nucleophilic substitution (p. 448), an increase in solvent polarity increases the possibility of an ionizing mechanism, in this case S_E1, in comparison with the second-order mechanisms, which do not involve ions. As previously mentioned (p. 763), the solvent can also exert an influence between the S_E2 (front or back) and S_Ei mechanisms in that the rates of S_E2 mechanisms should be increased by an increase in solvent polarity, while S_Ei mechanisms are much less affected.

REACTIONS

The reactions in this chapter are arranged in order of leaving group: hydrogen, metals, halogen, and carbon. Electrophilic substitutions at a nitrogen atom are treated last.

Hydrogen as Leaving Group

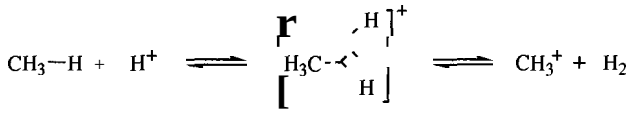
A. *Hydrogen as the Electrophile*

12-1 *Hydrogen Exchange*

DEUTERIO-DE-HYDROGENATION OR DEUTERIATION

$$R\text{-}H + D^+ \rightleftharpoons R\text{-}D + H^+$$

Hydrogen exchange can be accomplished by treatment with acids or bases. As with **11-1,** the exchange reaction is mostly used to study mechanistic questions such as relative acidities, but it can be used synthetically to prepare deuterated or tritiated molecules. When ordinary strong acids such as H_2SO_4 are used, only fairly acidic protons exchange (e.g., acetylenic and allylic). However, primary, secondary, and tertiary hydrogens of alkanes can be exchanged by treatment with superacids (p. 328).[47] The order of hydrogen reactivity is tertiary > secondary > primary. Where C—C bonds are present, they may be cleaved also **(12-45).** The mechanism of the exchange (illustrated for methane) has been formulated as involving attack of H^+ on the C—H bond to give the pentavalent methanonium ion which loses H_2 to give a



Methanonium ion

tervalent carbocation.[48] The methanonium ion CH_5^+ has a three-center, two-electron bond.[49] It is not known whether the methanonium ion is a transition state or a true intermediate, but an ion CH_5^+ has been detected in mass spectra.[50] The IR spectrum of the ethanonium ion $C_2H_7^+$ has been measured in the gas phase.[51] Note that the two electrons in the three-center, two-electron bond can move in three directions, in accord with the threefold symmetry of such a structure. The electrons can move to unite the two hydrogens, leaving the CH_3^+ free (the forward reaction), or they can unite the CH_3 with either of the two hydrogens, leaving the other hydrogen as a free H^+ ion (the reverse reaction). Actually, the methyl cation is not stable under these conditions. It can go back to CH4 by the route shown (leading to H^+ exchange) or it can react with additional CH4 molecules **(12-17)** to yield, eventually, the terr-butyl cation, which is stable in these superacid solutions. Hydride ion can also be removed from alkanes (producing tervalent carbocations) by treatment with pure SbF_5 in the absence of any source of H^+.[52] Complete or almost complete perdeuteriation of cyclic alkenes has been achieved by treatment with dilute DCl/D_2O in sealed Pyrex tubes at 165-280°C.[53]

Exchange with bases involves an S_E1 mechanism.

Step 1 $\quad RH + B^- \longrightarrow R^- + BH$

Step 2 $\quad R^- + BD \longrightarrow RD + B^-$

Of course, such exchange is most successful for relatively acidic protons, such as those α to a carbonyl group, but even weakly acidic protons can exchange with bases if the bases are strong enough (see p. 228).

Alkanes and cycloalkanes, of both low and high molecular weight, can be fully perdeuterated treatment with D_2 gas and a catalyst such as Rh, Pt, or Pd.[54]

OS VI, 432.

12-2 *Migration of Double Bonds*

3/HYDRO-DE-HYDROGENATION

$$C_5H_{11}-CH_2-CH=CH_2 \xrightarrow{KNH_2} C_5H_{11}-CH=CH-CH_3$$

The double bonds of many unsaturated compounds are shifted[55] on treatment with strong bases.[56] In many cases, equilibrium mixtures are obtained and the thermodynamically most stable isomer predominates.[57] Thus, if the new double bond can be in conjugation with one already present or with an aromatic ring, it goes that way.[58] If the choice is between an exocyclic and an endocyclic double bond (in a six-membered ring), it chooses the latter. In the absence of considerations like these, Zaitsev's rule (p. 1314) applies and the double bond goes to the carbon with the fewest hydrogens. All these considerations lead us to predict that terminal alkenes can be isomerized to internal ones, nonconjugated alkenes to conjugated, exo six-membered ring alkenes to endo, and so on, and not the other way around. This is indeed usually the case.

This reaction, for which the term *prototropic rearrangement* is sometimes used, is an example of electrophilic substitution with accompanying allylic rearrangement. The mechanism involves abstraction by the base to give a resonance-stabilized carbanion, which then combines with a proton at the position that will give the more stable alkene:[59]

Step 1 $R-CH_2-CH=CH_2 + B \longrightarrow \left[R-\bar{C}H-CH=CH_2 \longleftrightarrow R-CH=CH-\bar{C}H_2\right] + BH^+$

Step 2 $\left[R-\bar{C}H-CH=CH_2 \longleftrightarrow R-CH=\bar{C}H-\bar{C}H_2\right] \xrightarrow{BH^+} R-CH=CH-CH_3 + B$

This mechanism is exactly analogous to the allylic rearrangement mechanism for nucleophilic substitution (p. 421). The UV spectra of allylbenzene and 1-propenylbenzene in solutions containing NH_2^- are identical, which shows that the same carbanion is present in both cases, as required by this mechanism.[60] The acid BH^+ protonates the position that will give the more stable product, though the ratio of the two possible products can vary with the identity of BH^+.[61] It has been shown that base-catalyzed double-bond shifts are partially intramolecular, at least in some cases.[62] The intramolecularity has been ascribed to a conducted tour mechanism (p. 766) in which the base leads the proton from one carbanionic site to the other:[63]

$$RCH_2CH=CH_2 + B \rightleftharpoons R-\underset{\displaystyle CH}{\overset{\displaystyle H\text{-}B}{CH}}\!\!\diagup\!\!\diagdown CH_2 \rightleftharpoons R-\underset{\displaystyle CH}{\overset{\displaystyle H\text{-}B}{CH}}\!\!\diagup\!\!\diagdown CH_2 \rightleftharpoons RCH=CHCH_3 + B$$

Triple bonds can also migrate in the presence of bases,[64] but through the allene intermediate:[65]

$$R-CH_2-C\equiv CH \rightleftharpoons R-CH=C=CH_2 \rightleftharpoons R-C\equiv C-CH_3$$

In general, strong bases such as $NaNH_2$ convert internal alkynes to terminal alkynes [a particularly good base for this purpose is potassium 3-aminopropylamide ($NH_2CH_2CH_2CH_2NHK$)[66]], because the equilibrium is shifted by formation of the

acetylid ion; with weaker bases such as NaOH, which are not strong enough to remove the acetylenic proton, the internal alkynes are favored because of their greater thermodynamic stability. In some cases the reaction can be stopped at the allene stage. The reaction then becomes a method for the preparation of allenes.[67] The reaction of propargylic alcohols with tosylhydrazine, PPh_3, and diethyl azodicarboxylate (DEAD) also generates allenes.[68]

Double-bond rearrangements can also take place on treatment with acids. Both proton and Lewis[69] acids can be used. The mechanism in the case of proton acids is the reverse of the previous one; first, a proton is gained, giving a carbocation, and then another is lost:

Step 1 $CH_3-CH_2-CH=CH_2 + H^+ \longrightarrow CH_3-CH_2-\overset{+}{C}H-CH_3$

Step 2 $CH3-CH2-\overset{+}{C}H-CH3 \longrightarrow CH_3-CH=CH-CH_3 + H^+$

As in the case of the base-catalyzed reaction, the thermodynamically most stable alkene is the one predominantly formed. However, the acid-catalyzed reaction is much less synthetically useful because carbocations give rise to many side products. If the substrate has several possible locations for a double bond, mixtures of all possible isomers are usually obtained. Isomerization of 1-decene, for example, gives a mixture that contains not only 1-decene and *cis*- and *trans*-2-decene but also the cis and trans isomers of 3-, 4-, and 5-decene as well as branched alkenes resulting from rearrangement of carbocations. It is true that the most stable alkenes predominate, but many of them have stabilities that are close together. Acid-catalyzed migration of triple bonds (with allene intermediates) can be accomplished if very strong acids (e.g., $HF-PF_5$) are used.[70] If the mechanism is the same as that for double bonds, vinyl cations are intermediates.

Double-bond isomerization can also take place in other ways. Nucleophilic allylic rearrangements were discussed in Chapter 10 (p. 421). Electrocyclic and sigmatropic rearrangements are treated at **18-27-18-35.** Double-bond migrations have also been accomplished photochemically,[71] and by means of metallic ion (most often complex ions containing Pt, Rh, or Ru) or metal carbonyl catalysts.[72] In the latter case there are at least two possible mechanisms. One of these, which requires external hydrogen, is called the *metal hydride addition–elimination mechanism:*

$$RCH_2CH=CH_2 \overset{MH}{\rightleftharpoons} RCH_2\overset{M}{\underset{|}{C}}HCH_3 \overset{-MH}{\rightleftharpoons} RCH=CHCH_3$$

The other mechanism, called the *π-allyl complex mechanism,* does not require external hydrogen:

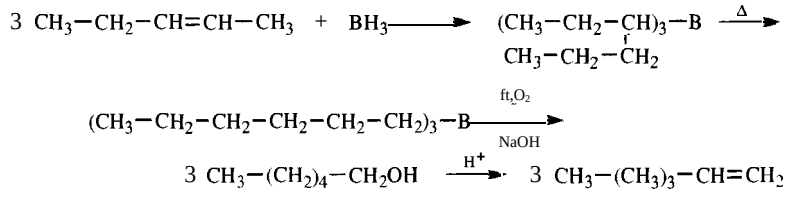
$$RCH_2CH=CH_2 \overset{M}{\rightleftharpoons} RCH_2\overset{M}{\underset{\bullet}{C}}H=CH_2 \rightleftharpoons R-\overset{M}{\underset{\diagdown\ \diagup}{CH}}-CH_2 \longrightarrow$$

$$RCH=CHCH_3 \overset{-M}{\rightleftharpoons} RCH=CHCH_3$$

Another difference between the two mechanisms is that the former involves 1,2 and the latter 1,3 shifts. The isomerization of 1-butene by rhodium(I) is an example of a reaction that takes place by the metal hydride mechanism,[73] while an example of the π-allyl complex mechanism is found in the $Fe_3(CO)_{12}$ catalyzed isomerization of 3-ethyl-1-pentene.[74] A palladium acetate or palladium complex catalyst was used to convert alkynones $RCOC{\equiv}CCH_2CH_2R'$ to 2,4-alkadien-1-ones $RCOCH{=}CHCH{=}CHCHR'$.[75]

The metal catalysis method has been used for the preparation of simple enols, for example, by isomerization of allylic alcohols.[76] These enols are stable enough for isolation (see p. 75), but slowly tautomerize to the aldehyde or ketone, with half-lives ranging from 40–50 min to several days.[76]

No matter which of the electrophilic methods of double-bond shifting is employed, the thermodynamically most stable alkene is usually formed in the largest amount in most cases, though a few anomalies are known. However, there is another, indirect, method of double-bond isomerization, by means of which migration in the other direction can often be carried out. This involves conversion of the alkene to a borane **(15-16),** rearrangement of the borane **(18-11),** oxidation and hydrolysis of the newly formed borane to the alcohol **(12-28),** and dehydration of the alcohol (17-1):



Since the migration reaction is always toward the end of a chain, terminal alkenes can be produced from internal ones, so the migration is often opposite to that with the other methods. Alternatively, the rearranged borane can be converted directly to the alkene by heating with an alkene of molecular weight higher than that of the product **(17-14).** Photochemical isomerization can also lead to the thermodynamically less stable isomer.[77]

If a hydroxy group is present in the chain, *it* may lose a proton, so that a ketone is the product, for example,[78]

Similarly, α-hydroxy triple-bond compounds have given α,β-unsaturated ketones.[79]

See **15-1** for related reactions in which double bonds migrate or isomerize.

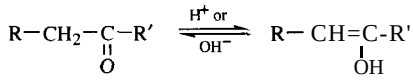
12-3 *Keto–Enol Tautomerization*

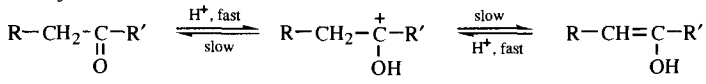
3/O-HYDRO-DE-HYDROGENATION



The tautomeric equilibrium between enols and ketones or aldehydes is not normally a preparative reaction, though for some ketones both forms can be prepared (see p. 75 for a discussion of this and other aspects of tautomerism). For most ketones and aldehydes only the keto form is detectable under ordinary conditions, though the equilibrium must occur, since aldehydes and ketones often react through their enol forms.

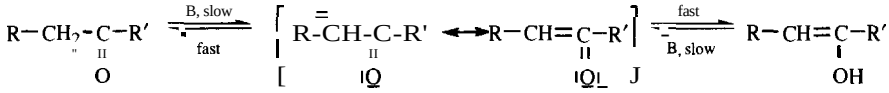
Neither the forward nor the reverse reaction can take place without at least a trace of acid or base,[80] ruling out a direct shift of a hydrogen from carbon to oxygen or vice versa. The mechanisms are identical to those in 12-2.[81]

Acid-catalyzed



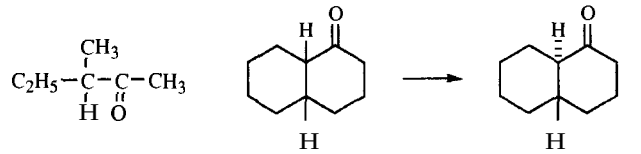
[82]

Base-catalyzed



For each catalyst, the mechanism for one direction is the exact reverse of the other, by the principle of microscopic reversibility.[83] As expected from mechanisms in which the C—H bond is broken in the rate-determining step, substrates of the type RCD_2COR show deuterium isotope effects (of ~ 5) in both the basic-[84] and the acid[85]-catalyzed processes.

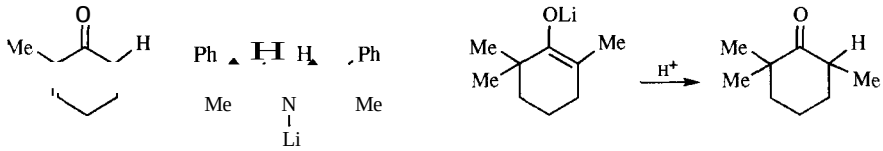
Although the conversion of an aldehyde or a ketone to its enol tautomer is not generally a preparative procedure, the reactions do have their preparative aspects. If a full mole of base per mole of ketone is used, the enolate ion (10) is formed and can be isolated[86] (see, e.g., **10-105**).[87] When enol ethers or esters are hydrolyzed, the enols initially formed immediately tautomerize to the aldehydes or ketones. In addition, the overall processes (forward plus reverse reactions) are often used for equilibration purposes. When an optically active compound in which the chirality is due to an asymmetric carbon α to a carbonyl group (as in 11) is treated with acid or base, racemization results.[88] If there is another asymmetric center in the molecule,



11 *cis*-Decalone *trans*-Decalone

the less stable epimer can be converted to the more stable one in this manner, and this is often done. For example, *cis*-decalone can be equilibrated to the trans isomer. Isotopic exchange can also be accomplished at the a position of an aldehyde or ketone in a similar manner. The role of additives such as $ZnCl_2$ on the asymmetric enolization reactions using chiral cases has been discussed.[89] For the acid-catalyzed

process, exchange or equilibration is accomplished only if the carbonyl compound is completely converted to the enol and then back, but in the base-catalyzed process exchange or equilibration can take place if only the first step (conversion to the enolate ion) takes place. The difference is usually academic. In cyclic compounds, cis- to trans- isomerization can occur via the enol.[90]



Racemic — Optically active

12 13 14 12

In the case of the ketone (12), a racemic mixture was converted to an optically active mixture (optical yield 46%) by treatment with the chiral base (**13**).[91] This happened because 13 reacted with one enantiomer of **12** faster than with the other (an example of kinetic resolution). The enolate (14) must remain coordinated with the chiral amine, and it is the amine that reprotonates **14,** not an added proton donor.

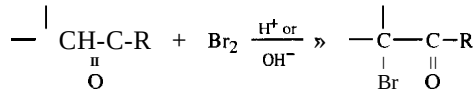
Enolizable hydrogens can be replaced by deuterium (and ^{16}O by ^{18}O) by passage of a sample through a deuterated (or ^{18}O containing) gas chromatography column.[92]

There are many enol–keto interconversions and acidifications of enolate ions to the keto forms listed in *Organic Syntheses.* No attempt is made to list them here.

B. *Halogen Electrophiles*

12-4 *Halogenation of Aldehydes and Ketones*

HALOGENATION OR HALO-DE-HYDROGENATION



Aldehydes and ketones can be halogenated in the a position with bromine, chlorine, or iodine.[93] The reaction is not successful with fluorine.[94] l-Fluoro-4-hydroxy-l,4-diazoniabicyclo[2.2.2]octane bistetrafluoroborate has been used for the monofluorination of ketones,[95] as has a mixture of $KI–KIO_3–H_2SO_4$.[96] Active compounds, such as β-keto esters and P-diketones, have been fluorinated with an N-fluoro-N-alkylsulfonamide[97] (this can result in enantioselective fluorination, if an optically active N-fluorosulfonamide is used[98]), with F_2/N_2—HCOOH.[99] and with acetyl hypofluorite.[100] The last reagent also fluorinates simple ketones in the form of their lithium enolates.[101] Silyl enol ethers can also be fluorinated, with XeF_2[102] or with 5% F_2 in N_2 at -78°C in $FCCl_3$.[103] Electrochemical fluorination has also been reported.[104] Sulfuryl chloride,[105] $NaClO_2/Mn(acac)_3$,[106] $Me_3SiCl–Me_2SO$,[107] $Me_3SiCl–MnO_2$,[108] $TiCl_3$,[109] and cupric chloride[110] have been used as reagents for chlorination, and NBS (see 14-2), *t*-BuBr—Me_2SO,[111] $Me_3SiBr–Me_2SO$,[112] and

tetrabutylammonium tribromide,[113] for bromination. Iodination has been accomplished with I_2—$HgCl_2$[114] and with I_2— cerium(IV) ammonium nitrate.[115]

For unsymmetrical ketones the preferred position of halogenation is usually a CH group, then a CH_2 group, and then CH_3;[116] however, mixtures are frequent. With aldehydes the aldehydic hydrogen is sometimes replaced (see 14-3). It is also possible to prepare di- and polyhalides. When basic catalysts are used, one a position of a ketone is completely halogenated before the other is attacked, and the reaction cannot be stopped until all the hydrogens of the first carbon have been replaced (see below). If one of the groups is methyl, the haloform reaction (12-42) takes place. With acid catalysts, it is easy to stop the reaction after only one halogen has entered, though a second halogen can be introduced by the use of excess reagent. In chlorination, the second halogen generally appears on the same side as the first,"[7] while in bromination the α,α′-dibromo product is found.[118] Actually, with both halogens it is the α,α-dihalo ketone that is formed first, but in the case of bromination this compound isomerizes under the reaction conditions to the α,α′ isomer.[117] Aryl methyl ketones can be dibrominated ($ArCOCH_3 \rightarrow ArCOCHBr_2$) in high yields with benzyltrimethylammonium tribromide.[119]

It is not the aldehyde or ketone itself that is halogenated, but the corresponding enol or enolate ion. The purpose of the catalyst is to provide a small amount of enol or enolate. The reaction is often done without addition of acid or base, but traces of acid or base are always present, and these are enough to catalyze formation of the enol or enolate. With acid catalysis the mechanism is

Step 1
$$R_2CH-\underset{\underset{O}{\|}}{C}-R' \xrightarrow[\text{slow}]{H^+} R_2C=\underset{\underset{OH}{|}}{C}-R'$$

Step 2
$$R_2C=\underset{\underset{OH}{|}}{C}-R' + Br-Br \longrightarrow R_2C-\overset{+}{\underset{\underset{Br\ OH}{|}}{C}}-R' + Br^-$$

Step 3
$$R_2C-\overset{+}{\underset{\underset{Br\ OH}{|}}{C}}-R' \longrightarrow R_2C-\underset{\underset{Br\ O}{|\ \|}}{C}-R'$$

The first step, as we have already seen (12-3), actually consists of two steps. The second step is very similar to the first step in electrophilic addition to double bonds (p. 970). There is a great deal of evidence for this mechanism: (1) the rate is first order in substrate; (2) bromine does not appear in the rate expression at all,[120] a fact consistent with a rate-determining first step;[121] (3) the reaction rate is the same for bromination, chlorination, and iodination under the same conditions;[122] (4) the reaction shows an isotope effect; and (5) the rate of the step 2–step 3 sequence has been independently measured (by starting with the enol) and found to be very fast.[123]

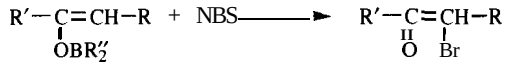
With basic catalysts the mechanism may be the same as that given above (since bases also catalyze formation of the enol), or the reaction may go directly through the enolate ion without formation of the enol:

Step 1
$$R_2CH-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{OH^-} R_2C=\underset{\underset{O^-}{|}}{C}-R'$$

Step 2
$$R_2C=\underset{\underset{O^-}{|}}{C}-R' + Br-Br \longrightarrow R_2C-\underset{\underset{Br\ O}{|\ \|}}{C}-R' + Br^-$$

It is difficult to distinguish the two possibilities. It was mentioned above that in the base-catalyzed reaction, if the substrate has two or three a halogens on the same side of the C=O group, it is not possible to stop the reaction after just one halogen atom has entered. The reason is that the electron-withdrawing field effect of the first halogen increases the acidity of the remaining hydrogens, that is, a CHX group is more acidic than a CH_2 group, so that initially formed halo ketone is converted to enolate ion (and hence halogenated) more rapidly than the original substrate.

Regioselectivity in the halogenation of unsymmetrical ketones can be attained by treatment of the appropriate enol borinate of the ketone with NBS or NCS.[124] The desired halo ketone is formed in high yield. Another method for achieving the



same result involves bromination of the appropriate lithium enolate at a low temperature (see p. 554 for the regioselective formation of enolate ions).[125] In a similar process, α-halo aldehydes have been prepared in good yield by treatment of silyl enol ethers $R_2C{=}CHOSiMe_3$ with Br_2 or Cl_2,[126] with sulfuryl chloride (SO_2Cl_2);[127] or with I_2 and silver acetate.[128] Enol acetates have been regioselectively iodinated with I_2 and either thallium(I) acetate[129] or copper(II) acetate.[130] α,β-Unsaturated ketones can be converted to α-halo-α,β-unsaturated ketones by treatment with phenylselenium bromide or chloride,[131] and to α-halo-β,γ-unsaturated ketones by two-phase treatment with HOCl.[132]

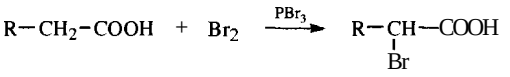
12-5 *Halogenation of Carboxylic Acids and Acyl Halides*

HALOGENATION OR HALO-DE-HYDROGENATION



The α hydrogens of carboxylic acids can be replaced by bromine or chlorine with a phosphorus halide as catalyst.[133] The reaction, known as the *Hell–Volhard–Zelinskii reaction,* is not applicable to iodine or fluorine. When there are two α hydrogens, one or both may be replaced, though it is often hard to stop with just one. The reaction actually takes place on the acyl halide formed from the carboxylic acid and the catalyst. The acids alone are inactive, except for those with relatively high enol content, such as malonic acid. Less than one full mole of catalyst (per mole of substrate) is required, because of the exchange reaction between carboxylic acids and acyl halides (see **10-77).** Each molecule of acid is α halogenated while it is in the acyl halide stage. The halogen from the catalyst does not enter the α position. For example, the use of Cl_2 and PBr_3 results in α chlorination, not bromination. As expected from the foregoing, acyl halides undergo a halogenation without a catalyst.

So do anhydrides and many compounds that enolize easily (e.g., malonic ester and aliphatic nitro compounds). The mechanism is usually regarded as proceeding through the enol as in **12-4**.[134] If chlorosulfuric acid ($ClSO_2OH$) is used as a catalyst, carboxylic acids can be a-iodinated,[135] as well as chlorinated or brominated.[136] *N*-Bromosuccinimide in a mixture of sulfuric acid–trifluoroacetic acid can monobrominate simple carboxylic acids.[137]

A number of other methods exist for the a halogenation of carboxylic acids or their derivatives.[138] Acyl halides can be a brominated or chlorinated by use of NBS or NCS and HBr or HC1.[139] The latter is an ionic, not a free-radical halogenation (see 14-2). Direct iodination of carboxylic acids has been achieved with I_2—Cu^{II} acetate in HOAc.[140] Acyl chlorides can be a iodinated with I_2 and a trace of HI.[141] Carboxylic esters can be a halogenated by conversion to their enolate ions with lithium *N*-isopropylcyclohexylamide in THF and treatment of this solution at $-78°C$ with I_2[141] or with a carbon tetrahalide.[142] Carboxylic acids, esters, and amides have been α-fluorinated at $-78°C$ with F_2 diluted in N_2.[143] Amides have been a-iodinated using iodine and *s*-collidine.[144]

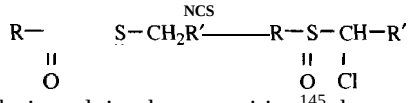
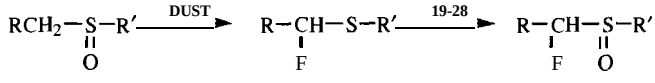
12-6 *Halogenation of Sulfoxides and Sulfones*

HALOGENATION OR HALO-DE-HYDROGENATION



Sulfoxides can be chlorinated in the a position[145] by treatment with Cl_2[146] or NCS,[147] in the presence of pyridine. These methods involve basic conditions. The reaction can also be accomplished in the absence of base with SO_2Cl_2 in CH_2Cl_2,[148] or with $TsNCl_2$.[149] The bromination of sulfoxides with bromine[150] and with NBS-bromine[151] have also been reported. Sulfones have been chlorinated by treatment of their conjugate bases RSO_2C^-HR' with various reagents, among them SO_2Cl_2, CCl_4,[152] NCS,[153] and hexachloroethane.[154] The α-fluorination of sulfoxides has been accomplished in a two-step procedure. Treatment with DAST produces an

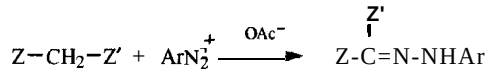


α-fluoro thioether, usually in high yield. Oxidation of this compound with *m*-chloroperoxybenzoic acid gives the sulfoxide.[155]

C. *Nitrogen Electrophiles*

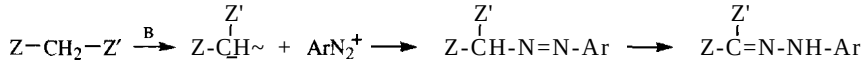
12-7 *Aliphatic Diazonium Coupling*

ARYLHYDRAZONO-DE-DIHYDRO-BISUBSTITUTION



If a C—H bond is acidic enough, it couples with diazonium salts in the presence of a base, most often aqueous sodium acetate.[156] The reaction is commonly carried out on compounds of the form $Z{-}CH_2{-}Z'$, where Z and Z' are as defined on pages 548, e.g., P-keto esters, β-keto amides, malonic ester.

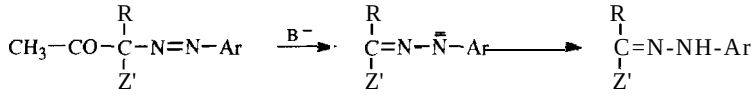
The mechanism is probably of the simple S_E1 type:



15

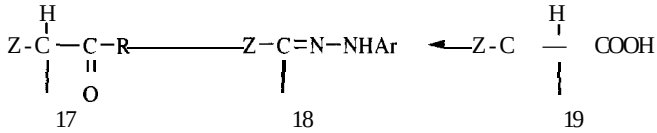
Aliphatic azo compounds in which the carbon containing the azo group is attached to a hydrogen are unstable and tautomerize to the isomeric hydrazones (**15**), which are therefore the products of the reaction.

When the reaction is carried out on a compound of the form $Z{-}CHR{-}Z'$, so that the azo compound does not have a tautomerizable hydrogen, if at least one Z is acyl or carboxyl, this group usually cleaves:



16

so the product in this case is also the hydrazone, and not the azo compound. In fact, compounds of the type 16 are seldom isolable from the reaction, though this has been accomplished.[157] The cleavage step shown is an example of **12-41** and, when a carboxyl group cleaves, of **12-38.** The overall process in this case is called the *Japp-Klingemann reaction*[158] and involves conversion of a ketone (17) or a carboxylic



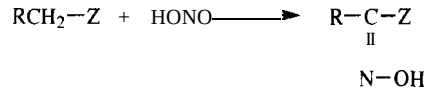
17 18 19

acid (18) to a hydrazone (19). When an acyl and a carboxyl group are both present, the leaving group order has been reported to be MeCO > COOH > PhCO.[159] When there is no acyl or carboxyl group present, the aliphatic azo compound is stable.

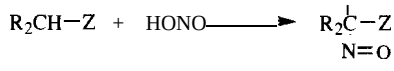
OS **III,** 660; IV, 633.

12-8 *Nitrosation at a Carbon Bearing an Active Hydrogen*

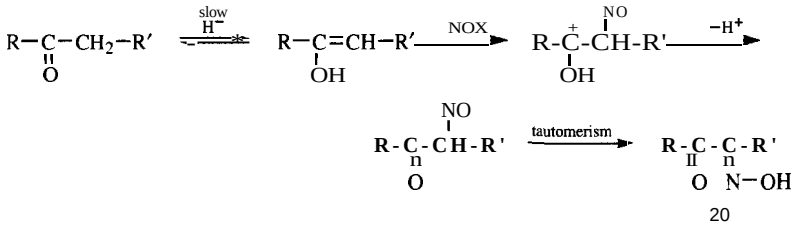
HYDROXYIMINO-DE-DIHYDRO-BISUBSTITUTION



NITROSATION OR NITROSO-DE-HYDROGENATION



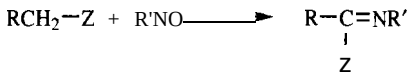
Carbons adjacent to a Z group (as defined on p. 548) can be nitrosated with nitrous acid or alkyl nitrites.[160] The initial product is the C-nitroso compound, but these are stable only when there is no tautomerizable hydrogen. When there is, the product is the more stable oxime. The situation is analogous to that with azo compounds and hydrazones (12-7). The mechanism is similar to that in **12-7**:[161] $R{-}H \rightarrow R'' + {}^{+}N{=}O \rightarrow R{-}N{=}O$. The attacking species is either NO^+ or a carrier of it. When the substrate is a simple ketone, the mechanism goes through the enol (as in halogenation **12-4):**



Evidence is that the reaction, in the presence of X~ (Br~, Cl~, or SCN~) was first order in ketone and in H^+, but zero order in HNO_2 and X^-.[162] Furthermore, the rate of the nitrosation was about the same as that for enolization of the same ketones. The species NOX is formed by HONO + X" + $H^+ \rightarrow$ HOX + H_2O. In the cases of $F_3CCOCH_2COCF_3$ and malononitrile, the nitrosation went entirely through the enolate ion rather than the enol.[163]

As in the Japp–Klingemann reaction, when Z is an acyl or carboxyl group (in the case of $R_2CH{-}Z$), it can be cleaved. Since oximes and nitroso compounds can be reduced to primary amines, this reaction often provides a route to amino acids. As in the case of **12-4,** the silyl enol ether of a ketone can be used instead of the ketone itself.[164] Good yields of α-oximinoketones (20) can be obtained by treating ketones with *tert*-butyl thionitrate.[165]

Imines can be prepared in a similar manner by treatment of an active hydrogen compound with a nitroso compound:

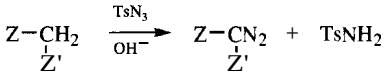


Alkanes can be nitrosated photochemically, by treatment with NOCl and UV light.[166] For nitration at an activated carbon, see **14-12.**

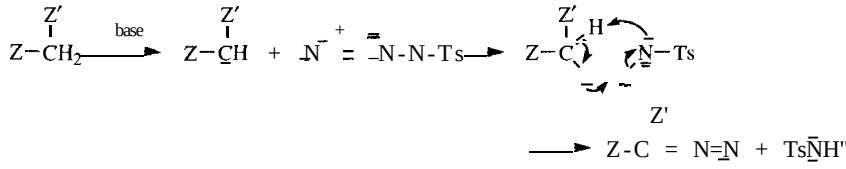
OS **II,** 202, 204, 223, 363; **III,** 191, 513; **V,** 32, 373; **VI,** 199, 840. Also see OS V, 650.

12-9 *Direct Formation of Diazo Compounds*

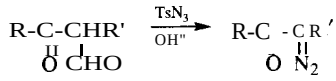
DIAZO-DE-DIHYDRO-BISUBSTITUTION



Compounds containing a CH_2 bonded to two Z groups (as defined on p. 548) can be converted to diazo compounds on treatment with tosyl azide in the presence of a base.[167] The use of phase-transfer catalysis increases the convenience of the method.[168] *p*-Dodecylbenzenesulfonyl azide,[169] methanesulfonyl azide,[170] and *p*-acetamidobenzenesulfonyl azide[171] also give the reaction. The reaction, which is called the *diazo transfer reaction,* can also be applied to other reactive positions, for example, the 5 position of cyclopentadiene.[172] The mechanism is probably as follows:



A diazo group can be introduced adjacent to a single carbonyl group indirectly by first converting the ketone to an α-formyl ketone **(10-118),** and then treating it with tosyl azide. As in the similar cases of **12-7** and **12-8,** the formyl group is cleaved

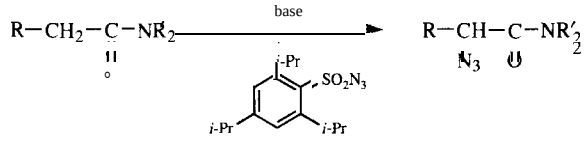


during the reaction.[173]

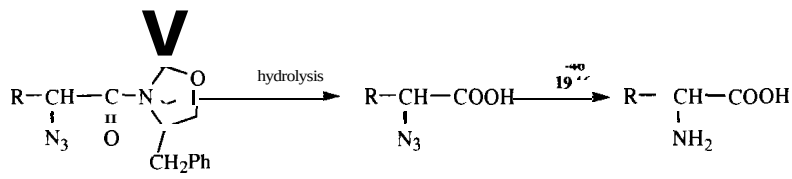
OS V, 179; VI, 389, 414.

12-10 *Conversion of Amides to* α-Azido Amides

AZIDATION OR AZIDO-DE-HYDROGENATION

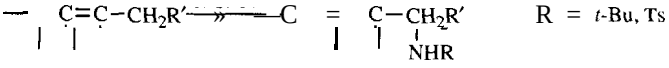


In Reaction **12-9** treatment of $Z{-}CH_2{-}Z'$ with tosyl azide gives diazo transfer. When this reaction is performed on a compound with a single Z group, formation of the azide becomes a competing process.[174] Factors favoring azide formation rather than diazo transfer include K^+ as the enolate counterion rather than Na^+ or Li^+ and the use of 2,4,6-triisopropylbenzenesulfonyl azide rather than TsN_3. When the reaction was applied to amides with a chiral R', it was highly stereoselective, and the product could be converted to an optically active amino acid.[174]

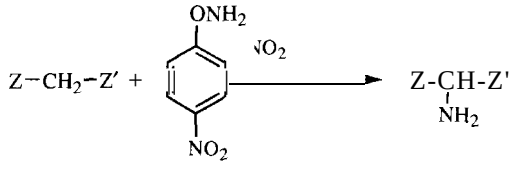


12-11 *Direct Amination at an Activated Position*

ALKYAMINO-DE-HYDROGENATION, AND SO ON



Alkenes can be aminated[175] in the allylic position by treatment with solutions of imido selenium compounds R–N=Se=N–R.[176] The reaction, which is similar to the allylic oxidation of alkenes with SeO_2 (see **14-4),** has been performed with R = *t*-Bu and R = Ts. The imido sulfur compound TsN=S=NTs has also been used[177] as well as PhNHOH–$FeCl_2$/$FeCl_3$.[178] Benzylic positions can be aminated with *t*-BuOOCONHTs in the presence of a catalytic amount of $Cu(OTf)_2$.[179] In another reaction, compounds containing an active hydrogen can be converted to primary amines in moderate yields by treatment with *O*-(2,4-dinitrophenyl)hydroxylamine.[180]

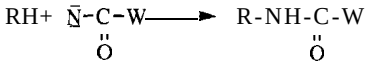


In an indirect amination process, acyl halides are converted to amino acids.[181] Reaction of the acyl halide with a chiral oxazolidinone leads to a chiral amide, which reacts with the N=N unit of a dialkyl azodicarboxylate [$R''O_2C–N=N–CO_2R'$]. Hydrolysis and catalytic hydrogenation leads to an amino acid with good enantioselectivity.[179]

See also **10-53.**

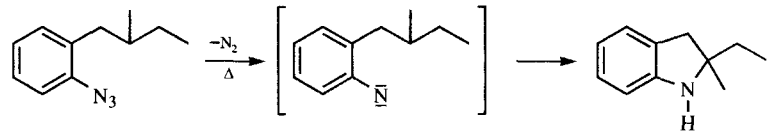
12-12 *Insertion by Nitrenes*

CH-[ACYLIMINO]-INSERTION, AND SO ON



Carbonylnitrenes NCOW (W = R', Ar, or OR') are very reactive species (p. 253) and insert into the C–H bonds of alkanes to give amides (W = R' or Ar) or carbamates (W = OR').[182] The nitrenes are generated as discussed on page 253. The order of reactivity among alkane C–H bonds is tertiary > secondary > primary.[183] Indications are that in general it is only singlet and not triplet nitrenes that insert.[184] Retention of configuration is found at a chiral carbon.[185] The mechanism is presumably similar to the simple one-step mechanism for insertion of carbenes **(12-19).** Other nitrenes (e.g., cyanonitrene, NCN,[186] and arylnitrenes, NAr[187]) can also insert into C–H bonds, but alkylnitrenes usually undergo rearrangement before they can react with the alkane. The insertion reactions are not generally useful synthetically, since they usually lead to mixtures of products, but exceptions are known,[188] chiefly

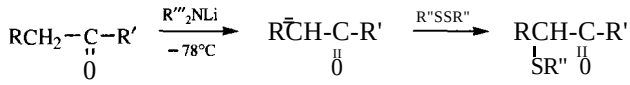
in cyclizations.[189] For example, heating of 2-(2-methylbutyl)phenyl azide gave ~ 60% 2-ethyl-2-methylindoline.[185]



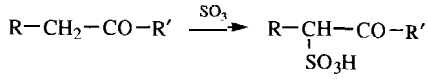
D. *Sulfur Electrophiles*

12-13 *Sulfenylation, Sulfonation, and Selenylation of Ketones and Carboxylic Esters*

ALKYLTHIO-DE-HYDROGENATION, AND SO ON



SULFONATION OR SULFO-DE-HYDROGENATION



Ketones, carboxylic esters (including lactones),[190] and amides (including lactams)[191] can be sulfenylated in the α position by conversion to the enolate ion with a base such as lithium *N*-isopropylcyclohexylamide and treatment of this with a disulfide.[192] The reaction, shown above for ketones, involves nucleophilic substitution at sulfur. Analogously, α-phenylseleno ketones, RCH(SePh)COR,′ and α-phenylseleno esters, RCH(SePh)COOR′, can be prepared[193] by treatment of the corresponding enolates with PhSeBr,[194] PhSeSePh,[195] or benzeneseleninic anhydride, PhSe(O)OSe(O)Ph.[196] Another method for the introduction of a phenylseleno group into the a position of a ketone involves simple treatment of an ethyl acetate solution of the ketone with PhSeCl (but not PhSeBr) at room temperature.[197] This procedure is also successful for aldehydes but not for carboxylic esters. *N*-Phenylselenophthalimide has been used to convert ketones to the a- PhSe derivative.[198] In another method that avoids the use of PhSeX reagents, aketone enolate is treated with selenium to give an R′COCHRSe$^-$ ion, which is treated with MeI, producing the α-methylseleno ketone R′COCHRSeMe.[199] This method has also been applied to carboxylic esters.

The α-seleno and α-sulfenyl carbonyl compounds prepared by this reaction can be converted to α,β-unsaturated carbonyl compounds (17-11). The sulfenylation reaction has also been used[200] as a key step in a sequence for moving the position of a carbonyl group to an adjacent carbon.[201]

O O OH

OS VI, 23, 109; 688.

Aldehydes, ketones, and carboxylic acids containing α hydrogens can be sulfonated with sulfur trioxide.[202] The mechanism is presumably similar to that of **12-4.** Sulfonation has also been accomplished at vinylic hydrogen.

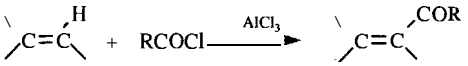
OS **VI,** 23, 109; **VIII,** 550. **OS IV,** 846, 862.

E. *Carbon Electrophiles*

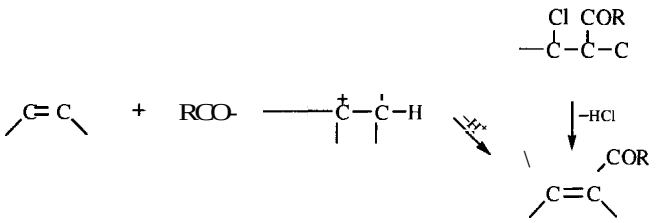
With respect to the attacking molecule, these are nucleophilic substitutions.

12-14 *Acylation at an Aliphatic Carbon*

ACYLATION OR ACYL-DE-HYDROGENATION



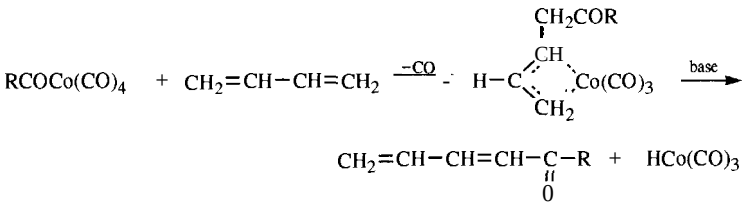
Alkenes can be acylated with an acyl halide and a Lewis acid catalyst in what is essentially a Friedel-Crafts reaction at an aliphatic carbon.[203] The product can arise by two paths. The initial attack is by the acyl cation RCO^+ (or by the acyl halide free or complexed; see **11-14)** at the double bond to give a carbocation:



Ion 21 can either lose a proton or combine with chloride ion. If it loses a proton, the product is an unsaturated ketone; the mechanism is similar to the tetrahedral mechanism of Chapter 10, but with the charges reversed. If it combines with chloride, the product is a P-halo ketone, which can be isolated, so that the result is addition to the double bond (see **15-45).** On the other hand, the P-halo ketone may, under the conditions of the reaction, lose HC1 to give the unsaturated ketone, this time by an addition-elimination mechanism. In the case of unsymmetrical alkenes, the attacking ion prefers the position at which there are more hydrogens, following Markovnikov's rule (p. 984). Anhydrides and carboxylic acids (the latter with a proton acid such as anhydrous HF, H_2SO_4, or polyphosphoric acid as a catalyst) are sometimes used instead of acyl halides. With some substrates and catalysts double-bond migrations are occasionally encountered so that, for example, when 1-methylcyclohexene was acylated with acetic anhydride and zinc chloride, the major product was 6-acetyl-1-methylcyclohexene.[204]

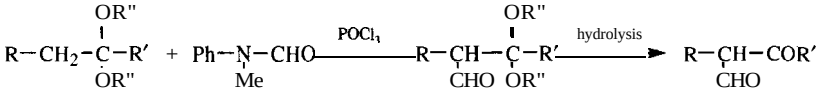
Conjugated dienes can be acylated by treatment with acyl- or alkylcobalt tetracarbonyls, followed by base-catalyzed cleavage of the resulting π-allyl carbonyl derivatives.[205] The reaction is very general. With unsymmetrical dienes, the acyl

group generally substitutes most readily at a cis double bond, next at a terminal



alkenyl group, and least readily at a trans double bond. The most useful bases are strongly basic, hindered amines such as dicyclohexylethylamine. The use of an alkylcobalt tetracarbonyl, RCo(CO)4, gives the same product as that shown above. Acylation of vinylic ethers has been accomplished with aromatic acyl chlorides, a base, and a palladium catalyst: $ROCH{=}CH_2 \rightarrow ROCH{=}CHCOAr$.[206]

Formylation of alkenes can be accomplished with N-disubstituted formamides and $POCl_3$.[207] This is an aliphatic Vilsmeier reaction (see 11-15). Vilsmeier formylation can also be performed on the α position of acetals and ketals, so that hydrolysis of the products gives keto aldehydes or dialdehydes:[208]

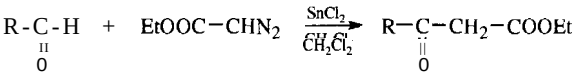


Acetylation of acetals or ketals can be accomplished with acetic anhydride and BF_3-etherate.[209] The mechanism with acetals or ketals also involves attack at an alkenyl carbon, since enol ethers are intermediates.[209] Ketones can be formylated in the α position by treatment with CO and a strong base.[210]

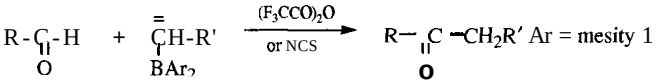
OS IV, 555, 560; VI, 744. Also see OS VI, 28.

12-15 *Conversion of Aldehydes to* P-Keto Esters or Ketones

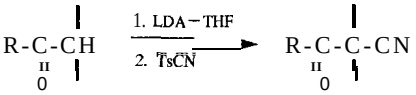
ALKOXYCARBONYLALKYLATION OR ALKOXYCARBONYLALKYL-DE-HYDROGENATION



P-Keto esters have been prepared in moderate to high yields by treatment of aldehydes with diethyl diazoacetate in the presence of a catalytic amount of a Lewis acid such as $SnCl_2$, BF3, or $GeCl_2$.[211] The reaction was successful for both aliphatic and aromatic aldehydes, but the former react more rapidly than the latter, and the difference is great enough to allow selective reactivity. In a similar process, aldehydes react with certain carbanions stabilized by boron, in the presence of $(F_3CCO)_2O$ or NCS, to give ketones.[212]



12-16 *Cyanation or Cyano-de-hydrogenation*

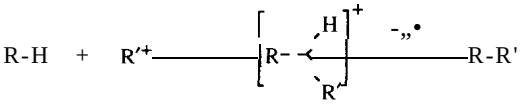


Introduction of a cyano group α to the carbonyl group of a ketone can be accomplished by prior formation of the enolate with lithium diisopropylamide (LDA) in THF and addition of this solution to *p*-TsCN at −78°C.[213] The products are formed in moderate to high yields but the reaction is not applicable to methyl ketones. Treatment of $TMSCH_2N(Me)C{=}Nt\text{-}Bu$ with *sec*-butyllithium and $R_2C{=}O$, followed by iodomethane and NaOMe leads to the nitrile, $R_2CH{-}CN$.[214] In a different kind of reaction, nitro compounds are α-cyanated by treatment with CN^- and $K_3Fe(CN)_6$.[215] The mechanism probably involves ion radicals. In still another reaction, secondary amines are converted to α-cyanoamines by treatment with phenylseleninic anhydride and NaCN or Me_3SiCN.[216] The compound Me_3SiCN has also been used in a reaction that cyanates benzylic positions.[217]

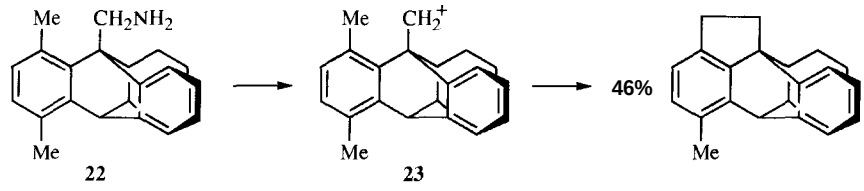
12-17 *Alkylation of Alkanes*

ALKYLATION OR ALKYL-DE-HYDROGENATION

Alkanes can be alkylated by treatment with solutions of stable carbocations (p. 218),[218] though the reaction is not generally useful for synthesis. Mixtures are usually obtained. In a typical experiment, the treatment of propane with isopropyl fluoroantimonate ($Me_2C^+\ SbF_6^-$) gave 26% 2,3-dimethylbutane, 28% 2-methylpentane, 14% 3-methylpentane, and 32% n-hexane, as well as some butanes, pentanes (formed by 12-45), and higher alkanes. Mixtures arise in part because intermolecular hydrogen exchange ($RH + R'^+ \rightleftharpoons R^+ + R'H$) is much faster than alkylation, so that alkylation products are also derived from the new alkanes and carbocations formed in the exchange reaction. Furthermore, the carbocations present are subject to rearrangement (Chapter 18), giving rise to new carbocations. Products result from all the hydrocarbons and carbocations present in the system. As expected from their relative stabilities, secondary alkyl cations alkylate alkanes more readily than tertiary alkyl cations (the *tert*-butyl cation does not alkylate methane or ethane). Stable primary alkyl cations are not available, but alkylation has been achieved with complexes formed between CH_3F or C_2H_5F and SbF_5.[219] The mechanism of alkylation can be formulated (similar to that shown in hydrogen exchange with superacids, 12-1) as



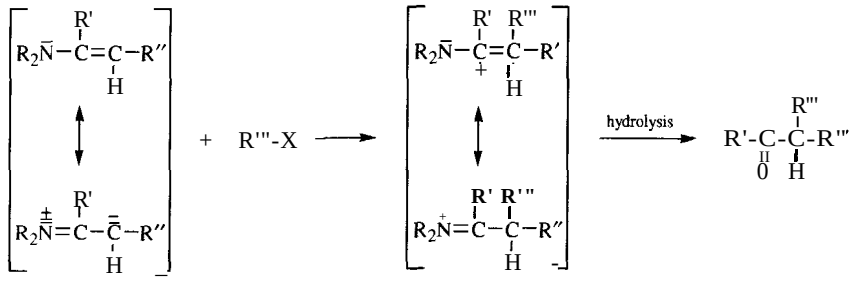
It is by means of successive reactions of this sort that simple alkanes like methane and ethane give *tert*-butyl cations in super acid solutions (p. 219).[220]



Intramolecular insertion has been reported. The positively charged carbon of the carbocation (23), generated from the diazonium salt of the triptycene compound (22), reacted with the CH_3 group in close proximity with it.[221]

12-18 *The Stork Enamine Reaction*

α-ACYLALKYL-DE-HALOGENATION[222]

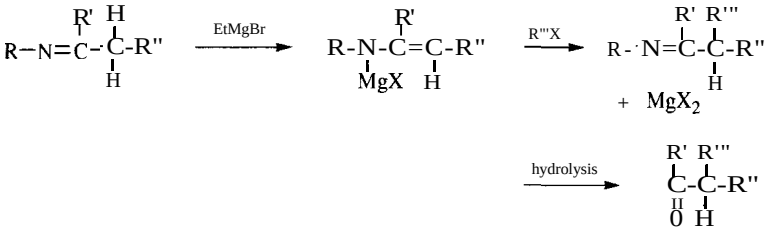


When enamines are treated with alkyl halides, an alkylation occurs that is analogous to the first step of **12-14.** Hydrolysis of the imine salt gives a ketone. Since the enamine is normally formed from a ketone **(16-12),** the net result is alkylation of the ketone at the a position. The method, known as the *Stork enamine reaction.*[223] is an alternative to the ketone alkylation considered at **10-105.** The Stork method has the advantage that it generally leads almost exclusively to monoalkylation of the ketone, while **10-105,** when applied to ketones, is difficult to stop with the introduction of just one alkyl group. Alkylation usually takes place on the less substituted side of the original ketone. The most commonly used amines are the cyclic amines piperidine, morpholine, and pyrrolidine.

The method is quite useful for particularly active alkyl halides such as allylic, benzylic, and propargylic halides, and for α-halo ethers and esters, but is not very serviceable for ordinary primary and secondary halides. Tertiary halides do not give the reaction at all since, with respect to the halide, this is nucleophilic substitution and elimination predominates. The reaction can also be applied to activated aryl halides (such as 2,4-dinitrochlorobenzene; see Chapter 13), to epoxides,[224] and to activated alkenes such as acrylonitrile. The latter is a Michael type reaction (p. 976) with respect to the alkene.

Acylation[225] can be accomplished with acyl halides or with anhydrides. Hydrolysis of the resulting iminium salt leads to a 1,3-diketone. A COOEt group can be introduced by treatment of the enamine with ethyl chloroformate (ClCOOEt),[226] a CN group with cyanogen chloride (not cyanogen bromide or iodide, which leads to halogenation of the enamine),[227] a CHO group with the mixed anhydride of formic and acetic acids[226] or with DMF and phosgene,[228] and a C(R)=NR′ group with a nitrilium salt ($RC{\equiv}N^{\oplus}R'$).[229] The acylation of the enamine can take place by the same mechanism as alkylation, but another mechanism is also possible, if the acyl halide has an a hydrogen and if a tertiary amine is present, as it often is (it is added to neutralize the HX given off). In this mechanism, the acyl halide is dehydrohalogenated by the tertiary amine, producing a ketene **(17-13),** which adds to the enamine to give a cyclobutanone **(15-61).** This compound can be cleaved in the solution to form the same acylated imine salt (27) that would form by the more direct mechanism, or it can be isolated (in the case of enamines derived from aldehydes), or it may cleave in other ways.[230]

Primary and secondary halides do not perform well, mostly because N-alkylation becomes important, particularly with enamines derived from aldehydes. An alternative method, which gives good yields of alkylation with primary and secondary halides, is alkylation of enamine *salts*, which are prepared by treating an imine with ethylmagnesium bromide in THF:[231]



The imines are prepared by **16-12.** The enamine salt method has also been used to give good yields of mono α alkylation of α,β-unsaturated ketones.[232] Enamines prepared from aldehydes and butylisobutylamine can be alkylated by simple primary alkyl halides in good yields.[233] N-alkylation in this case is presumably prevented by steric hindrance.

When the nitrogen of the substrate contains a chiral R group, both the Stork enamine synthesis and the enamine salt method can be used to perform enantioselective syntheses.[234]

Although not formally the enamine synthesis, reaction of an enamine with methyl bromoacetate in the presence of indium metal leads to α-alkylation: $R_2N{-}CH{=}CHR \rightarrow R_2N{-}CH(R')CHR$.[235]

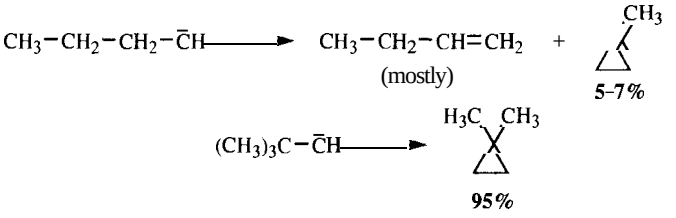
OS V, 533, 869; VI, 242, 496, 526; **VII,** 473.

12-19 *Insertion by Carbenes*

CH-METHYLENE-INSERTION

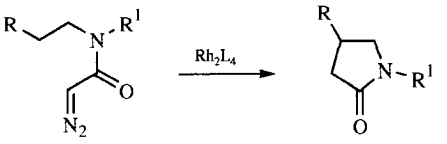
$$RH + \bar{C}H_2 \longrightarrow RCH_3$$

The highly reactive species methylene inserts into C—H bonds,[236] both aliphatic and aromatic,[237] though with aromatic compounds ring expansion is also possible (see 15-62). This version of the reaction is useless for synthetic purposes because of its nonselectivity (see p. 248). This contrasts with the metal carbene insertion reaction, which can be highly selective, and is very useful in synthesis.[238] Alkylcarbenes usually rearrange rather than give insertion (p. 249), but, when this is impossible,



intramolecular insertion[239] is found rather than intermolecular.[240] CH_2 generated by photolysis of CH_2N_2 in the liquid phase is indiscriminate—totally nonselective—in its reactivity (p. 248). The CH_2 group is generated in other ways and other carbenes are less reactive and insert in the order tertiary > secondary > primary.[241] Carbenes have been generated in the presence of ultrasound.[242] Halocarbenes insert much less readily, though a number of instances have been reported.[243] The insertion reaction has been used for synthetic purposes.[244] The carbenes can be generated in any of the ways mentioned in Chapter 5 (p. 247). For the similar insertion of nitrenes, see 12-12.

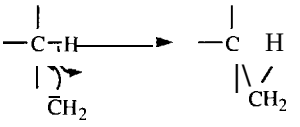
There are numerous examples of metal carbene insertion reactions, usually requiring a catalyst.[245] The C—H insertion reactions of metal carbenes can be highly selective.[246] Intramolecular insertion reactions are very versatile and tolerate a variety of functional groups.[247] A typical example is[248]



L = organic ligands

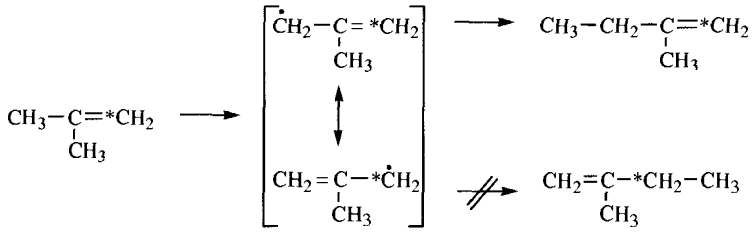
The mechanism[249] of the insertion reaction is not known with certainty, but there seem to be at least two possible pathways.

1. A simple one-step process involving a three-center cyclic transition state:



The most convincing evidence for this mechanism is that in the reaction between isobutene-1-^{14}C and carbene the product 2-methyl-1-butene was labeled only in the 1 position.[250] This rules out a free radical or other free

intermediate such as a carbocation or carbanion. If 24 (or a corresponding ion) were an intermediate, resonance would ensure that some carbene attacked at the 1 position:



24 Not found

Other evidence is that retention of configuration, which is predicted by this mechanism, has been found in a number of instances.[251] An ylid intermediate was trapped in the reaction of $:CH_2$ with allyl alcohol.[252]

2. A free-radical process in which the carbene directly abstracts a hydrogen from the substrate to generate a pair of free radicals:

$$RH + CH_2 \longrightarrow R\cdot + \cdot CH_3$$
$$R\cdot + \cdot CH_3 \longrightarrow RCH_3$$

One fact supporting this mechanism is that among the products obtained (beside butane and isobutane) on treatment of propane with CH_2 (generated by photolysis of diazomethane and ketene) were propene and ethane,[253] which could arise, respectively, by

$$2\ CH_3CH_2CH_2\cdot \longrightarrow CH_3CH{=}CH_2 + CH_3CH_2CH_3 \quad \text{(disproportionation)}$$

and

$$CH_3CH_2CH_3 + \bar{C}H_2 \longrightarrow CH_3CH_2CH_2\cdot + \cdot CH_3$$
$$2\,\dot{C}H_3 \longrightarrow CH_3CH_3$$

That this mechanism can take place under suitable conditions has been demonstrated by isotopic labeling[254] and by other means.[255] However, the formation of disproportionation and dimerization products does not always mean that the free-radical abstraction process takes place. In some cases these products arise in a different manner.[256] We have seen that the product of the reaction between a carbene and a molecule may have excess energy (p. 247). Therefore it is possible for the substrate and the carbene to react by mechanism 1 (the direct-insertion process) and for the excess energy to cause the compound thus formed to cleave to free radicals. When this pathway is in operation, the free radicals are formed *after* the actual insertion reaction.

The mechanism of cyclopropylcarbene reactions has also been discussed.[257]

It has been suggested[258] that singlet carbenes insert by the one-step direct-insertion process and triplets (which, being free radicals, are more likely to abstract hydrogen) by the free-radical process. In support of this suggestion is that CIDNP signals (p. 240)[259] were observed in the ethylbenzene produced from toluene and triplet CH_2, but not from the same reaction with singlet CH_2.[260] Carbenoids (e.g., compounds of the form R_2CMCl, see 12-37) can insert into a C—H bond by a different mechanism, similar to pathway 2, but involving abstraction of a hydride ion rather than a hydrogen atom.[261]

The reaction in which aldehydes are converted to methyl ketones, RCHO + $CH_2N_2 \rightarrow RCOCH_3$, while apparently similar, does not involve a free carbene intermediate. It is considered in Chapter 18 (18-9).

OS VII, 200.

F. *Metal Electrophiles*

12-20 *Metalation With Organometallic Compounds*

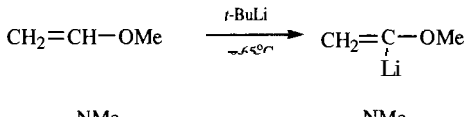
METALATION OR METALLO-DE-HYDROGENATION

$$RH + R'M \longrightarrow RM + R'H$$

Many organic compounds can be metalated by treatment with an organometallic compound.[262] Since the reaction involves a proton transfer, the equilibrium lies on the side of the weaker acid.[263] For example, fluorene reacts with butyllithium to give butane and 9-fluoryllithium. Since aromatic hydrocarbons are usually stronger acids than aliphatic ones, R is most often aryl. The most common reagent is butyllithium.[264] Normally, only active aromatic rings react with butyllithium. Benzene itself is not reactive enough, though benzene can be metalated by butyllithium either in the presence of *t*-BuOK[265] or coordinated with various diamines.[266] Metalation of aliphatic RH is most successful when the carbanions are stabilized by resonance (allylic, benzylic, propargylic,[267] etc.) or when the negative charge is at an *sp* carbon (at triple bonds). Very good reagents for allylic metalation are trimethylsilylmethyl potassium (Me_3SiCH_2K)[268] and a combination of an organolithium compound with a bulky alkoxide (LICKOR superbase).[269] The former is also useful for benzylic positions. A combination of BuLi, *t*-BuOK, and tetramethylethylenediamine has been used to convert ethylene to vinylpotassium.[270] In certain cases *gem*-dialkali metal or 1,1,1-trialkali metal compounds can be prepared.[271] Examples are the conversion of phenylacetonitrile to 1,1-dilithiophenylacetonitrile ($PhCLi_2CN$)[272] and propyne to tetralithiopropyne ($Li_3CC{\equiv}CLi$)[273] in each case by treatment with excess butyllithium. The reaction can be used to determine relative acidities of very weak acids by allowing two R—H compounds to compete for the same R'M and to determine which proton in a molecule is the most acidic.[274]

In general, the reaction can be performed only with organometallics of active metals such as lithium, sodium, and potassium, but Grignard reagents abstract protons from a sufficiently acidic C—H bond, as in $R{-}C{\equiv}C{-}H \rightarrow R{-}C{\equiv}C{-}MgX$. This method is best for the preparation of alkynyl Grignard reagents.[275]

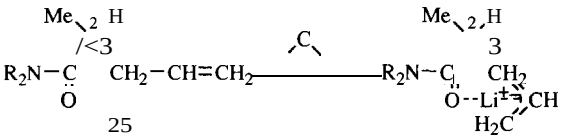
When a heteroatom, such as N, O, S,[276] or a halogen,[277] is present in a molecule containing an aromatic ring or a double bond, lithiation is usually quite regioselective.[278] The lithium usually bonds with the sp^2 carbon closest to the hetero atom, probably because the attacking species coordinates with the hetero atom.[279] Such reactions with compounds such as anisole are often called directed metalations.[280] In the case of aromatic rings, this means attack at the ortho position.[281] Two examples are



Ref 282

Ref. 283

In the second example, the lithium goes into the 2 position so as to be ortho to both substituents.[284] This regioselectivity can be quite valuable synthetically. In the case of γ,δ-unsaturated disubstituted amides (25), the lithium does not go to the closest position, but in this case too the regiochemistry is controlled by coordination to the

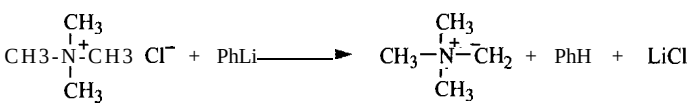


oxygen.[285] The 2 position is much more acidic than the 3 position (Table 8.1), but a negative charge at C-3 is in a more favorable position to be stabilized by the Li^+. Ortho magnesiation has been accomplished with bases of the form $(R_2N)_2Mg$.[286]

The mechanism involves a nucleophilic attack by R'^- (or a polar R') on the *hydrogen*.[287] Evidence is that resonance effects of substituents in R seem to make little difference. When R is aryl, OMe and CF_3 *both* direct ortho, while isopropyl directs meta and para (mostly meta).[288] These results are exactly what would be expected from pure field effects, with no contribution from resonance effects, which implies that attack occurs at the hydrogen and not at R. Other evidence for the involvement of H in the rate-determining step is that there are large isotope effects.[289] The nature of R' also has an effect on the rate. In the reaction between triphenylmethane and R'Li, the rate decreased in the order R' = allyl > Bu > Ph > vinyl > Me, though this order changed with changing concentration of R'Li, because of varying degrees of aggregation of the R'Li.[290]

With respect to the reagent, this reaction is a special case of 12-23.

A closely related reaction is formation of nitrogen ylids from quaternary ammonium salts (see 17-7):



Phosphonium salts undergo a similar reaction (see **16-47).**

OS II, 198; **HI,** 413, 757; **IV,** 792; **V,** 751; **VI,** 436, 478, 737, 979; **VII,** 172, 334, 456, 524; **VIII,** 19, 391, 396, 606.

12-21 *Metalation with Metals and Strong Bases*

METALATION OR METALLO-DE-HYDROGENATION

$$2\ RH + M \longrightarrow 2\ RM + H_2$$

Organic compounds can be metalated at suitably acidic positions by active metals and by strong bases.[291] The reaction has been used to study the acidities of very weak acids (see p. 228). The conversion of terminal alkynes to acetylid ions is one important application.[292] Synthetically, the most important use of the method is to convert aldehydes and ketones,[293] carboxylic esters, and similar compounds to their enolate forms,[294] for example, for use in nucleophilic substitutions (**10-104**, **10-105**,

$$CH_3-\underset{\underset{O}{\|}}{C}-CH_2-\underset{\underset{O}{\|}}{C}-OEt \xrightarrow{NaOEt} CH_3-\underset{\underset{O}{\|}}{C}-\overset{\ominus}{C}H-\underset{\underset{O}{\|}}{C}-OEt + HOEt$$

and **13-12)** and in additions to multiple bonds **(15-21** and **16-52).** It has been shown that lithiation with lithium amides can also be regioselective (see 12-20).[295] Lithium enolates exist as aggregates in solution.[296] For very weak acids, the most common reagents for synthetic purposes are lithium amides, especially LDA, which has the structure $(i\text{-Pr})_2NLi$.[297] The mechanism for this deprotonation reaction has been studied,[298] as has the rate of deprotonation.[299]

Mercuration of aromatic compounds[300] can be accomplished with mercuric salts, most often $Hg(OAc)_2$[301] to give ArHgOAc. This is ordinary electrophilic aromatic substitution and takes place by the arenium ion mechanism (p. 675).[302] Aromatic compounds can also be converted to arylthallium bis(trifluoroacetates), $ArTl(OOCCF_3)_2$, by treatment with thallium(III) trifluoroacetate[303] in trifluoroacetic acid.[304] These arylthallium compounds can be converted to phenols, aryl iodides or fluorides **(12-28),** aryl cyanides **(12-31),** aryl nitro compounds,[305] or aryl esters **(12-30).** The mechanism of thallation appears to be complex, with electrophilic and electron-transfer mechanisms both taking place.[306]

OS **I,** 70, 161, 490; **IV,** 473; **VI,** 468, 542, 611, 683, 709; **VII,** 229, 339. Conversions of ketones or esters to enolates are not listed.

12-22 *Conversion of Enolates to Silyl Enol Ethers*

3/O-TRIMETHYLSILYL-DE-HYDROGENATION

$$R-\underset{\underset{O}{\|}}{C}-\underset{\underset{H}{|}}{\overset{\overset{R'}{|}}{C}}-R'' \xrightarrow[\text{LDA}]{Me_2SiCl} R-C=\underset{\underset{OSiMe_3}{|}}{\overset{\overset{R'}{|}}{C}}-R''$$

Silyl enol ethers,[307] important reagents with a number of synthetic uses (see, e.g., **10-105, 12-4, 15-21, 15-62, 16-40),** can be prepared by base treatment of a ketone (converting it to its enolate) followed by addition of a trialkylchlorosilane. Other silylating agents have also been used.[308] Both strong bases (e.g., LDA), and weaker bases (e.g. Et_3N) have been used for this purpose. In some cases, the base and the silylating agent can be present at the same time.[309] Enolates prepared in other ways (e.g., as shown for **118** on p. 540) also give the reaction.[310] The reaction can be applied to aldehydes by the use of the base KH in 1,2-dimethoxyethane.[311] A particularly mild method for conversion of ketones or aldehydes to silyl enol ethers uses Me_3SiI and the base hexamethyldisilazane, $(Me_3Si)_2NH$.[312] Cyclic ketones can be converted to silyl enol ethers in the presence of acyclic ketones, by treatment with Me_3SiBr, tetraphenylstibonium bromide Ph_4SbBr, and an aziridine.[313]

Unsymmetrical ketones can give the more substituted (thermodynamic) silylenol ether or the less substituted (kinetic) product. Enolates formed using $LiNR_2$ in ether solvents at low temperatures tend to give the latter, and reaction with the silylating agent gives the kinetic product. Formation of the enolate anion in protic solvents with alkoxide bases at higher temperatures usually gives a significant amount of the thermodynamic enolate, that can be trapped with the silylating agent. Reaction with Me_3SiCl/KI in DMF also gives primarily the thermodynamic silyl enol ether.[314]

OS **VI,** 327, 445; **VII,** 282, 312, 424, 512; **VIII,** 1, 286, 460; **IX,** 573. See also OS **VII,** 66, 266. For the conversion of ketones to vinylic triflates.[315]

See OS **VIII**, 97, 126.

Metals as Leaving Groups

A. *Hydrogen as the Electrophile*

12-23 *Replacement of Metals by Hydrogen*

HYDRO-DE-METALATION OR DEMETALATION

$$RM + HA \longrightarrow RH + MA$$

Organometallic compounds, including enolates, react with acids in reactions in which the metal is replaced by hydrogen.[316] R may be aryl (see **11-44).** The reaction is often used to introduce deuterium or tritium into susceptible positions. For Grignard reagents, water is usually a strong enough acid, but stronger acids are also used. An important method for the reduction of alkyl halides consists of the process $RX \rightarrow RMgX \rightarrow RH$.

Other organometallic compounds that are hydrolyzed by water are those of sodium, potassium, lithium, zinc, and so on, the ones high in the electromotive series. Enantioselective protonation of lithium enolates[317] and cyclopropyllithium compounds[318] have been reported. When the metal is less active, stronger acids are required. For example, R_2Zn compounds react explosively with water, R_2Cd slowly, and R_2Hg not at all, though the latter can be cleaved with concentrated HC1. How-

ever, this general statement has many exceptions, some hard to explain. For example, BR_3 compounds are completely inert to water, and GaR_3 at room temperature cleave just one R group, but AlR_3 react violently with water. However, BR_3 can be converted to RH with carboxylic acids.[319] For less active metals it is often possible to cleave just one R group from a multivalent metal. For example,

$$R_2Hg + HCl \longrightarrow RH + RHgCl$$

Organometallic compounds of less active metals and metalloids, such as silicon,[320] antimony, bismuth, and so on, are quite inert to water. Organomercury compounds (RHgX or R_2Hg) can be reduced to RH by H_2, $NaBH_4$, or other reducing agents.[321] The reduction with $NaBH_4$ takes place by a free-radical mechanism.[322] Alkyl–silicon bonds can be cleaved by H_2SO_4, for example, $HOOCCH_2CH_2SiMe_3 \rightarrow 2\,CH_4 + (HOOCCH_2CH_2SiMe_2)_2O$.[323]

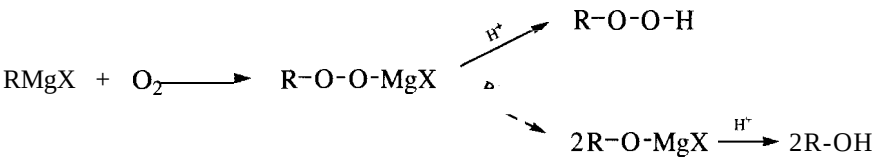
When the hydrogen of the HA is attached to carbon, this reaction is the same as 12-20.

We do not list the many hydrolyses of sodium or potassium enolates, and so on, found in *Organic Syntheses.* The hydrolysis of a Grignard reagent to give an alkane is found at OS II, 478; the reduction of a vinylic tin compound at OS VIII, 381; and the reduction of an alkynylsilane at OS VIII, 281.

B. *Oxygen Electrophiles*

12-24 *The Reaction between Organometallic Reagents and Oxygen*[324]

HYDROPEROXY-DE-METALATION; HYDROXY-DE-METALATION



Oxygen reacts with Grignard reagents to give either hydroperoxides or alcohols. The reaction can be used to convert alkyl halides to alcohols without side reactions. With aryl Grignard reagents yields are lower and only phenols are obtained, not hydroperoxides. It is because of the possibility of this reaction that oxygen should be excluded when Grignard reagents are desired for other purposes. A better procedure for the conversion of aryl Grignard reagents to phenols involves the use of trimethyl borate followed by oxidation with H_2O_2 in acetic acid (see 12-28).[325]

Most other organometallic compounds also react with oxygen. Aryllithium reagents have been converted to phenols by treatment with oxygen.[326] Trialkylboranes and alkyldichloroboranes ($RBCl_2$) can be conveniently converted to hydroperoxides by

treatment with oxygen followed by hydrolysis.[327] Dilithiated carboxylic acids (see **10-106)** react with oxygen to give (after hydrolysis) α-hydroxy carboxylic acids.[328] There is evidence that the reaction between Grignard reagents and oxygen involves a free-radical mechanism.[329]

The 1,1-dimetallic compounds, $R_2C(SnMe_3)ZnBr$, were oxidized by dry air at −10 to 0°C in the presence of Me_3SiCl to give aldehydes or ketones, $R_2C{=}O$.[330]

In a related indirect method, arylthallium bis(trifluoroacetates) (prepared by **12-21)** can be converted to phenols by treatment with lead tetraacetate followed by triphenylphosphine, and then dilute NaOH.[331] Diarylthallium trifluoroacetates undergo the same reaction.[332]

OS V, 918. See also OS **VIII,** 315.

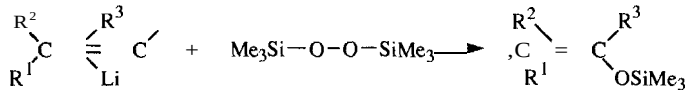
12-25 *Reaction between Organometallic Reagents and Peroxides*

TERT-BUTOXY-DE-METALATION

$$RMgX + t\text{-}Bu{-}O{-}O{-}\underset{\underset{O}{\|}}{C}{-}R' \longrightarrow R{-}O{-}t\text{-}Bu + R'COOMgX$$

A convenient method of preparation of *tert*-butyl ethers consists of treating Grignard reagents with *tert-butyl* acyl peroxides.[333] Both alkyl and aryl Grignard reagents can be used. The application of this reaction to Grignard reagents prepared from cyclopropyl halides permits cyclopropyl halides to be converted to tert-butyl ethers of cyclopropanols,[334] which can then be easily hydrolyzed to the cyclopropanols. The direct conversion of cyclopropyl halides to cyclopropanols by **10-1** is not generally feasible, because cyclopropyl halides do not generally undergo nucleophilic substitutions without ring opening.

Vinylic lithium reagents (26) react with silyl peroxides to give high yields of silyl enol ethers with retention of configuration.[335] Since the preparation of 26 from vinylic halides **(12-37)** also proceeds with retention, the overall procedure is a



26

method for the stereospecific conversion of a vinylic halide to a silyl enol ether. In a related reaction, alkynyl esters can be prepared from lithium acetylides and phenyliodine(III) dicarboxylates.[336]

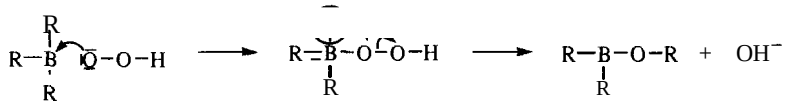
$$RC{=}CLi + PhI(O_2CR')_2 \longrightarrow RC{\equiv}C{-}O{-}\underset{\underset{O}{\|}}{C}{-}R'$$

OS V, 642, 924.

12-26 *Oxidation of Trialkylboranes to Borates*

$$R_3B \xrightarrow[NaOH]{H_2O_2} (RO)_3B \xrightarrow{3\ ROH} B(OH)_3$$

Treatment with alkaline H_2O_2 oxidizes trialkylboranes to esters of boric acid.[337] This reaction does not affect double or triple bonds, aldehydes, ketones, halides, or nitriles. The R group does not rearrange, and this reaction is a step in the hydroboration method of converting alkenes to alcohols (15-16). The mechanism has been formulated as involving a rearrangement from boron to oxygen:[337]



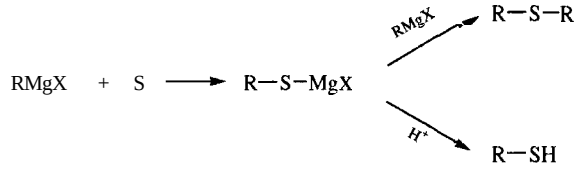
The other two R groups then similarly migrate. Retention of configuration is observed in R. Boranes can also be oxidized to borates in good yields with oxygen,[338] with sodium perborate ($NaBO_3$),[339] and with trimethylamine oxide, either anhydrous[340] or in the form of the dihydrate.[341] The reaction with oxygen is free radical in nature.[342]

OS V, 918; VI, 719, 852, 919.

C. *Sulfur Electrophiles*

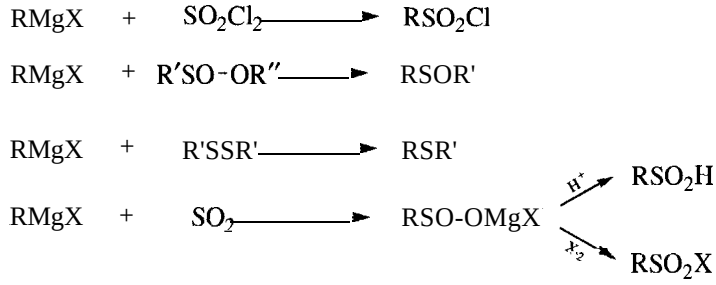
12-27 *Conversion of Grignard Reagents to Sulfur Compounds*

THIO-DE-DIMETALLO-AGGRE-SUBSTITUTION



MERCAPTO-DE-METALATION

Thiols and sulfides are occasionally prepared by treatment of Grignard reagents with sulfur.[343] Analogous reactions are known for selenium and tellurium compounds. Grignard reagents and other organometallic compounds[344] react with sulfuryl



chloride to give sulfonyl chlorides,[345] with esters of sulfinic acids to give (stereospecifically) sulfoxides,[346] with disulfides to give sulfides,[347] and with SO_2 to give

sulfinic acid salts,[348] which can be hydrolyzed to sulfinic acids or treated with halogens to give sulfonyl halides.[349]

OS **III,** 771; IV, 667; VI, 533, 979.

D. *Halogen Electrophiles*

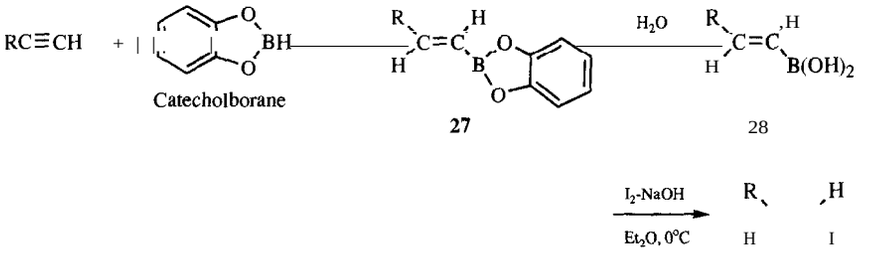
12-28 *Halo-de-metalation*

$$RMgX + I_2 \longrightarrow RI + MgIX$$

Grignard reagents react with halogens to give alkyl halides. The reaction is useful for the preparation of iodo compounds from the corresponding chloro or bromo compounds. The reaction is not useful for preparing chlorides, since the reagents RMgBr and RMgI react with Cl_2 to give mostly RBr and RI, respectively.[350]

Most organometallic compounds, both alkyl and aryl, also react with halogens to give alkyl or aryl halides.[351] The reaction can be used to convert acetylide ions to 1-haloalkynes.[352] Since acetylide ions are easily prepared from alkynes (12-21), this provides a means of making the conversion $RC{\equiv}CH \rightarrow RC{\equiv}CX$. Trialkylboranes react rapidly with I_2[353] or Br_2[354] in the presence of NaOMe in methanol, or with $FeCl_3$ or other reagents[355] to give alkyl iodides, bromides, or chlorides, respectively. Combined with the hydroboration reaction (15-16), this is an indirect way of adding HBr, HI, or HC1 to a double bond to give products with an anti-Markovnikov orientation (see **15-1).** Trialkylboranes can also be converted to alkyl iodides by treatment with allyl iodide and air in a free-radical process.[356]

trans-1-Alkenylboronic acids (**28**), prepared by hydroboration of terminal alkynes with catecholborane **(27)**[357] **(15-16)** followed by hydrolysis, react with I_2 in the presence of NaOH at 0°C in ethereal solvents to give trans vinylic iodides.[358] Treatment with IC1 also gives the vinyl iodide.[359] This is an indirect way of accomplishing the anti-Markovnikov addition of HI to a terminal triple bond. The



reaction cannot be applied to alkenylboronic acids prepared from internal alkynes. However, alkenylboronic acids prepared from both internal and terminal alkynes react with Br_2 (2 mol of Br_2 must be used) followed by base to give the corresponding vinylic bromide, but in this case with *inversion* of configuration; so the product is the cis vinylic bromide.[360] Alkenylboronic acids also give vinylic bromides and iodides when treated with a mild oxidizing agent and NaBr or NaI, respectively.[361] Treatment of 28 (prepared from terminal alkynes) with Cl_2 gave

vinylic chlorides with inversion.[362] Vinylic halides can also be prepared from vinylic silanes[363] and from vinylic copper reagents. The latter react with I_2 to give iodides,[364] and with NCS or NBS at −45°C to give chlorides or bromides.[365] Treatment of $PhB(OH)_2$ with *N*-iodosuccinimide gives iodobenzene.[366]

Aryl iodides[367] and fluorides can be prepared from arylthallium bis(trifluoroacetates) (see **12-21),** indirectly achieving the conversions ArH → ArI and ArH → ArF. The bis(trifluoroacetates) react with KI to give ArI in high yields.[368] Aryllead triacetates, $ArPb(OAc)_3$, can be converted to aryl fluorides by treatment with BF_3–etherate.[369]

For the reaction of lithium enolates of esters with I_2 or CX_4 see **12-5.**

It is unlikely that a single mechanism suffices to cover all conversions of organometallic compounds to alkyl halides.[370] In a number of cases the reaction has been shown to involve inversion of configuration (see p. 762), indicating an S_E2 (back) mechanism, while in other cases retention of configuration has been shown,[371] implicating an S_E2 (front) or S_Ei mechanism. In still other cases, complete loss of configuration as well as other evidence have demonstrated the presence of a free-radical mechanism.[372]

OS **I,** 125, 325, 326; **III,** 774, 813; V, 921; **VI,** 709; **VII,** 290; **VIII,** 586; **IX,** 573. Also see OS II, 150.

E. *Nitrogen Electrophiles*

12-29 *The Conversion of Organometallic Compounds to Amines*

AMINO-DE-METALATION

$$RLi \xrightarrow[MeLi]{CH_3ONH_2} RNH_2$$

There are several methods for conversion of alkyl- or aryllithium compounds to primary amines.[373] The two most important are treatment with hydroxylamine derivatives and with certain azides.[374] In the first of these methods, treatment of RLi with methoxyamine and MeLi in ether at − 78°C gives RNH_2.[375] Grignard reagents give lower yields. However, reaction of arylmagnesium halides with allyl azide ($CH_2{=}CHCH_2N_3$) followed by hydrolysis leads to the corresponding aniline derivative.[376] The reaction can be extended to give secondary amines by the use of N-substituted methoxyamines (CH3ONHR').[377] There is evidence[378] that the mechanism involves the direct displacement of OCH_3 by R on an intermediate CH_2ONR^{-} ($CH_3ONR'^{-}\ Li^+ + RLi \rightarrow CH_3OLi + RNR'^{-}Li^+$). The most useful azide is tosyl azide (TsN_3).[379] The initial product is usually RN_3, but this is easily reducible to the amine **(19-46).** With some azides, such as azidomethyl phenyl sulfide ($PhSCH_2N_3$), the group attached to the N_3 is a poor leaving group, so the initial product is a triazene (in this case $ArNHN{=}NCH_2SPh$ from ArMgX), which can be hydrolyzed to the amine.[380]

$$R_3B \xrightarrow{NH_3\text{-}NaOCl} 2\ RNH_2 + RB(OH)_2$$

Organoboranes react with a mixture of aqueous NH_3 and NaOCl to produce primary amines.[381] It is likely that the actual reagent is chloramine NH_2Cl. Chloramine itself,[382] hydroxylamine-O-sulfonic acid in diglyme,[383] and trimethylsilyl azide[384] also give the reaction. Since the boranes can be prepared by the hydroboration of alkenes (15-16), this is an indirect method for the addition of NH_3 to a double bond with anti-Markovnikov orientation. Secondary amines can be prepared[385] by the treatment of alkyl- or aryldichloroboranes or dialkylchloroboranes with alkyl or aryl azides.

$$RBCl_2 + R'N_3 \longrightarrow RR'NBCl_2 \xrightarrow[OH]{H_2O} RNHR'$$

$$R_2BCl + R'N_3 \xrightarrow[2.\ H_2O]{1.\ Et_2O} RNHR'$$

The use of an optically active R^*BCl_2 (where R* is a substituent boaring a chiral center) gave secondary amines of essentially 100% optical purity.[386] Aryllead triacetates, ArPb(OAc)3, give secondary amines, ArNHAr', when treated with primary aromatic amines, $Ar'NH_2$, and $Cu(OAc)_2$.[387]

Secondary amines have been converted to tertiary amines by treatment with lithium dialkylcuprate reagents: $R_2CuLi + NHR \rightarrow RNR_2'$.[388] The reaction was also used to convert primary amines to secondary, but yields were lower.[367] However, primary aromatic amines ($ArNH_2$) were converted to diaryl amines (ArNHPh) by treatment with $Ph_3Bi(OAc)_2$[389] and a copper powder catalyst.[390]

Molecular nitrogen (N_2) reacts with aryllithium compounds in the presence of compounds of such transition metals as titanium, chromium, molybdenum, or vanadium (e.g., $TiCl_4$) to give (after hydrolysis) primary aromatic amines.[391]

$$ArLi + N_2 \xrightarrow[2.\ H_2O]{1.\ MX_n} ArNH_2 + NH_3$$

OS VI, 943.

F. *Carbon Electrophiles*

12-30 *The Conversion of Organometallic Compounds to Ketones, Aldehydes, Carboxylic Esters, or Amides*

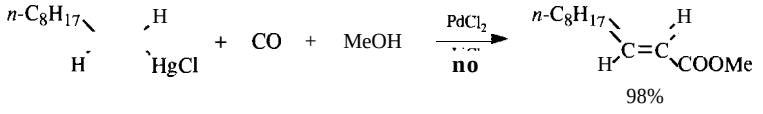
ACYL-DE-METALATION, AND SO ON

$$RHgX + Co_2(CO)_8 \xrightarrow{THF} R\text{-}\overset{\overset{O}{\|}}{C}\text{-}R$$

Symmetrical ketones[392] can be prepared in good yields by the reaction of organomercuric halides[393] with dicobalt octacarbonyl in THF,[394] or with nickel carbonyl in DMF or certain other solvents.[395] The R group may be aryl or alkyl. However, when R is alkyl, rearrangements may intervene in the $CO_2(CO)_8$ reaction, though the $Ni(CO)_4$ reaction seems to be free from such rearrangements.[395] Divinylic ketones

have been prepared in high yields by treatment of vinylic mercuric halides with CO and a rhodium catalyst.[396] When arylmercuric halides are treated with nickel carbonyl in the presence of Ar′I, unsymmetrical diaryl ketones can be obtained.[395] In a more general synthesis of unsymmetrical ketones, tetraalkyltin (R_4Sn) compounds are treated with a halide R'X (R' = aryl, vinylic, benzylic), CO, and a Pd complex catalyst.[397] Similar reactions use Grignard reagents, $Fe(CO)_5$, and an alkyl halide.[398] Aryl ketones can be prepared from aryltrimethylsilanes $ArSiMe_3$ and acyl chlorides in the presence of $AlCl_3$.[399]

Grignard reagents react with formic acid to give good yields of aldehydes. Two moles of RMgX are used; the first converts HCOOH to $HCOO^-$, which reacts with the second mole to give RCHO.[400] Aryllithium and Grignard reagents react with iron pentacarbonyl to give aldehydes ArCHO,[401] while alkyllithium reagents react with CO to give symmetrical ketones.[402] The reaction of CO with aryllithium may occur by electron transfer.[403] An interesting variation reacts CO_2 with an organolithium, which is then treated with a different organolithium reagent to give the unsymmetrical ketone.[404] α,β-Unsaturated aldehydes can be prepared by treatment of vinylic silanes with dichloromethyl methyl ether and $TiCl_4$ at −90°C.[405] α,β-Unsaturated esters can be prepared by treating boronic esters (27) with CO, $PdCl_2$, and NaOAc in MeOH.[406] The synthesis of α,β-unsaturated esters has also been accomplished by treatment of vinylic mercuric chlorides with CO at atmospheric pressure and a Pd catalyst in an alcohol as solvent, for example,[407]

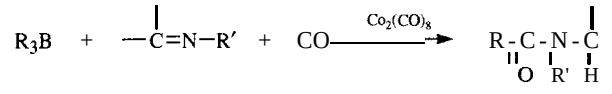


Arylthallium bis(trifluoroacetates) (see 12-21) can be carbonylated with CO, an alcohol, and a $PdCl_2$ catalyst to give esters:[408]

$$ArTl(OOCCF_3)_2 + ROH + CO \xrightarrow{PdCl_2} ArCOOR$$

Organomercury compounds undergo a similar reaction.[409] Alkyl and aryl Grignard reagents can be converted to carboxylic esters with $Fe(CO)_5$ instead of CO.[410]

Amides have been prepared by the treatment of trialkyl or triarylboranes with CO and an imine, in the presence of catalytic amounts of cobalt carbonyl:[411]



In another method for the conversion RM → RCONR′, Grignard reagents and organolithium compounds are treated with a formamide ($HCONR_2'$) to give the intermediate $RCH(OM)NR_2'$, which is not isolated, but treated with PhCHO or Ph_2CO to give the product $RCONR_2'$.[412]

A silica-supported palladium reagent has been used to convert iodobenzene to butyl benzoate, in the presence of CO and butanol.[413] Diaryl ketones can also be

prepared by coupling aryl iodides with $PhB(OH)_2$, in the presence of CO and a palladium catalyst.[414]

See also reactions **10-112, 15-27,** and **18-23-18-24.**

OS VIII, 97.

12-31 *Cyano-de-metalation*

$$ArTl(OOCCF_3)_2 + CuCN \longrightarrow ArCN$$

Arylthallium bis(trifluoroacetates) (see **12-21)** can be converted to aryl nitriles by treatment with copper(I) cyanide in acetonitrile.[415] Another procedure uses excess aqueous KCN followed by photolysis of the resulting complex ion $ArTl(CN)_3^-$ in the presence of excess KCN.[332] Alternatively, arylthallium acetates react with $Cu(CN)_2$ or CuCN to give aryl nitriles.[416] Yields from this procedure are variable, ranging from almost nothing to 90 or 100%.

Vinylic copper reagents react with C1CN to give vinyl cyanides, though BrCN and ICN give the vinylic halide instead.[417] Vinylic cyanides have also been prepared by the reaction between vinylic lithium compounds and phenyl cyanate PhOCN.[418] Alkyl cyanides (RCN) have been prepared, in varying yields, by treatment of sodium trialkylcyanoborates with NaCN and lead tetraacetate.[419] Vinyl bromides reacted with KCN, in the presence of a nickel complex and zinc metal to give the vinyl nitrile.[420] Vinyl inflates react with LiCN, in the presence of a palladium catalyst, to give the vinyl nitrile.[421]

For other electrophilic substitutions of the type RM → RC, see **10-93-10-117,** which are discussed under nucleophilic substitutions in Chapter 10. See also **16-67.**

OS **IX,** 548

G. *Metal Electrophiles*

12-32 *Transmetalation With a Metal*

METALO-DE-METALATION

$$RM + M' \rightleftharpoons RM' + M$$

Many organometallic compounds are best prepared by this reaction, which involves replacement of a metal in an organometallic compound by another metal. The compound RM' can be successfully prepared only when M' is above M in the electromotive series, unless some other way is found to shift the equilibrium. That is, RM is usually an unreactive compound and M' is a metal more active than M. Most often, RM is R_2Hg, since mercury alkyls[393] are easy to prepare and mercury is far down in the electromotive series.[422] Alkyls of Li, Na, K, Be, Mg, Al, Ga, Zn, Cd, Te, Sn, and so on have been prepared this way. An important advantage of this method over **12-36** is that it ensures that the organometallic compound will be prepared free of any possible halide. This method can be used for the isolation of solid sodium and potassium alkyls.[423] If the metals lie too close together in the series, it may not be

possible to shift the equilibrium. For example, alkylbismuth compounds cannot be prepared in this way from alkylmercury compounds.

OS V, 1116.

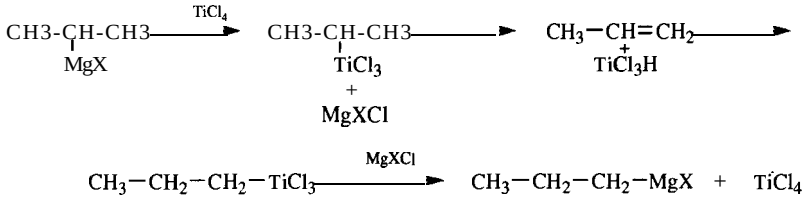
12-33 *Transmetalation With a Metal Halide*

METALLO-DE-METALATION

$$RM + M'X \rightleftharpoons RM' + MX$$

In contrast to 12-32, the reaction between an organometallic compound and a metal *halide* is successful only when M' is *below* M in the electromotive series.[424] The two reactions considered together therefore constitute a powerful tool for preparing all kinds of organometallic compounds. In this reaction the most common substrates are Grignard reagents and organolithium compounds.[425]

The MgX of Grignard reagents[426] can migrate to terminal positions in the presence of small amounts of $TiCl_4$.[427] The proposed mechanism consists of metal exchange (12-33), elimination-addition, and metal exchange:



The addition step is similar to 15-16 or 15-17 and follows Markovnikov's rule, so the positive titanium goes to the terminal carbon.

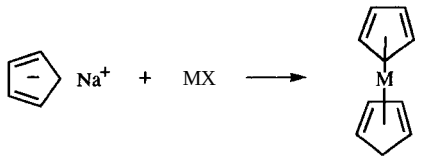
Among others, alkyls of Be, Zn,[428] Cd, Hg, Al, Sn, Pb, Co, Pt, and Au have been prepared by treatment of Grignard reagents with the appropriate halide.[429] The reaction has been used to prepare alkyls of almost all non-transition metals and even of some transition metals. Alkyls of metalloids and of nonmetals, including Si, B,[430] Ge, P, As, Sb, and Bi, can also be prepared in this manner.[431] Except for alkali metal alkyls and Grignard reagents, the reaction between RM and M'X is the most common method for the preparation of organometallic compounds.[432]

Lithium dialkylcopper reagents can be prepared by mixing 2 mol of RLi with 1 mol of a cuprous halide in ether at low temperatures:[433]

$$2\ RLi + CuX \longrightarrow R_2CuLi + LiX$$

Another way is to dissolve an alkylcopper compound in an alkyllithium solution. Higher order cuprates can also be prepared, as well as "non-ate" copper reagents.[434]

Metallocenes (see p. 53) are usually made by this method:



Among others, metallocenes of Sc, Ti, V, Cr, Mn, Fe, Co, and Ni have been prepared in this manner.[435]

Metal nitrates are sometimes used instead of halides.

OS I, 231, 550; **III,** 601; IV, 258, 473, 881; V, 211, 496, 727, 918, 1001; VI, 776, 875, 1033; **VII,** 236, 290, 524; **VIII,** 23, 57, 268, 474, 586, 606, 609. Also see OS IV, 476

12-34 *Transmetalation With an Organometallic Compound*

METALLO-DE-METALATION

$$RM + R'M' \rightleftharpoons RM' + R'M$$

This type of metallic exchange is used much less often than **12-32** and **12-33.** It is an equilibrium reaction and is useful only if the equilibrium lies in the desired direction. Usually the goal is to prepare a lithium compound that is not prepared easily in other ways,[436] for example, a vinylic or an allylic lithium, most commonly from an organotin substrate. Examples are the preparation of vinyllithium from phenyllithium and tetravinyltin and the formation of α-dialkylamino organolithium compounds from the corresponding organotin compounds[437]

$$RR'NCH_2SnBu_3 + BuLi \xrightarrow{0°C} RR'NCH_2Li + Bu_4Sn$$

The reaction has also been used to prepare 1,3-dilithiopropanes[438] and 1,1-dilithiomethylenecyclohexane[439] from the corresponding mercury compounds. In general, the equilibrium lies in the direction in which the more electropositive metal is bonded to that alkyl or aryl group that is the more stable carbanion (p. 228). The reaction proceeds with retention of configuration;[440] an S_Ei mechanism is likely.[441]

"Higher order" cuprates (see Ref. 1277 in Chapter 10) have been produced by this reaction starting with a vinylic tin compound:[442]

$$RSnR'_3 + Me_2Cu(CN)Li_2 \longrightarrow RCuMe(CN)Li_2 + MeSnR'_3$$

R = a vinylic group

These compounds are not isolated, but used directly *in situ* for conjugate addition reactions **(15-24).** Another method for the preparation of such reagents (but with Zn instead of Li) allows them to be made from α-acetoxy halides:[443]

$$R{-}\underset{\underset{OAc}{|}}{CH}{-}Br \xrightarrow[2.\ CuCN{\cdot}2\ LiCl]{1.\ Zn\ dust,\ THF,\ Me_2SO} R{-}\underset{\underset{OAc}{|}}{CH}{-}Cu(CN)ZnBr$$

OS **V,** 452; **VI,** 815; **VIII, 97.**

Halogen as Leaving Group

A. *Hydrogen as the Electrophile*

12-35 *Reduction of Alkyl Halides*

Although this reaction can proceed by an electrophilic substitution mechanism, it is considered in Chapter 10 **(10-79).**

B. *Metal* ***Electrophiles***

12-36 *Metallo-de-halogenation*

$$RX + M \longrightarrow RM$$

Alkyl halides react directly with certain metals to give organometallic compounds.[444] The most common metal is magnesium, and, of course, this is by far the most common method for the preparation of Grignard reagents.[445] The order of halide activity is I > Br > Cl. The reaction can be applied to many alkyl halides primary, secondary, and tertiary and to aryl halides, though aryl *chlorides* require the use of THF or another higher boiling solvent instead of the usual ether, or special entrainment methods.[446] Aryl iodides and bromides can be treated in the usual manner. Allylic Grignard reagents can also be prepared in the usual manner (or in THF),[447] though in the presence of excess halide these may give Wurtz-type coupling products (see **10-94**).[448] Like aryl chlorides, vinylic halides require higher boiling solvents (see OS IV, 258). A good procedure for benzylic and allylic halides is to use magnesium anthracene (prepared from Mg and anthracene in THF)[449] instead of ordinary magnesium,[450] though activated magnesium turnings have also been used.[451] Alkynyl Grignard reagents are not generally prepared by this method at all. For these, **12-20** is used.

Dihalides[452] can be converted to Grignard reagents if the halogens are different and are at least three carbons apart. If the halogens are the same, it is possible to obtain dimagnesium compounds, for example, $BrMg(CH_2)_4MgBr$.[453] 1,2-Dihalides give elimination[454] instead of Grignard reagent formation **(17-22),** and the reaction is seldom successful with 1,1-dihalides, though the preparation of *gem-di* substituted compounds, such as $CH_2(MgBr)_2$, has been accomplished with these substrates.[455] α-Halo Grignard reagents and α-halolithium reagents can be prepared by the method given in 12-37.[456] Alkylmagnesium fluorides can be prepared by refluxing alkyl fluorides with Mg in the presence of appropriate catalysts (e.g., I_2 or EtBr) in THF for several days.[457]

The presence of other functional groups in the halide usually affects the preparation of the Grignard reagent. Groups that contain active hydrogen (defined as any hydrogen that will react with a Grignard reagent), such as OH, NH_2, and COOH, can be present in the molecule, but only if they are converted to the salt form (O^-, NH^-, COO^-, respectively). Groups that react with Grignard reagents, such as $C{=}O$, $C{\equiv}N$, NO_2, COOR, and so on, inhibit Grignard formation entirely. In general, the only functional groups that may be present in the halide molecule without any interference at all are double and triple bonds (except terminal triple bonds) and OR and NR_2 groups. However, β-halo ethers generally give (3 elimination when treated with magnesium (see **17-24),** and Grignard reagents from α-halo ethers[458] can only be formed in THF or dimethoxymethane at a low temperature, for example,[459]

$$EtOCH_2Cl + Mg \xrightarrow[-30^\circ C]{THF \text{ or } CH_2(OMe)_2} EtOCH_2MgCl$$

because such reagents immediately undergo a elimination (see 12-37) at room temperature in ether solution.

Because Grignard reagents react with water (12-23) and with oxygen (12-24), it is generally best to prepare them in an anhydrous nitrogen atmosphere. Grignard reagents are generally neither isolated nor stored; solutions of Grignard reagents are used directly for the required synthesis. Grignard reagents can also be prepared in benzene or toluene, if a tertiary amine is added to complex with the RMgX.[460] This method eliminates the need for an ether solvent. With certain primary alkyl halides it is even possible to prepare alkylmagnesium compounds in hydrocarbon solvents in the absence of an organic base.[461] It is also possible to obtain Grignard reagents in powdered form, by complexing them with the chelating agent tris(3,6-dioxaheptyl)amine, $N(CH_2CH_2OCH_2CH_2OCH_3)_3$.[462]

Next to the formation of Grignard reagents, the most important application of this reaction is the conversion of alkyl and aryl halides to organolithium compounds,[463] but it has also been carried out with many other metals, (e.g., Na, Be, Zn, Hg, As, Sb, and Sn). With sodium, the Wurtz reaction (10-93) is an important side reaction. In some cases, where the reaction between a halide and a metal is too slow, an alloy of the metal with potassium or sodium can be used instead. The most important example is the preparation of tetraethyl lead from ethyl bromide and a Pb–Na alloy.

The efficiency of the reaction can often be improved by use of the metal in its powdered[464] or vapor[465] form. These techniques have permitted the preparation of some organometallic compounds that cannot be prepared by the standard procedures. Among the metals produced in an activated form are Mg,[466] Ca,[467] Zn,[468] Al, Sn, Cd,[469] Ni, Fe, Ti, Cu,[470] Pd, and Pt.[471]

The mechanism of Grignard reagent formation involves free radicals,[472] and there is much evidence for this, from CIDNP (p. 240)[473] and from stereochemical, rate, and product studies.[474] Further evidence is that free radicals have been trapped,[475] and that experiments that studied the intrinsic reactivity of MeBr on a magnesium single-crystal surface showed that Grignard reagent formation does not take place by a single-step insertion mechanism.[476] The following SET mechanism has been proposed:[473]

$$\mathrm{R\text{-}X + \bar{M}g \longrightarrow R{-}X^{\bullet -} + Mg_s^{\bullet +}}$$

$$\mathrm{R{-}X^{\bullet -} \longrightarrow R^{\bullet} + X^{-}}$$

$$\mathrm{X^{-} + Mg_s^{\bullet +} \longrightarrow XMg_s^{\bullet}}$$

$$\mathrm{R^{\bullet} + XMg_s^{\bullet} \longrightarrow RMgX}$$

The species $R{-}X^{-\cdot}$ and $Mg^{+\cdot}$ are radical ions.[477] The subscript "s" is meant to indicate that the species so marked are bound to the surface of the magnesium. Its is known that this is a surface reaction.[478] It has been suggested that some of the R· radicals diffuse from the magnesium surface into the solution and then return to the surface to react with the XMg·. There is evidence both for[479] and against[480] this suggestion. Another proposal is that the fourth step is not the one shown here, but

that the $R\cdot$ is reduced by Mg^+ to the carbanion R^-, which combines with MgX^+ to give RMgX.[481]

There are too many preparations of Grignard reagents in *Organic Syntheses* for us to list here. Use of the reaction to prepare other organometallic compounds can be found in OS I, 228; II, 184, 517, 607; III, 413, 757; VI, 240; VII, 346; VIII, 505. The preparation of unsolvated butylmagnesium bromide is described at OS V, 1141. The preparation of highly reactive (powdered) magnesium is given at OS VI, 845.

12-37 *Replacement of a Halogen by a Metal from an Organometallic Compound*

METALLO-DE-HALOGENATION

$$RX + R'M \longrightarrow RM + R'X$$

The exchange reaction between halides and organometallic compounds is almost entirely limited to the cases where M is lithium and X is bromide or iodide,[482] though it has been shown to occur with magnesium.[483] The R' group is usually, though not always, alkyl, and often butyl; R is usually aromatic.[484] Alkyl halides are generally not reactive enough, while allylic and benzylic halides usually give Wurtz coupling. Of course, the R that becomes bonded to the halogen is the one for which RH is the weaker acid. Vinylic halides react with retention of configuration.[485] The reaction can be used to prepare α-halo organolithium and α-halo organomagnesium compounds,[486] for example,[487]

$$CCl_4 + BuLi \xrightarrow[105°C]{THF} Cl_2C{-}Li$$

Such compounds can also be prepared by hydrogen-metal exchange, for example,[488]

$$BR_3CH + i\text{-}PrMgCl \xrightarrow[-95°C]{THF\text{-}HMPA} Br_3C{-}MgCl + C_3H_8$$

This is an example of 12-20. However, these α-halo organometallic compounds are stable (and configurationally stable as well[489]) only at low temperatures ($\approx -100°C$) and only in THF or mixtures of THF and other solvents (e.g., HMPA). At ordinary temperatures they lose MX (a elimination) to give carbenes (which then react further) or carbenoid reactions. The α-chloro-α-magnesio sulfones, $ArSO_2CH(Cl)MgBr$, are exceptions, being stable in solution at room temperature and even under reflux.[490] Compounds in which a halogen and a transition metal are on the same carbon can be more stable than the ones with lithium.[491]

There is evidence that the mechanism[492] of the reaction of alkyllithium compounds with alkyl and aryl iodides involves free radicals.[493]

$$RX + R'M \rightleftharpoons \underbrace{[R\cdot, X, M, R'\cdot]}_{\text{Solvent cage}} \rightleftharpoons RM + R'X$$

Among the evidence is the fact that coupling and disproportionation products are obtained from R· and R′· and the observation of CIDNP.[494] However, in the degenerate exchange between PhI and PhLi the ate complex $Ph_2I^-\ Li^+$ has been shown to be an intermediate,[495] and there is other evidence that radicals are not involved in all instances of this reaction.[496]

In a completely different kind of process, alkyl halides can be converted to certain organometallic compounds by treatment with organometallate ions, for example,

$$RX + R'_3SnLi \longrightarrow RSnR'_3 + LiX$$

Most of the evidence is in accord with a free-radical mechanism involving electron transfer, though an S_N2 mechanism can compete under some conditions.[497]

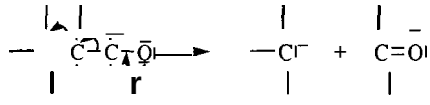
OS **VI,** 82; **VII,** 271, 326, 495; **VIII,** 430. See also OS **VII,** 512; **VIII,** 479.

Carbon Leaving Groups

In these reactions **(12-38-12-46)** a carbon-carbon bond cleaves. We regard as the substrate that side that retains the electron pair; hence the reactions are considered electrophilic substitutions. The incoming group is hydrogen in all but one **(12-40)** of the cases. The reactions in groups A and B are sometimes called *anionic cleavages*,[498] though they do not always occur by mechanisms involving free carbanions (S_E1). When they do, the reactions are facilitated by increasing stability of the carbanion.

A. *Carbonyl-Forming Cleavages*

These reactions follow the pattern



The leaving group is stabilized because the electron deficiency at its carbon is satisfied by a pair of electrons from the oxygen. With respect to the leaving group the reaction is elimination to form a C=O bond. Retrograde aldol reactions **(16-38)** and cleavage of cyanohydrins **(16-51)** belong to this classification but are treated in Chapter 16 under their more important reverse reactions. Other eliminations to form C=O bonds are discussed in Chapter 17 **(17-34).**

12-38 *Decarboxylation of Aliphatic Acids*

HYDRO-DE-CARBOXYLATION

$$RCOOH \longrightarrow RH + CO_2$$

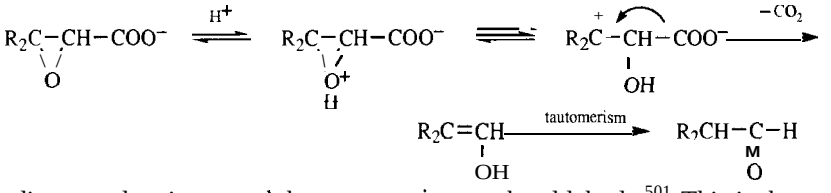
Many carboxylic acids can be successfully decarboxylated, either as the free acid or in the salt form, but not simple fatty acids.[499] An exception is acetic acid, which as

TABLE **12.2** Some **Acids that Undergo Decarboxylation Fairly Readily**"

	Acid Type	Decarboxylation Product
Malonic	HOOC−C(H)(−)−COOH	HOOC−C(H)(−)−H
α-Cyano	NC−C(H)(−)−COOH	NC-C(H)(−)-H or HOOC-C(H)(−)-H
α-Nitro	O_2N−C(H)(−)−COOH	O_2N−C(H)(−)−H
α-Aryl	Ar−C(H)(−)−COOH	Ar-C(H)(−)-H
α,α,α-Trihalo	X3C-COOH	X_3C−H
β-Keto	−C(=O)−C(H)(−)−COOH	−C(=O)−C(H)(−)−H
β,γ-Unsaturated	−C=C−C(H)(−)−COOH	−C=C−C(H)(−)−H

"Other are described in the text.

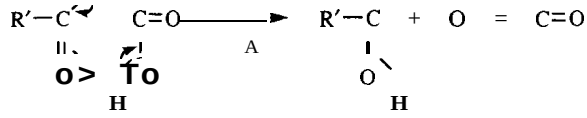
the acetate, heated with base, gives good yields of methane. Aliphatic acids that do undergo successful decarboxylation have certain functional groups or double or triple bonds in the α or (3 position. Some of these are shown in Table 12.2. For decarboxylation of aromatic acids, see 11-38. Decarboxylation of an α-cyano acid can give a nitrile or a carboxylic acid, since the cyano group may or may not be hydrolyzed in the course of the reaction. In addition to the compounds listed in Table 12.2, decarboxylation can also be carried out on α,β-unsaturated and α,β-acetylenic acids. α,β-Unsaturated acids can also be decarboxylated with copper and quinoline in a manner similar to that discussed in 11-38. Glycidic acids give aldehydes on decarboxylation. The following mechanism has been suggested:[500]



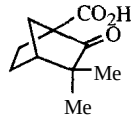
The direct product is an enol that tautomerizes to the aldehyde.[501] This is the usual last step in the Darzens reaction (16-45).

Decarboxylations can be regarded as reversals of the addition of carbanions to carbon dioxide (16-33), but free carbanions are not always involved.[502] When the carboxylate *ion* is decarboxylated, the mechanism can be either S_E1 or S_E2. In the

case of the S_E1 mechanism, the reaction is of course aided by the presence of electron-withdrawing groups, which stabilize the carbanion.[503] Decarboxylations of carboxylate ions can be accelerated by the addition of a suitable crown ether, which in effect removes the metallic ion.[504] The reaction without the metallic ion has also been performed in the gas phase.[505] But some acids can also be decarboxylated directly and, in most of these cases, there is a cyclic, six-center mechanism:

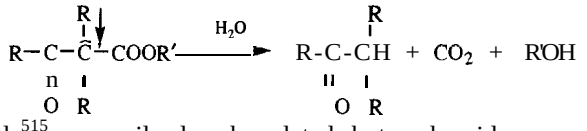


Here too there is an enol that tautomerizes to the product. The mechanism is illustrated for the case of (3-keto acids,[506] but it is likely that malonic acids, α-cyano acids, α-nitro acids, and β,γ-unsaturated acids[507] behave similarly, since similar six-membered transition states can be written for them. Some α,β-unsaturated acids are also decarboxylated by this mechanism by isomerizing to the p,y-isomers before



29

they actually decarboxylate.[508] Evidence is that 29 and similar bicyclic P-keto acids resist decarboxylation.[509] In such compounds, the six-membered cyclic transition state cannot form for steric reasons, and if it could, formation of the intermediate enol would violate Bredt's rule (p. 188).[510] Some carboxylic acids that cannot form a six-membered transition state can still be decarboxylated, and these presumably react through an S_E1 or S_E2 mechanism.[511] Further evidence for the cyclic mechanism is that the reaction rate varies very little with a change from a nonpolar to a polar solvent (even from benzene to water[512]), and is not subject to acid catalysis.[513] The rate of decarboxylation of a p,y-unsaturated acid was increased $\sim 10^5$–10^6 times by introduction of a p-methoxy group, indicating that the cyclic transition state has dipolar character.[514]



(3-Keto acids[515] are easily decarboxylated, but such acids are usually prepared from P-keto esters, and the esters are easily decarboxylated themselves on hydrolysis without isolation of the acids.[516] This decarboxylation of p-keto esters involving cleavage on the carboxyl side of the substituted methylene group (arrow) is carried out under acidic, neutral, or slightly basic conditions to yield a ketone. When strongly basic conditions are used, cleavage occurs on the other side of the CR_2 group (12-41). (3-Keto esters can be decarbalkoxylated without passing through the

free-acid stage by treatment with boric anhydride B_2O_3 at 150°C.[517] The alkyl portion of the ester (R') is converted to an alkene or, if it lacks a (3 hydrogen, to an ether R'OR'. Another method for the decarbalkoxylation of (3-keto esters, malonic esters, and α-cyano esters consists of heating the substrate in wet DMSO containing NaCl, Na_3PO_4, or some other simple salt.[518] In this method too, the free acid is probably not an intermediate, but here the alkyl portion of the substrate is converted to the corresponding alcohol. Ordinary carboxylic acids, containing no activating groups, can be decarboxylated by conversion to esters of *N*-hydroxypyridine-2-thione and treatment of these with Bu_3SnH.[519] A free-radical mechanism is likely. α-Amino acids have been decarboxylated by treatment with a catalytic amount of 2-cyclohexenone.[520] Certain decarboxylations can also be accomplished photochemically.[521] See also the decarbonylation of acyl halides, mentioned in **14-39.** In some cases, decarboxylations can give organometallic compounds: RCOOM → RM + CO_2.[522]

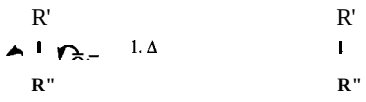
Some of the decarboxylations listed in *Organic Syntheses* are performed with concomitant ester or nitrile hydrolysis and others are simple decarboxylations.

With ester or nitrile hydrolysis: OS **I,** 290, 451, 523; **II,** 200, 391; **III,** 281, 286, 313, 326, 510, 513, 591; **IV,** 55, 93, 176, 441, 664, 708, 790, 804; **V,** 76, 288, 572, 687, 989; **VI,** 615, 781, 873, 932; **VII,** 50, 210, 319; **VIII,** 263.

Simple decarboxylations: OS **I,** 351, 401, 440, 473, 475; **II,** 21, 61, 93, 229, 302, 333, 368, 416, 474, 512, 523; **III,** 213, 425, 495, 705, 733, 783; **IV,** 234, 254, 278, 337, 555, 560, 597, 630, 731, 857; V, 251, 585; **VI,** 271, 965; **VII,** 249, 359; **VIII,** 235, 444, 536; 75, 195. Also see OS IV, 633.

12-39 *Cleavage of Alkoxides*

HYDRO-DE-(α-OXIDOALKYL)-SUBSTITUTION



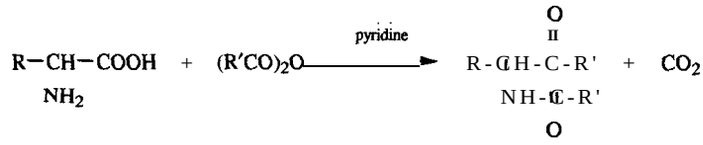
Alkoxides of tertiary alcohols can be cleaved in a reaction that is essentially the reverse of addition of carbanions to ketones (16-27).[523] The reaction is unsuccessful when the R groups are simple unbranched alkyl groups (e.g., the alkoxide of triethylcarbinol). Cleavage is accomplished with branched alkoxides such as the alkoxides of diisopropylneopentylcarbinol or tri-*tert*-butylcarbinol.[524] Allylic,[525] benzylic,[526] and aryl groups also cleave; for example, the alkoxide of triphenylcarbinol gives benzene and benzophenone. Studies in the gas phase show that the cleavage is a simple one, giving the carbanion and ketone directly in one step.[527] However, with some substrates in solution, substantial amounts of dimer R—R have been found, indicating a radical pathway.[528] Hindered alcohols (not the alkoxides) also lose one R group by cleavage, also by a radical pathway.[529]

The reaction has been used for extensive mechanistic studies (see p. 764).

OS **VI,** 268.

12-40 *Replacement of a Carboxyl Group by an Acyl Group*

ACYL-DE-CARBOXYLATION

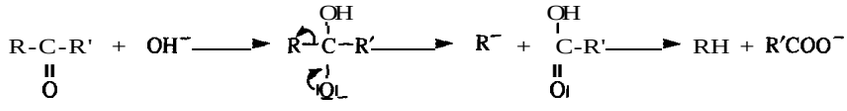


When an α-amino acid is treated with an anhydride in the presence of pyridine, the carboxyl group is replaced by an acyl group and the NH_2 becomes acylated. This is called the *Dakin-West reaction.*[530] The mechanism involves formation of an oxazolone.[531] The reaction sometimes takes place on carboxylic acids even when an amino group is not present. A number of N-substituted amino acids, RCH(NHR')COOH, give the corresponding N-alkylated products.

OS IV, 5; V, 27.

B. *Acyl Cleavages*

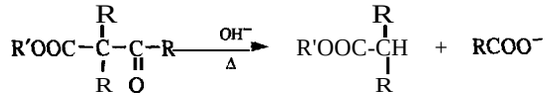
In these reactions (12-41-12-44), a carbonyl group is attacked by a hydroxide ion (or amide ion) giving an intermediate that undergoes cleavage to a carboxylic acid (or an amide). With respect to the leaving group, this is nucleophilic substitution at a carbonyl group and the mechanism is the tetrahedral one discussed in Chapter 10.



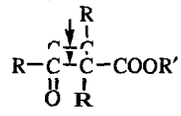
With respect to R this is of course electrophilic substitution. The mechanism is usually S_E1.

12-41 *Basic Cleavage of* P-Keto Esters and P-Diketones

HYDRO-DE-ACYLATION

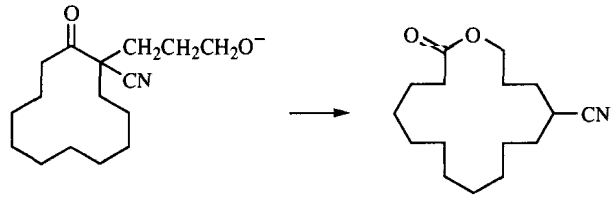


When P-keto esters are treated with concentrated base, cleavage occurs, but is on the keto side of the CR_2 group (arrow) in contrast to the acid cleavage mentioned on page 810. The products are a carboxylic ester and the salt of an acid. However, the



utility of the reaction is somewhat limited by the fact that decarboxylation is a side reaction, even under basic conditions. P-Diketones behave similarly to give a ketone and the salt of a carboxylic acid. With both p-keto esters and p-diketones, OEt^- can be used instead of OH^-, in which case the ethyl esters of the corresponding acids are

obtained instead of the salts. In the case of |3-keto esters, this is the reverse of Claisen condensation (**10-118**). The similar cleavage of cyclic α-cyano ketones, in an intramolecular fashion, has been used to effect a synthesis of macrocyclic lactones, for example,[532]



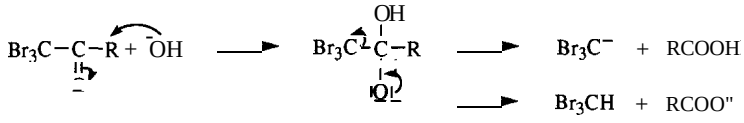
Activated F^- (from KF and a crown ether) has been used as the base to cleave an α-cyano ketone.[533]

OS **II,** 266, 531; **III,** 379; IV, 415, 957; V, 179, 187, 277, 533, 747, 767.

12-42 *Haloform Reaction*

$$CH_3-\underset{\underset{O}{\|}}{C}-R \xrightarrow[OH^-]{Br_2} HCBr_3 + RCOO^-$$

In the *haloform reaction,* methyl ketones (and the only methyl aldehyde, acetaldehyde) are cleaved with halogen and a base.[534] The halogen can be bromine, chlorine, or iodine. What takes place is actually a combination of two reactions. The first is an example of 12-4, in which, under the basic conditions employed, the methyl group is trihalogenated. Then the resulting trihalo ketone is attacked by hydroxide ion:[535]

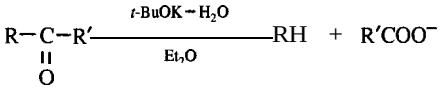


Primary or secondary methylcarbinols also give the reaction, because they are oxidized to the carbonyl compounds under the conditions employed. As with 12-4, the rate-determining step is the preliminary enolization of the methyl ketone.[536] A side reaction is α halogenation of the non-methyl R group. Sometimes these groups are also cleaved.[537] The reaction cannot be applied to F_2, but ketones of the form $RCOCF_3$ (R = alkyl or aryl) give fluoroform and RCOO when treated with base.[538] Rate constants for cleavage of X_3CCOPh (X = F, Cl, Br) were found to be in the ratio 1:5.3 x 10^{10}: 2.2 x 10^{13}, showing that an F_3C^- group cleaves much more slowly than the others.[539] The haloform reaction is often used as a test for methylcarbinols and methyl ketones. Iodine is most often used as the test reagent, since iodoform is an easily identifiable yellow solid. The reaction is also frequently used for synthetic purposes. Methyl ketones ($RCOCH_3$) can be converted directly to methyl esters ($RCOOCH_3$) by an electrochemical reaction.[540] Trifluoromethyl ketones have been converted to ethyl esters via treatment with NaH in aqueous DMF followed by reaction with bromoethane.[541]

OS I, 526; **II,** 428; **III,** 302; IV, 345; V, 8. Also see OS VI, 618.

12-43 *Cleavage of Non-enolizable Ketones*

HYDRO-DE-ACYLATION

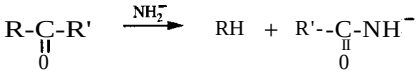


Ordinary ketones are generally much more difficult to cleave than trihalo ketones or p-diketones, because the carbanion intermediates in these cases are more stable than simple carbanions. However, nonenolizable ketones can be cleaved by treatment with a 10:3 mixture of *t*-BuOK–H_2O in an aprotic solvent such as ether, dimethyl sulfoxide, 1,2-dimethoxyethane (glyme), and so on,[542] or with solid *t*-BuOK in the absence of a solvent.[543] When the reaction is applied to mono substituted diaryl ketones, that aryl group preferentially cleaves that comes off as the more stable carbanion, except that aryl groups substituted in the ortho position are more readily cleaved than otherwise because of the steric effect (relief of stain).[544] In certain cases, cyclic ketones can be cleaved by base treatment, even if they are enolizable.[545]

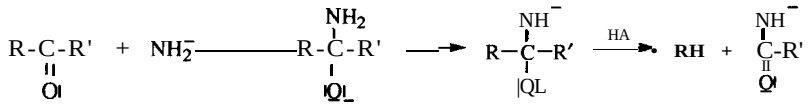
OS VI, 625. See also OS **VII,** 297.

12-44 *The Haller–Bauer Reaction*

HYDRO-DE-ACYLATION



Cleavage of ketones with sodium amide is called the *Haller-Bauer reaction.*[546] As with **12-43,** which is exactly analogous, the reaction is usually applied only to nonenolizable ketones, most often to ketones of the form $ArCOCR_3$, where the products R3CCONH2 are not easily attainable by other methods. However, many other ketones have been used, though benzophenone is virtually unaffected. It has been shown that the configuration of optically active alkyl groups (R) is retained.[547] The NH_2 loses its proton before the R group is cleaved:[548]



OS V, 384, 1074.

C. *Other Cleavages*

12-45 *The Cleavage of Alkanes*

HYDRO-DE-TERT-BUTYLATION, AND SO ON

The C–C bonds of alkanes can be cleaved by treatment with superacids[47] (p. 219). For example, neopentane in FSO_3H–SbF_5 can cleave to give methane and the *tert*-butyl cation. The C–H cleavage (see 12-1) is a competing reaction and, for example, neopentane can give H_2 and the *tert*-pentyl cation (formed by rearrangement of the initially formed neopentyl cation) by this pathway. In general, the order of reactivity is tertiary C–H > C–C > secondary C–H ≫ primary C–H, though steric factors cause a shift in favor of C–C cleavage in such a hindered compound as tri-*tert*-butylmethane. The mechanism is similar to that shown in 12-1 and 12-17 and involves attack by H^+ on the C–C bond to give a pentavalent cation.

Catalytic hydrogenation seldom breaks unactivated C–C bonds (i.e., $R{-}R' + H_2 \rightarrow RH + R'H$), but methyl and ethyl groups have been cleaved from substituted adamantanes by hydrogenation with a Ni-Al_2O_3 catalyst at about 250°C.[549] Certain C–C bonds have been cleaved by alkali metals.[550]

12-46 *Decyanation or Hydro-de-cyanation*

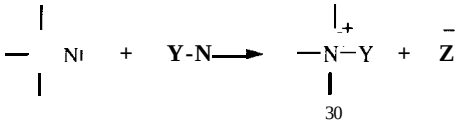
$$RCN \xrightarrow{Na\text{-}NH_3 \text{ or } Na\text{—}Fe(acac)_3} RH$$

The cyano group of alkyl nitriles can be removed[551] by treatment with metallic sodium, either in liquid ammonia,[552] or together with tris(acetylacetonato)iron(III), that is i.e., $Fe(acac)_3$[553] or, with lower yields, titanocene. The two procedures are complementary. Although both can be used to decyanate many kinds of nitriles, the Na–NH_3 method gives high yields with R groups such as trityl, benzyl, phenyl, and tertiary alkyl, but lower yields (≈35-50%) when R = primary or secondary alkyl. On the other hand, primary and secondary alkyl nitriles are decyanated in high yields by the Na–$Fe(acac)_3$ procedure. Sodium in liquid ammonia is known to be a source of solvated electrons, and the reaction may proceed through the free radical R·, which would then be reduced to the carbanion R^-, which by abstraction of a proton from the solvent, would give RH. The mechanism with $Fe(acac)_3$ is presumably different. Another procedure,[554] which is successful for R = primary, secondary, or tertiary, involves the use of potassium metal and the crown ether dicyclohexano-18-crown-6 in toluene.[555]

α-Amino and α-amido nitriles, $RCH(CN)NR_2'$ and $RCH(CN)NHCOR'$, can be decyanated in high yield by treatment with $NaBH_4$.[556]

Electrophilic Substitution at Nitrogen

In most of the reactions in this section, an electrophile bonds with the unshared pair of a nitrogen atom. The electrophile may be a free positive ion or a positive species attached to a carrier that breaks off in the course of the attack or shortly after:



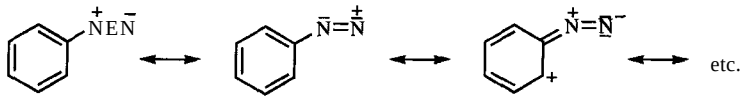
30

Further reaction of 30 depends on the nature of Y and of the other groups attached to the nitrogen.

12-47 *Diazotization*

$$Ar-NH_2 + HONO \longrightarrow Ar-\overset{+}{N}\equiv\bar{N}$$

When primary aromatic amines are treated with nitrous acid, diazonium salts are formed.[557] The reaction also occurs with aliphatic primary amines, but aliphatic diazonium ions are extremely unstable, even in solution (see p. 448). Aromatic diazonium ions are more stable, because of the resonance interaction between the nitrogens and the ring:



31 **32**

Incidentally, **31** contributes more to the hybrid than **32,** as shown by bond-distance measurements.[558] In benzenediazonium chloride, the C–N distance is $\approx$ 1.42 Å, and the N–N distance $\approx$ 1.08 Å,[559] which values fit more closely to a single and a triple bond than to two double bonds (see Table 1.5). Even aromatic diazonium salts are stable only at low temperatures, usually only below 5°C, though more stable ones, such as the diazonium salt obtained from sulfanilic acid, are stable up to 10 or 15°C. Diazonium salts are usually prepared in aqueous solution and used without isolation,[560] though it is possible to prepare solid diazonium salts if desired (see **13-20).** The stability of aryl diazonium salts can be increased by crown ether complexion.[561]

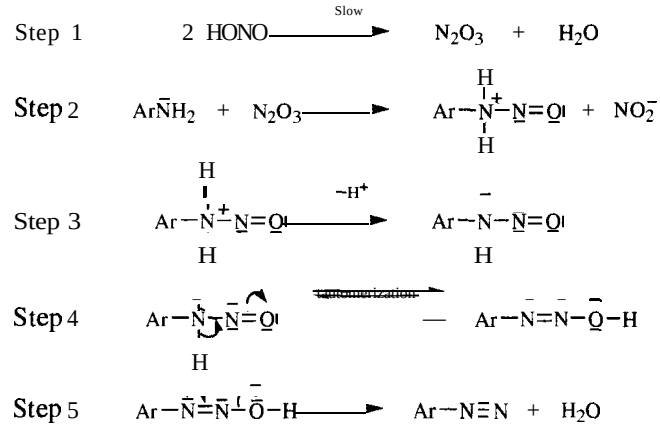
For aromatic amines, the reaction is very general. Halogen, nitro, alkyl, aldehyde, sulfonic acid, and so on, groups do not interfere. Since aliphatic amines do not react with nitrous acid below a pH of ~ 3, it is even possible, by working at a pH of ~ 1, to diazotize an aromatic amine without disturbing an aliphatic amino group in the same molecule.[562]

$$EtOOC-CH_2-NH_2 + HONO \longrightarrow EtOOC-CH=\overset{+}{N}=\bar{N}$$

If an aliphatic amino group is to a COOR, CN, CHO, COR, and so on, and has an a hydrogen, treatment with nitrous acid gives not a diazonium salt, but a *diazo compound.*[563] Such diazo compounds can also be prepared, often more conveniently, by treatment of the substrate with isoamyl nitrite and a small amount of acid.[564] Certain heterocyclic amines also give diazo compounds rather than diazonium salts.[565]

Despite the fact that diazotization takes place in acid solution, the actual species attacked is not the salt of the amine, but the small amount of free amine present.[566] It is because aliphatic amines are stronger bases than aromatic ones that at pH values below 3 there is not enough free amine present for the former to be diazotized, while the latter still undergo the reaction. In dilute acid the actual attacking species is N_2O_3, which acts as a carrier of NO^+. Evidence is that the reaction is second order

in nitrous acid and, at sufficiently low acidities, the amine does not appear in the rate expression.[567] Under these conditions the mechanism is



There exists other evidence for this mechanism.[568] Other attacking species can be N0C1, $H_2NO_2^+$, and at high acidities even NO^+. Nucleophiles (e.g., Cl^-, SCN^-, thiourea) catalyze the reaction by converting the HONO to a better electrophile (e.g., $HNO_2 + Cl^- + H^+ \rightarrow$ N0C1 + H_2O).[569]

There are many preparations of diazonium salts listed in *Organic Syntheses*, but they are always prepared for use in other reactions. We do not list them here, but under reactions in which they are used. The preparation of aliphatic diazo compounds can be found in OS **III,** 392; IV, 424. See also OS VI, 840.

12-48 *The Conversion of Hydrazines to Azides*

HYDRAZINE-AZIDE TRANSFORMATION

Monosubstituted hydrazines treated with nitrous acid give azides in a reaction exactly analogous to the formation of aliphatic diazo compounds mentioned in 12-**47**. Among other reagents used for this conversion have been N_2O_4[570] and nitrosyl tetrafluoroborate ($NOBF_4$).[571]

OS **III,** 710; **IV,** 819; V, 157.

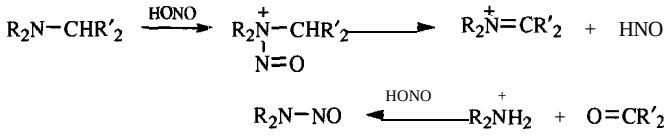
12-49 *N*-Nitrosation or *N*-Nitroso-de-hydrogenation

When secondary amines are treated with nitrous acid, N-nitroso compounds (also called nitrosamines) are formed.[572] The reaction can be accomplished with dialkyl-, diaryl-, or alkylarylamines, and even with mono-N-substituted amides: RCONHR'+HONO → RCON(NO)R'.[573] Tertiary amines have also been N-nitrosated, but in these cases one group cleaves, so that the product is the nitroso derivative of a secondary amine.[574] The group that cleaves appears as an aldehyde or

ketone. Other reagents have also been used, for example NOCl, which is useful for amines or amides that are not soluble in an acidic aqueous solution or where the N-nitroso compounds are highly reactive. N-Nitroso compounds can be prepared in basic solution by treatment of secondary amines with gaseous N_2O_3, N_2O_4,[575] or alkyl nitrites,[576] and, in aqueous or organic solvents, by treatment with $BrCH_2NO_2$.[577]

33

The mechanism of nitrosation is essentially the same as in **12-47** up to the point where **33** is formed. Since this species cannot lose a proton, it is stable and the reaction ends there. The attacking entity can be any of those mentioned in **12-47.** The following has been suggested as the mechanism for the reaction with tertiary amines:[578]



The evidence for this mechanism includes the facts that nitrous oxide is a product (formed by 2 HNO → H_2O + N_2O) and that quinuclidine, where the nitrogen is at a bridgehead, and therefore cannot give elimination, does not react. Tertiary amines have also been converted to nitrosamines with nitric acid in Ac_2O[579] and with N_2O_4.[580]

Amines and amides can be N-nitrated[581] with nitric acid,[582] or NO_2^+,[583] and aromatic amines can be converted to triazenes with diazonium salts. Aliphatic primary amines can also be converted to triazenes if the diazonium salts contain electron-withdrawing groups.[584] C-Nitrosation is discussed at **11-3** and **12-8.**

OS I, 177, 399, 417; **II,** 163, 211, 290, 460, 461, 462, 464 (also see V, 842); **III,** 106, 244; IV, 718, 780, 943; V, 336, 650, 797, 839, 962; VI, 542, 981. Also see OS **III,** 711.

12-50 *Conversion of Amines to Azo Compounds*

N-ARYLIMINO-DE-DIHYDRO-BISUBSTITUTION

Aromatic nitroso compounds combine with primary arylamines in glacial acetic acid to give symmetrical or unsymmetrical azo compounds (the *Mills reaction*).[585] A wide variety of substituents may be present in both aryl groups. Unsymmetrical azo compounds have also been prepared by the reaction between aromatic nitro compounds $ArNO_2$ and N-acyl aromatic amines Ar′NHAc.[586] The use of phase transfer catalysis increased the yields.

12-51 *Conversion of Nitroso Compounds to Azoxy Compounds*

$$RNO + R'NHOH \longrightarrow R-\overset{+}{N}=N-R' \quad (O^-)$$

In a reaction similar to 12-50, azoxy compounds can be prepared by the condensation of a nitroso compound with a hydroxylamine.[587] The position of the oxygen in the final product is determined by the nature of the R groups, not by which R groups came from which starting compound. Both R and R' can be alkyl or aryl, but when two different aryl groups are involved, mixtures of azoxy compounds (ArNONAr, ArNONAr', and Ar'NONAr') are obtained[588] and the unsymmetrical product (ArNONAr') is likely to be formed in the smallest amount. This behavior is probably caused by an equilibration between the starting compounds prior to the actual reaction (ArNO + Ar'NHOH → Ar'NO + ArNHOH).[589] The mechanism[590] has been investigated in the presence of base. Under these conditions both reactants are converted to radical anions, which couple:

$$ArNO + ArNHOH \longrightarrow 2\,Ar-\dot{N}(O^-) \longrightarrow Ar\text{-}N(O^-)\text{-}N(O)\text{-}Ar \xrightarrow[H_2O]{-2OH^-} Ar-\overset{+}{N}=N-Ar \quad (O^-)$$

These radical anions have been detected by ESR.[591] This mechanism is consistent with the following result: when nitrosobenzene and phenylhydroxylamine are coupled, ^{18}O and ^{15}N labeling show that the two nitrogens and the two oxygens become equivalent.[592] Unsymmetrical azoxy compounds can be prepared[593] by combination of a nitroso compound with an N,N-dibromoamine. Symmetrical and unsymmetrical azo and azoxy compounds are produced when aromatic nitro compounds react with aryliminodimagnesium reagents, $ArN(MgBr)_2$.[594]

12-52 *N-Halogenation or N-Halo-de-hydrogenation*

$$RNH_2 + NaOCl \longrightarrow RNHCl$$

Treatment with sodium hypochlorite or hypobromite converts primary amines into N-halo- or N,N-dihaloamines. Secondary amines can be converted to N-halo secondary amines. Similar reactions can be carried out on unsubstituted and N-substituted amides and on sulfonamides. With unsubstituted amides the N-halogen product is seldom isolated but usually rearranges (see 18-13); however, N-halo-N-alkyl amides and N-halo imides are quite stable. The important reagent NBS is made in this manner. N-Halogenation has also been accomplished with other reagents, (e.g., sodium bromite $NaBrO_2$)[595] benzyltrimethylammonium tribromide ($PhCH_2NMe_3^+ Br_3^-$),[596] and NCS.[597] The mechanisms of these reactions[598] involve attack by a positive halogen and are probably similar to those of 12-47 and 12-49.[599] N-Fluorination can be accomplished by direct treatment of amines[600] or

amides[601] with F_2. Fluorination of N-alkyl-N-fluoro amides results in cleavage to N,N-difluoroamines.[602]

$$\text{RNFCOR}' \xrightarrow{F_2} \text{RNF}_2$$

OS **HI,** 159; **IV,** 104, 157; V, 208, 663, 909; **VI,** 968; **VII,** 223; **VIII,** 167, 427.

12-53 *The Reaction of Amines With Carbon Monoxide or Carbon Dioxide*

N-FORMYLATION OR **N-FORMYL-DE-HYDROGENATION,** AND SO ON

$$\text{RNH}_2 + \text{CO} \xrightarrow{\text{catalyst}} \text{RNH-C-H (O)} \text{ or } \text{RNH-C-NHR (O)} \text{ or } \text{RNCO}$$

Three types of product can be obtained from the reaction of amines with carbon monoxide, depending on the catalyst. (1) Both primary and secondary amines react with CO in the presence of various catalysts [e.g., $Cu(CN)_2$, Me_3N– H_2Se, rhodium or ruthenium complexes] to give N-substituted and N,N-disubstituted formamides, respectively.[603] Tertiary amines react with CO and a palladium catalyst to give an amide.[604] (2) Symmetrically substituted ureas can be prepared by treatment of a primary amine (or ammonia) with CO in the presence of selenium[605] or sulfur.[606] The R group can be alkyl or aryl. The same thing can be done with secondary amines, by using $Pd(OAc)_2$–I_2– K2CO3.[607] (3) When $PdCl_2$ is the catalyst, primary amines yield isocyanates.[608] Isocyanates can also be obtained by treatment of CO with azides: RN3 + CO → RNCO,[609] or with an aromatic nitroso or nitro compound and a rhodium complex catalyst.[610] A fourth type of product, a carbamate RNHCOOR', can be obtained from primary or secondary amines, if these are treated with CO, O_2, and an alcohol R'OH in the presence of a catalyst.[611] Carbamates can also be obtained from nitroso compounds, by treatment with CO, R'OH, $Pd(OAc)_2$, and $Cu(OAc)_2$,[612] and from nitro compounds.[613] When allylic amines $R_2C{=}CHR$-$CHRNR'_2$ are treated with CO and a palladium–phosphine catalyst, the CO inserts to produce the |3,y-unsaturated amides $R_2C{=}CHRCHRCONR_2'$ in good yields.[614] Ring-expanded lactams are obtained from cyclic amines via a similar reaction.[615] See also **16-18.**

Carbon dioxide reacts with amines ($ArNH_2$) and iodoethane, under electrolysis conditions, to give the corresponding carbamate, ($ArNHCO_2Et$).[616] Urea derivatives were obtained from amines, CO_2, and an antimony catalyst.[617]

Pure Appl.Chem.*, **1967**, *17*, 83; Orchi , M. *Adv. Catal.* **1966,** *16,* 1.

[73] Cramer, R. *J. Am. Chem. Soc,* **1966,** *88,* 2272.

[74] Casey, C.P.; Cyr, C.R. *J. Am. Chem. Soc,* **1973,** *95,* 2248.

[75] Trost, B.M.; Schmidt, T. *J. Am. Chem. Soc,* **1988,** *110,* 2301.

[76] Bergens, S.H.; Bosnich, B. *J. Am. Chem. Soc,* **1991,** *113,* 958.

[77] For example, see Kropp, P.J.; Krauss, H.J. *J. Am. Chem. Soc,* **1967,** *89,* 5199; Reardon Jr., E.J.; Krauss, H. *J. Am. Chem. Soc,* **1971,** *93,* 5593; Duhaime, R.M.; Lombardo, D.A.; Skinner, I.A.; Weedon, A.C. *J. Org. Chem., 1985, 50,* 873.

[78] Colonge, J.; Brunie, J. *Bull. Soc. Chim. Fr.*, **1963,** 1799. For an example with basic catalysis, see Hoffmann, H.M.R.; Kover, A.; Pauluth, D. *J. Chem. Soc, Chem. Commun.*, **1985**,812. For an example with a ruthenium-complex catalyst, see Trost, B.M.; Kulawiec, R.J. *Tetrahedron Lett.*, **1991,** *32,* 3039.

[79] For example, see Chabardes, P. *Tetrahedron Lett,* **1988,** *29,* 6253.

[80] In the case of the "uncatalyzed" ketonization of CH2=C(Ph)OH, it was shown that water functions as the basic catalyst: Chiang, Y; Kresge, A.J.; Santaballa, J.A.; Wirz, J. *J. Am. Chem. Soc,* **1988,** *110,* 5506.

[81] For reviews of the mechanism, see Keeffe, J.R.; Kresge, A.J. in Rappoport *The Chemistry of Enols;* Wiley: NY, **1990,** p. 399; Toullec, J. *Adv. Phys. Org. Chem.,* **1982**, *18*,1; Lamaty, G. *Isot. Org. Chem.,* **1976,** *2,* 33. For discussions, see Ingold, C.K. *Structure and Mechanism in Organic Chemistry,* 2nd ed.; Cornell University Press: Ithaca, NY, **1969,** p. 794; Bell, R.P. *The Proton in Chemistry,* 2nd ed.; Cornell University Press: Ithaca, NY, **1973,** p. 171; Bruice, P.Y; Bruice, T.C. *J. Am. Chem. Soc,* **1976,** *98,* 844; Shelly, K.P.; Venimadhavan, S.; Nagarajan, K.; Stewart, R. *Can. J. Chem.,* **1989,** *67*, 1274For a review of stereoelectronic control in this mechanism, see Pollack, R.M. *Tetrahedron,* **1989,** *45,* 4913.

[82] Another mechanism for base-catalyzed enolization has been reported when the base is a tertiary amine: See Bruice, P.Y. *J. Am. Chem. Soc,* **1983**, *105*, 4982; **1989,** *111*, 962; **1990,** *112,* 7361.

[83] It has been proposed that the acid-catalyzed ketonization of simple enols is concerted; that is, both of the processes shown in the equation take place simultaneously. This would mean that in these cases the forward reaction is also concerted. For evidence in favor of this proposal, see Capon, B.; Siddhanta, A.K.; Zucco, C. *J. Org. Chem., 1985, 50,* 3580. For evidence against it, see Chiang, Y; Hojatti, M.; Keeffe, J.R.; Kresge, A.J.; Schepp, N.R; Wirz, J. *J. Amer. Chem. Soc,* **1987,** *109,* 4000 and cited references.

[119] Kajigaeshi, S.; Kakinami, T.; Tokiyama, H.; Hirakawa, T.; Okamoto, T. *Bull. Chem. Soc. Jpn., 1987, 60,* 2667.

[120] When the halogenating species is at low concentration or has a low reactivity, it can appear in the rate expression. The reaction becomes first order in the halogenating species. See, for example, Tapuhi, E.; Jencks, W.P. *J. Am. Chem. Soc, 1982, 104,* 5758. For a case in which the reaction is first order in bromine, even at relatively high Br_2 contentration, see Pinkus, A.G.; Gopalan, R. *J. Am. Chem. Soc, 1984, 106,* 2630. For a study of the kinetics of iodination, see Pinkus, A.G.; Gopalan, R. *Tetrahedron, 1986, 42,* 3411.

[121] Under some conditions it is possible for step 2 to be rate-determining: Deno, N.C.; Fishbein, R. *J. Am. Chem. Soc, 1973, 95,* 7445.

CHAPTER 13

Aromatic Nucleophilic Substitution

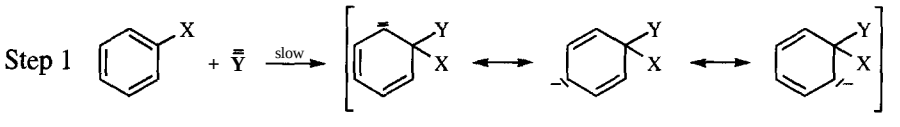
On page 433 it was pointed out that nucleophilic substitutions proceed so slowly at an aromatic carbon that the reactions of Chapter 10 are not feasible for aromatic substrates. There are, however, exceptions to this statement, and it is these exceptions that form the subject of this chapter.[1] Reactions that *are* successful at an aromatic substrate are largely of four kinds: (1) reactions activated by electron-withdrawing groups ortho and para to the leaving group; (2) reactions catalyzed by very strong bases and proceeding through aryne intermediates; (3) reactions initiated by electron donors; and (4) reactions in which the nitrogen of a diazonium salt is replaced by a nucleophile. However, not all the reactions discussed in this chapter fit into these categories.

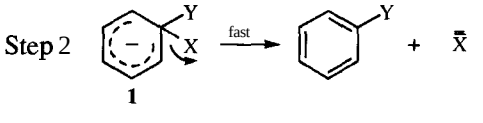
MECHANISMS

There are four principal mechanisms for aromatic nucleophilic substitution.[2] Each of the four is similar to one of the aliphatic nucleophilic substitution mechanisms discussed in Chapter 10.

The S_NAr Mechanism

By far, the most important mechanism for nucleophilic aromatic substitution consists of two steps:



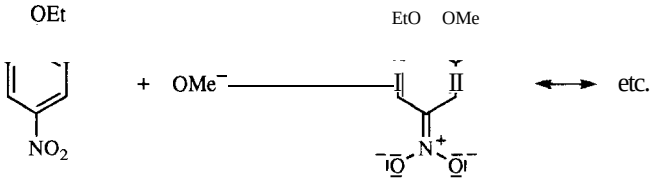


1

The first step is usually, but not always, rate determining. It can be seen that this mechanism greatly resembles the tetrahedral mechanism discussed in Chapter 10 and, in another way, the arenium ion mechanism of electrophilic aromatic substitution. In all three cases, the attacking species forms a bond with the

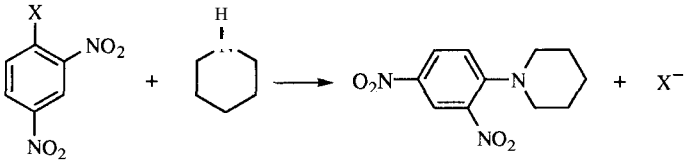
substrate, giving an intermediate, and then the leaving group departs. We refer to this mechanism as the S_NAr mechanism.[3] The IUPAC designation is $A_N + D_N$ (the same as for the tetrahedral mechanism; cf. the designation $A_E + D_E$ for the arenium ion mechanism). This mechanism is generally found where activating groups are present on the ring (see p. 857).

There is a great deal of evidence for the mechanism; we shall discuss only some of it.[2] Probably the most convincing evidence was the isolation, as long ago as 1902, of the intermediate 2 in the reaction between 2,4,6-trinitrophenetole and methoxide ion.[4] Intermediates of this type are stable salts, called *Meisenheimer* or *Meisenheimer–Jackson salts,* and many more have been isolated since 1902.[5] The structures of several of these intermediates have been proved by NMR[6] and by



2

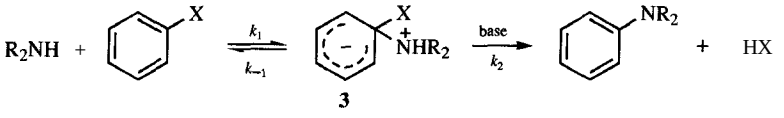
X-ray crystallography.[7] Further evidence comes from studies of the effect of the leaving group on the reaction. If the mechanism were similar to either the S_N1 or S_N2 mechanisms described in Chapter 10, the Ar—X bond would be broken in the rate-determining step. In the S_NAr mechanism, this bond is not broken until after the rate-determining step (i.e., if step 1 is rate determining). There is some evidence that electron transfer may be operative during this process.[8] We would predict from this that if the S_NAr mechanism is operating, a change in leaving group should not have much effect on the reaction rate. In the reaction when X was Cl, Br, I, SOPh, SO_2Ph,



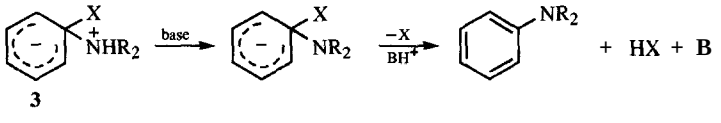
or *p*-nitrophenoxy, the rates differed only by a factor of ~ 5.[9] This behavior would not be expected in a reaction in which the Ar–X bond is broken in the rate-determining step. We do not expect the rates to be *identical,* because the nature of X affects the rate at which Y attacks. An increase in the electronegativity of X causes a decrease in the electron density at the site of attack, resulting in a faster attack by a nucleophile. Thus, in the reaction just mentioned, when X = F, the relative rate was 3300 (compared with I = 1). The very fact that fluoro is the best leaving group among the halogens in most aromatic nucleophilic substitutions is good evidence that the mechanism is different from the S_N1 and the S_N2 mechanisms, where fluoro is by far the poorest leaving group of the halogens. This is an example of the element effect (p. 429).

The pattern of base catalysis of reactions with amine nucleophiles provides additional evidence. These reactions are catalyzed by bases only when a relatively

poor leaving group (such as OR) is present (not Cl or Br) and only when relatively bulky amines are nucleophiles.[10] Bases could not catalyze step 1, but if amines are nucleophiles, bases can catalyze step 2. Base catalysis is found precisely in those cases where the amine moiety cleaves easily but X does not, so that k_{-1} is large and step 2 is rate determining. This is evidence for the S_NAr mechanism because it implies two steps. Furthermore, in cases where bases *are* catalysts, they catalyze only at low base concentrations: A plot of the rate against the base concentration

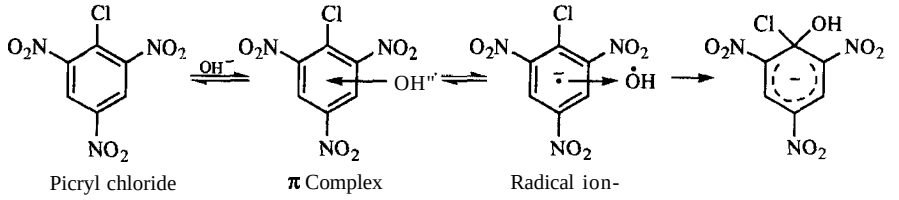


shows that small increments of base rapidly increase the rate until a certain concentration of base is reached, after which further base addition no longer greatly affects the rate. This behavior, based on a partitioning effect (see p. 677), is also evidence for the S_NAr mechanism. At low base concentration, each increment of base, by increasing the rate of step 2, increases the fraction of intermediate that goes to product rather than reverting to reactants. At high base concentration, the process is virtually complete: there is very little reversion to reactants and the rate becomes dependent on step 1. Just how bases catalyze step 2 has been investigated. For protic solvents two proposals have been presented. One is that step 2 consists of two steps: rate-determining deprotonation of 3 followed by rapid loss of X, and that bases catalyze the reaction by increasing the rate of the deprotonation step.[11] According



to the other proposal, loss of X assisted by BH^+ is rate determining.[12] Two mechanisms, both based on kinetic evidence, have been proposed for aprotic solvents such as benzene. In both proposals, the ordinary S_NAr mechanism operates, but in one the attacking species involves two molecules of the amine (the *dimer mechanism),*[13] while in the other there is a cyclic transition state.[14] Further evidence for the S_NAr mechanism has been obtained from $^{18}O/^{16}O$ and $^{15}N/^{14}N$ isotope effects.[15]

Step 1 of the S_NAr mechanism has been studied for the reaction between picryl chloride (as well as other substrates) and OH^- ions (13-1), and spectral evidence has been reported[16] for two intermediates, one a *n* complex (p. 679), and the other a radical ion-radical pair:

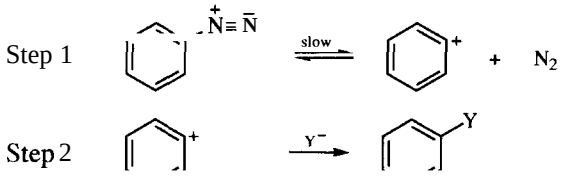


Picryl chloride — π Complex — Radical ion-Radical pair

As with the tetrahedral mechanism at an acyl carbon, nucleophilic catalysis (p. 427) has been demonstrated with an aryl substrate, in certain cases.[17]

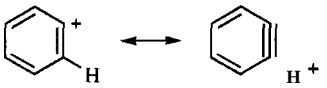
The S_N1 Mechanism

For aryl halides and sulfonates, even active ones, a unimolecular S_N1 mechanism (IUPAC: $D_N + A_N$) is very rare; it has only been observed for aryl triflates in which both ortho positions contain bulky groups (*tert*-butyl or SiR_3).[18] It is in reactions with diazonium salts[19] that this mechanism is important:[20]



Among the evidence for the S_N1 mechanism[21] with aryl cations as intermediates,[22] is the following:[23]

1. The reaction rate is first order in diazonium salt and independent of the concentration of Y.
2. When high concentrations of halide salts are added, the product is an aryl halide but the rate is independent of the concentration of the added salts.
3. The effects of ring substituents on the rate are consistent with a unimolecular rate-determining cleavage.[24]
4. When reactions were run with substrate deuterated in the ortho position, isotope effects of ~ 1.22 were obtained.[25] It is difficult to account for such high secondary isotope effects in any other way except that an incipient phenyl cation is stabilized by hyperconjugation,[26] which is reduced when hydrogen is replaced by deuterium.



5. That the first step is reversible cleavage[27] was demonstrated by the observation that when $Ar^{15}\overset{+}{N}{\equiv}N$ was the reaction species, recovered starting material contained not only $Ar^{15}\overset{+}{N}{\equiv}N$ but also $Ar^{15}\overset{+}{N}{\equiv}N$.[28] This could arise only if the nitrogen breaks away from the ring and then returns. Additional evidence was obtained by treating $Ph\overset{+}{N}{\equiv}{}^{15}N$ with unlabeled N_2 at various pressures. At 300 atm the recovered product had lost ~ 3% of the labeled nitrogen, indicating that PhN_2^+ was exchanging with atmospheric N_2.[29]

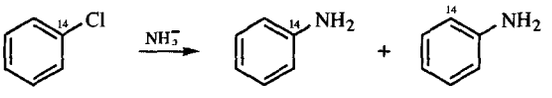
There is kinetic and other evidence[30] that step 1 is more complicated and involves two steps, both reversible:

$$ArN_2^+ \rightleftharpoons [Ar^+\ N_2] \rightleftharpoons Ar + N_2$$

Compound 4, which is probably some kind of a tight ion-molecule pair, has been trapped with carbon monoxide.[31]

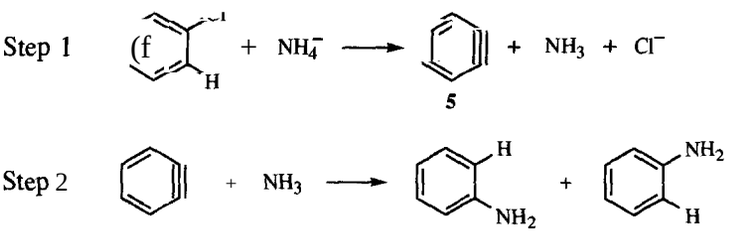
The Benzyne Mechanism[32]

Some aromatic nucleophilic substitutions are clearly different in character from those that occur by the S_NAr mechanism (or the S_N1 mechanism). These substitutions occur on aryl halides that have no activating groups; bases are required that are stronger than those normally used; and most interesting of all, the incoming group does not always take the position vacated by the leaving group. That the latter statement is true was elegantly demonstrated by the reaction of 1-^{14}C-chlorobenzene with potassium amide:



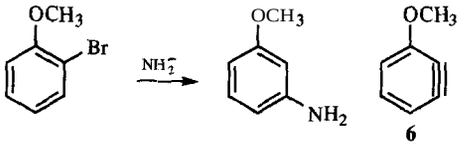
The product consisted of almost equal amounts of aniline labeled in the 1 position and in the 2 position.[33]

A mechanism that can explain all these facts involves elimination followed by addition:



The symmetrical intermediate 5 can be attacked by the NH_3 at either of two positions, which explains why about one-half of the aniline produced from the radioactive chlorobenzene was labeled at the 2 position. The fact that the 1 and 2 positions were not labeled equally is the result of a small isotope effect. Other evidence for this mechanism is the following:

1. If the aryl halide contains two ortho substituents, the reaction should not be able to occur. This is indeed the case.[31]
2. It had been known many years earlier that aromatic nucleophilic substitution occasionally results in substitution at a different position. This is called *cine substitution* and can be illustrated by the conversion of *o*-bromoanisole to *m*-aminoanisole.[34] In this particular case, only the meta isomer is formed. The

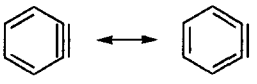


reason a 1:1 mixture is not formed is that the intermediate 6 is not symmetrical and the methoxy group directs the incoming group meta but not ortho (see p. 859). However, not all cine substitutions proceed by this kind of mechanism (see **13-21**).

3. The fact that the order of halide reactivity is Br > I > Cl > F (when the reaction is performed with KNH_2 in liquid NH_3) shows that the S_NAr mechanism is not operating here.[33]

In the conversion of the substrate to 6, either proton removal or subsequent loss of halide ion can be rate determining. In fact, the unusual leaving-group order just mentioned (Br > I > Cl) stems from a change in the rate determining step. When the leaving group is Br or I, proton removal is rate determining and the rate order for this step is F > Cl > Br > I. When Cl or F is the leaving group, cleavage of the C–X bond is rate determining and the order for this step is I > Br > Cl > F. Confirmation of the latter order was found in a direct competitive study. *m*-Dihalobenzenes in which the two halogens are different were treated with NH_2^-.[35] In such compounds, the most acidic hydrogen is the one between the two halogens; when it leaves, the remaining anion can lose either halogen. Therefore a study of which halogen is preferentially lost provides a direct measure of leaving-group ability. The order was found to be I > Br > Cl.[35]

Species such as 5 and 6 are called *benzynes* (sometimes *dehydrobenzenes*), or more generally, *arynes*, and the mechanism is known as the *benzyne mechanism.* Benzynes are very reactive. Neither benzyne nor any other aryne has yet been isolated under ordinary conditions,[36] but benzyne has been isolated in an argon matrix at 8 K,[37] where its IR spectrum could be observed. In addition, benzynes can be trapped; for example, they undergo the Diels–Alder reaction (see **15-58).** It should be noted that the extra pair of electrons does not affect the aromaticity. The



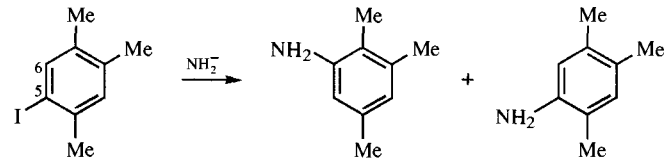
A B

original sextet still functions as a closed ring, and the two additional electrons are merely located in a π orbital that covers only two carbons. Benzynes do not have a formal triple bond, since two canonical forms (A and B) contribute to the hybrid. The IR spectrum, mentioned above, indicates that A contributes more than B. Not only benzene rings but other aromatic rings[38] and even non-aromatic rings (p. 430) can react through this kind of intermediate. Of course, the non-aromatic rings do have a formal triple bond.

The $S_{RN}1$ Mechanism

When 5-iodo-l,2,4-trimethylbenzene (7) was treated with KNH_2 in NH_3, 8 and 9 were formed in the ratio 0.63:1. From what we have already seen, the presence of an

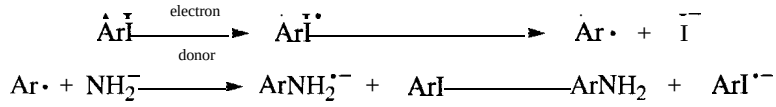
unactivated substrate, a strong base, and the occurrence of cine along with normal substitution would be strong indications of a benzyne mechanism. Yet if that were



7 8 9

so, the 6-iodo isomer of 7 should have given 8 and 9 in the same ratio (because the same aryne intermediate would be formed in both cases), but in this case the ratio of 8 to 9 was 5.9:1 (the chloro and bromo analogs did give the same ratio, 1.46:1, showing that the benzyne mechanism may be taking place there).

To explain the iodo result, it has been proposed[39] that besides the benzyne mechanism, this free radical mechanism is also operating here:



followed by termination steps

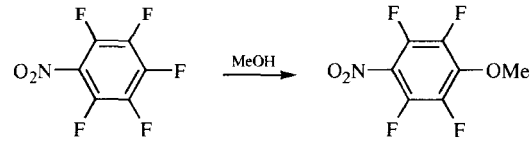
This is called the $S_{RN}1$ mechanism,[40] and many other examples are known (see **13-3**, **13-4**, **13-6**, **13-12**). The IUPAC designation is T | $D_N + A_N$.[41] Note that the last step of the mechanism produces $ArI^{\cdot -}$ radical ions, so the process is a chain mechanism (see p. 895).[42] An electron donor is required to initiate the reaction. In the case above it was solvated electrons from KNH_2 in NH_3. Evidence was that the addition of potassium metal (a good producer of solvated electrons in ammonia) completely suppressed the cine substitution. Further evidence for the $S_{RN}1$ mechanism was that addition of radical scavengers (which would suppress a free-radical mechanism) led to 8:9 ratios much closer to 1.46:1. Numerous other observations of $S_{RN}1$ mechanisms that were stimulated by solvated electrons and inhibited by radical scavengers have also been recorded.[43] Further evidence for the $S_{RN}1$ mechanism in the case above was that some 1,2,4-trimethylbenzene was found among the products. This could easily be formed by abstraction by Ar· of H from the solvent NH_3. Besides initiation by solvated electrons,[44] $S_{RN}1$ reactions have been initiated photochemically,[45] electrochemically,[46] and even thermally.[47]

The $S_{RN}1$ reactions have a fairly wide scope. The efficiency of the reaction has been traced to the energy level of the radical anion of the substitution product.[48] There is no requirement for activating groups or strong bases, but in DMSO haloarenes are less reactive as the stability of the anion increases.[49] The reaction has also been done in liquid ammonia, promoted by ultrasound (p. 456),[50] and ferrous ion has been used as a catalyst.[51] Alkyl, alkoxy, aryl, and COO^- groups do not interfere, although Me_2N, O^-, and NO_2 groups do interfere. Cine substitution is not found.

Other Mechanisms

There is no clear-cut proof that a one-step S_N2 mechanism, so important at a saturated carbon, ever actually occurs with an aromatic substrate. The hypothetical aromatic S_N2 process is sometimes called the *one-stage* mechanism to distinguish it from the *two-stage* S_NAr mechanism. A "clean" example of a $S_{RN}2$ reaction has been reported, the conversion of 10 to **11** in methanol.[52] Both the $S_{RN}1$ and $S_{RN}2$ reactions have been reviewed.[53]

Some of the reactions in this chapter operate by still other mechanisms, among them an addition-elimination mechanism (see 13-15). A new mechanism has been reported in aromatic chemistry, a reductively activated "polar" nucleophilic aromatic substitution.[54] The reaction of phenoxide with *p*-dinitrobenzene in DMF shows radical features that cannot be attributed to a radical anion, and it is not $S_{RN}2$. The new designation was proposed to account for these results.



10 **11**

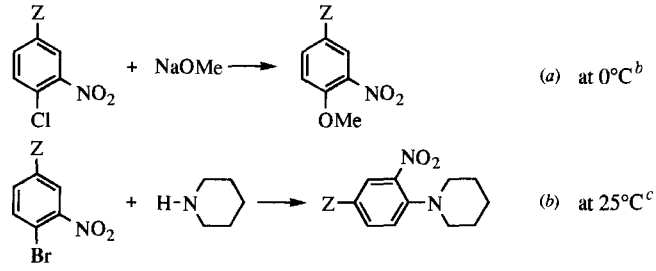
REACTIVITY

The Effect of Substrate Structure

In the discussion of electrophilic aromatic substitution (Chapter 11) equal attention was paid to the effect of substrate structure on reactivity (activation or deactivation) and on orientation. The question of orientation was important because in a typical substitution there are four or five hydrogens that could serve as leaving groups. This type of question is much less important for aromatic nucleophilic substitution, since in most cases there is only one potential leaving group in a molecule. Therefore attention is largely focused on the reactivity of one molecule compared with another and not on the comparison of the reactivity of different positions within the same molecule.

S_NAr Mechanism. These substitutions are accelerated by electron-withdrawing groups, especially in positions ortho and para to the leaving group[55] and hindered by electron-attracting groups. This is, of course, opposite to the effects of these groups on electrophilic substitutions, and the reasons are similar to those discussed in Chapter 11 (p. 677). Table 13.1[56] contains a list of groups arranged approximately in order of activating or deactivating ability. Hetero nitrogen atoms are also strongly activating (especially to the α and y positions) and are even more so when quaternized.[57] Thus 2- and

TABLE 13.1 Groups Listed in Approximate Descending Order of Activating Ability in the S_NAr Mechanism[a]



Comments[d]	Group Z	Relative Rate of Reaction (a) H = 1[e]	(b) NH_2 = 1[f]
Activates halide exchange at room temperature	N_2^+		
Activates reaction with strong nucleophiles at room temperature	$\overset{\backslash}{\underset{//}{N}}\overset{+}{-}R$ (heterocylic)		
Activate reactions with strong nucleophiles at 80–100°C	NO	5.22×10^6	
	NO_2	6.73×10^5	Very fast
	$\overset{\backslash}{\underset{//}{N}}$ (heterocylic)		
With nitro also present, activate reactions with strong nucleophiles at room temperature	SO_2Me		
	NMe_3^+		
	CF_3		
	CN	3.81×10^4	
	CHO	2.02×10^4	
With nitro also present, activate reactions with strong nucleophiles at 40–60°C	COR		
	COOH		
	SO_3^-		
	Br		6.31×10^4
	Cl		4.50×10^4
	I		4.36×10^4
	COO^-		2.02×10^4
	H		8.06×10^3
	F		2.10×10^3
	CMe_3		1.37×10^3
	Me		1.17×10^3
	OMe		145
	NMe_2		9.77
	OH		4.70
	NH_2		1

[a] For Reaction (a), the rates are relative to H and for Reaction (b) they are relative to NH_2.
[b] See Ref. 59.

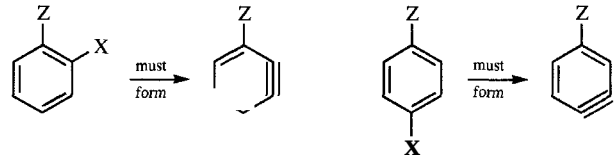
[e] See Ref. 57.
[f] See Ref. 58.

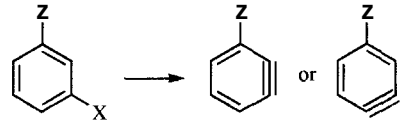
4-chloropyridine, for example, are often used as substrates. Heterocyclic N-oxides are readily attacked by nucleophiles in the 2 and 4 positions, but the oxygen is generally lost in these reactions.[58] The most highly activating group, N_2^+, is seldom deliberately used to activate a reaction, but it sometimes happens that in the diazotization of a compound such as *p*-nitroaniline or *p*-chloroaniline the group para to the diazonium group is replaced by OH from the solvent or by X from ArN_2^+ X^-, to the surprise and chagrin of the investigator, who was trying only to replace the diazonium group and to leave the para group untouched. By far the most common activating group is the nitro group and the most common substrates are 2,4-dinitrophenyl halides and 2,4,6-trinitrophenyl halides (also called picryl halides).[61] Polyfluorobenzenes, (e.g., C_6F_6)[62] also undergo aromatic nucleophilic substitution quite well.[63] Benzene rings that lack activating substituents are generally not useful substrates for the S_NAr mechanism, because the two extra electrons in 1 are in an antibonding orbital (p. 33). Activating groups, by withdrawing electron density, are able to stabilize the intermediates and the transition states leading to them. Reactions taking place by the S_NAr mechanism are also accelerated when the aromatic ring is coordinated with a transition metal (e.g., 7 in Chapter 3).[64]

Just as electrophilic aromatic substitutions were found more or less to follow the Hammett relationship (with a^+ instead of a; see p. 692), so do nucleophilic substitutions, with σ^- instead of σ for electron-withdrawing groups.[65]

Benzyne Mechanism. Two factors affect the position of the incoming group, the first being the direction in which the aryne forms.[66] When there are groups ortho or para to the leaving group, there is no choice:

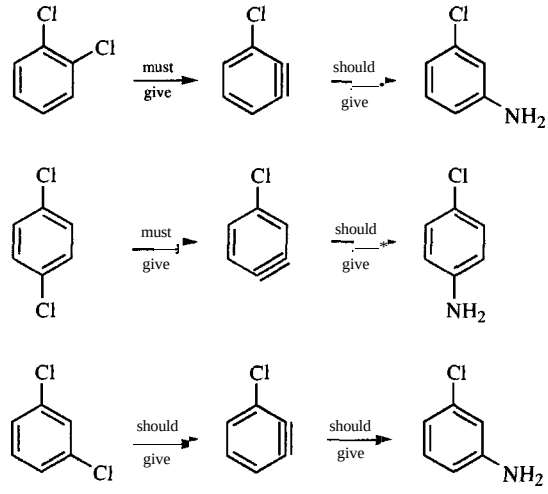


but when a meta group is present, the aryne can form in two different ways:



In such cases, the more acidic hydrogen is removed. Since acidity is related to the field effect of Z, it can be stated that an electron-attracting Z favors removal of the ortho hydrogen while an electron-donating Z favors removal of the para hydrogen. The second factor is that the aryne, once formed, can be attacked at two positions. The favored position for nucleophilic attack is the one that leads to the more stable carbanion intermediate, and this in turn also

depends on the field effect of Z. For –/ groups, the more stable carbanion is the one in which the negative charge is closer to the substituent. These principles are illustrated by the reaction of the three dichlorobenzenes with alkali metal amides. The predicted products are



In each case the predicted product was the one chiefly formed.[67] The observation that *m*-aminoanisole is obtained, mentioned on page 855, is also in accord with these predictions.

The Effect of the Leaving Group[68]

The common leaving groups in aliphatic nucleophilic substitution (halide, sulfate, sulfonate, NR_3^+, etc.) are also common leaving groups in aromatic nucleophilic substitutions, but the groups NO_2, OR, OAr, SO_2R,[69] and SR, which are not generally lost in aliphatic systems, *are* leaving groups when attached to aromatic rings. Surprisingly, NO_2 is a particularly good leaving group.[70] An approximate order of leaving-group ability is[71] F > NO_2 > OTs > SOPh > Cl, Br, I > N_3 > NR_3^+ > OAr, OR, SR, NH_2. However, this depends greatly on the nature of the nucleophile, as illustrated by the fact that $C_6Cl_5OCH_3$ treated with NH_2^- gives mostly $C_6Cl_5NH_2$; that is, one methoxy group is replaced in preference to five chlorines.[72] As usual, OH can be a leaving group if it is converted to an inorganic ester. Among the halogens, fluoro is generally a much better leaving group than the other halogens, which have reactivities fairly close together. The order is usually Cl > Br > I, but not always.[73] The leaving-group order is quite different from that for the S_N1 or S_N2 mechanisms. The most likely explanation is that the first step of the S_NAr mechanism is usually rate determining, and this step is promoted by groups with strong —/ effects. This would explain why fluoro and nitro are such good leaving groups when this mechanism is operating. Fluoro is the poorest leaving

group of the halogens when the second step of the S_NAr mechanism is rate determining or when the benzyne mechanism is operating. The four halogens, as well as SPh, NMe_3^+, and $OPO(OEt)_2$, have been shown to be leaving groups in the $S_{RN}1$ mechanism.[43] The only important leaving group in the S_N1 mechanism is N_2^+.

The Effect of the Attacking Nucleophile[74]

It is not possible to construct an invariant nucleophilicity order because different substrates and different conditions lead to different orders of nucleophilicity, but an overall approximate order is $NH_2^- > Ph_3C^- >$ PhNH~ (aryne mechanism) > ArS" > RO^- > R_2NH > ArO" > OH^- > $ArNH_2$ > NH_3 > I" > Br^- > Cl^- > H_2O > ROH.[75] As with aliphatic nucleophilic substitution, nucleophilicity is generally dependent on base strength and nucleophilicity increases as the attacking atom moves down a column of the periodic table, but there are some surprising exceptions (e.g., OH^-, a stronger base than ArO^-, is a poorer nucleophile).[76] In a series of similar nucleophiles, such as substituted anilines, nucleophilicity *is* correlated with base strength. Oddly, the cyanide ion is not a nucleophile for aromatic systems, except for sulfonic acid salts and in the von Richter **(13-21)** and Rosenmund-von Braun **(13-10)** reactions, which are special cases.

REACTIONS

In the first part of this section, reactions are classified according to attacking species, with all leaving groups considered together, except for hydrogen and N_2^+, which are treated subsequently. Finally, a few rearrangement reactions are discussed.

All Leaving Groups Except Hydrogen and N_2^+

A. *Oxygen Nucleophiles*

13-1 *Hydroxy-de-halogenation*

$$ArBr + OH" \longrightarrow ArOH$$

Aryl halides can be converted to phenols only if activating groups are present or if exceedingly strenuous conditions are employed.[77] Other leaving groups, including nitro,[78] azide, NR_3^+, and so on, can also be replaced by OH groups. When the reaction is carried out at high temperatures, cine substitution is observed, indicating a benzyne mechanism.[79] Phenols have been obtained from unactivated aryl halides by treatment with borane and a metal such as lithium, followed by oxidation with alkaline H_2O_2.[80]

A slightly related reaction involves the amino group of naphthylamines can be replaced by a hydroxyl group by treatment with aqueous bisulfite.[81] The scope is greatly limited; the amino group (which may be NH_2 or NHR) must be on a naphthalene ring, with very few exceptions. The reaction is reversible (see **13-6),** and both the forward and reverse reactions are called the *Bucherer reaction.*

OS I, 455; II, 451; V, 632. Also see OS V, 918.

13-2 *Alkali Fusion of Sulfonate Salts*

OXIDO-DE-SULFONATO-SUBSTITUTION

$$ArSO_3^- \xrightarrow[300\text{–}320^\circ C]{\text{NaOH fusion}} ArO^-$$

Aryl sulfonic acids can be converted, through their salts, to phenols, by alkali fusion. In spite of the extreme conditions, the reaction gives fairly good yields, except when the substrate contains other groups that are attacked by alkali at the fusion temperatures. Milder conditions can be used when the substrate contains activating groups, but the presence of deactivating groups hinders the reaction. The mechanism is obscure, but a benzyne intermediate has been ruled out by the finding that cine substitution does not occur.[82]

OS I, 175; HI, 288.

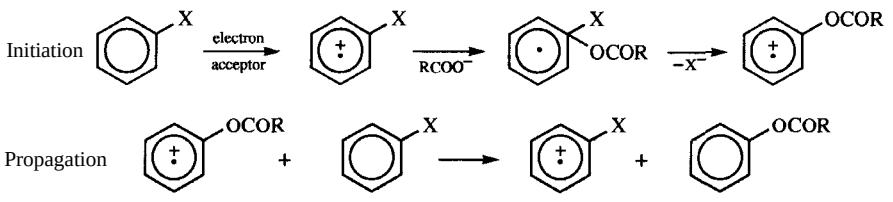
13-3 *Replacement by OR or OAr*

ALKOXY-DE-HALOGENATION

$$ArBr + OR^- \longrightarrow ArOR$$

This reaction is similar to 13-1 and, like that one, generally requires activated substrates.[77] With unactivated substrates, side reactions predominate, though aryl methyl ethers have been prepared from unactivated chlorides by treatment with MeO^- in HMPA.[83] This reaction gives better yields than 13-1 and is used more often. A good solvent is liquid ammonia. The compound NaOMe reacted with *o*- and *p*-fluoronitrobenzenes $\sim 10^9$ times faster in NH_3 at $-70^\circ C$ than in MeOH.[84] Phase-transfer catalysis has also been used.[85] The reaction of 4-iodotoluene and 3,4-dimethylphenol, in the presence of a copper catalyst and cesium carbonate, gave the diaryl ether (Ar–O–Ar′).[86] Alcohols were coupled with aryl halides in the presence of palladium catalysts to give the Ar–O–R ether.[87] Nickel catalysts have also been used.[88]

In addition to halides, leaving groups can be nitro, NR_3^+, other OR, and so on even OH.[89] Acid salts, $RCOO^-$, are sometimes used as nucleophiles. Good yields of aryl benzoates can be obtained by the treatment of aryl halides with cuprous benzoate in diglyme or xylene at 140–160°C.[90] Unactivated substrates have been converted to carboxylic esters in low-to-moderate yields under oxidizing conditions.[91] The following chain mechanism, called the $S_{ON}2$ mechanism,[92] has been suggested:[91]



For aroxide nucleophiles, the reaction is promoted by copper salts,[93] and when these are used, activating groups need not be present. This method of preparation of diaryl ethers is called the *Ullmann ether synthesis*[94] and should not be confused with the Ullmann biaryl synthesis **(13-14).** The reactivity order is typical of nucleophilic substitutions, despite the presence of the copper salts.[95] Because aryloxycopper(I) reagents ArOCu react with aryl halides to give ethers, it has been suggested that they are intermediates in the Ullmann ether synthesis.[96] Indeed, high yields of ethers can be obtained by reaction of ROCu or ArOCu with aryl halides.[97] Unactivated substrates also react with phenoxide ion with electrochemical catalysis in liquid NH_3-Me_2SO, to give diaryl ethers, presumably by the $S_{RN}1$ mechanism.[98] Diaryl ethers can be prepared from activated aryl halides by treatment with a triaryl phosphate, $(ArO)_3PO$.[99]

OS I, 219; I, 445; HI, 293, 566; V, 926; VI, 150.

B. *Sulfur Nucleophiles*

13-4 *Replacement by SH or SR*

Mercapto-de-halogenation	ArBr	+	SH^- ⟶	ArSH
Alkylthio-de-halogenation	ArBr	+	SR^- ⟶	ArSr

Aryl thiols and thioethers can be prepared by reactions that are similar to **13-1** and **13-3**.[100] Activated aryl halides generally give good results, but side reactions are occasionally important. Some reagents give the thiol directly. 4-Bromonitrobenzene reacts with Na_3SPO_3, in refluxing methanol, to give 4-nitrothiophenol.[101] Diaryl sulfides can be prepared by the use of SAr^-. Even unactivated aryl halides react with SAr^- if polar aprotic solvents, for example, DMF,[102] Me_2SO,[103] 1-methyl-2-pyrrolidinone,[104] or HMPA,[105] are used, though the mechanisms are still mostly or entirely nucleophilic substitution. 2-Iodothiophene reacts directly with thiophenol to give 2-phenylthiothiophene.[106] Unactivated aryl halides also give good yields of sulfides on treatment with SAr^- or SR^- in the presence of a catalytic amount of $(Ph_3P)_4Pd$.[107] Copper catalysts have also been used.[108] Diaryl sulfides can also be prepared (in high yields) by treatment of unactivated aryl iodides with ArS^- in liquid ammonia under irradiation.[109] The mechanism in this case is probably $S_{RN}1$. The reaction (with unactivated halides) has also been carried out electrolytically, with a nickel complex catalyst.[110]

Other sulfur nucleophiles also react with activated aryl halides:

$$2\,ArX + S_2^{2-} \longrightarrow Ar\text{-}S\text{-}S\text{-}Ar \qquad ArX + SCN^- \longrightarrow ArSCN$$

$$ArX + SO_3^{2-} \longrightarrow Ar\text{-}SO_3^- \qquad ArX + RSO_2^- \longrightarrow Ar\text{-}SO_2\text{-}R$$

Aryl sulfones have been prepared from sulfinic acid salts, aryl iodides and CuI.[111] Unactivated thiocyanation has been accomplished with charcoal supported copper(I) thiocyanate.[112]

OS I, 220; III, 86, 239, 667; V, 107, 474; VI, 558, 824. Also see OS V, 977.

C. Nitrogen Nucleophiles

13-5 Replacement by NH_2, NHR, or NR_2

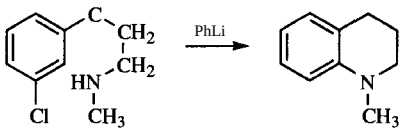
AMINO-DE-HALOGENATION

$$\begin{aligned} &ArBr + NH_3 \longrightarrow ArNH_2 \\ &ArBr + RNH_2 \longrightarrow ArNHR \\ &ArBr + R_2NH \longrightarrow ArNR_2 \end{aligned}$$

Activated aryl halides react quite well with ammonia and with primary and secondary amines to give the corresponding arylamines. Primary and secondary amines usually give better results than ammonia, with piperidine especially reactive. Picryl chloride (2,4,6-trinitrochlorobenzene) is often used to form amine derivatives. 2,4-Dinitrofluorobenzene is used to tag the amino end of a peptide or protein chain. Other leaving groups in this reaction may be NO_2, N3, OSO_2R, OR, SR, N=NAr (where Ar contains electron-withdrawing groups)[113] and even NR_2.[114] Activated halides can be converted to diethylamino compounds ArX → $ArNMe_2$ by treatment with HMPA.[115]

Nickel catalysts have been used in the reaction of aryl halides with N-alkyl aniline derivatives[116] and palladium catalysts with secondary amines[117] to give the corresponding tertiary amine. Palladium catalysts have been used with aniline and aryl halides[118] or triflates[119] to give the secondary amine. Aryl halides (Ar–X) have also been converted to the aniline derivative ($Ar–NH_2$) by reaction of the halide with an imine and a palladium catalyst, followed by hydrolysis.[120]

Unactivated aryl halides can be converted to amines by the use of $NaNH_2$, NaNHR, or $NaNR_2$.[121] With these reagents, the benzyne mechanism generally operates, so cine substitution is often found. Ring closure has been effected by this type of reaction,[122] for example,



It has also proved possible to close larger rings in this manner: 8 and even 12-membered. Triarylamines have been prepared in a similar manner from ArI and Ar'_2NLi, even with unactivated ArI.[123] In the *Goldberg reaction*, an aryl bromide reacts with an acetanilide in the presence of K_2CO_3 and CuI to give an *N*-acetyldiarylamine, which can be hydrolyzed to a diarylamine: ArBr+ Ar′NHAc → ArAr′NAc.[124]

The reaction with ammonia or amines, which undoubtedly proceeds by the S_NAr mechanism, is catalyzed by copper[93,125] and nickel[126] salts, though these are normally used only with rather unreactive halides.[127] This reaction, with phase-transfer catalysis, has been used to synthesize triarylamines.[128] Copper ion catalysts (especially cuprous oxide or iodide) also permit the Gabriel synthesis (10-61) to be

applied to aromatic substrates. Aryl bromides or iodides are refluxed with potassium phthalimide and Cu_2O or CuI in dimethylacetamide to give N-aryl phthalimides, which can be hydrolyzed to primary aryl amines.[129]

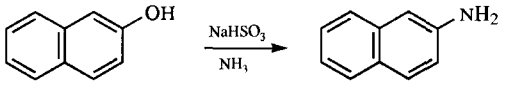
In certain cases, the $S_{RN}1$ mechanism has been found (p. 856). When the substrate is a heterocyclic aromatic nitrogen compound, still a different mechanism [the SN(ANRORC) mechanism], involving opening and reclosing of the aromatic ring, has been shown to take place.[130]

Activated aromatic compounds can be directly aminated with hydroxylamine in the presence of strong bases.[131] Conditions are mild and yields are high.

OS I, 544; **II,** 15, 221, 228; HI, 53, 307, 573; IV, 336, 364; V, 816, 1067; **VII,** 15. OS HI, 664.

13-6 *Replacement of a Hydroxy Group by an Amino Group*

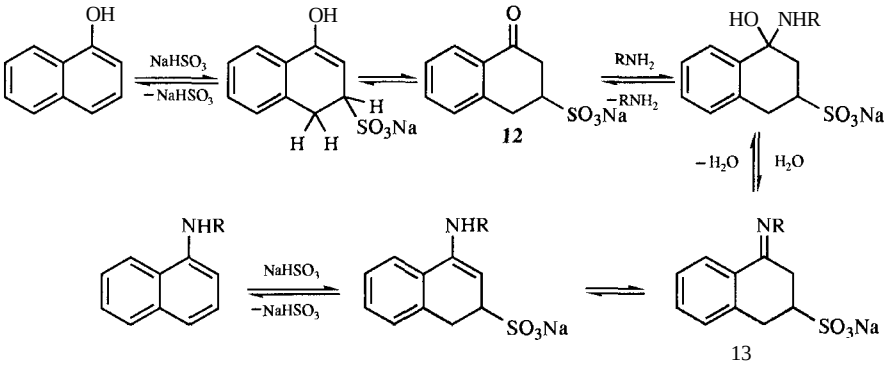
AMINO-DE-HYDROXYLATION



The reaction of naphthols with ammonia and sodium bisulfite[81] is called the *Bucherer reaction.* Primary amines can be used instead of ammonia, in which case N-substituted naphthylamines are obtained. In addition, primary naphthylamines can be converted to secondary, by a transamination reaction:

$$ArNH_2 + RNH_3 \xrightarrow{NaHSO_3} ArNHR$$

The mechanism of the Bucherer reaction amounts to a kind of overall addition-elimination:[132]



The first step in either direction consists of addition of $NaHSO_3$ to one of the double bonds of the ring, which gives an enol (or enamine) that tautomerizes to the keto (or imine) form. The conversion of **12** to 13 (or vice versa) is an example of **16-12** (or **16-2).** Evidence for this mechanism was the isolation of 12[133] and the demonstrati on that for P-naphthol treated with ammonia and HSO_3^-, the rate of the reaction depends only on the substrate and on HSO_3^-, indicating that ammonia is not involved in the rate-determining step.[134] If the starting compound is a P-naphthol,

the intermediate is a 2-keto-4-sulfonic acid compound, so the sulfur of the bisulfite in either case attacks meta to the OH or NH_2.[135]

Hydroxy groups on benzene rings can be replaced by NH_2 groups if they are first converted to aryl diethyl phosphates. Treatment of these with KNH_2 and potassium metal in liquid ammonia gives the corresponding primary aromatic amines.[136] The mechanism of the second step is $S_{RN}1$.[137]

OS III, 78.

D. *Halogen Nucleophiles*

13-7 *The Introduction of Halogens*

HALO-DE-HALOGENATION, AND SO ON

$$Ar\text{-}X + X' \longrightarrow Ar\text{-}X' + X^-$$

It is possible to replace a halogen on a ring by another halogen[138] if the ring is activated. There is an equilibrium, but it is usually possible to shift this in the desired direction by the use of an excess of added halide ion.[139] Another common leaving group is nitro, which can be replaced with chloro by use of NH_4Cl, PCl_5, $SOCl_2$, HC1, Cl_2, or CCl_4. Some of these reagents operate only at high temperatures and the mechanism is not always nucleophilic substitution. Activated aromatic nitro compounds can be converted to fluorides with F^-.[140]

A phenolic hydroxy group can be replaced by chloro with PCl_5 or $POCl_3$, but only if activated. Unactivated phenols give phosphates when treated with $POCl_3$: $3\,ArOH + POCl_3 \longrightarrow (ArO)_3PO$. Phenols, even unactivated ones, can be converted to aryl bromides by treatment with Ph_3PBr_2 (see 10-69)[141] and to aryl chlorides by treatment with $PhPCl_4$.[142]

Halide exchange is particularly useful for putting fluorine into a ring, since there are fewer alternate ways of doing this than for the other halogens. Activated aryl chlorides give fluorides when treated with KF in DMF, Me_2SO, or dimethyl sulfone.[143] Reaction of aryl halides with Bu_4PF/HF is also effective for exchanging a halogen with fluorine.[144] Halide exchange can also be accomplished with copper halides. Since the leaving-group order in this case is I > Br > Cl > >F (which means that iodides cannot normally be made by this method), the S_NAr mechanism is probably not operating.[145] However, aryl iodides have been prepared from bromides, by the use of Cu supported on charcoal or Al_2O_3,[146] and by treatment with excess KI and a nickel catalyst.[147]

OS III, 194, 272, 475; V, 142, 478; VIII, 57.

E. *Hydrogen as Nucleophile*

13-8 *Reduction of Phenols and Phenolic Esters and Ethers*[148]

HYDRO-DE-HYDROXYLATION OR DEHYDROXYLATION, AND SO ON

$$ArOH \xrightarrow{Zn} ArH$$

Phenols can be reduced by distillation over zinc dust or with HI and red phosphorus, but these methods are quite poor and are seldom feasible. Catalytic hydrogenation has also been used, but the corresponding cyclohexanol (see **15-14)** is a side product.[149]

Much better results have been obtained by conversion of phenols to certain esters or ethers and reduction of the latter:

$$ArOSO_2CF_3 \xrightarrow[Pd(OAc)_2,\ Ph_3P,\ DMF]{HCOOH,\ Et_3N} ArH \qquad \text{Ref. 150}$$

$$ArOTs + NaBH_4/NiCl_2 \longrightarrow ArH \qquad \text{Ref. 151}$$

$$ArO-\overset{\overset{O}{\|}}{P}(OEt)_2 \xrightarrow[THF]{Ti} ArH \qquad \text{Ref. 152}$$

OS VI, 150. See also OS **VII,** 476.

13-9 *Reduction of Halides and Nitro Compounds*

The reaction $ArX \rightarrow ArH$ is treated in Chapter 11 (Reaction **11-42),** although, depending on reagent and conditions, it can be nucleophilic or free-radical substitution, as well as electrophilic.

The nitro group of aromatic nitro compounds has been removed with sodium borohydride.[153] This reaction involves an addition-elimination mechanism.

F. *Carbon Nucleophiles*[154]

Some formations of new aryl–carbon bonds formed from aryl substrates have been considered in Chapter 10 (see **10-94, 10-105, 10-112, 10-113).**

13-10 *The Rosenmund–vonBraun Reaction*

CYANO-DE-HALOGENATION

$$ArBr + \text{anhydrous } CuCN \xrightarrow{200°C} ArCN$$

The reaction between aryl halides and cuprous cyanide is called the *Rosenmund–von Braun_reaction.*[155]Reactivity is in the order I > Br > Cl > F, indicating that the S_NAr mechanism does not apply.[156] Other cyanides (e.g., KCN and NaCN), do not react with aryl halides, even activated ones. However, alkali cyanides do convert aryl halides to nitriles[157] in dipolar aprotic solvents in the presence of Pd(II) salts'[158] or copper[159] or nickel[160] complexes. A nickel complex also catalyzes the reaction between aryl triflates and KCN to give aryl nitriles.[161] Aromatic ethers ArOR[162] have been photochemically converted to ArCN.

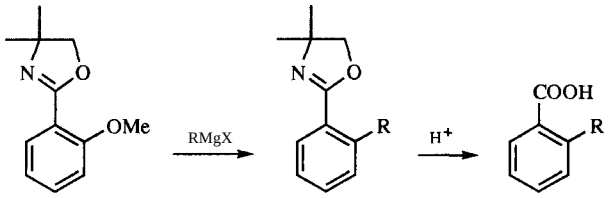
OS III, 212, 631.

13-11 *Coupling of Organometallic Compounds with Aryl Halides, Ethers, and Carboxylic Esters*

ALKYL-DE-HALOGENATION, AND SO ON

$$ArI + R_2CuLi \longrightarrow ArR$$

Aryl iodides, which need not be activated, couple with lithium dialkylcopper reagents. The reaction is discussed at 10-94. Aryl halides, even when activated, generally do not couple with Grignard reagents, though certain transition metal catalysts do effect this reaction in variable yields.[163] The reaction with Grignard reagents proceeds better when OR can be the leaving group, providing that activating groups are present in the ring. The oxazoline group actives *o*-methoxy and *o*-fluoro groups to reaction with Grignard reagents and organolithiums; the product can be hydrolyzed after coupling (see **10-108**):[164]



Unactivated aryl halides couple with alkyllithium reagents in THF[165] and with organotin compounds and a Pd complex catalyst[166] to give moderate-to-good yields of alkyl arenes. Unactivated aryl triflates[167] $ArOSO_2CF_3$ react to give ArR in good yields when treated with $R_2Cu(CN)Li_2$,[168] with R_3Al,[169] or with R'_3SnR and a Pd complex catalyst.[170] The coupling reaction between aryl halides and alkenes, with a Pd catalyst, is treated at 14-19.

Unactivated aryl halides react with copper acetylides to give good yields of arylacetylenes *(Stephens-Castro coupling).*[111]

$$ArI + RC{\equiv}CCu \longrightarrow ArC{\equiv}CR$$

R may be alkyl or aryl. A wide variety of aryl iodides has been used and the reaction is of considerable synthetic importance.

A number of methods, all catalyzed by palladium complexes, have been used to prepare unsymmetrical biaryls (see also 13-14). In these methods, aryl bromides or iodides are coupled with aryl Grignard reagents,[172] with aryltin compounds ArSnR3,[173] and with arylmercury compounds.[174] Aryl triflates react with arylboronic acids $ArB(OH)_2$,[175] or with organoboranes,[176] in the presence of a palladium catalyst, to give the arene in what is called *Suzuki coupling.*[111] Cyclopropyl groups can be attached to aromatic rings by this reaction.[178] Even hindered boronic acids give good yields of the coupled product.[179]

$$Ar\text{-}Br + Ar'B(OH)_2 \xrightarrow{PdL_4} Ar\text{-}Ar'$$

Unsymmetrical binaphthyls were synthesized by photochemically stimulated reaction of naphthyl iodides with naphthoxide ions in an $S_{RN}1$ reaction.[180] Methyl

chloroacetate coupled with aryl iodides under electrolysis conditions, using a nickel catalyst.[181] Grignard reagents also couple with aryl halides without a palladium catalyst, by the benzyne mechanism.[182] Aryl Grignard reagents coupled with phenyl allyl sulfone, in the presence of an iron catalyst, to give $ArCH_2CH{=}CH_2$.[183] In a similar manner, aryl sulfone coupled with aryl Grignard reagents in the presence of a nickel catalyst.[184]

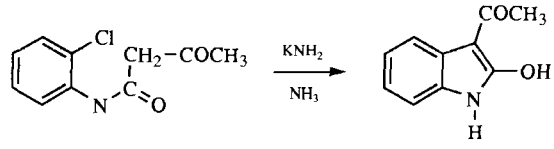
OS **VI,** 916; **VIII,** 430, 586; **75,** 53, 61 (Suzuki).

13-12 *Arylation at a Carbon Containing an Active Hydrogen*

BIS(ETHOXYCARBONYL)METHYL-DE-HALOGENATION, AND SO ON

$$ArBr + Z{-}\bar{\bar{C}}H{-}Z' \longrightarrow Z\text{-}\underset{Ar}{CH}\text{-}Z'$$

The arylation of compounds of the form ZCH_2Z' is analogous to **10-104,** and Z is as defined there. Activated aryl halides generally give good results.[185] Even unactivated aryl halides can be employed if the reaction is carried out in the presence of a strong base such as $NaNH_2$[186] or LDA. Compounds of the form ZCH_2Z' and even simple ketones[187] and carboxylic esters have been arylated in this manner. The reaction with unactivated halides proceeds by the benzyne mechanism and represents a method for extending the malonic ester (and similar) syntheses to aromatic compounds. The base performs two functions: it removes a proton from ZCH_2Z' and catalyzes the benzyne mechanism. The reaction has been used for ring closure:[188]



The reaction on unactivated halides can also be done with copper halide catalysts[93] (the *Hurtley reaction*),[189] and with palladium complex catalysts.[190]

Compounds of the form CH3Z can be arylated by treatment with an aryl halide in liquid ammonia containing Na or K, for example, [191]

$$ArX + CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_3 \xrightarrow[K]{NH_3} ArCH_2{-}\underset{\underset{O}{\|}}{C}{-}CH_3 + ArCH_2{-}\underset{\underset{OH}{|}}{CH}{-}CH_3$$

The same products are obtained (though in different proportions) when Na or K is omitted but the solution is irradiated with near-UV light.[192] In either case other leaving groups can be used instead of halogens (e.g., NR_3^+, SAr) and the mechanism is the $S_{RN}1$ mechanism. Iron(II) salts have also been used to initiate this reaction.[193] The reaction can also take place without an added initiator: Enolate ions of ketones react with PhI in the dark.[194] In this case, it has been suggested [167] that initiation takes place by

$$R_2C{=}\underset{\underset{cr}{|}}{C}\text{-}R + ArI \longrightarrow R_2\dot{C}{-}\underset{\underset{O}{\|}}{C}{-}R + ArI^{\bullet -}$$

This is an SET mechanism (see p. 402). The photostimulated reaction has also been used for ring closure.[195] In certain instances of the intermolecular reaction there is evidence that the leaving group exerts an influence on the product ratios, even when it has already departed at the time that product selection takes place.[196] Malonic and P-keto esters can be arylated in high yields by treatment with aryllead tricarboxylates: $RCOCHR'COOEt + ArPb(OAc)_3 \rightarrow RCOCArR'COOEt$,[197] and with triphenylbismuth carbonate (Ph_3BiCO_3)[198] and other bismuth reagents.[199] In a related process, manganese(III) acetate was used to convert a mixture of ArH and ZCH_2Z' to ArCHZZ'.[200]

OS V, 12, 263; VI, 36, 873, 928; **VII,** 229.

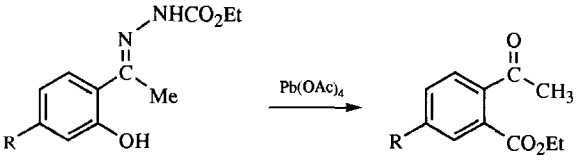
13-13 *Conversion of Aryl Substrates to Carboxylic Acids, Their Derivatives, Aldehydes, and Ketones*[201]

ALKOXYCARBONYL-DE-HALOGENATION, AND SO ON

$$ArX + ROH + CO \xrightarrow[\text{Pd complex}]{\text{base}} ArCOOR$$

Aryl bromides and iodides, when treated with carbon monoxide, an alcohol ROH, a base, and a palladium complex catalyst, give carboxylic esters. Even very sterically hindered alkoxides can be used to produce the corresponding ester.[202] The use of H_2O, RNH_2, or an alkali metal or calcium carboxylate[203] instead of ROH, gives the carboxylic acid,[204] amide,[205] or mixed anhydride, respectively.[206] With certain palladium catalysts, aryl chlorides[207] and aryl triflates[208] can also be substrates. Another reagent used (instead of CO) is dicobalt octacarbonyl, $Co_2(CO)_8$.[209] Aryl chlorides have been converted to carboxylic acids by an electrochemical synthesis,[210] and aryl iodides to aldehydes by treatment with CO, Bu_3SnH, and NCC $Me_2N{=}NCMe_2CN$ (AIBN).[211]

Lead tetraacetate has been used to convert phenols, with a hydrazone group in the ortho position, to carboxylic esters,[212] for example,



The hydrazone group is hydrolyzed **(16-2)** during the course of the reaction. Yields are high. Aryl iodides are converted to unsymmetrical diaryl ketones on treatment with arylmercury halides and nickel carbonyl: $ArI + Ar'HgX + Ni(CO)_4 \rightarrow ArCOAr'$.[213]

13-14 *The Ullmann Reaction*

DE-HALOGEN-COUPLING

$$2\ ArI \xrightarrow[\Delta]{Cu} Ar{-}Ar$$

The coupling of aryl halides with copper is called the *Ullmann reaction.*[214] The reaction is of broad scope and has been used to prepare many symmetrical and

unsymmetrical biaryls.[215] When a mixture of two different aryl halides is used, there are three possible products, but often only one is obtained. For example, picryl chloride and iodobenzene gave only 2,4,6-trinitrobiphenyl.[216] The best leaving group is iodo, and the reaction is most often done on aryl iodides, but bromides, chlorides, and even thiocyanates have been used.

The effects of other groups on the ring are unusual. The nitro group is strongly activating, but only in the ortho (not meta or para) position.[217] The R and OR groups activate in all positions. Not only do OH, NH_2, NHR, and NHCOR inhibit the reaction, as would be expected for aromatic nucleophilic substitution, but so do COOH (but not COOR), SO_2NH_2, and similar groups for which the reaction fails completely. These groups inhibit the coupling reaction by causing side reactions.

The mechanism is not known with certainty. It seems likely that it is basically a two-step process, similar to that of the Wurtz reaction **(10-93),** which can be represented schematically by

Step 1 $\quad ArI + Cu \longrightarrow ArCu$

Step 2 $\quad ArCu + ArI \longrightarrow Ar\text{-}Ar$

Organocopper compounds have been trapped by coordination with organic bases.[218] In addition, arylcopper compounds (ArCu) have been independently prepared and shown to give biaryls (ArAr') when treated with aryl iodides (Ar'I).[219] A similar reaction has been used for ring closure.[220]

An important alternative to the Ullmann method is the use of certain nickel complexes.[221] This method has also been used intramolecularly.[222] Aryl halides ArX can also be converted to Ar–Ar [223] by treatment with activated Ni metal,[224] with Zn and nickel complexes,[225] with aqueous alkaline sodium formate, Pd–C, and a phase transfer catalyst,[226] and in an electrochemical process catalyzed by a nickel complex.[227]

An asymmetric Ullmann reaction has also been reported.[228]

For other methods of coupling aromatic rings, see **13-11, 13-15, 14-17, 14-21,** and **14-22.**

OS **HI,** 339; V, 1120.

Hydrogen as Leaving Group[229]

13-15 *Alkylation and Arylation*

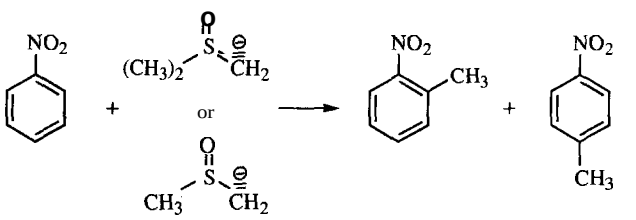
ALKYLATION OR ALKYL-DE-HYDROGENATION, AND SO ON

The alkylation of heterocyclic nitrogen compounds[230] with alkyllithium reagents is called *Ziegler alkylation.* Aryllithium reagents give arylation. The reaction occurs by an addition–elimination mechanism and the adduct can be isolated.[231] Upon

heating of the adduct, elimination of LiH occurs and an alkylated product is obtained. With respect to the 2 carbon the first step is the same as that of the S_NAr mechanism. The difference is that the unshared pair of electrons on the nitrogen combines with the lithium, so the extra pair of ring electrons has a place to go: it becomes the new unshared pair on the nitrogen.

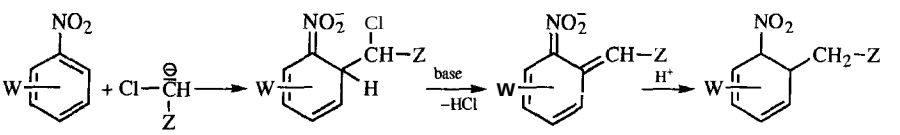
The reaction has been applied to nonheterocyclic aromatic compounds: Benzene, naphthalene, and phenanthrene have been alkylated with alkyllithium reagents, though the usual reaction with these reagents is **12-20**,[232] and Grignard reagents have been used to alkylate naphthalene.[233] The addition-elimination mechanism apparently applies in these cases too. A protected form of benzaldehyde (protected as the benzyl imine) has been similarly alkylated at the ortho position with butyllithium.[234]

Aromatic nitro compounds can be methylated with dimethyloxosulfonium methylid[235] or the methylsulfinyl carbanion (obtained by treatment of DMSO with a strong base):[236]



The latter reagent also methylates certain heterocyclic compounds (e.g., quinoline) and certain fused aromatic compounds (e.g., anthracene, phenanthrene).[237] The reactions with the sulfur carbanions are especially useful, since none of these substrates can be methylated by the Friedel–Crafts procedure (11-12). It has been reported[238] that aromatic nitro compounds can also be alkylated, not only with methyl but with other alkyl and substituted alkyl groups as well, in ortho and para positions, by treatment with an alkyllithium compound (or, with lower yields, a Grignard reagent), followed by an oxidizing agent such as Br_2 or DDQ (p. 1511).

A different kind of alkylation of nitro compounds uses carbanion nucleophiles that have a chlorine at the carbanionic carbon. The following process takes place:[239]



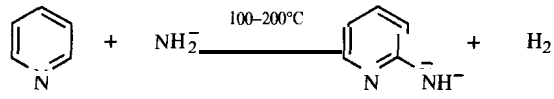
This type of process is called *vicarious nucleophilic substitution of hydrogen?*[240] The Z group is an electron-withdrawing group such as SO_2R, SO_2OR, SO_2NR_2, COOR, or CN; it stabilizes the negative charge. The carbanion attacks the activated ring ortho or para to the nitro group. Hydride ion (H^-) is not normally a leaving group, but in this case the presence of the adjacent Cl allows the hydrogen to be replaced. Hence, Cl is a "vicarious"leaving group. Other leaving groups have been used (e.g., OMe, SPh), but Cl is generally the best. Many groups W in ortho, meta, or para positions do not interfere. The reaction is also successful for di- and trinitro

compounds, for nitronaphthalenes,[241] and for many nitro heterocycles. $Z-{}^{0}CR-Cl$ may also be used.[242] When Br_3C^- or Cl_3C^- is the nucleophile the product is $ArCHX_2$, which can easily be hydrolyzed to ArCHO.[243] This is therefore an indirect way of formylating an aromatic ring containing one or more NO_2 groups, which cannot be done by any of the formylations mentioned in Chapter 11 **(11-1-11-8).**

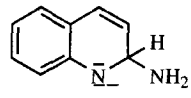
For the introduction of CH_2SR groups into phenols, see **11-26.** See also **14-23.** OS **II,** 517.

13-16 *Amination of Nitrogen Heterocycles*

AMINATION OR AMINO-DE-HYDROGENATION



Pyridine and other heterocyclic nitrogen compounds can be aminated with alkali metal amides in a process called the *Chichibabin reaction.*[244] The attack is always in the 2 position unless both such positions are filled, in which case the 4 position is attacked. Substituted alkali metal amides (e.g., RNH^- and R_2N^-) have also been used. The mechanism is probably similar to that of **13-15.** The existence of intermediate ions such as **15**



14

(from quinoline) has been demonstrated by NMR spectra.[245] A pyridyne type of intermediate was ruled out by several observations including the facts that 3-ethylpyridine gave 2-amino-3-ethylpyridine[246] and that certain heterocycles that cannot form an aryne could nevertheless be successfully aminated. Nitro compounds do not give this reaction,[247] but they have been aminated (ArH → $ArNH_2$ or ArNHR) via the vicarious substitution principle (see **13-15),** using 4-amino- or 4-alkylamino-1,2,4-triazoles as nucleophiles.[248] The vicarious leaving group in this case is the triazole ring.

Analogous reactions have been carried out with hydrazide ions (R_2NNH^-).[249] A mixture of NO_2 and O_3, with excess $NaHSO_3$, converted pyridine to 3-aminopyridine.[250] For other methods of aminating aromatic rings, see **11-6.**

There are no *Organic Syntheses* references, but see OS V, 977, for a related reaction.

N_2^+ as Leaving Group

The diazonium group can be replaced by a number of groups.[251] Some of these are nucleophilic substitutions, with S_N1 mechanisms (p. 853), but others are free-radical reactions and are treated in Chapter 14. The solvent in all these reactions is usually

water. With other solvents it has been shown that the S_N1 mechanism is favored by solvents of low nucleophilicity, while those of high nucleophilicity favor free-radical mechanisms.[252] (For *formation* of diazonium ions, see **12-47.**) The N_2^+ group can be replaced by Cl^-, Br^-, and CN^-, by a nucleophilic mechanism (see OS IV, 182), but the Sandmeyer reaction is much more useful **(14-25).** As mentioned on page 859 it must be kept in mind that the N_2^+ group can activate the removal of another group on the ring.

13-17 *Hydroxy-de-diazoniation*

$$ArN_2^+ + H_2O \longrightarrow ArOH$$

Water is usually present whenever diazonium salts are made, but at these temperatures (0-5°C) the reaction proceeds very slowly. When it is *desired* to have OH replace the diazonium group, the excess nitrous acid is destroyed and the solution is usually boiled. Some diazonium salts require even more vigorous treatment, for example, boiling with aqueous sulfuric acid or with trifluoroacetic acid containing potassium trifluoroacetate.[253] The reaction can be performed on solutions of any diazonium salts, but hydrogen sulfates are preferred to chlorides or nitrates, since in these cases there is competition from the nucleophiles Cl^- or NO_3^-. A better method, which is faster, avoids side reactions, takes place at room temperature, and gives higher yields consists of adding Cu_2O to a dilute solution of the diazonium salt dissolved in a solution containing a large excess of $Cu(NO_3)_2$.[254] Aryl radicals are intermediates when this method is used. It has been shown that aryl radicals are at least partly involved when ordinary hydroxy-de-diazoniation is carried out in weakly alkaline aqueous solution.[255] Decomposition of arenediazonium tetrafluoroborates in F_3CSO_2OH gives aryl triflates directly, in high yields.[256]

OS I, 404; **III,** 130, 453, 564; V, 1130.

13-18 *Replacement by Sulfur-Containing Groups*

MERCAPTO-DE-DIAZONIATION, AND SO ON

$$ArN_2^+ + HS^- \longrightarrow ArSH$$
$$ArN_2^+ + S^{2-} \longrightarrow ArSAr$$
$$ArN_2^+ + RS^- \longrightarrow ArSR$$
$$ArN_2^+ + SCN^- \longrightarrow ArSCN + ArNCS$$

These reactions are convenient methods for putting sulfur-containing groups onto an aromatic ring. With $Ar'S^-$, diazosulfides $Ar{-}N{=}N{-}S{-}Ar'$ are intermediates,[257] which can in some cases be isolated.[258] Thiophenols can be made as shown above, but more often the diazonium ion is treated with $EtO{-}CSS^-$ or S_2^{2-}, which give the expected products, and these are easily convertible to thiophenols. Aryl triflates have been converted to the aryl thiol using NaST(P5) and a palladium catalyst, followed by treatment with tetrabutylammonium fluoride.[259] See also **14-27.**

OS II, 580; **III,** 809 (but see **OS V, 1050).** Also see OS **II,** 238.

13-19 *Iodo-de-diazoniation*

$$ArN_2^+ + I^- \longrightarrow ArI$$

One of the best methods for the introduction of iodine into aromatic rings is the reaction of diazonium salts with iodide ions. Analogous reactions with chloride, bromide, and fluoride ions give poorer results, and **14-25** and **13-20** are preferred for the preparation of aryl chlorides, bromides, and fluorides. However, when other diazonium reactions are carried out in the presence of these ions, halides are usually side products. Aniline has also been converted to fluorobenzene by treatment with *t*-BuONO and SiF_4 followed by heating.[260] A related reaction between PhN=N-N C_4H_8 and iodine gave iodobenzene.[261]

The actual attacking species is probably not only I", if it is I^- at all. The iodide ion is oxidized (by the diazonium ion, nitrous acid, or some other oxidizing agent) to iodine, which in a solution containing iodide ions is converted to I_3^-; this is the actual attacking species, at least partly. This was shown by isolation of $ArN_2^+I_3^-$ salts, which, on standing, gave ArI.[262] From this, it can be inferred that the reason the other halide ions give poor results is not that they are poor nucleophiles but that they are poor reducing agents (compared with iodide). There is also evidence for a free-radical mechanism.[263]

OS II, 351, 355, 604; V, 1120.

13-20 *The Schiemann Reaction*

FLUORO-DE-DIAZONIATION (OVERALL TRANSFORMATION)

$$ArN_2^+ + BF_4^- \xrightarrow{\Delta} ArF + N_2 + BF_3$$

Heating of diazonium fluoroborates (the *Schiemann* or *Balz–Schiemann reaction)* is by far the best way of introducing fluorine into an aromatic ring.[264] In the most common procedure, the fluoroborate salts are prepared by diazotizing as usual with nitrous acid and HC1, and then adding a cold aqueous solution of $NaBF_4$, HBF4, or NH4BF4. A precipitate forms, which is dried, and the salt is heated in the dry state. These salts are unusually stable for diazonium salts, and the reaction is usually successful. In general, any aromatic amine that can be diazotized will form a BF_4^- salt, usually with high yields. The diazonium fluoroborates can be formed directly from primary aromatic amines with *tert*-butyl nitrite and BF_3–etherate.[265] The reaction has also been carried out on $ArN_2^+ PF_6^-$, $ArN_2^+ SbF_6^-$, and $ArN_2^+ AsF_6^-$ salts, in many cases with better yields.[266] Aryl chlorides and bromides are more commonly prepared by the Sandmeyer reaction **(14-25).** In an alternative procedure, aryl fluorides have been prepared by treatment of aryltriazenes $Ar–N=N–NR_2$ with 70% HF in pyridine.[267]

The mechanism is of the S_N1 type. That aryl cations are intermediates was shown by the following experiments:[268] aryl diazonium chlorides are known to arylate other aromatic rings by a free-radical mechanism (see **14-17).** In radical arylation it does not matter whether the other ring contains electron-withdrawing or electron-

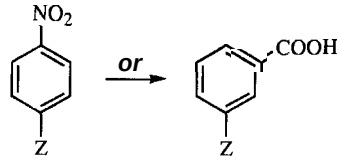
donating groups; in either case a mixture of isomers is obtained, since the attack is not by a charged species. If an aryl radical were an intermediate in the Schiemann reaction and the reaction were run in the presence of other rings, it should not matter what kinds of groups were on these other rings: Mixtures of biaryls should be obtained in all cases. But if an aryl cation is an intermediate in the Schiemann reaction, compounds containing meta-directing groups, that is, meta directing for *electrophilic* substitutions, should be meta arylated and those containing ortho-para directing groups should be ortho- and para arylated, since an aryl cation should behave in this respect like any electrophile (see Chapter 11). Experiments have shown[269] that such orientation is observed, demonstrating that the Schiemann reaction has a positively charged intermediate. The attacking species, in at least some instances, is not F" but BF_4^-.[270]

OS II, 188, 295, 299; V, 133.

Rearrangements

13-21 *The von Richter Rearrangement*

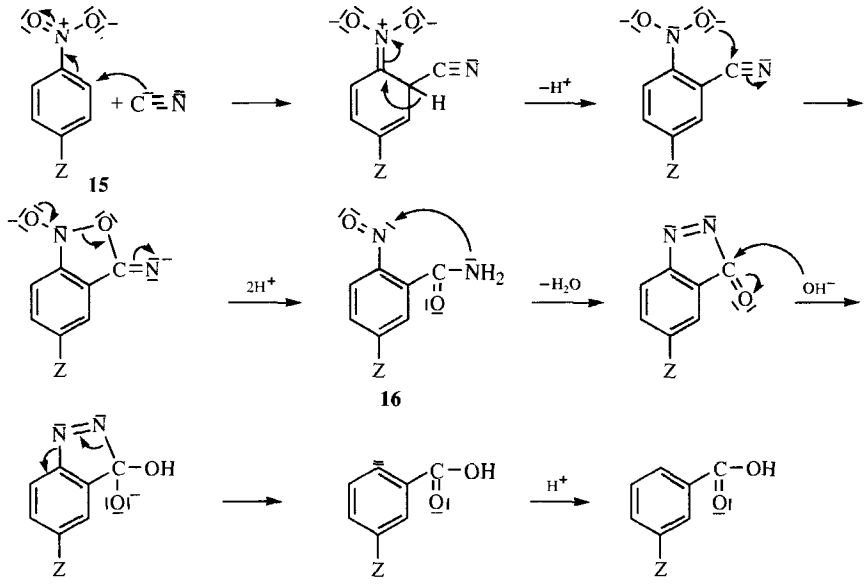
HYDRO-DE-NITRO-*cine*-substitution



When aromatic nitro compounds are treated with cyanide ion, the nitro group is displaced and a carboxyl group enters with cine substitution (p. 854), always ortho to the displaced group, never meta or para. The scope of this reaction, called the *von Richter rearrangement,* is variable.[271] As with other nucleophilic aromatic substitutions, the reaction gives best results when electron-withdrawing groups are in ortho and para positions, but yields are low, usually < 20% and never > 50%.

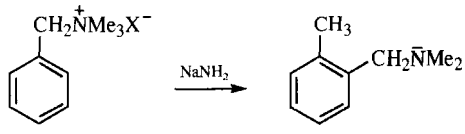
At one time it was believed that a nitrile, ArCN, was an intermediate, since cyanide is the reagent and nitriles are hydrolyzable to carboxylic acids under the reaction conditions (16-4). However, a remarkable series of results proved this belief to be in error. Bunnett and Rauhut[272] demonstrated that α-naphthyl cyanide is *not* hydrolyzable to α-naphthoic acid under conditions at which β-nitronaphthalene undergoes the von Richter rearrangement to give a-naphthoic acid. This proved that the nitrile cannot be an intermediate. It was subsequently demonstrated that N_2 is a major product of the reaction.[273] It had previously been assumed that all the nitrogen in the reaction was converted to ammonia, which would be compatible with a nitrile intermediate, since ammonia is a hydrolysis product of nitriles. At the same time it was shown that NO_2^- is not a major product. The discovery of nitrogen indicated that a nitrogen-nitrogen bond must be formed during the course of the reaction. A

mechanism in accord with all the facts was proposed by Rosenblum:[273]



It may be noted that 16 are stable compounds; hence it should be possible to prepare them independently and to subject them to the conditions of the von Richter rearrangement. This was done and the correct products are obtained.[274] Further evidence is that when 15 (Z = C1 or Br) was treated with cyanide in $H_2^{18}O$, one-half the oxygen in the product was labeled, showing that one of the oxygens of the carboxyl group came from the nitro group and one from the solvent, as required by this mechanism.[275]

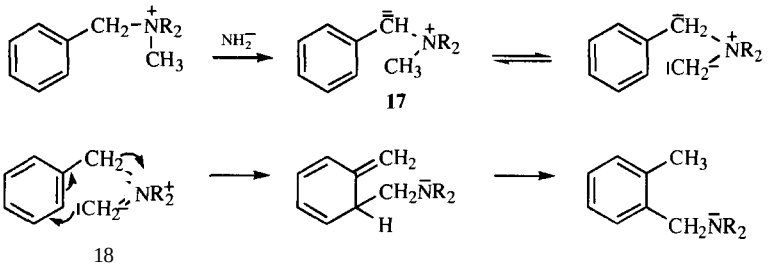
13-22 *The Sommelet–Hauser Rearrangement*



Benzylic quaternary ammonium salts, when treated with alkali metal amides, undergo a rearrangement called the *Sommelet-Hauser rearrangement*.[276] Since the product is a benzylic tertiary amine, it can be further alkylated and the product again subjected to the rearrangement. This process can be continued around the ring until an ortho position is blocked.[277]

The rearrangement occurs with high yields and can be performed with various groups present in the ring.[278] The reaction is most often carried out with three methyl groups on the nitrogen, but other groups can also be used, though if a p-hydrogen is present, Hofmann elimination (17-6) often competes. The Stevens

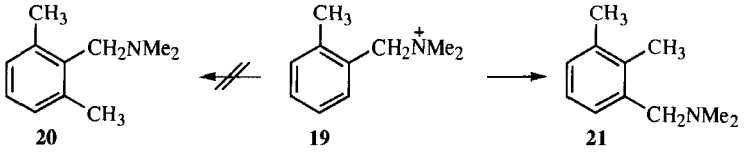
rearrangement **(18-21)** is also a competing process.[279] When both rearrangements are possible, the Stevens is favored at high temperatures and the Sommelet–Hauser at low temperatures.[280] The mechanism is



17

18

The benzylic hydrogen is most acidic and is the one that first loses a proton to give the ylid 17. However, **18,** which is present in smaller amount, is the species that undergoes the rearrangement, shifting the equilibrium in its favor. This mechanism is an example of a [2,3] sigmatropic rearrangement (see **18-35).** Another mechanism that might be proposed is one in which a methyl group actually breaks away (in some form) from the nitrogen and then attaches itself to the ring. That this is not so was shown by a product study.[281] If the second mechanism were true, 19 should give 20, but the first mechanism predicts the formation of **21,** which is what was actually obtained.[282]



20 **19** **21**

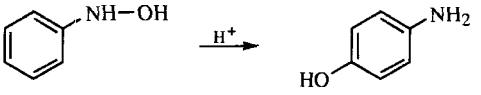
The mechanism as we have pictured it can lead only to an ortho product. However, a small amount of para product has been obtained in some cases.[283] A mechanism[284] in which there is a dissociation of the ArC–N bond (similar to the ion-pair mechanism of the Stevens rearrangement, p. 1419) has been invoked to explain the para products that are observed.

Sulfur ylids containing a benzylic group (analogous to **18)** undergo an analogous rearrangement.[285]

OS IV, 585.

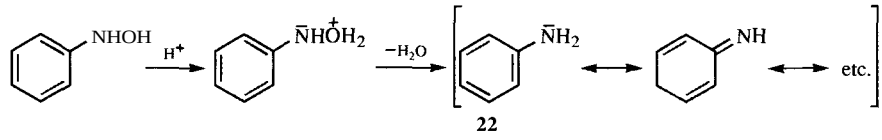
13-23 *Rearrangement of Aryl Hydroxylamines*

1/*C*-HYDRO-5/*N*-HYDROXY-INTERCHANGE

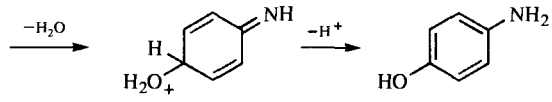


Aryl hydroxylamines treated with acids rearrange to aminophenols.[286] Although this reaction (known as the *Bamberger rearrangement)* is similar in appearance to

11-31-11-35, the attack on the ring is not electrophilic but nucleophilic. The rearrangement is intermolecular, with the following mechanism:



22

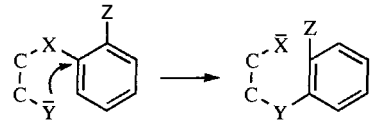


23

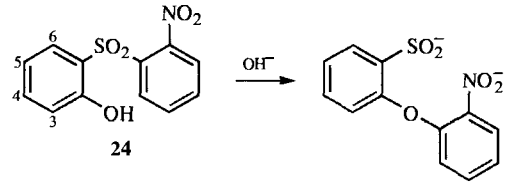
Among the evidence[287] for this mechanism are the facts that other products are obtained when the reaction is run in the presence of competing nucleophiles, for example, *p*-ethoxyaniline when ethanol is present, and that when the para position is blocked, compounds similar to 23 are isolated. In the case of 2,6-dimethylphenylhydroxylamine, the intermediate nitrenium ion 22 was trapped, and its lifetime in solution was measured.[288] The reaction of 22 with water was found to be diffusion controlled.[288]

OS IV, 148.

13-24 *The Smiles Rearrangement*



The *Smiles rearrangement* actually comprises a group of rearrangements that follow the pattern give above.[289] A specific example is



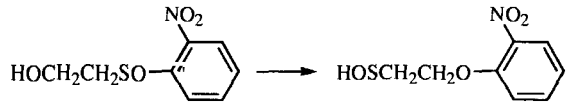
24

Smiles rearrangements are simply intramolecular nucleophilic substitutions. In the example given, SO_2Ar is the leaving group and ArO^- the nucleophile, and the nitro group serves to activate its ortho position. The ring at which the substitution takes place is nearly always activated, usually by ortho or para nitro groups. The X group is usually S, SO, SO_2,[290] O, or COO. The Y group is usually the conjugate base of OH, NH_2, NHR, or SH. The reaction has even been carried out with Y = CH_2^- (phenyllithium was the base here).[291]

The reaction rate is greatly enhanced by substitution in the 6 position of the attacking ring, for steric reasons. For example, a methyl, chloro, or bromo group in

the 6 position of 24 caused the rate to be $\sim 10^5$ times faster than when the same groups were in the 4 position,[292] though electrical effects should be similar at these positions. The enhanced rate comes about because the most favorable conformation the molecule can adopt to suit the bulk of the 6 substituent is also the conformation required for the rearrangement. Thus, less entropy of activation is required.

Although the Smiles rearrangement is usually carried out on compounds containing two rings, this need not be the case; for example,[293]



25

In this case, the sulfenic acid (25) is unstable[294] and the actual products isolated were the corresponding sulfinic acid (RSO2H) and disulfide (R_2S_2).

CHAPTER 14

Free-Radical Substitution

MECHANISMS

Free-Radical Mechanisms in General[1]

A free-radical process consists of at least two steps. The first step involves the *formation* of free radicals, usually by homolytic cleavage of bond, that is, a cleavage in which each fragment retains one electron:

$$A\text{-}B \longrightarrow A\cdot + B\cdot$$

This is called an *initiation* step. It may happen spontaneously or may be induced by heat or light (see the discussion on p. 245), depending on the type of bond. Peroxides, including hydrogen peroxide, dialkyl, diacyl, alkyl acyl peroxides, and peroxyacids are the most common source of free radicals induced spontaneously or by heat, but other organic compounds with low-energy bonds, such as azo compounds, are also used. Molecules that are cleaved by light are most often chlorine, bromine, and various ketones (see Chapter 7). Radicals can also be formed in another way, by a one-electron transfer (loss or gain), for example, $A^+ + e^- \rightarrow A\cdot$. One-electron transfers usually involve inorganic ions or electrochemical processes.

The second step involves the *destruction* of free radicals. This usually happens by a process opposite to the first, namely, a combination of two like or unlike radicals to form a new bond:[2]

$$A\cdot + B\cdot \longrightarrow A\text{-}B$$

This type of step is called *termination*, and it ends the reaction as far as these particular radicals are concerned.[3] However, it is not often that termination follows *directly* upon initiation. The reason is that most radicals are very reactive and will react with the first available species with which they come in contact. In the usual situation, in which the concentration of radicals is low, this is much more likely to be a molecule than another radical. When a radical (which has an odd number of electrons) reacts with a molecule (which has an even number), the total number of electrons in the products must be odd. The product in a particular step of this kind may be one particle, for example,

$$R\cdot + -\overset{|}{C}=\overset{|}{C}- \longrightarrow -\overset{|}{\underset{R}{C}}-\overset{|}{\dot{C}}-$$

in which case it may be another free radical; or it may consist of two particles, for example,

$$R\cdot + R'H \longrightarrow RH + R'\cdot$$

in which case one must be a molecule and one a free radical, but in any case a *new radical is generated.* This type of step is called *propagation,* since the newly formed radical can now react with another molecule and produce another radical, and so on, until two radicals do meet each other and terminate the sequence. The process just described is called a *chain reaction,*[4] and there may be hundreds or thousands of propagation steps between an initiation and a termination. Two other types of propagation reactions do not involve a molecule at all. These are (1) cleavage of a radical into, necessarily, a radical and a molecule and (2) rearrangement of one radical to another (see Chapter 18). When radicals are highly reactive, (e.g., alkyl radicals), chains are long, since reactions occur with many molecules; but with radicals of low reactivity (e.g., aryl radicals), the radical may be unable to react with anything until it meets another radical, so that chains are short, or the reaction may be a nonchain process. In any particular chain process, there is usually a wide variety of propagation and termination steps. Because of this, these reactions lead to many products and are often difficult to treat kinetically.[5]

$$R{-}CH_2\cdot + n\text{-}Bu_3Sn{-}H \longrightarrow R{-}CH_2{-}H + n\text{-}Bu_3Sn\cdot$$

$$\text{rt-Bu}\text{\^{}}Sn^* + n\text{-}Bu_3Sn\cdot \longrightarrow n\text{-}Bu_3Sn{-}Sn\,n\text{-}Bu_3$$

A useful variation of propagation and termination combines the two processes. When a carbon radical ($R\cdot$) is generated in the presence of tributyltin hydride (n-Bu_3SnH), a hydrogen atom is transferred to the radical to give R—H and a new radical, n-$Bu_3Sn\bullet$. The tin radical reacts with a second tin radical to give n-$Bu_3Sn{-}Sn\,n$-Bu_3. The net result is that the carbon radical is reduced to give the desired product and the tin dimer can be removed from the reaction. Tin hydride transfers a hydrogen atom in a chain propagation sequence that produces a new radical but terminates the carbon radical sequence. Dimerization of the tin radical then terminates that radical process. Silanes such as triethylsilane (Et_3SiH) has also been used as an effective radical reducing agent.[6] The rate constants for the reaction of both tributytin hydride and $(Me_3Si)_3Si{-}H$ with acyl radical has been measured and the silane quenches the radical faster than the tin hydride.[7] Bis(tri-n-butylstannyl)benzopinacolate has also been used as a thermal source of n-$Bu_3Sn\cdot$, used to mediate radical reactions.[8]

The following are some general characteristics of free-radical reactions:[9]

1. Reactions are fairly similar whether they are occurring in the vapor or liquid phase, though solvation of free radicals in solution does cause some differences.[10]
2. They are largely unaffected by the presence of acids or bases or by changes in the polarity of solvents, except that nonpolar solvents may suppress competing ionic reactions.

3. They are initiated or accelerated by typical free-radical sources, such as the peroxides referred to, or by light. In the latter case the concept of quantum yield applies (p. 1316). Quantum yields can be quite high, for example, 1000, if each quantum generates a long chain, or low, in the case of nonchain processes.
4. Their rates are decreased or the reactions are suppressed entirely by substances that scavenge free radicals (e.g., nitric oxide, molecular oxygen, or benzoquinone). These substances are called *inhibitors*.[11]

In this chapter, we discuss free-radical substitution reactions. Free-radical additions to unsaturated compounds and rearrangements are discussed in Chapters 15 and 18, respectively. In addition, many of the oxidation-reduction reactions considered in Chapter 19 involve free-radical mechanisms. Several important types of free-radical reactions do not usually lead to reasonable yields of pure products and are not generally treated in this book. Among these are polymerizations and high-temperature pyrolyses.

Free-Radical Substitution Mechanisms[12]

In a free-radical substitution reaction

$$\text{R–X} \longrightarrow \text{R-Y} \qquad (14.1)$$

there must first be a cleavage of the substrate RX so that R· radicals are produced. This can happen by a spontaneous cleavage

$$\text{R–X} \longrightarrow \text{R}\cdot + \text{X}\cdot \qquad (14.2)$$

or it can be caused by light or heat, or, more often, there is no actual cleavage, but R· is produced by an *abstraction*

$$\text{R-X} + \text{W}\cdot \longrightarrow \text{R}\cdot + \text{W-X} \qquad (14.3)$$

W· is produced by adding a compound, such as a peroxide, that spontaneously forms free radicals. Such a compound is called an *initiator*. Once R· is formed, it can go to product in two ways, by abstraction

$$\text{R}\cdot + \text{Y-W} \longrightarrow \text{R-Y} + \text{W} \qquad (14.4)$$

or by coupling with another radical

$$\text{R}\cdot + \text{Y}\cdot \longrightarrow \text{R-Y} \qquad (14.5)$$

In a reaction with a moderately long chain, much more of the product will be produced by abstraction (14.4) than by coupling (14.5). Cleavage steps like (14.2)

have been called S_H1 (H for homolytic), and abstraction steps like (14.3) and (14.4) have been called S_H2; reactions can be classified as S_H1 or S_H2 on the basis of whether RX is converted to R by (14.2) or (14.3).[13] Most chain substitution mechanisms follow the pattern (14.3), (14.4), (14.3), (14.4)____Chains are long and reactions go well where both (14.3) and (14.4) are energetically favored (no worse that slightly endothermic, see pp. 900, 910). The IUPAC designation of a chain reaction that follows the pattern (14.3), (14.4)... is $A_rD_R + A_RD_r$ (R stands for radical).

With certain radicals the transition state in an abstraction reaction has some polar character. For example, consider the abstraction of hydrogen from the methyl group of toluene by a bromine atom. Since bromine is more electronegative than carbon, it is reasonable to assume that in the transition state there is a separation of charge, with a partial negative charge on the halogen and a partial positive charge on the carbon:

$$\overset{\delta+}{\text{PhCH}_2}\cdots\text{H}\cdots\overset{\delta-}{\text{Br}}$$

Evidence for the polar character of the transition state is that electron-withdrawing groups in the para position of toluene (which would destabilize a positive charge) decrease the rate of hydrogen abstraction by bromine while electron-donating groups increase it.[14] However, as we might expect, substituents have a smaller effect here ($\rho \approx -1.4$) than they do in reactions where a completely ionic intermediate is involved, for example, the S_N1 mechanism (see p. 437). Other evidence for polar transition states in radical abstraction reactions is mentioned on page 902. For abstraction by radicals such as methyl or phenyl, polar effects are very small or completely absent. For example, rates of hydrogen abstraction from ring-substituted toluenes by the methyl radical were relatively unaffected by the presence of electron-donating or electron-withdrawing substituents.[15] Those radicals (e.g., Br·) that have a tendency to abstract electron-rich hydrogen atoms are called *electrophilic radicals.*

When the reaction step $R{-}X \rightarrow R\cdot$ takes place at a chiral carbon, racemization is almost always observed because free radicals do not retain configuration. Exceptions to this rule are found at cyclopropyl substrates, where both inversion[16] and retention[17] of configuration have been reported, and in the reactions mentioned on page 899.

Mechanisms at an Aromatic Substrate[18]

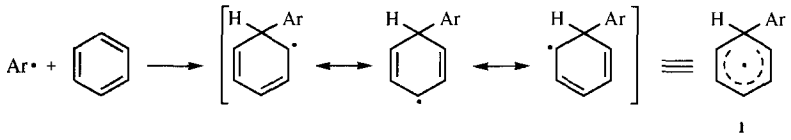
When R in Reaction (14.1) is aromatic, the simple abstraction mechanism just discussed may be operating, especially in gas-phase reactions. However, mechanisms of this type cannot account for all reactions of aromatic substrates. In processes such as the following (see **14-17, 14-21,** and **14-22):**

$$\text{Ar}\cdot + \text{ArH} \longrightarrow \text{Ar}{-}\text{Ar} \qquad (14.6)$$

which occur in solution, the coupling of two rings cannot be explained on the basis of a simple abstraction

$$Ar\cdot + ArH \longrightarrow Ar\text{-}Ar + H\cdot \qquad (14.7)$$

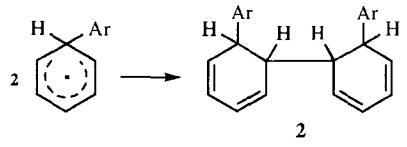
since, as discussed on page 900, abstraction of an entire group such as phenyl by a free radical is very unlikely. The products can be explained by a mechanism similar to that of electrophilic and nucleophilic aromatic substitution. In the first step, the radical attacks the ring in much the same way as would an electrophile or a nucleophile:



(14.8)

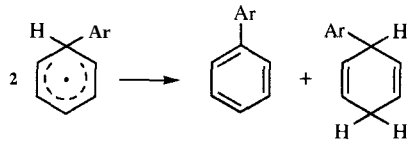
1

The intermediate is relatively stable because of the resonance. The reaction can terminate in three ways: by simple coupling, or by disproportionation



(14.9)

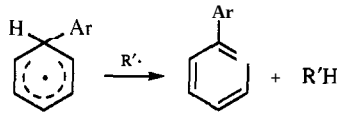
2



(14.10)

3

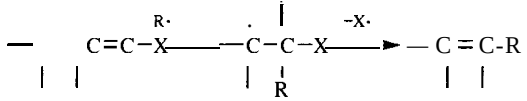
or, if a species (R'*) is present that abstracts hydrogen, by abstraction[19]



(14.11)

2 is a partially hydrogenated quaterphenyl. Of course, the coupling need not be ortho-ortho, and other isomers can also be formed. Among the evidence for Reactions (14.9) and (14.10) was isolation of compounds of types 2 and 3,[20] though normally under the reaction conditions dihydrobiphenyls like 3 are oxidized to the corresponding biphenyls. Other evidence for this mechanism is the detection of the intermediate 1 by CIDNP[21] and the absence of isotope effects, which would be

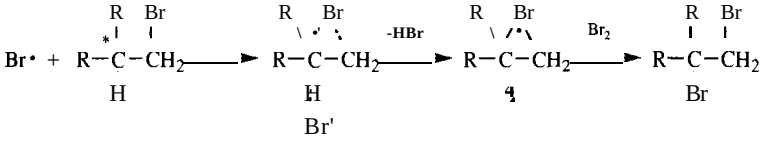
expected if the rate-determining step were Reaction (14-7), which involves cleavage of the Ar—H bond. In the mechanism just given, the rate-determining step in Reaction **(14-8)** does not involve loss of hydrogen. The reaction between aromatic rings and the OH· radical takes place by the same mechanism. A similar mechanism has been shown for substitution at some vinylic and acetylenic substrates, for example:[22]



This is reminiscent of the nucleophilic tetrahedral mechanism at a vinylic carbon (p. 429).

Neighboring-Group Assistance in Free-Radical Reactions

In a few cases, it has been shown that cleavage steps in Reaction **(14-2)** and abstraction steps in Reaction **(14-3)** have been accelerated by the presence of neighboring groups. Photolytic halogenation **(14-1)** is a process that normally leads to mixtures of many products. However, bromination of carbon chains containing a bromine atom occurs with high regioselectivity. Bromination of alkyl bromides gave 84-94% substitution at the carbon adjacent to the bromine already in the molecule.[23] This result is especially surprising because, as we shall see (p. 902), positions close to a polar group such as bromine should actually be *deactivated* by the electron-withdrawing field effect of the bromine. The unusual regioselectivity is explained by a mechanism in which abstraction in Reaction **(14-3)** is assisted by a neighboring bromine atom:[24]



In the normal mechanism, Br abstracts a hydrogen from RH, leaving R·. When a bromine is present in the proper position, it assists this process, giving a cyclic intermediate (a *bridged free radical*, 4).[25] In the final step (very similar to $R\cdot + Br_2 \rightarrow RBr + Br$), the ring is broken. If this mechanism is correct, the configuration at the substituted carbon (marked*) should be retained. This has been shown to be the case: optically active 1-bromo-2-methylbutane gave 1,2-dibromo-2-raethylbutane with retention of configuration.[24] Furthermore, when this reaction was carried out in the presence of DBr, the "recovered" 1-bromo-2-methylbutane was found to be deuterated in the 2 position, and its configuration was retained.[26] This is just what would be predicted if some of the 4 present abstracted D from DBr. There is evidence that Cl can form bridged radicals,[27] though ESR spectra show that the bridging is not necessarily symmetrical.[28] Still more evidence for bridging by Br has been found in isotope effect and other studies.[29] However, evidence from CIDNP shows that the methylene protons of the β-bromoethyl radical are not equivalent, at

least while the radical is present in the radical pair [$PhCOO\cdot\cdot CH_2CH_2Br$] within a solvent cage.[30] This evidence indicates that under these conditions $BrCH_2CH_2\cdot$ is not a symmetrically bridged radical, but it could be unsymmetrically bridged. A bridged intermediate has also been invoked, when a bromo group is in the proper position, in the Hunsdiecker reaction (14-37),[31] and in abstraction of iodine atoms by the phenyl radical.[32] Participation by other neighboring groups (e.g. SR, SiR_3, SnR_3), has also been reported.[33]

REACTIVITY

Reactivity for Aliphatic Substrates[34]

In a chain reaction, the step that determines what the product will be is most often an abstraction step. What is abstracted by a free radical is almost never a tetra-[35] or tervalent atom[36] (except in strained systems, see p. 989)[37] and seldom a divalent one.[38] Nearly always it is univalent, and so, for organic compounds, it is hydrogen or halogen. For example, a reaction between a chlorine atom and ethane gives an ethyl radical, not a hydrogen atom:

$$\begin{array}{rl} & H{-}Cl + CH_3CH_2\cdot \qquad Mi = -3\ \text{kcal mol}^{-1},\ -13\ \text{kJ mol}^{-1} \\ CH_3CH_3 + Cl\cdot & \\ & CH_3CH_2{-}Cl + H\cdot \qquad AH = +18\ \text{kcal mol}^{-1},\ +76\ \text{kJ mol}^{-1} \end{array}$$

The principal reason for this is steric. A univalent atom is much more exposed to attack by the incoming radical than an atom with a higher valence. Another reason is that in many cases abstraction of a univalent atom is energetically more favored. For example, in the reaction given above, a $C_2H_5{-}H$ bond is broken (D = 100 kcal mol^{-1}, 419 kJ mol^{-1}, from Table 5.3) whichever pathway is taken, but in the former case an H–Cl bond is formed (D = 103 kcal mol^{-1}, 432 kJ mol^{-1}) while in the latter case it is a C_2H_5–Cl bond (D = 82 kcal mol^{-1}, 343 kJ mol^{-1}). Thus the first reaction is favored because it is exothermic by 3 kcal mol^{-1} [13 kJ mol^{-1}], while the latter is endothermic by 18 kcal mol^{-1} [76 kJ mol^{-1}].[39] However, the steric reason is clearly more important, because even in cases where AH is not very different for the two possibilities, the univalent atom is chosen.[40] *Ab initio* studies have probed the transition structures for radical hydrogen abstractions.[41]

Most studies of aliphatic reactivity have been made with hydrogen as the leaving atom and chlorine atoms as the abstracting species.[42] In these reactions, every hydrogen in the substrate is potentially replaceable and mixtures are usually obtained. However, the abstracting radical is not totally unselective, and some positions on a molecule lose hydrogen more easily than others. *Ab initio* studies have studied the factors controlling hydrogen abstraction by radicals.[43] For hydrogen abstraction by the *tert*-butoxy radical (*t*-Bu–O·) the factors that influence rate in

TABLE 14.1 Relative Susceptibility to Attack by Cl· of Primary, Secondary, and Tertiary Positions at 100 and 600° C in the Gas Phase

Temperature (°C)	Primary	Secondary	Tertiary
100	1	4.3	7.0
600	1	2.1	2.6

their order of importance are structure of the radical > substituent effects > solvent effects.[44] We discuss the position of attack under several headings:[45]

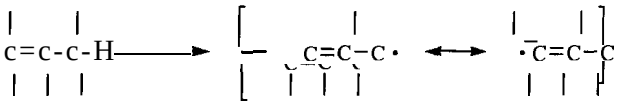
1. *Alkanes.* The tertiary hydrogens of an alkane are the ones preferentially abstracted by almost any radical, with secondary hydrogens being next preferred. This is in the same order as *D* values for these types of C–H bonds (Table 5.3). The extent of the preference depends on the selectivity of the abstracting radical and on the temperature. Table 14.1[46] shows that at high temperatures selectivity decreases, as might be expected.[47] An example of the effect of radical selectivity may be noted in a comparison of fluorine atoms with bromine atoms. For the former, the ratio of primary to tertiary abstraction (of hydrogen) is 1:1.4, while for the less reactive bromine atom this ratio is 1:1600. With certain large radicals there is a steric factor that may change the selectivity pattern. For example, in the photochemical chlorination of isopentane in H_2SO_4 with *N*-chloro-di-*tert*-butylamine and *N*-chloro-*tert*-butyl-tert-pentylamine, the primary hydrogens are abstracted 1.7 times *faster* than the tertiary hydrogen.[48] In this case, the attacking radicals (the radical ions $R_2NH\cdot^+$, see p. 909) are bulky enough for steric hindrance to become a major factor.

5

Cyclopropylcarbinyl radicals (5) are alkyl radicals but they undergo rapid ring opening to give butenyl radicals.[49] The rate constant for this process has been measured by picosecond radical kinetic techniques to be in the range of $10^7 M^{-1} s^{-1}$ for the parent[50] to $10^{10} M^{-1} s^{-1}$ for substituted derivatives.[51] This process has been observed in bicyclo[4.1.0]heptan-4-ones.[52]

2. *Alkenes.* When the substrate molecule contains a double bond, treatment with chlorine or bromine usually leads to addition rather than substitution. However, for other radicals (and even for chlorine or bromine atoms when they do abstract a hydrogen) the position of attack is perfectly clear. Vinylic hydrogens are practically never abstracted, and allylic hydrogens are greatly preferred to other positions of the molecule. Allylic hydrogen abstraction from a cyclic alkenes is usually faster than abstraction from an acyclic alkene.[53]

This is generally attributed[54] to resonance stabilization of the allylic radical:



As might be expected, allylic rearrangements (see p. 421) are common in these cases.[55]

3. *Alkyl Side Chains of Aromatic Rings.* The preferential position of attack on a side chain is usually the one a to the ring. Both for active radicals such as chlorine and phenyl and for more selective ones such as bromine such attack is faster than that at a primary carbon, but for the active radicals benzylic attack is slower than for tertiary positions, while for the selective ones it is faster. Two or three aryl groups on a carbon activate its hydrogens even more, as would be expected from the resonance involved. These statements can be illustrated by the following abstraction ratios:[56]

	Me-H	$MeCH_2$–H	Me_2CH–H	Me_3C–H	$PhCH_2$–H	Ph_2CH–H	Ph_3C–H
Br	0.0007	1	220	19,400	64,000	1.1×10^6	6.4×10^6
Cl	0.004	1	4.3	6.0	1.3	2.6	9.5

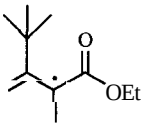
However, many anomalous results have been reported for these substrates. The benzylic position is not always the most favored. One thing certain is that *aromatic* hydrogens are seldom abstracted if there are aliphatic ones to compete (note from Table 5.3, that *D* for Ph–H is higher than that for any alkyl H bond). Several $\sigma\cdot$ scales (similar to the cr, σ^+, and σ^- scales discussed in Chapter 9) have been developed for benzylic radicals.[57]

4. *Compounds Containing Electron-Withdrawing Substituents.* In halogenations, electron-withdrawing groups greatly deactivate adjacent positions. Compounds of the type $Z–CH_2–CH_3$ are attacked predominantly or exclusively at the (3 position when Z is COOH, COCl, COOR, SO_2Cl, or CX_3. Such compounds as acetic acid and acetyl chloride are not attacked at all. This is in sharp contrast to electrophilic halogenations **(12-4-12-6),** where *only* the α-position is substituted. This deactivation of a positions is also at variance with the expected stability of the resulting radicals, since they would be expected to be stabilized by resonance similar to that for allylic and benzylic radicals. This behavior is a result of the polar transition states discussed on page 896. Halogen atoms are electrophilic radicals and look for positions of high electron density. Hydrogens on carbon atoms next to electron-withdrawing groups have low electron densities (because of the field effect of Z) and are therefore shunned. Radicals that are not electrophilic do not display this behavior. For example, the methyl radical is essentially nonpolar and does not avoid positions next to electron-withdrawing groups; relative rates of abstraction at the a and β carbons of propionic acid are[58]

	$CH_3–CH_2–COOH$	
Me·	1	7.8
Cl·	1	0.02

It is possible to generate radicals adjacent to electron-withdrawing groups. Radical 6 can be generated and it undergoes coupling reactions with little selectivity. When 7 is generated, however, it rapidly disproportionates rather than couples, giving the corresponding alkene and alkane.[59] Such radicals have also been shown to have a conformational preference for orientation of the orbital containing the single electron. In such cases, hydrogen abstraction proceeds with good stereoselectivity.[60]

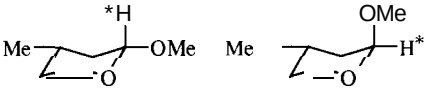
6



7

Some radicals (e.g., terf-butyl,[61] benzyl,[62] and cyclopropyl),[63] are *nucleophilic* (they tend to abstract electron-poor hydrogen atoms). The phenyl radical appears to have a very small degree of nucleophilic character.[64] For longer chains, the field effect continues, and the (3 position is also deactivated to attack by halogen, though much less so than the a position. We have already mentioned (p. 896) that abstraction of an a hydrogen atom from ring-substituted toluenes can be correlated by the Hammett equation.

5. *Stereoelectronic Effects.* On page 427, we saw an example of a stereoelectronic effect. It has been shown that such effects are important where a hydrogen is abstracted from a carbon adjacent to a C–O or C–N bond. In such cases hydrogen is abstracted from C–H bonds that have a relatively small dihedral angle ($\approx$30°) with the unshared orbitals of the O or N much more easily than from those with a large angle ($\approx$90°). For example, the starred hydrogen of 8 was abstracted about eight times faster than the starred hydrogen of 9.[65]



8

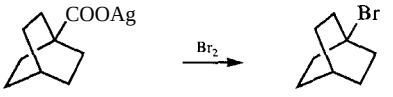
9

The presence of an OR or SiR_3 substituent β to the carbon bearing the radical accelerates the rate of halogen abstraction.[66]

Abstraction of a halogen has been studied much less,[67] but the order of reactivity is RI > RBr > RCl $\gg$ RF. There are now many cases where free-radical reactions are promoted by transition metals.[68]

Reactivity at a Bridgehead[69]

Many free-radical reactions have been observed at bridgehead carbons (e.g., see 14-37),[70]

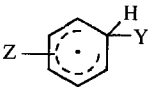


87%

demonstrating that the free radical need not be planar. However, treatment of norbornane with sulfuryl chloride and benzoyl peroxide gave mostly 2-chloronorbornane, though the bridgehead position is tertiary.[71] So, while bridgehead free-radical substitution is possible, it is not preferred, presumably because of the strain involved.[72]

Reactivity in Aromatic Substrates

Free-radical substitution at an aromatic carbon seldom takes place by a mechanism in which a hydrogen is abstracted to give an aryl radical. Reactivity considerations here are similar to those in Chapters 11 and 13; that is, we need to know which position on the ring will be attacked to give the intermediate



The obvious way to obtain this information is to carry out reactions with various Z groups and to analyze the products for percent ortho, meta, and para isomers, as has so often been done for electrophilic substitution. However, this procedure is much less accurate in the case of free-radical substitutions because of the many side reactions. It may be, for example, that in a given case the ortho position is more reactive than the para, but the intermediate from the para attack may go on to product while that from ortho attack gives a side reaction. In such a case, analysis of the three products does not give a true picture of which position is most susceptible to attack. The following generalizations can nevertheless be drawn, though there has been much controversy over just how meaningful such conclusions are[73]

1. All substituents increase reactivity at ortho and para positions over that of benzene. There is no great difference between electron-donating and electron-withdrawing groups.
2. Reactivity at meta positions is usually similar to that of benzene, perhaps slightly higher or lower. This fact, coupled with the preceding one, means that all substituents are activating and ortho-para directing; none are deactivating or (chiefly) meta directing.
3. Reactivity at ortho positions is usually somewhat greater than at para positions, except where a large group decreases ortho reactivity for steric reasons.

TABLE 14.2 Partial Rate Factors for Attack of Substituted Benzenes by Phenyl Radicals Generated from Bz_2O_2 (Reaction 14-21)

	Partial Rate Factor		
Z	o	m	p
H	1	1	1
NO_2	5.50	0.86	4.90
CH_3	4.70	1.24	3.55
CMe_3	0.70	1.64	1.81
Cl	3.90	1.65	2.12
Br	3.05	1.70	1.92
MeO	5.6	1.23	2.31

4. In direct competition, electron-withdrawing groups exert a somewhat greater influence than electron-donating groups. Arylation of para-disubstituted compounds XC_6H_4Y showed that substitution ortho to the group X became increasingly preferred as the electron-withdrawing character of X increases (with Y held constant).[74] The increase could be correlated with the Hammett σ_p values for X.
5. Substituents have a much smaller effect than in electrophilic or nucleophilic substitution; hence the partial rate factors (see p. 690) are not great.[75] Partial rate factors for a few groups are given in Table 14.2.[76]
6. Although hydrogen is the leaving group in most free-radical aromatic substitutions, ipso attack (p. 687) and ipso substitution (e.g., with Br, NO_2, or CH3CO as the leaving group) have been found in certain cases.[77]

Reactivity in the Attacking Radical[78]

We have already seen that some radicals are much more selective than others (p. 901). The bromine atom is so selective that when only primary hydrogens are available, as in neopentane or tert-butylbenzene, the reaction is slow or nonexistent; and isobutane can be selectively brominated to give tert-butyl bromide in high yields. However, toluene reacts with bromine atoms instantly. Bromination of other alkylbenzenes (e.g., ethylbenzene and cumene) takes place exclusively at the a position,[79] emphasizing the selectivity of Br. The dissociation energy (D) of the C–H bond is more important for radicals of low reactivity than for highly reactive radicals, since bond breaking in the transition state is greater. Thus, bromine shows a greater tendency than chlorine to attack a to an electron-withdrawing group because the energy of the C–H bond there is lower than in other places in the molecule.

Some radicals (e.g., triphenylmethyl) are so unreactive that they abstract hydrogens very poorly if at all. Table 14.3 lists some common free radicals in approximate order of reactivity.[80]

TABLE 14.3 Some Common Free Radicals in Decreasing Order of **Activity**[a]

$$X\cdot + C_2H_6 \rightarrow X{-}H + C_2H_5\cdot$$[b]

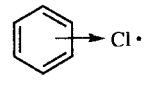
	E			E	
Radical	kcal mol^{-1}	kJ mol^{-1}	Radical	kcal mol^{-1}	kJ mol^{-1}
F·	0.3	1.3	H·	9.0	38
Cl·	1.0	4.2	Me·	11.8	49.4
MeO	7.1	30	Br·	13.2	55.2
CF_3·	7.5	31			

[a] The E values represent activation energies for the reaction *i*-Pr· is less active than Me· and *t*-Bu· still less so.[81]
[b] See Ref. 80.

It has been mentioned that some free radicals (e.g., chloro) are electrophilic and some (e.g., *tert*-butyl) are nucleophilic. It must be borne in mind that these tendencies are relatively slight compared with the electrophilicity of a positive ion or the nucleophilicity of a negative ion. The predominant character of a free radical is neutral, whether it has slight electrophilic or nucleophilic tendencies.

The Effect of Solvent on Reactivity[82]

As has been noted earlier, the solvent usually has little effect on free-radical substitutions in contrast to ionic ones: indeed, reactions in solution are often quite similar in character to those in the gas phase, where there is no solvent at all. However, in certain cases the solvent *can* make an appreciable difference. Chlorination of 2,3-dimethylbutane in aliphatic solvents gave ~60% $(CH_3)_2CHCH(CH_3)CH_2Cl$ and 40% $(CH_3)_2CHCCl(CH_3)_2$, while in aromatic solvents the ratio became ~10:90.[83] This result is attributed to complex formation between the



10

aromatic solvent and the chlorine atom that makes the chlorine more selective.[84] This type of effect is not found in cases where the differences in abstractability are caused by field effects of electron-withdrawing groups (p. 902). In such cases, aromatic solvents make little difference.[85] Complex 10 has been detected[86] as a very short-lived species by observation of its visible spectrum in the pulse radiolysis of a solution of benzene in CCl_4.[87] Differences caused by solvents have also been reported in reactions of other radicals.[88] Some of the anomalous results obtained in the chlorination of aromatic side chains (p. 902) can also be explained by this type of complexing, in this case not with the solvent but with the reacting species.[89] Much

smaller, though real, differences in selectivity have been found when the solvent in the chlorination of 2,3-dimethylbutane is changed from an alkane to CCl_4.[90] However, these differences are not caused by formation of a complex between Cl· and the solvent. There are cases, however, where the rate of reaction for trapping a radical depends on the polarity of the solvent, particularly in water.[91]

REACTIONS

The reactions in this chapter are classified according to leaving group. The most common leaving groups are hydrogen and nitrogen (from the diazonium ion); these are considered first.

Hydrogen as Leaving Group

A. *Substitution by Halogen*

14-1 *Halogenation at an Alkyl Carbon*[92]

HALOGENATION OR HALO-DE-HYDROGENATION

$$R\text{-}H + Cl_2 \xrightarrow{h\nu} R\text{-}Cl$$

Alkanes can be chlorinated or brominated by treatment with chlorine or bromine in the presence of visible or UV light.[93] The reaction can also be applied to alkyl chains containing many functional groups. The chlorination reaction is usually not useful for preparative purposes precisely because it is so general: not only does substitution take place at virtually every alkyl carbon in the molecule, but di- and polychloro substitution almost invariably occur even if there is a large molar ratio of substrate to halogen. When functional groups are present, the principles are those outlined on page 901; favored positions are those a to aromatic rings, while positions a to electron-withdrawing groups are least likely to be substituted. Tertiary carbons are most likely to be attacked and primary least. Positions a to an OR group are very readily attacked. Nevertheless, mixtures are nearly always obtained. This can be contrasted to the regioselectivity of electrophilic halogenation (12-4-12-6), which always takes place a to a carbonyl group (except when the reaction is catalyzed by $AgSbF_6$; see the following). Of course, if a *mixture* of chlorides is wanted, the reaction is usually quite satisfactory. For obtaining pure compounds, the chlorination reaction is essentially limited to substrates with only one type of replaceable hydrogen (e.g., ethane, cyclohexane, neopentane). The most common are methylbenzenes and other substrates with methyl groups on aromatic rings, since few cases are known where halogen atoms substitute at an aromatic position.[94] Of course, ring substitution *does* take place in the presence of a positive ion forming catalyst (11-11). In addition to mixtures of various alkyl halides, traces of other products are obtained. These include dihydrogen, alkenes, higher alkanes, lower alkanes, and

halogen derivatives of these compounds. Solvent plays an important role in this process.[95]

The bromine atom is much more selective than the chlorine atom. As indicated on page 906, it is often possible to brominate tertiary and benzylic positions selectively. High regioselectivity can also be obtained where the neighboring-group mechanism (p. 899) can operate.

As already mentioned, halogenation can be performed with chlorine or bromine. Fluorine has also been used,[96] but seldom, because it is too reactive and hard to control.[97] It often breaks carbon chains down into smaller units, a side reaction that sometimes becomes troublesome in chlorinations too. Fluorination[98] has been achieved by the use of chlorine trifluoride ClF_3 at $-75°C$.[99] For example, cyclohexane gave 41% fluorocyclohexane and methylcyclohexane gave 47% 1-fluoro-1-methylcyclohexane. Fluoroxytrifluoromethane (CF_3OF) fluorinates tertiary positions of certain molecules in good yields with high regioselectivity.[100] For example, adamantane gave 75% 1-fluoroadamantane. Difluorine (F_2) at -70°C, diluted with N_2,[101] and bromine trifluoride at 25-35°C[102] are also highly regioselective for tertiary positions. These reactions probably have electrophilic,[103] not free-radical mechanisms. In fact, the success of the F_2 reactions depends on the suppression of free-radical pathways, by dilution with an inert gas, by working at low temperatures, and/or by the use of radical scavengers.

Iodine can be used if the activating light has a wavelength of 184.9 nm,[104] but iodinations are seldom attempted, largely because the HI formed reduces the alkyl iodide.

Many other halogenation agents have been employed, the most common of which is sulfuryl chloride (SO_2Cl_2).[105] A mixture of Br_2 and HgO is a more active brominating agent than bromine alone.[106] The actual brominating agent in this case is believed to be bromine monoxide (Br_2O). Among other agents used have been NBS (see 14-2), CCl_4,[107] $BrCCl_3$,[108] PCl_5,[109] and N-haloamines and sulfuric acid.[110] In all these cases a chain-initiating catalyst is required, usually peroxides or UV light.

A base-induced bromination has been reported. 2-Methyl butane reacts with 50% aqueous NaOH and CBr_4, in a phase-transfer catalyst, to give a modest yields of 2-bromo-2-methylbutane.[111]

When chlorination is carried out with N-haloamines and sulfuric acid (catalyzed by either UV light or metal ions), selectivity is much greater than with other reagents.[110] In particular, alkyl chains are chlorinated with high regioselectivity at the position next to the end of the chain (the $\omega - 1$ position).[112] Some typical selectivity values are[113]

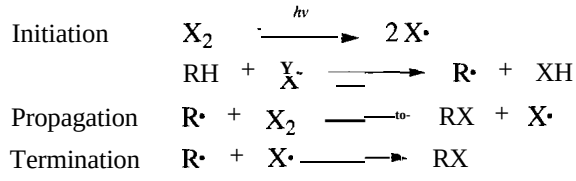
$$\underset{1}{CH_3}-\underset{56}{CH_2}-\underset{29}{CH_2}-\underset{14}{CH_2}-CH_2-CH_2-CH_3 \qquad \text{Ref. 114}$$

$$\underset{1}{CH_3}-\underset{92}{CH_2}-\underset{3}{CH_2}-\underset{1}{CH_2}-\underset{1}{CH_2}-\underset{2}{CH_2}-\underset{0}{CH_2}-\underset{0}{CH_2}-OH \qquad \text{Ref 115}$$

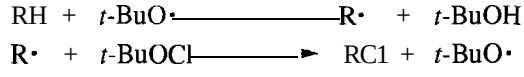
$$\underset{3}{CH_3}-\underset{72}{CH_2}-\underset{20}{CH_2}-\underset{4}{CH_2}-\underset{1}{CH_2}-\underset{0}{CH_2}-COOMe \qquad \text{Ref 116}$$

Furthermore, di- and polychlorination are much less prevalent. Dicarboxylic acids are predominantly chlorinated in the middle of the chain,[117] and adamantane and bicyclo[2.2.2]octane at the bridgeheads[118] by this procedure. The reasons for the high $\omega-1$ specificity are not clearly understood.[119] Alkyl bromides can be regioselectively chlorinated one carbon away from the bromine (to give *vic*-bromochlorides) by treatment with PCl_5.[120] Alkyl chlorides can be converted to *vic*-dichlorides by treatment with $MoCl_5$.[121] Enhanced selectivity at a terminal position of *n*-alkanes has been achieved by absorbing the substrate onto a pentasil zeolite.[122] In another regioselective chlorination, alkanesulfonamides $RCH_2CH_2CH_2SO_2NHR'$ are converted primarily to $RCHClCH_2CH_2SO_2NHR'$ by sodium peroxydisulfate ($Na_2S_2O_8$) and $CuCl_2$.[123] For regioselective chlorination at certain positions of the steroid nucleus, see **19-2.**

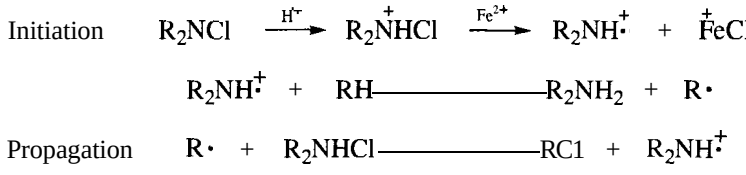
In almost all cases, the mechanism involves a free-radical chain:



When the reagent is halogen, initiation occurs as shown above.[124] When it is another reagent, a similar cleavage occurs (catalyzed by light or, more commonly, peroxides), followed by propagation steps that do not necessarily involve abstraction by halogen. For example, the propagation steps for chlorination by *t*-BuOCl have been formulated as[125]



and the abstracting radicals in the case of N-haloamines are the aminium radical cations $R_2NH^{\cdot+}$ (p. 701), with the following mechanism (in the case of initiation by Fe^{2+}):[110]



This mechanism is similar to that of the Hofmann–Löffler reaction **(18-40).**

The two propagation steps shown above for X_2 are those that lead directly to the principal products (RX and HX), but many other propagation steps are possible and many occur. Similarly, the only termination step shown is the one that leads to RX, but any two radicals may combine. Thus, products like H_2, higher alkanes, and higher alkyl halides can be accounted for by steps like these (these are for

chlorination of methane, but analogous steps can be written for other substrates):

$$Cl\cdot + HCl \longrightarrow Cl{-}Cl + H\cdot$$
$$H + H\cdot \longrightarrow H{-}H$$
$$\cdot CH_3 + \cdot CH_3 \longrightarrow CH3CH3$$
$$CH_3CH_3 + Cl\cdot \longrightarrow CH_3CH_2\cdot + HC1$$
$$CH_3CH_2\cdot + Cl_2 \longrightarrow CH_3CH_2Cl + Cl\text{-}$$
$$CH_3CH_2\cdot + CH_3CH_2\cdot \longrightarrow CH_3CH_3 + CH_2{=}CH_2$$
$$CH_3CH_2\cdot + CH_3CH_2\cdot \longrightarrow CH_3CH_2{-}CH_2CH_3$$
$$CH_3CH_2\cdot + HC1 \longrightarrow CH_3CH_3 + Cl\cdot$$

etc.

At least when methane is the substrate, the rate-determining step is

$$CH4 + Cl\cdot \longrightarrow \cdot CH_3 + HCl$$

since an isotope effect of 12.1 was observed at 0°C.[126] For chlorinations, chains are very long, typically 10^4–10^6 propagations before a termination step takes place.

The order of reactivity of the halogens can be explained by energy considerations. For the substrate methane, *AH* values for the two principal propagation steps are

	F_2	Cl_2	Br_2	I2	F2	Cl_2	Br_2	I_2
	(kcal mol^{-1})				(kJ/mol^{-1})			
CH4 + X· → CH_3· + HX	-31	+2	+ 17	+34	-132	+6	+72	+ 140
CH4 + X2 → CH_3X + X·	-70	-26	-24	-21	-293	-113	-100	-87

In each case, *D* for CH_3–H is 105 kcal mol^{-1} (438 kJ mol^{-1}), while *D* values for the other bonds involved are given in Table 14.4.[127] The F_2 compound is so reactive[128] that neither UV light nor any other initiation is needed (total $AH = -101$ kcal mol^{-1}; -425 kJ mol^{-1});[129] while Br_2 and I_2 essentially do not react with methane. The second step is exothermic in all four cases, but it cannot take place before the first, and it is this step that is very unfavorable for Br_2 and I_2. It is apparent that the most important single factor causing the order of halogen reactivity to be $F_2 > Cl_2 > Br_2 > I_2$ is the decreasing strength of the HX bond in the order HF > HC1 > HBr > HI. The increased reactivity of secondary and tertiary positions is in accord with the decrease in *D* values for R–H in the order primary > secondary > tertiary (Table 5.3). (Note that for chlorination step 1 is exothermic for practically all substrates other than CH4, since most other aliphatic C–H bonds are weaker than those in CH4.)

Bromination and chlorination of alkanes and cycloalkanes can also take place by an electrophilic mechanism if the reaction is catalyzed by $AgSbF_6$.[130] Direct chlorination at a vinylic position by an electrophilic mechanism has been achieved with benzeneseleninyl chloride, PhSe(O)Cl, and $AlCl_3$ or $AlBr_3$.[131] However, while

TABLE 14.4 Some *D* Values

	D	
Bond	(kcal mol^{-1})	(kJ mol^{-1})
H–F	136	570
H–Cl	103	432

CH_3–Cl	85	356
CH_3–Br	70	293
CH_3–I	57	238

some substituted alkenes give high yields of chloro substitution products, others (such as styrene) undergo addition of Cl_2 to the double bond (**15-37**).[131] Electrophilic fluorination has already been mentioned (p. 908).

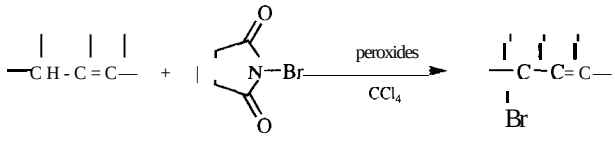
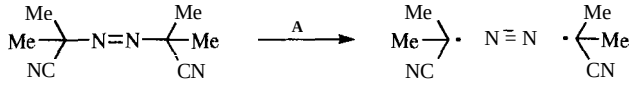
14-2 *Allylic and Benzylic Halogenation*

HALOGENATION OR HALO-DE-HYDROGENATION

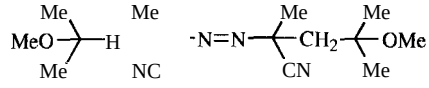


This reaction is a special case of **14-1,** but is important enough to be treated separately.[132] Alkenes can be halogenated in the allylic position and also a benzylic position by a number of reagents, of which NBS[133] is by far the most common. When this reagent is used, the reaction is known as *Wohl–Ziegler bromination.* A nonpolar solvent is used, most often CCl_4. Other N-bromo amides have also been used. To a much lesser extent, allylic chlorination has been carried out, with NCS or tert-butyl hypochlorite.[134] With any reagent an initiator is needed; this is usually a peroxide such as di-*tert*-butyl peroxide or benzoyl peroxide or, less often, UV light. An extremely useful radical initiator is AIBN (**11**), which decomposes to give cyano radicals (12) and nitrogen gas upon heating.[135] A new derivative has been developed that decomposes to initiate radical reactions at room temperature, 2,2'-azobis-(2,4-

dimethyl-4-methoxyvaleronitrile), 13.[136]

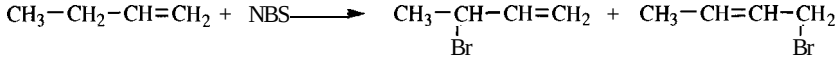


11 12 12



13

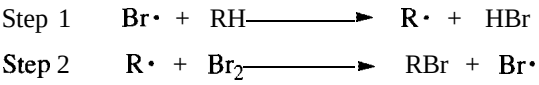
The reaction is usually quite specific at the allylic position and good yields are obtained. However, when the allylic radical intermediate is unsymmetrical, allylic rearrangements can take place, so that mixtures of both possible products are obtained, for example,



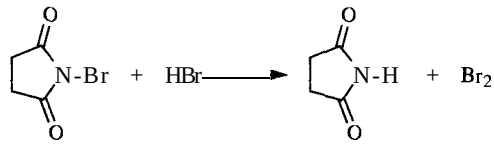
When a double bond has two different allylic positions (e.g., $CH_3CH{=}CHCH_2CH_3$) a secondary position is substituted more readily than a primary. The relative reactivity of tertiary hydrogen is not clear, though many substitutions at allylic tertiary positions have been performed.[137] It is possible to brominate both sides of the double bond.[138] Because of the electron-withdrawing nature of bromine, the second bromine substitutes on the other side of the double bond rather than a to the first bromine. Molecules with a benzylic hydrogen, such as toluene, react rapidly to give α-bromomethyl benzene (e.g., $PhCH_3 \rightarrow PhCH_2Br$).

N-Bromosuccinimide is also a highly regioselective brominating agent at other positions, including positions a to a carbonyl group, to a C≡C triple bond, and to an aromatic ring (benzylic position). When both a double and a triple bond are in the same molecule, the preferred position is a to the triple bond.[139]

That the mechanism of allylic bromination is of the free-radical type was demonstrated by Dauben and McCoy,[140] who showed that the reaction is very sensitive to free-radical initiators and inhibitors and indeed does not proceed at all unless at least a trace of initiator is present. Subsequent work indicated that the species that actually abstracts hydrogen from the substrate is the bromine atom. The reaction is initiated by small amounts of Br. Once it is formed, the main propagation steps are

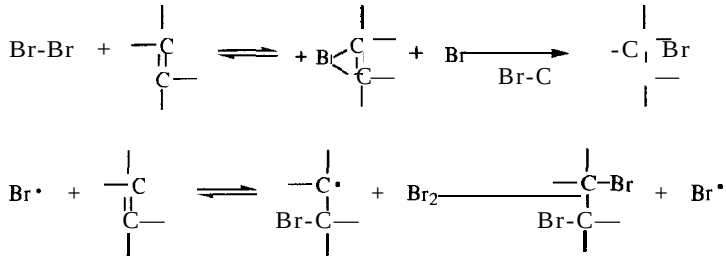


The source of the Br_2 is a fast ionic reaction between NBS and the HBr liberated in step 1:

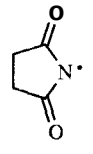


The function of the NBS is therefore to provide a source of Br_2 in a low, steady-state concentration and to use up the HBr liberated in step 1.[141] The main evidence for this mechanism is that NBS and Br_2 show similar selectivity[142] and that the various N-bromo amides also show similar selectivity,[143] which is consistent with the hypothesis that the same species is abstracting in each case.[144]

It may be asked why, if Br_2 is the reacting species, it does not add to the double bond, either by an ionic or by a free-radical mechanism (see **15-37**). Apparently, the concentration is too low. In bromination of a double bond, only one atom of an attacking bromine molecule becomes attached to the substrate, whether the addition is electrophilic or free radical:



The other bromine atom comes from another bromine-containing molecule or ion. This is clearly not a problem in reactions with benzylic species since the benzene ring is not prone to such addition reactions. If the concentration is sufficiently low, there is a low probability that the proper species will be in the vicinity once the intermediate forms. The intermediate in either case reverts to the initial species and the allylic substitution competes successfully. If this is true, it should be possible to brominate an alkene in the allylic position without competition from addition, even in the absence of NBS or a similar compound, if a very low concentration of bromine is used and if the HBr is removed as it is formed so that it is not available to complete the addition step. This has indeed been demonstrated.[145]



14

When NBS is used to brominate non-alkenyl substrates such as alkanes, another mechanism, involving abstraction of the hydrogen of the substrate by the succinimidyl radical[146] 14 can operate.[147] This mechanism is facilitated by solvents (such as CH_2Cl_2, $CHCl_3$, or MeCN) in which NBS is more soluble, and by the presence of small amounts of an alkene that lacks an allylic hydrogen (e.g., ethene).

The alkene serves to scavenge any Br· that forms from the reagent. Among the evidence for the mechanism involving 14 are abstraction selectivities similar to those of Cl· atoms and the isolation of β-bromopropionyl isocyanate ($BrCH_2CH_2C$-ONCO), which is formed by ring opening of 14.

Allylic chlorination has also been carried out[148] with NCS and either arylselenyl chlorides (ArSeCl), aryl diselenides (ArSeSeAr), or TsNSO as catalysts. Use of the selenium catalysts produces almost entirely the allylically rearranged chlorides in high yields. With TsNSO the products are the unrearranged chlorides in lower yields. Dichlorine monoxide (Cl_2O), with no catalyst, also gives allylically rearranged chlorides in high yields.[149] A free-radical mechanism is unlikely in these reactions.

Allyl silanes react with transition metals bearing chlorine ligands to give allyl chlorides, where a chlorine replaces a Me_3Si unit.[150]

OS IV, 108; V, 825; VI, 462; IX, 191.

14-3 *Halogenation of Aldehydes*

HALOGENATION OR HALO-DE-HYDROGENATION

$$RCHO + Cl_2 \longrightarrow RCOCl$$

Aldehydes can be directly converted to acyl chlorides by treatment with chlorine; however, the reaction operates only when the aldehyde does not contain an a hydrogen and even then it is not very useful. When there is an a hydrogen, a halogenation **(12-4)** occurs instead. Other sources of chlorine have also been used, among them SO_2Cl_2[151] and *t*-BuOCl.[152] The mechanisms are probably of the free-radical type. *N*-Bromosuccinimide, with AIBN (p. 912) as a catalyst, has been used to convert aldehydes to acyl bromides.[153]

OS I, 155.

B. *Substitution by Oxygen*

14-4 *Hydroxylation at an Aliphatic Carbon*

HYDROXYLATION OR HYDROXY-DE-HYDROGENATION

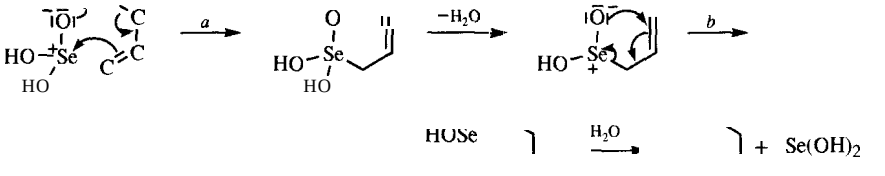
$$R_3CH \xrightarrow[\text{silica gel}]{O_3} R_3COH$$

Compounds containing susceptible C—H bonds can be oxidized to alcohols.[154] Nearly always, the C—H bond involved is tertiary, so the product is a tertiary alcohol. This is partly because tertiary C—H bonds are more susceptible to free-radical attack than primary and secondary bonds and partly because the reagents involved would oxidize primary and secondary alcohols further. In the best method, the reagent is ozone and the substrate is absorbed on silica gel.[155] Yields as high as 99% have been obtained by this method. Other reagents are chromic acid,[156] potassium hydrogen persulfate ($KHSO_5$),[157] ruthenium tetroxide (RuO_4),[158] 2,6-dichloropyridine *N*-oxide with a ruthenium catalyst,[159] thallium acetate,[160] sodium chlorite ($NaClO_2$)

with a metalloporphyrin catalyst,[161] and certain peroxybenzoic acids.[162] Alkanes and cycloalkanes have been oxidized at secondary positions, to a mixture of alcohols and trifluoroacetates, by 30% aqueous H_2O_2 in trifluoroacetic acid.[163] This reagent does not oxidize the alcohols further and ketones are not found. As in the case of chlorination with N-haloamines and sulfuric acid (see **14-1),** the 00— 1 position is the most favored. Another reagent[164] that oxidizes secondary positions is iodosylbenzene, catalyzed by $Fe^{(III)}$–porphyrin catalysts.[165] Use of an optically active $Fe^{(III)}$–porphyrin gave enantioselective hydroxylation, with moderate enantiomeric excesses.[166]

When chromic acid is the reagent, the mechanism is probably as follows: A Cr^{6+} species abstracts a hydrogen to give $R_3C\cdot$, which is held in a solvent cage near the resulting Cr^{5+} species. The two species then combine to give R_3COCr^{4+}, which is hydrolyzed to the alcohol. This mechanism predicts retention of configuration; this is largely observed.[167] The oxidation by permanganate also involves predominant retention of configuration, and a similar mechanism has been proposed.[168]

Treatment of double-bond compounds with selenium dioxide introduces an OH group into the allylic position (see also **19-14**).[169] This reaction also produces conjugated aldehydes in some cases.[170] Allylic rearrangements are common. There is evidence that the mechanism does not involve free radicals but includes two pericyclic steps (a and *b*):[171]

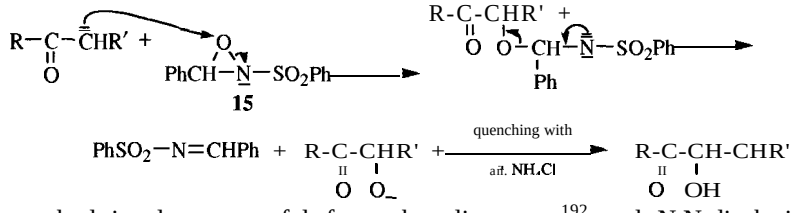


The step marked *a* is similar to the ene synthesis **(15-20).** The step marked *b* is a [2,3] sigmatropic rearrangement (see **18-35).** The reaction can also be accomplished with *tert*-butyl hydroperoxide, if SeO_2 is present in catalytic amounts (the *Sharpless method*).[172] The SeO_2 is the actual reagent; the peroxide reoxidizes the $Se(OH)_2$.[173] This method makes work up easier, but gives significant amounts of side products when the double bond is in a ring.[174] Alkynes generally give α,α' dihydroxylation.[175]

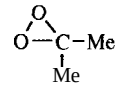
Ketones and carboxylic esters can be a hydroxylated by treatment of their enolate forms (prepared by adding the ketone or ester to LDA) with a molybdenum peroxide reagent (MoO_5–pyridine–HMPA) in THF-hexane at -70°C.[176] The enolate forms of amides and esters[177] and the enamine derivatives of ketones[178] can similarly be converted to their a hydroxy derivatives by reaction with molecular oxygen. The MoO_5 method can also be applied to certain nitriles.[179] Ketones have also been a hydroxylated by treating the corresponding silyl enol ethers with *m*-chloroperoxybenzoic acid,[179] or with certain other oxidizing agents.[180] When the silyl enol ethers are treated with iodosobenzene in the presence of trimethylsilyl trifluoromethyl sulfonate, the product is the α-keto triflate.[181]

Ketones can be a hydroxylated in good yields, without conversion to the enolates, by treatment with the hypervalent iodine reagents[182] *o*-iodosobenzoic acid[183] or phenyliodoso acetate $PhI(OAc)_2$ in methanolic NaOH.[184] The latter reagent has also been used on carboxylic esters.[185] Dioxysen and a chiral phase-transfer catalyst gave enantioselective a hydroxylation of ketones, if the a position was tertiary.[186] Titanium enolates can be oxidized with *tert*-butyl hydroperoxide [187] or with dimethyl dioxirane[188] and hydrolyzed with aqueous ammonium fluoride to give the α-hydroxy ketone. Dimethyl dioxirane is quite effective for hydroxylation of 1,3-dicarbonyl compounds.[189] Ceric ammonium nitrate has been used to hydroxylate C-2 of dibenzyl malonate.[190] α-Lithio sulfones have been hydroxylated with Me_3SiOOt-Bu.[191]

A different method for the conversion of ketones to a-hydroxy ketones consists of treating the enolate with a 2-sulfonyloxaziridine (such as **15**).[192] This is not a free-radical process; the following mechanism is likely:



This method is also successful for carboxylic esters[192] and N,N-disubstituted amides,[193] and can be made enantioselective by the use of a chiral oxaziridine.[194] Dimethyldioxirane also oxidizes ketones (through their enolate forms) to a-hydroxy ketones.[195]



Dimethyldioxirane

Tetrahydrofuran was converted to the hemiacetal 2-hydroxytetrahydrofuran (which was relatively stable under the conditions used) by electrolysis in water.[196]

OS IV, 23; VI, 43, 946; VII, 263, 277, 282.

14-5 *Hydroxylation at an Aromatic Carbon*[197]

HYDROXYLATION OR HYDROXY-DE-HYDROGENATION

$$ArH + H_2O_2 + FeSO_4 \longrightarrow ArOH$$

A mixture of hydrogen peroxide and ferrous sulfate,[198] called *Fenton's reagent*,[199] can be used to hydroxylate aromatic rings, though yields are usually not high.[200] Biaryls are usually side products.[201] Among other reagents used have been H_2O_2 and titanous ion; O_2 and Cu(I)[202] or Fe(III),[203] a mixture of ferrous ion, oxygen, ascorbic acid, and ethylenetetraaminetetraacetic acid *(Udenfriend's reagent);*[204] O_2 and KOH in liquid NH_3;[205] and peroxyacids such as peroxynitrous and trifluoroperoxyacetic acids.

Much work has been done on the mechanism of the reaction with Fenton's reagent, and it is known that free aryl radicals (formed by a process such as HO· + ArH → AR· 4- H_2O) are not intermediates. The mechanism is essentially that outlined on page 898, with HO· as the attacking species,[206] formed by

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^- + HO\text{-}$$

The rate-determining step is formation of HO· and not its reaction with the aromatic substrate.

See also **11-29.**

14-6 *Oxidation of Aldehydes to Carboxylic Acids*

HYDROXYLATION OR HYDROXY-DE-HYDROGENATION

$$R\text{-}\underset{\underset{O}{\|}}{C}\text{-}H \xrightarrow{MnO_4^-} R\text{-}\underset{\underset{O}{\|}}{C}\text{-}OH$$

Oxidation of aldehydes to carboxylic acids is one of the most common oxidation reactions in organic chemistry[207] and has been carried out with many oxidizing agents, the most popular of which is permanganate in acid, basic, or neutral solution.[208] Chromic acid,[209] bromine, and Oxone®,[210] are other reagents frequently employed. Silver oxide is a fairly specific oxidizing agent for aldehydes and does not readily attack other groups. Benedict's and Fehling's solutions oxidize aldehydes,[211] and a test for aldehydes depends on this reaction, but the method is seldom used for preparative purposes and in any case gives very poor results with aromatic aldehydes. α,β-Unsaturated aldehydes can be oxidized by sodium chlorite without disturbing the double bond.[212] Aldehydes are also oxidized to carboxylic acids by atmospheric oxygen, but the actual direct oxidation product in this case is the peroxy acid RCO_3H,[213] which with another molecule of aldehyde disproportionates to give two molecules of acid (see 14-8).[214]

Mechanisms of aldehyde oxidation[215] are not firmly established, but there seem to be at least two main types—a free-radical mechanism and an ionic one. In the free-radical process, the aldehydic hydrogen is abstracted to leave an acyl radical, which obtains OH from the oxidizing agent. In the ionic process, the first step is addition of a species OZ^- to the carbonyl bond to give 16 in alkaline solution and 17 in acid or neutral solution. The aldehydic hydrogen of 16 or 17 is then lost as a proton to a base, while Z leaves with its electron pair.

$$R\text{-}\underset{\underset{O}{\|}}{C}\text{-}H + OZ^- \longrightarrow R\text{-}\underset{\underset{O\text{-}Z}{|}}{\overset{\overset{O\text{-}Z}{|}}{C}}\text{-}H \xrightarrow{B^-} R\text{-}\underset{\underset{O\text{-}Z}{|}}{\overset{\overset{O}{\|}}{C}} + BH + Z^-$$

16

$$R\text{-}\underset{\underset{O}{\|}}{C}\text{-}H + HOZ \longrightarrow R\text{-}\underset{\underset{O\text{-}H}{|}}{\overset{\overset{O\text{-}Z}{|}}{C}}\text{-}H \xrightarrow{B^-} R\text{-}\underset{\underset{O\text{-}H}{|}}{\overset{\overset{O}{\|}}{C}} + BH + Z^-$$

17

For oxidation with acid dichromate the picture seems to be quite complex, with several processes of both types going on:[216]

Step 1 $RCHO + H_2CrO_4 \rightleftharpoons R\text{-}CH(O\text{-}CrO_3H)(OH)$

Step 2 $R\text{-}CH(O\text{-}CrO_3H)(OH) \xrightarrow{B^-} R\text{-}C(=O)(OH) + BH + Cr^{IV}$

Step 3 $RCHO + Cr^{IV} \longrightarrow RC(=O)\cdot$

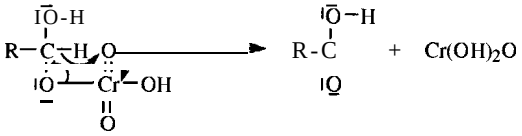
Step 4 $R\text{-}CH(OH)(OH) + Cr^{IV} \longrightarrow R\text{-}C(OH)(OH)\cdot \xrightarrow{-H_2O} R\text{-}C(=O)\cdot + Cr^{III}$

Step 5 $RC(=O)\cdot + H_2CrO_4 \longrightarrow RCOOH + Cr^{V}$

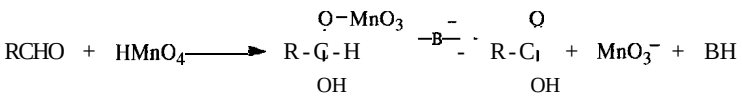
Step 6 $RCHO + Cr^{V} \rightleftharpoons R\text{-}CH(OCr^{V})(OH)$

Step 7 $R\text{-}CH(O\text{-}Cr^{V})(OH) \xrightarrow{B^-} R\text{-}C(=O)(OH) + BH + Cr^{III}$

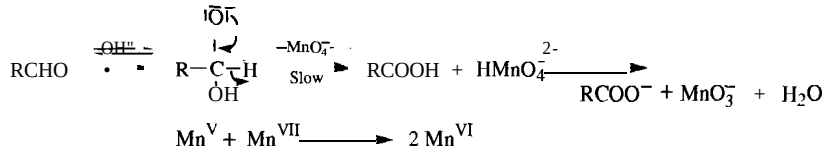
Steps 1 and 2 constitute an oxidation by the ionic pathway by $Cr^{(VI)}$, and steps 6 and 7 a similar oxidation by $Cr^{(V)}$, which is produced by an electron-transfer process. Either $Cr^{(VI)}$ (step 3) or $Cr^{(IV)}$ (step 4) [$Cr^{(IV)}$ is produced in step 2] may abstract a hydrogen and the resulting acyl radical is converted to carboxylic acid in step 5. Thus, chromium in three oxidation states is instrumental in oxidizing aldehydes. Still another possible process has been proposed in which the chromic acid ester decomposes as follows:[217]



The mechanism with permanganate is less well known, but an ionic mechanism has been proposed[218] for neutral and acid permanganate, similar to steps 1 and 2 for dichromate:



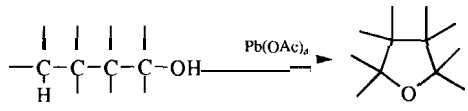
For alkaline permanganate, the following mechanism has been proposed:[219]



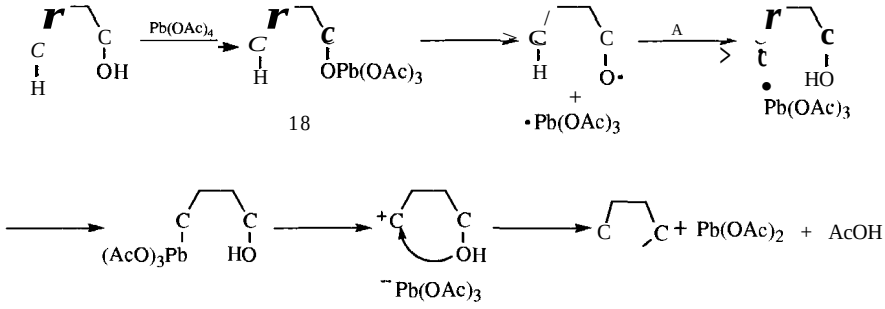
OS I, 166; II, 302, 315, 538; **III,** 745; IV, 302, 493, 499, 919, 972, 974.

14-7 *Formation of Cyclic Ethers*

(5)OC-CYCLO-ALKOXY-DE-HYDRO-SUBSTITUTION



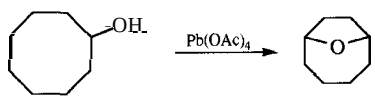
Alcohols with a hydrogen in the 8 position can be cyclized with lead tetraacetate.[220] The reaction is usually carried out at ~ 80°C (most often in refluxing benzene) but can also be done at room temperature if the reaction mixture is irradiated with UV light. Tetrahydrofurans are formed in high yields. Little or no four- and six-membered cyclic ethers (oxetanes and tetrahydropyrans, respectively) are obtained even when *y* and E hydrogens are present. The reaction has also been carried out with a mixture of halogen (Br_2 or I_2) and a salt or oxide of silver or mercury (especially HgO or AgOAc),[221] with iodosobenzene diacetate and I2,[222] and with *ceric* ammonium nitrate (CAN).[223] The following mechanism is likely for the lead tetraacetate reaction:[224]



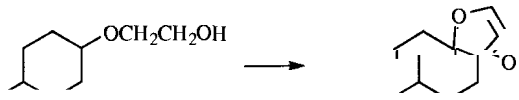
though 18 has never been isolated. The step marked A is a 1,5 internal hydrogen abstraction. Such abstractions are well known (see p. 1462) and are greatly favored over 1,4 or 1,6 abstractions (the small amounts of tetrahydropyran formed result from 1,6 abstractions).[225]

Reactions that sometimes compete are oxidation to the aldehyde or acid **(19-3** and **19-21)** and fragmentation of the substrate. When the OH group is on a ring of at

least seven members, a transannular product can be formed, for example,[226]



β-Hydroxy ethers can give cyclic acetals, for example,[227]



There are no references in *Organic Syntheses*, but see OS V, 692; VI, 958, for related reactions.

14-8 *Formation of Hydroperoxides*

HYDROPEROXY-DE-HYDROGENATION

$$RH + O_2 \longrightarrow R{-}O{-}O{-}H$$

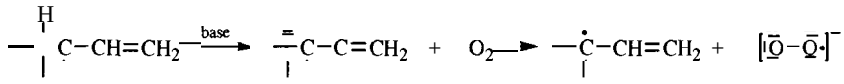
The slow atmospheric oxidation *(slow* meaning without combustion) of C—H to C—O—O—H is called *autoxidation*.[228] The reaction occurs when compounds are allowed to stand in air and is catalyzed by light, so unwanted autoxidations can be greatly slowed by keeping the compounds in dark places. The hydroperoxides produced often react further to give alcohols, ketones, and more complicated products, so the reaction is not often used for preparative purposes, although in some cases hydroperoxides have been prepared in good yield.[229] It is because of autoxidation that foods, rubber, paint, lubricating oils, and so on deteriorate on exposure to the atmosphere over periods of time. On the other hand, a useful application of autoxidation is the atmospheric drying of paints and varnishes. As with other free-radical reactions of C—H bonds, some bonds are attacked more readily than others,[230] and these are the ones we have seen before (pp. 900-903), though the selectivity is very low at high temperatures and in the gas phase. The reaction can be carried out successfully at tertiary (to a lesser extent, secondary), benzylic,[231] and allylic (though allylic rearrangements are common) R.[232] 2-Phenylpropane reacted with oxygen to give $PhMe_2C$— OOH, for example. Another susceptible position is aldehydic C—H, but the peroxyacids so produced are not easily isolated[213] since they are converted to the corresponding carboxylic acids (14-6). The a positions of ethers are also easily attacked by oxygen (RO—C—H → RO—C—OOH), but the resulting hydroperoxides are seldom isolated. However, this reaction constitutes a hazard in the storage of ethers since solutions of these hydroperoxides and their rearrangement products in ethers are potential spontaneous explosives.[233]

Oxygen itself (a diradical) is not reactive enough to be the species that actually abstracts the hydrogen. But if a trace of free radical (say R′·) is produced by some

initiating process, *it* reacts with oxygen[234] to give R′—O—O·; since this type of radical *does* abstract hydrogen, the chain is

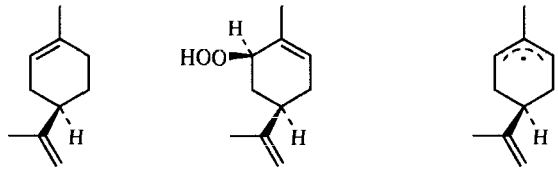
$$R'OO\cdot + RH \longrightarrow R\cdot + R'OOH$$
$$R\cdot + O_2 \longrightarrow R{-}O{-}O\cdot$$

In at least some cases (in alkaline media)[235] the radical R· can be produced by formation of a carbanion and its oxidation (by O_2) to a radical, for example,[236]



Autoxidations in alkaline media can also proceed by a different mechanism: R-H + base $\rightarrow R^- + O_2 \rightarrow ROO^-$.[237]

When alkenes are treated with oxygen that has been photosensitized (p. 316), they are substituted by OOH in the allylic position in a synthetically useful reaction.[238] Although superficially similar to autoxidation, this reaction is clearly different because 100% allylic rearrangement always takes place. The reagent here is not the ground-state oxygen (a triplet) but an excited singlet state (in which all electrons are paired),[239] and the function of the photosensitization is to promote the oxygen to this singlet state. Singlet oxygen can also be produced by nonphotochemical means,[240] for example, by the reaction between H_2O_2 and NaOCl[241] or sodium molybdate,[242] or between ozone and triphenyl phosphite.[243] The oxygen generated by either photochemical or nonphotochemical methods reacts with alkenes in the same way;[244] this is evidence that singlet oxygen is the reacting species in the photochemical reaction and not some hypothetical complex between triplet oxygen and the photosensitizer, as had previously been suggested. The fact that 100% allylic rearrangement always takes place is incompatible with a free-

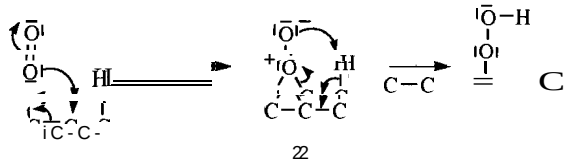


19 20 **21**

radical mechanism, and further evidence that free radicals are not involved comes from the treatment of optically active limonene (**19**) with singlet oxygen. Among other products is the optically active hydroperoxide 20, though if 21 were an intermediate, it could not give an optically active product since it possesses a plane of symmetry.[245] In contrast, autoxidation of 19 gave optically inactive 20 (a mixture of four diastereomers in which the two pairs of enantiomers are present as racemic mixtures). As this example shows, singlet oxygen reacts faster with more highly substituted than with less highly substituted alkenes. The order of alkene reactivity is tetrasubstituted > trisubstituted > disubstituted. Electron-withdrawing substituents

deactivate the alkene.[246] In simple trisubstituted alkenes, there is a general preference for the hydrogen to be removed from the more highly congested side of the double bond.[247] With *cis*-alkenes of the form RCH=CHR′, the hydrogen is removed from the larger R group.[248] Many functional groups in an allylic position cause the hydrogen to be removed from that side rather than the other (geminal selectivity).[249] Also, in alkyl-substituted alkenes, the hydrogen that is preferentially removed is the one geminal to the larger substituent on the double bond.[250]

Several mechanisms have been proposed for the reaction with singlet oxygen.[251] One of these is a pericyclic mechanism, similar to that of the ene synthesis (15-20) and to the first step of the reaction between alkenes and SeO_2 (14-4). However, there is strong evidence against this mechanism,[252] and a more likely mechanism involves addition of singlet oxygen to the double bond to give a perepoxide (22),[253] followed by internal proton transfer.[254]



22

Still other proposed mechanisms involve diradicals or dipolar intermediates.[255]

OS IV, 895.

14-9 *Formation of Peroxides*

ALKYLDIOXY-DE-HYDROGENATION

$$RH + R'OOH \xrightarrow{CuCl} ROOR'$$

Peroxy groups (ROO) can be introduced into susceptible organic molecules by treatment with a hydroperoxide in the presence of cuprous chloride or other catalysts (e.g., cobalt and manganese salts).[256] Very high yields can be obtained. The type of hydrogen replaced is similar to that with NBS (14-2), that is, mainly benzylic, allylic, and tertiary. The mechanism is therefore of the free-radical type, involving ROO· formed from ROOH and the metal ion. The reaction can be used to demethylate tertiary amines of the form R_2NCH_3, since the product R_2NHCH_2OOR' can easily be hydrolyzed by acid (10-6) to give R_2NH.[257]

14-10 *Acyloxylation or Acyloxy-de-hydrogenation*

$$RH + Me_3C{-}O{-}O{-}\overset{\overset{O}{\|}}{C}{-}R' \xrightarrow{Cu^{+}/Cu^{2+}} R{-}O{-}\overset{\overset{O}{\|}}{C}{-}R'$$

Susceptible positions of organic compounds can be directly acyloxylated[258] by *tert*-butyl peroxyesters, the most frequently used being acetic and benzoic (R′ = Me or Ph).[259] The reaction requires a catalyst (cuprous ion is the actual catalyst, but a trace is all that is necessary, and such traces are usually present in cupric compounds, so that these are often used) and without it is not selective. Susceptible positions are similar to those in 14-7: benzylic, allylic, and the a position of ethers and sulfides. Terminal alkenes are substituted almost entirely in the 3 position, that is, with only a small amount of allylic rearrangement, but internal alkenes generally give mixtures containing a large amount of allylic-shift product. If the reaction with alkenes is carried out in an excess of another acid R″COOH, the ester produced is of *that* acid ROCOR″. Aldehydes give anhydrides:

$$\underset{\underset{\text{O}}{\text{n}}}{\text{R-C-H}} + \underset{\underset{\text{O}}{\text{n}}}{\text{Me}_3\text{COOCR}'} \xrightarrow{\text{Cu}^+} \underset{\underset{\text{O}}{\text{II}}}{\text{R-C-O-}}\underset{\underset{\text{O}}{\text{II}}}{\text{C-R}'}$$

Acyloxylation has also been achieved with metallic acetates such as lead tetraacetate,[260] mercuric acetate,[261] and palladium(II) acetate.[262] In the case of the lead and mercuric acetates, not only does the reaction take place at allylic and benzylic positions and at those a to an OR or SR group but also at positions a to the carbonyl groups of aldehydes, ketones, or esters and at those a to two carbonyl groups (ZCH_2Z'). It is likely that in the latter cases it is the enol forms that react. Ketones can be α-acyloxylated indirectly by treatment of various enol derivatives with metallic acetates, for example, silyl enol ethers with silver carboxylates-iodine,[263] enol thioethers with lead tetraacetate,[264] and enamines[265] with lead tetraacetate[266] or thallium triacetate.[267] α,β-Unsaturated ketones can be acyloxylated in good yields in the α′ position with manganese triacetate.[268] Palladium acetate converts alkenes to vinylic and/or allylic acetates.[269] Lead tetraacetate even acyloxylates alkanes, in a slow reaction (10 days to 2 weeks), with tertiary and secondary positions greatly favored over primary ones.[270] Yields are as high as 50%. Acyloxylation of certain alkanes has also been reported with palladium(II) acetate.[271]

Studies of the mechanism of the cuprous-catalyzed reaction show that the most common mechanism is the following:[272]

Step 1 $\underset{\underset{\text{O}}{\text{II}}}{\text{R}'\text{COO}}\text{—}t\text{-Bu} + \text{Cu}^+ \longrightarrow \underset{\underset{\text{O}}{\text{II}}}{\text{R}'\text{CO}}\text{—Cu}^{+\text{II}} + t\text{-BuO}\cdot$

Step 2 $\text{RH} + t\text{-BuO}\cdot \longrightarrow \text{R}\cdot + t\text{-BuOH}$

Step 3 $\text{R}\cdot + \underset{\underset{\text{O}}{\text{II}}}{\text{R}'\text{CO}}\text{—Cu}^{+\text{II}} \longrightarrow \underset{\underset{\text{O}}{\text{II}}}{\text{ROCR}'} + \text{Cu}^+$

23

This mechanism, involving a free radical (R·), is compatible with the allylic rearrangements found.[273] The finding that tert-butyl peroxyesters labeled with ^{18}O in the carbonyl oxygen gave ester with 50% of the label in each oxygen[274] is in accord with a combination of R· with the intermediate 23, in which the copper is

ionically bound, so that the oxygens are essentially equivalent. Other evidence is that *tert*-butoxyradicals have been trapped with dienes.[275] Much less is known about the mechanisms of the reactions with metal acetates.[276]

Free-radical acyloxylation of aromatic substrates[277] has been accomplished with a number of reagents including copper(II) acetate,[278] benzoyl peroxide-iodine,[279] silver(II) complexes,[280] and cobalt(III) trifluoroacetate.[281]

OS **III,** 3; **V,** 70, 151; **VIII,** 137.

C. *Substitution by Sulfur*

14-11 *Chlorosulfonation or Chlorosulfo-de-hydrogenation*

$$RH + SO_2 + Cl_2 \xrightarrow{h\nu} RSO_2Cl$$

The chlorosulfonation of organic molecules with chlorine and sulfur dioxide is called the *Reed reaction.*[282] In scope and range of products obtained, the reaction is similar to **14-1.** The mechanism is also similar, except that there are two additional main propagation steps:

$$R\cdot + SO_2 \longrightarrow R{-}SO_2\cdot$$
$$R{-}SO_2\cdot + Cl_2 \longrightarrow R{-}SO_2Cl + Cl\text{-}$$

Chlorosulfenation[283] can be accomplished by treatment with SCl_2 and UV light: $RH + SCl_2 \xrightarrow{h\nu} RSC1$.

D. *Substitution by Nitrogen*

14-12 *Nitration of Alkanes*

NITRATION OR NITRO-DE-HYDROGENATION

$$RH + HNO_3 \xrightarrow{400°C} RNO_2$$

Nitration of alkanes[284] can be carried out in the gas phase at ~400°C or in the liquid phase. The reaction is not practical for the production of pure products for any alkane except methane. For other alkanes, not only does the reaction produce mixtures of the mono-, di-, and polynitrated alkanes at every combination of positions, but extensive chain cleavage occurs.[285] A free-radical mechanism is involved.[286]

$$-\overset{|}{\underset{|}{C}}H^- + MeONO_2 \longrightarrow -\overset{|}{\underset{|}{C}}{-}NO_2 + OMe^-$$

Activated positions (e.g., ZCH_2Z' compounds) can be nitrated by fuming nitric acid in acetic acid, by acetyl nitrate and an acid catalyst,[287] or by alkyl nitrates under alkaline conditions.[288] In the latter case, it is the carbanionic form of the substrate that is actually nitrated. What is isolated under these alkaline conditions is the

conjugate base of the nitro compound. Yields are not high. Of course, the mechanism in this case is not of the free-radical type, but is electrophilic substitution with respect to the carbon (similar to the mechanisms of **12-7** and **12-8).** Positions activated by only one electron-withdrawing group (e.g., a positions of simple ketones, nitriles, sulfones, or N,N-dialkyl amides) can be nitrated with alkyl nitrates if a very strong base (e.g., *t*-BuOK or $NaNH_2$) is present to convert the substrate to the carbanionic form.[289] Electrophilic nitration of alkanes has been performed with nitronium salts (e.g., $NO_2^+ PF_6^-$ and with $HNO_3 - H_2SO_4$ mixtures, but mixtures of nitration and cleavage products are obtained and yields are generally low.[290]

Aliphatic nitro compounds can be a nitrated $[R_2\bar{C}\,\bar{N}O_2 \rightarrow R_2C(NO_2)_2]$ by treatment of their conjugate bases $RCNO_2$ with NO_2^- and $K_3Fe(CN)_6$.[291]

OS I, 390; II, 440, 512.

14-13 *The Direct Conversion of Aldehydes to Amides*

AMINATION OR AMINO-DE-HYDROGENATION

$$ArCHO \xrightarrow[NBS-AIBN]{NH_3} ArCONH_2$$

Aliphatic and aromatic aldehydes have been converted to the corresponding amides with ammonia or a primary or secondary amine, NBS, and a catalytic amount of AIBN (p. 911).[292] In a reaction of more limited scope, amides are obtained from aromatic and α,β-unsaturated aldehydes by treatment with dry ammonia gas and nickel peroxide.[293] Best yields (80-90%) are obtained at -25 to -20°C. The reaction has also been performed with MnO_2 and NaCN along with ammonia or an amine at 0°C in isopropyl alcohol,[294] and with a secondary amine and a palladium acetate catalyst.[295] In the nickel peroxide reaction the corresponding alcohols ($ArCH_2OH$) have also been used as substrates. For an indirect way of converting aldehydes to amides, see **12-29.** Thioamides ($RCSNR'_2$) have been prepared in good yield from thioaldehydes (produced *in situ* from phosphoranes and sulfur) and secondary amines.[296]

14-14 *Amidation and Amination at an Alkyl Carbon*

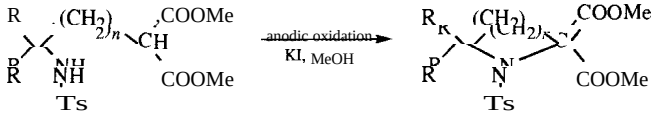
ACYLAMINO-DE-HYDROGENATION

$$R_3CH + CH_3CN \xrightarrow[H_3(PW_{12}O_{40})\cdot H_2O]{h\nu} R_3C\text{-}NH\text{-}C\text{-}CH_3 + H_2$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad O$$

When alkanes bearing a tertiary hydrogen are exposed to UV light in acetonitrile containing a heteropolytungstic acid, they are amidated.[297] The oxygen in the product comes from the tungstic acid. When the substrate bears two adjacent tertiary hydrogens, alkenes are formed (by loss of two hydrogens), rather than amides (19-2).

An electrochemical method for amination has been reported by Shono et al.[298] Derivatives of malonic esters containing an N-tosyl group were cyclized in high

yields by anodic oxidation:



Three-, four-, and five-membered rings were synthesized by this procedure.

E. *Substitution by Carbon*

In these reactions a new carbon-carbon bond is formed, and they may be given the collective title *coupling reactions.* In each case, an alkyl or aryl radical is generated and then combines with another radical (a termination process) or attacks an aromatic ring or alkene to give the coupling product.[299]

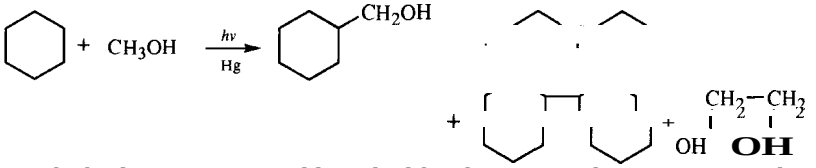
14-15 *Simple Coupling at a Susceptible Position*

DE-HYDROGEN-COUPLING

$$2\ RH \xrightarrow[Hg]{h\nu} R\text{-}R + H_2$$

Alkanes can be dimerized by vapor-phase mercury photosensitization[300] in a synthetically useful process. Best results are obtained for coupling at tertiary positions, but compounds lacking tertiary hydrogens (e.g., cyclohexane) also give good yields. Dimerization of *n* alkanes gives secondary–secondary coupling in a nearly statistical distribution, with primary positions essentially unaffected. Alcohols and ethers dimerize at the position a to the oxygen [e.g., 2 EtOH → MeCH(OH)-CH(OH)Me].

When a mixture of compounds is treated, cross-dimerization and homodimerization take place statistically, for example:



Even with the limitation on yield implied by the statistical process, cross-dimerization is still useful when one of the reactants is an alkane, because the products are easy to separate, and because of the few other ways to functionalize an alkane. The cross-coupling of an alkane with trioxane is especially valuable, because hydrolysis of the product **(10-6)** gives an aldehyde, thus achieving the conversion RH → RCHO. The mechanism probably involves abstraction of H by the excited Hg atom, and coupling of the resulting radicals.

The reaction has been extended to ketones, carboxylic acids and esters (all of which couple a to the C=O group), and amides (which couple a to the nitrogen) by running it in the presence of H_2.[301] Under these conditions it is likely that the excited Hg abstracts H· from H_2, and that the remaining H· abstracts H from the substrate.

Radicals have also been generated at benzylic positions and shown to couple with epoxides, forming an alcohol.[302]

In an older reaction, substrates RH are treated with peroxides, which decompose to give a radical that abstracts a hydrogen from RH to give R·, which dimerizes. Dialkyl and diacyl peroxides have been used, as well as Fenton's reagent (p. 916). This reaction is far from general, though in certain cases respectable yields have been obtained. Among susceptible positions are those at a tertiary carbon,[303] as well as those a to a phenyl group (especially if there is also an α-alkyl or α-chloro group),[304] an ether group,[305] a carbonyl group,[306] a cyano group,[307] a dialkylamino group,[308] or a carboxylic ester group, either the acid or alcohol side.[309]

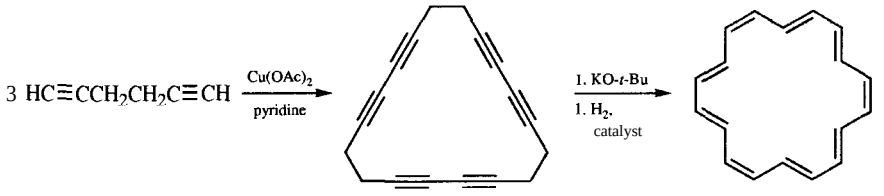
OS IV, 367; V, 1026; **VII,** 482.

14-16 *Coupling of Alkynes*

DE-HYDROGEN-COUPLING

$$2\ \text{R-C}\equiv\text{C-H} \xrightarrow[\text{pyridine}]{\text{CuX}_2} \text{R}-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{R}$$

Terminal alkynes can be coupled by heating with stoichiometric amounts of cupric salts in pyridine or a similar base. This reaction, which produces symmetrical diynes in high yields, is called the *Eglinton reaction*.[310] The large-ring annulenes of Sondheimer et al. (see p. 67)[312] were prepared by rearrangement and hydrogenation of cyclic polyynes,[311] prepared by Eglinton coupling of terminal diynes, for example,[312] 24 is a cyclic trimer of 1,5-hexadiyne. The corresponding tetramers



24

(C24), pentamers (C_{30}), and hexamers (C_{36}) were also formed.

The Eglinton reaction is of wide scope. Many functional groups can be present on the alkyne. The oxidation is usually quite specific for triple-bond hydrogen. Another common procedure is the use of catalytic amounts of cuprous salts in the presence of ammonia or ammonium chloride (this method is called the *Glaser reaction).* Atmospheric oxygen or some other oxidizing agent such as permanganate or hydrogen peroxide is required in the latter procedure. This method is not satisfactory for cyclic coupling. Unsymmetrical diynes can be prepared by *Cadiot–Chodkiewicz* coupling:[313]

$$\text{R}-\text{C}\equiv\text{C-H} + \text{R}'-\text{C}\equiv\text{C-Br} \xrightarrow{\text{Cu}^+} \text{R}-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{R}' + \text{HBr}$$

This may be regarded as a variation of **10-110** but it must have a different mechanism since acetylenic halides give the reaction but ordinary alkyl halides do

not, which is hardly compatible with a nucleophilic mechanism. However, the mechanism is not fully understood. One version of this reaction binds the alkynyl bromide unit to a polymer, and the diyne is released from the polymer after the solid-state transformation.[314] Alkynes have also been coupled using CuI and a palladium catalyst.[315] Propargyl halides also give the reaction.[316] A variation of the Cadiot-Chodkiewicz method consists of treating a haloalkyne ($R'C{\equiv}CX$) with a copper acetylide ($RC{\equiv}CCu$).[317] The Cadiot-Chodkiewicz procedure can be adapted to the preparation of diynes in which $R'=H$ by the use of $BrC{\equiv}CSiEt_3$ and subsequent cleavage of the $SiEt_3$ group.[318] This protecting group can also be used in the Eglinton or Glaser methods.[319]

The mechanism of the Eglinton and Glaser reactions probably begins with loss of a proton

$$R{-}C{\equiv}C{-}H \xrightarrow{\text{base}} R{-}C{\equiv}C^-$$

since there is a base present and acetylenic protons are acidic. The last step is probably the coupling of two radicals:

$$R{-}C{\equiv}C\cdot \longrightarrow R{-}C{\equiv}C{-}C{\equiv}C{-}R$$

but just how the carbanion becomes oxidized to the radical and what part the cuprous ion plays (other than forming the acetylide salt) are matters of considerable speculation,[320] and depend on the oxidizing agent. It is known, of course, that cuprous ion can form complexes with triple bonds.

OS V, 517; VI, 68, 925; VIII, 63.

14-17 *Arylation of Aromatic Compounds by Diazonium Salts*

ARYLATION OR ARYL-DE-HYDROGENATION

$$ArH + Ar'N_2^+ X^- \xrightarrow{OH^-} Ar\text{-}Ar'$$

When the normally acidic solution of a diazonium salt is made alkaline, the aryl portion of the diazonium salt can couple with another aromatic ring. Known as the *Gomberg* or *Gomberg–Bachmann reaction*,[321] it has been performed on several types of aromatic rings and on quinones. Yields are not high (usually under 40%) because of the many side reactions undergone by diazonium salts, though higher yields have been obtained under phase-transfer conditions.[322] The conditions of the Meerwein reaction (14-18), treatment of the solution with a copper-ion catalyst, have also been used, as has the addition of sodium nitrite in Me_2SO (to benzene diazonium fluoroborate in Me_2SO).[323] When the Gomberg-Bachmann reaction is

25

performed intramolecularly as in the formation of 25, either by the alkaline solution or by the copper-ion procedure, it is called the *Pschorr ring closure*[324] and yields are usually somewhat higher. Still higher yields have been obtained by carrying out the Pschorr reaction electrochemically.[325] The Pschorr reaction has been carried out for Z = CH=CH, CH_2CH_2, NH, C=O, CH_2, and quite a few others. A rapid and convenient way to carry out the Pschorr synthesis is to diazotize the amine substrate with isopropyl nitrite in the presence of sodium iodide, in which case the ring-closed product is formed in one step.[326]

Other compounds with nitrogen-nitrogen bonds have been used instead of diazonium salts. Among these are N-nitroso amides [ArN(NO)COR], triazenes,[327] and azo compounds. Still another method involves treatment of an aromatic primary amine directly with an alkyl nitrite in an aromatic substrate as solvent.[328]

In each case the mechanism involves generation of an aryl radical from a covalent azo compound. In acid solution diazonium salts are ionic and their reactions are polar. When they cleave, the product is an aryl cation (see p. 852). However, in neutral or basic solution, diazonium ions are converted to covalent compounds, and these cleave to give free radicals:

$$Ar-N=N-Z \longrightarrow Ar\cdot + N\equiv N + Z\cdot$$

Under Gomberg–Bachmann conditions, the species that cleaves is the anhydride:[329]

$$Ar-N=N-O-N=N-Ar \longrightarrow Ar\cdot + N_2 + \cdot O-N=N-Ar$$
26

The aryl radical thus formed attacks the substrate to give the intermediate 1 (p. 898), from which the radical 26 abstracts hydrogen to give the product. N-Nitroso amides probably rearrange to N-acyloxy compounds, which cleave to give aryl radicals:[330]

$$2\ Ar-\overset{\overset{O}{\|}}{N}-C-R \longrightarrow 2\ Ar-N=N-O-COR \longrightarrow AR\cdot + AR-N=N-O\cdot + N_2 + (RCO)_2O$$

There is evidence that the reaction with alkyl nitrites also involves attack by aryl radicals.[331]

The Pschorr reaction can take place by two different mechanisms, depending on conditions: (1) attack by an aryl radical (as in the Gomberg-Bachmann reaction) or (2) attack by an aryl cation (similar to the S_N1 mechanism discussed on p. 853).[332] Under certain conditions the ordinary Gomberg-Bachmann reaction can also involve attack by aryl cations.[333]

OS I, 113; IV, 718.

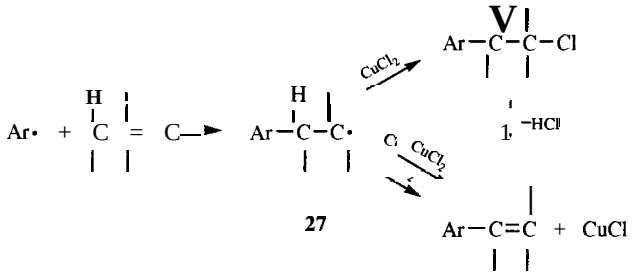
14-18 *Arylation of Activated Alkenes by Diazonium Salts: Meerwein Arylation*

ARYLATION OR ARYL-DE-HYDROGENATION

$$Z-\underset{H}{\overset{|}{C}}=\underset{|}{C} \xrightarrow[ArN_2^+\ Cl^-]{CuCl_2} Z-\overset{|}{C}=\underset{|}{C}-Ar$$

Alkenes activated by an electron-withdrawing group (Z may be C=C, halogen, C=O, Ar, CN, etc.) can be arylated by treatment with a diazonium salt and a cupric chloride[334] catalyst. This is called the *Meerwein arylation reaction.*[335] Addition of ArCl to the double bond (to give Z—C(Cl)—C(H)—Ar) is a side reaction (15-44). In an improved procedure, an arylamine is treated with an alkyl nitrite (generating ArN_2^+ *in situ)* and a copper(II) halide in the presence of the alkene.[336]

The mechanism is probably of the free-radical type, with AR· forming as in 14-25, and then[337]



Radical 27 can react with cupric chloride by two pathways, one of which leads to addition and the other to substitution. Even when the addition pathway is taken, however, the substitution product may still be formed by subsequent elimination of HCl.

OS IV, 15.

14-19 *Arylation and Alkylation of Alkenes by Organopalladium Compounds: The Heck Reaction*

ALKYLATION OR ALKYL-DE-HYDROGENATION, AND SO ON

$$R_2C{=}CH_2 + \text{"ArPdX"} \longrightarrow R_2C{=}CH{-}Ar$$

Arylation of alkenes can also be achieved[338] by treatment with an "arylpalladium" reagent that can be generated *in situ* by several[339] methods: (1) by treatment of an aryl bromide with a palladium–triarylphosphine complex (ArBr → "ArPdBr");[340] (2) by treatment of an aryl iodide[341] with palladium acetate[342] in the presence of a base such as tributylamine or potassium acetate (ArI → "ArPdI");[343] (3) by treatment of an arylmercury compound (either Ar_2Hg or ArHgX) with $LiPdCl_3$ (ArHgX → "ArPdX")[344] (in some cases, other noble metal salts have been used); or (4) by the reaction of an aromatic compound with palladium acetate or palladium metal and silver acetate in acetic acid [in this case, an aryl *hydrogen* is replaced (ArH → "ArPdOAc")].[345] Whichever of these methods is used, the reaction is known as *the Heck reaction.* The Heck reaction can be done with heterocyclic compounds such as 3-trifylpyridine.[346] The reaction is not limited to aryl halides, and vinyl halides can be coupled to alkenes to form dienes.[347]

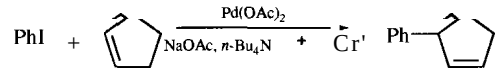
Unlike 14-18, the Heck reaction is not limited to activated substrates. The substrate can be a simple alkene, or it can contain a variety of functional groups, such as ester, ether,[348],[349] carboxyl, phenolic, or cyano groups.[350] It can also be a

diene.[351] Primary and secondary allylic alcohols (and even non-allylic unsaturated alcohols[352]) give aldehydes or ketones that are products of double-bond migration,[353] e.g.,

$$CH_2{=}CH{-}CH_2OH \xrightarrow{\text{"PdPdCl"}} PhCH_2CH_2CHO$$

Ethylene is the most reactive alkene. Increasing substitution lowers the reactivity. Substitution therefore takes place at the less highly substituted side of the double bond.[354] Alkylation can also be accomplished, but only if the alkyl group lacks a β-hydrogen, for example, the reaction is successful for the introduction of methyl, benzyl, and neopentyl groups.[355] However, vinylic groups, even those possessing β hydrogens, have been successfully introduced (to give 1,3-dienes) by the reaction of the alkene with a vinylic halide in the presence of a trialkylamine and a catalyst composed of palladium acetate and a triarylphosphine at 100–150°C.[356] Phosphine free catalysts are also known for the Heck reaction,[357] and halogen-free reactions are also known.[358] The Heck reaction can be done in aqueous media as well.[359] A Montmorillonite K10 clay mediated reaction has also been reported,[360] glass beads[361] have mediated the reaction, and microwaves[362] have been used to induce the reaction. The reaction has also been done with terminal alkynes as substrates.[363]

The evidence is in accord with an addition-elimination mechanism (addition of ArPdX followed by elimination of HPdX) in most cases.[364] The reactions are stereospecific, yielding products expected from syn addition followed by syn elimination.[365] Because the product is formed by an elimination step, with suitable substrates the double bond can go the other way, resulting in allylic rearrangement, for example,[366]



The Heck reaction has also been performed intramolecularly.[367] An intramolecular version that couples vinyl bromide with a C=C unit leads to cyclic compounds.[368] Asymmetric Heck reactions are known[369] and the effects of high pressure have been studied.[370]

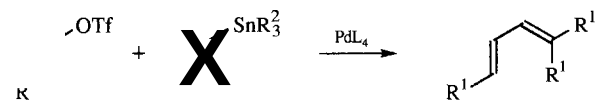
In a related reaction, aryl halides couple with vinyl tin reagents to form styrene derivatives in the presence of a nickel catalyst, for example,[371]

$$Ar\text{-}X + CH_2{=}CH{-}SnBu_3 \xrightarrow{Ni(acac)_2 - DIBAT\text{-}H} Ar{-}CH{=}CH_2$$

OS VI, 815; VII, 361.

14-20 *Arylation and Alkylation of Alkenes by Vinyltin Compounds: The Stille Reaction*

ALKYLATION OR ALKYL-DE-OXYSULFONATION, AND SO ON



Vinyl triflates ($C{=}C{-}OSO_2CF_3$) react with vinyl tin derivatives in the presence of palladium catalysts to form dienes, in what is known as the *Stille coupling?*[12] Vinyl triflates can be prepared from the enolate by reaction with *N*-phenyl triflimide.[373] This reaction is highly stereoselective. Cine substitution is known with this reaction, and its mechanism has been studied.[374] Vinylation of heterocyclic triflates is also possible.[375] By using $ArSnCl_3$ derivatives, Stille coupling can be done in aqueous KOH.[376] A related reaction couples reagents with $C{=}C{-}I^+Ph$ reagents, in the presence of a palladium catalyst.[377] Aryl halides can be coupled to reagents using a palladium catalyst.[378] Vinyl halides can be used,[379] and allenic tin compounds have been used.[380]

14-21 *Alkylation and Arylation of Aromatic Compounds by Peroxides*

ALKYLATION OR ALKYL-DE-HYDROGENATION

$$ArH + R{-}C(=O){-}O{-}O{-}C(=O){-}R \longrightarrow Ar{-}R$$

This reaction is most often carried out with R = aryl, so the net result is the same as in **14-17,** though the reagent is different.[381] It is used less often than **14-17,** but the scope is similar. When R = alkyl, the scope is more limited.[382] Only certain aromatic compounds, particularly benzene rings with two or more nitro groups, and fused ring systems, can be alkylated by this procedure. 1,4-Quinones can be alkylated with diacyl peroxides or with lead tetraacetate (methylation occurs with this reagent).

The mechanism is as shown on p. 898 (CIDNP has been observed[383]); the radicals are produced by

$$R{-}C(=O){-}O{-}O{-}C(=O){-}R \longrightarrow 2\ R{-}C(=O){-}O\cdot \longrightarrow 2\ R\cdot + 2\ CO_2$$

Since no relatively stable free radical is present (such as **26** in **14-17),** most of the product arises from dimerization and disproportionation.[384] The addition of a small amount of nitrobenzene increases the yield of arylation product because the nitrobenzene is converted to diphenyl nitroxide, which abstracts the hydrogen from 1 and reduces the extent of side reactions.[385]

$$ArH + Ar'Pb(OAc)_3 \longrightarrow ArAr'$$

Aromatic compounds can also be arylated by aryllead tricarboxylates.[386] Best yields ($\approx$70–85%) are obtained when the substrate contains alkyl groups; an electrophilic mechanism is likely. Phenols are phenylated ortho to the OH group (and enols are a phenylated) by triphenylbismuth dichloride or by certain other Bi(V) reagents.[387] O-Phenylation is a possible side reaction. As with the aryllead tricarboxylate reactions, a free-radical mechanism is unlikely.[388]

OS V, 51. See also OS V, 952; VI, 890.

14-22 *Photochemical Arylation of Aromatic Compounds*

ARYLATION OR ARYL-DE-HYDROGENATION

$$ArH + Ar'I \xrightarrow{h\nu} ArAr'$$

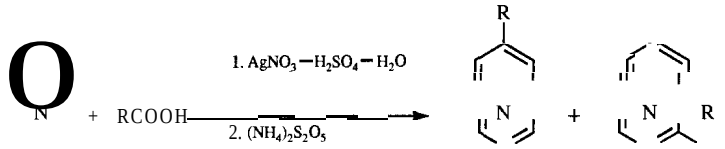
Another free-radical arylation method consists of the photolysis of aryl iodides in an aromatic solvent.[389] Yields are generally higher than in 14-17 or 14-21. The aryl iodide may contain OH or COOH groups. The mechanism is similar to that of 14-17. The aryl radicals are generated by the photolytic cleavage $ArI \rightarrow AR\cdot + I\cdot$. The reaction has been applied to intramolecular arylation (analogous to the Pschorr reaction).[390] A similar reaction is photolysis of an arylthallium bis(trifluoroacetate) (12-21) in an aromatic solvent. Here too, an unsymmetrical biaryl is produced in good yields.[391]

$$Ar'Tl(OCOCF_3)_2 \xrightarrow[ArH]{h\nu} ArAr'$$

In this case, it is the C—Tl bond that is cleaved to give aryl radicals.

14-23 *Alkylation, Acylation, and Carbalkoxylation of Nitrogen Heterocycles*[392]

ALKYLATION OR ALKYL-DE-HYDROGENATION, AND SO ON



Alkylation of protonated nitrogen heterocycles (e.g., pyridines, quinolines) can be accomplished by treatment with a carboxylic acid, silver nitrate, sulfuric acid, and ammonium peroxydisulfate.[393] The R group can be primary, secondary, or tertiary. The attacking species is $R\cdot$, formed by[394]

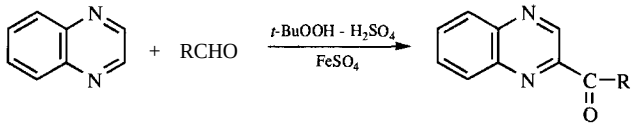
$$2\ Ag^+ + S_2O_8^{2-} \longrightarrow 2\ Ag^{2+} + 2\ SO_4^{2-}$$

$$RCOOH + Ag^{2+} \longrightarrow RCOO\cdot + H^+ + Ag^+$$

$$RCOO\cdot \longrightarrow R\cdot + CO_2$$

A hydroxymethyl group can be introduced ($ArH \rightarrow ArCH_2OH$) by several variations of this method.[395] Alkylation of these substrates can also be accomplished by generating the alkyl radicals in other ways: from hydroperoxides and $FeSO_4$,[396] from alkyl iodides and H_2O_2—Fe^{II},[397] from carboxylic acids and lead tetraacetate, or from the photochemically induced decarboxylation of carboxylic acids by iodosobenzene diacetate.[398]

Protonated nitrogen heterocycles can be acylated by treatment with an aldehyde, *tert*-butyl hydroperoxide, sulfuric acid, and ferrous sulfate, for example,[399]

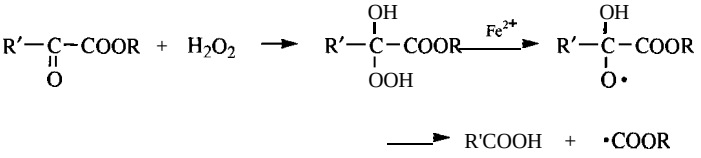


Photochemical alkylation of protonated quinoline occurred with $Ph_2Se(O_2C\ c\text{-}C_6H_{11})_2$.[400]

Other positively charged heterocycles react as well. When *N*-fluoropyridinium triflate was treated with the enolate anion of acetone, 2-(2-oxopropyl)pyridine was formed in modest yield.[401]

These alkylation and acylation reactions are important because Friedel-Crafts alkylation and acylation (11-12, 11-14) cannot be applied to most nitrogen heterocycles. See also 13-15.

Protonated nitrogen heterocycles can be carbalkoxylated[402] by treatment with esters of α-keto acids and Fenton's reagent. Pyridine is carbalkoxylated at C-2 and C-4, for example. The attack is by ·COOR radicals generated from the esters:



Similarly, a carbamoyl group can be introduced[403] by the use of the radicals $H_2N\text{—}\overset{\overset{O}{\|}}{C}\cdot$ or $Me_2N\text{—}\overset{\overset{O}{\|}}{C}\cdot$ generated from formamide or DMF and H_2SO_4, H_2O_2, and $FeSO_4$ or other oxidants.

N_2 as Leaving Group[404]

In these reactions, diazonium salts are cleaved to aryl radicals,[405] in most cases with the assistance of copper salts. Reactions 14-17 and 14-18 may also be regarded as belonging to this category with respect to the attacking compound. For nucleophilic substitutions of diazonium salts, see 13-17–13-20.

14-24 *Replacement of the Diazonium Group by Hydrogen*

DEDIAZONIATION OR HYDRO-DE-DIAZONIATION

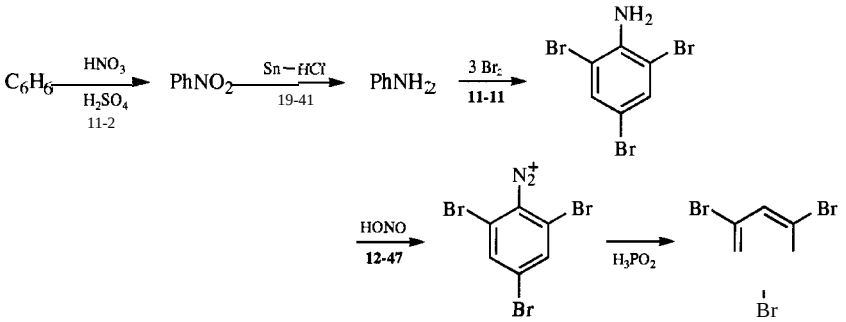
$$ArN_2^+ + H_3PO_2 \longrightarrow ArH$$

Reduction of the diazonium group *(dediazoniation)* provides an indirect method for the removal of an amino group from an aromatic ring.[406] The best and most common way of accomplishing this is by use of hypophosphorous acid H_3PO_2, though many

other reducing agents[407] have been used, among them ethanol, HMPA,[408] thiophenol,[409] and sodium stannite. Ethanol was the earliest reagent used, and it frequently gives good yields, but often ethers (ArOEt) are side products. When H_3PO_2 is used, 5-15 mol of this reagent are required per mole of substrate. Diazonium salts can be reduced in nonaqueous media by several methods,[358] including treatment with Bu_3SnH or Et_3SiH in ethers or MeCN[410] and by isolation as the BF_4^- salt and reduction of this with NaBH4 in DMF.[411] Aromatic amines can be deaminated ($ArNH_2 \rightarrow$ ArH) in one laboratory step by treatment with an alkyl nitrite in DMF[412] or boiling THE[413] The corresponding diazonium salt is an intermediate.

Not many investigations of the mechanism have been carried out. It is generally assumed that the reaction of diazonium salts with ethanol to produce ethers takes place by an ionic (S_N1) mechanism while the reduction to ArH proceeds by a free-radical process.[414] The reduction with H_3PO_2 is also believed to have a free-radical mechanism.[415] In the reduction with $NaBH_4$, an aryldiazene intermediate (ArN=NH) has been demonstrated,[416] arising from nucleophilic attack by BH_4^- on the β nitrogen. Such diazenes can be obtained as moderately stable (half-life of several hours) species in solution.[417] It is not entirely clear how the aryldiazene decomposes, but there are indications that either the aryl radical AR· or the corresponding anion Ar^- may be involved.[418]

An important use of the dediazoniation reaction is to remove an amino group after it has been used to direct one or more other groups to ortho and para positions. For example, the compound 1,3,5-tribromobenzene cannot be prepared by direct bromination of benzene because the bromo group is ortho-para directing; however, this compound is easily prepared by the following sequence:



Many other compounds that would otherwise be difficult to prepare are easily synthesized with the aid of the dediazoniation reaction.

Unwanted dediazoniation can be suppressed by using hexasulfonated calix[6]-arenes (see p. 106).[419]

OS I, 133, 415; II, 353, 592; III, 295; IV, 947; VI, 334.

14-25 *Replacement of the Diazonium Group by Chlorine or Bromine*

CHLORO-DE-DIAZONIATION, AND SO ON

$$ArN_2^+ + CuCl \longrightarrow ArCl$$

Treatment of diazonium salts with cuprous chloride or bromide leads to aryl chlorides or bromides, respectively. In either case the reaction is called the *Sandmeyer reaction.*[420] The reaction can also be carried out with copper and HBr or HC1, in which case it is called the *Gatterman reaction* (not to be confused with **11-16).** The Sandmeyer reaction is not useful for the preparation of fluorides or iodides, but for bromides and chlorides it is of wide scope and is probably the best way of introducing bromine or chlorine into an aromatic ring. The yields are usually high.

The mechanism is not known with certainty but is believed to take the following course:[421]

$$ArN_2^+ X^- + CuX \longrightarrow Ar\cdot + N_2 + CuX_2$$

$$Ar\cdot + CuX_2 \longrightarrow ArX + CuX$$

The first step involves a reduction of the diazonium ion by the cuprous ion, which results in the formation of an aryl radical. In the second step, the aryl radical abstracts halogen from cupric chloride, reducing it. The CuX compound is regenerated and is thus a true catalyst.

Aryl bromides and chlorides can be prepared from primary aromatic amines in one step by several procedures,[422] including treatment of the amine (1) with *tert*-butyl nitrite and anhydrous $CuCl_2$ or $CuBr_2$ at 65°C,[423] and (2) with tert-butyl thionitrite or tert-butyl thionitrate and $CuCl_2$ or $CuBr_2$ at room temperature.[424] These procedures are, in effect, a combination of **12-47** and the Sandmeyer reaction. A further advantage is that cooling to 0°C is not needed. A mixture of Me_3SiCl and $NaNO_2$ was used to convert aniline to chlorobenzene in a related reaction.[425]

For the preparation of fluorides and iodides from diazonium salts, see **13-23** and **13-22.**

$$ArN_2^+ + CuCN \longrightarrow ArCN$$

It is noted that the reaction of aryl diazonium salts with CuCN to give benzonitrile derivatives is also called the *Sandmeyer reaction.* It is usually conducted in neutral solution to avoid liberation of HCN.

OS I, 135, 136, 162, 170; **II,** 130; **III,** 185; IV, 160. Also see OS **III,** 136; IV, 182. For the reaction with CuCN see OS I, 514.

14-26 *Nitro-de-diazoniation*

$$ArN_2^+ + NaNO_2 \xrightarrow{Cu^+} ArNO_2$$

Nitro compounds can be formed in good yields by treatment of diazonium salts with sodium nitrite in the presence of cuprous ion. The reaction occurs only in neutral or alkaline solution. This is not usually called the Sandmeyer reaction, although, like **14-25,** it was discovered by Sandmeyer. The BF_4^- ion is often used as the negative ion to avoid competition from the chloride ion. The mechanism is probably like that

of 14-25.[426] If electron-withdrawing groups are present, the catalyst is not needed; $NaNO_2$ alone gives nitro compounds in high yields.[427]

An alternative procedure used electrolysis, in 60% HNO_3 to convert 1-aminonaphthalene to naphthalene.[428]

OS II, 225; **III,** 341.

14-27 *Replacement of the Diazonium Group by Sulfur-Containing Groups*

CHLOROSULFO-DE-DIAZONIATION

$$ArN_2^+ + SO_2 \xrightarrow[HCl]{CuCl_2} ArSO_2Cl$$

Diazonium salts can be converted to sulfonyl chlorides by treatment with sulfur dioxide in the presence of cupric chloride.[429] The use of $FeSO_4$ and copper metal instead of $CuCl_2$ gives sulfinic acids ($ArSO_2H$).[430] See also **13-18.**

OS **V,** 60; **VII,** 508.

14-28 *Aryl Dimerization with Diazonium Salts*

DE-DIAZONIO-COUPLING; ARYLAZO-DE-DIAZONIO-SUBSTITUTION

$$2ArN_2^+ \xrightarrow[\text{or } Cu + H^+]{Cu^+} Ar\text{-}Ar + 2\,N_2 \quad \text{or} \quad Ar{-}N{=}N{-}Ar + N_2$$

When diazonium salts are treated with cuprous ion (or with copper and acid, in which case it is called the *Gatterman method),* two products are possible. If the ring contains electron-withdrawing groups, the main product is the biaryl, but the presence of electron-donating groups leads mainly to the azo compound. This reaction is different from **14-17** (and from **11-4)** in that *both* aryl groups in the product originate from ArN_2^+, that is, hydrogen is not a leaving group in this reaction. The mechanism probably involves free radicals.[431]

OS I, 222; IV, 872. Also see OS IV, 273.

14-29 *Methylation, Vinylation, and Arylation of Diazonium Salts*

METHYL-DE-DIAZONIATION, AND SO ON

$$ArN_2^+ + Me_4Sn \xrightarrow[MeCN]{Pd(OAc)_2} ArMe$$

A methyl group can be introduced into an aromatic ring by treatment of diazonium salts with tetramethyltin and a palladium acetate catalyst.[432] The reaction has been performed with Me, Cl, Br, and NO_2 groups on the ring. A vinylic group can be introduced with $CH_2{=}CHSnBu_3$.

Aryl diazonium salts can be used coupled with alkenes in a Heck-like reaction (14-20).[433] Other reactive aryl species also couple with aryldiazonium salts in the

presence of a palladium catalyst.[434] A Suzuki type coupling (13-11) has also been reported using arylboronic acids, aryldiazonium salts and a palladium catalyst.[435]

14-30 *Conversion of Diazonium Salts to Aldehydes, Ketones, or Carboxylic Acids*

ACYL-DE-DIAZONIATION, AND SO ON

$$ArN_2^+ + RCH{=}NOH \xrightarrow[Na_2SO_3]{CuSO_4} Ar\text{-}\underset{\displaystyle R}{\underset{|}{C}}{=}NOH \xrightarrow[16\text{-}2]{\text{hydrolysis}} Ar\text{-}\underset{\displaystyle R}{\underset{|}{C}}{=}O$$

Diazonium salts react with oximes to give aryl oximes, which are easily hydrolyzed to aldehydes (R = H) or ketones.[436] A copper sulfate-sodium sulfite catalyst is essential. In most cases higher yields (40-60%) are obtained when the reaction is used for aldehydes than for ketones. In another method[437] for achieving the conversion $ArN_2^+ \rightarrow$ ArCOR, diazonium salts are treated with R_4Sn and CO with palladium acetate as catalyst.[438] In a different kind of reaction, silyl enol ethers of aryl ketones, $Ar'C(OSiMe_3){=}CHR$, react with solid diazonium fluoroborates, $ArN_2^+ BF_4^-$, to give ketones, ArCHRCOAr'.[439] This is, in effect, an arylation of the aryl ketone.

Carboxylic acids can be prepared in moderate-to-high yields by treatment of diazonium fluoroborates with carbon monoxide and palladium acetate[440] or copper(II) chloride.[441] The mixed anhydride ArCOOCOMe is an intermediate that can be isolated. Other mixed anhydrides can be prepared by the use of other salts instead of sodium acetate.[442] An arylpalladium compound is probably an intermediate.[442]

OS V, 139.

Metals as Leaving Groups

14-31 *Coupling of Grignard Reagents*

DE-METALLO-COUPLING

$$2\ RMgX \xrightarrow{TlBr} RR$$

Grignard reagents can be coupled to give symmetrical dimers[443] by treatment with either thallium(I) bromide[444] or with a transition metal halide such as $CrCl_2$, $CrCl_3$, $CoCl_2$, $CoBr_2$, or $CuCl_2$.[445] The metallic halide is an oxidizing agent and becomes reduced. Both aryl and alkyl Grignard reagents can be dimerized by either procedure, though the TlBr method cannot be applied to R = primary alkyl or to aryl groups with ortho substituents. Aryl Grignard reagents can also be dimerized by treatment with 1,4-dichloro-2-butene, 1,4-dichloro-2-butyne, or 2,3-dichloropropene.[446] Vinylic and alkynyl Grignard reagents can be coupled (to give 1,3-dienes and 1,3-diynes, respectively) by treatment with thionyl chloride.[447] Primary alkyl, vinylic, aryl, and benzylic Grignard reagents give symmetrical dimers in high yield ($\approx$90%)

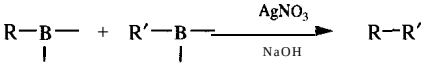
when treated with a silver(I) salt (e.g., $AgNO_3$, AgBr, $AgClO_4$) in the presence of a nitrogen-containing oxidizing agent such as lithium nitrate, methyl nitrate, or NO2.[448] This method has been used to close rings of four, five, and six members.[449]

The mechanisms of the reactions with metal halides, at least in some cases, probably begin with conversion of RMgX to the corresponding RM **(12-33),** followed by its decomposition to free radicals.[450]

OS VI, 488.

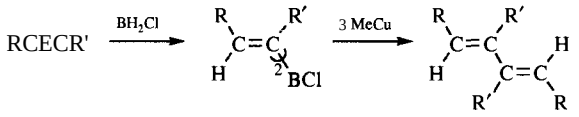
14-32 *Coupling of Boranes*

ALKYL-DE-DIALKYLBORATION



Alkylboranes can be coupled by treatment with silver nitrate and base.[451] Since alkylboranes are easily prepared from alkenes **(15-16),** this is essentially a way of coupling and reducing alkenes; in fact, alkenes can be hydroborated and coupled in the same flask. For symmetrical coupling (R = R') yields range from 60 to 80% for terminal alkenes and from 35 to 50% for internal ones. Unsymmetrical coupling has also been carried out,[452] but with lower yields. Arylboranes react similarly, yielding biaryls.[453] The mechanism is probably of the free-radical type.

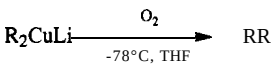
Vinylic dimerization can be achieved by treatment of divinylchloroboranes (prepared by addition of BH_2Cl to alkynes; see **15-16)** with methylcopper. (*E*,*E*)-1,3-Dienes are prepared in high yields.[454]



In a similar reaction, symmetrical conjugated diynes, $RC{\equiv}C{-}C{\equiv}CR$, can be prepared by reaction of lithium dialkyldialkynylborates, $Li^+[R'_2B(C{\equiv}CR)_2]^-$, with iodine.[455]

14-33 *Coupling of Other Organometallic* fleagenfs[388]

DE-METALLO-COUPLING



Lithium dialkylcopper reagents can be oxidized to symmetrical dimers by O_2 at -78°C in THF.[456] The reaction is successful for R = primary and secondary alkyl, vinylic, or aryl. Other oxidizing agents (e.g., nitrobenzene) can be used instead of O_2. Vinylic copper reagents dimerize on treatment with oxygen, or simply on standing at 0°C for several days or at 25°C for several hours, to yield 1,3-dienes.[457]

The finding of retention of configuration for this reaction demonstrates that free-radical intermediates are not involved. Lithium organoaluminates $LiAlR_4$ are dimerized to RR by treatment with $Cu(OAc)_2$.[458] Terminal vinylic alanes (prepared by 15-17) can be dimerized to 1,3-dienes with Cud in THE[459] Symmetrical 1,3-dienes can also be prepared in high yields by treatment of vinylic mercury chlorides[460] with LiCl and a rhodium catalyst[461] and by treatment of vinylic tin compounds with a palladium catalyst.[462] Arylmercuric salts are converted to biaryls by treatment with copper and a catalytic amount of $PdCl_2$.[463] Vinylic, alkynyl, and aryl tin compounds were dimerized with $Cu(NO3)_2$.[464] Alkyl- and aryllithium compounds can be dimerized by transition metal halides in a reaction similar to 14-31.[465] Triarylbismuth compounds Ar_3Bi react with palladium(O) complexes to give biaryls ArAr.[466] Diethylzinc reacted with $Ph_2I^+ BF_4^-$ in the presence of palladium acetate, to give biphenyl.[467]

Unsymmetrical coupling of vinylic, alkynyl, and arylmercury compounds was achieved in moderate-to-good yields by treatment with alkyl and vinylic dialkylcopper reagents (e.g., $PhCH{=}CHHgCl + Me_2CuLi \rightarrow PhCH{=}CHMe$).[468] Unsymmetrical biaryls were prepared by treating a cyanocuprate ArCu(CN)Li (prepared from ArLi and CuCN) with an aryllithium Ar'Li.[469]

Halogen as Leaving Group

The conversion of RX to RH can occur by a free-radical mechanism but is treated at 10-79.

Sulfur as Leaving Group

14-34 *Desulfurization with Raney Nickel*

HYDRO-DE-MERCAPTO-SUBSTITUTION, AND SO ON

$$RSH \xrightarrow[Ni]{H_2} RH$$

$$RSR' \xrightarrow[Ni]{H_2} RH + R'H$$

Thiols and thioethers,[470] both alkyl and aryl, can be desulfurized by hydrogenolysis with Raney nickel.[471] The hydrogen is usually not applied externally, since Raney nickel already contains enough hydrogen for the reaction. Other sulfur compounds can be similarly desulfurized, among them disulfides (RSSR), thiono esters (RCSOR'),[472] thioamides (RCDNHR'), sulfoxides, and dithioacetals. The last reaction, which is an indirect way of accomplishing reduction of a carbonyl to a methylene group (see 19-33), can also give the alkene if an a hydrogen is present.[473] In most of the examples given, R can also be aryl. Other reagents[474] have also been used.[475]

An important special case of RSR reduction is desulfurization of thiophene derivatives. This proceeds with concomitant reduction of the double bonds. Many compounds have been made by alkylation of thiophene, followed by reduction:

28

Thiophenes can also be desulfurized to alkenes ($RCH_2CH{=}CHCH_2R'$ from 28) with a nickel boride catalyst prepared from nickel(II) chloride and $NaBH_4$ in methanol.[476] It is possible to reduce just one SR group of a dithioacetal by treatment with borane-pyridine in trifluoroacetic acid or in CH_2Cl_2 in the presence of $AlCl_3$.[477] Phenyl selenides RSePh can be reduced to RH with Ph_3SnH[478] and with nickel boride.[479]

The exact mechanisms of the Raney nickel reactions are still in doubt, though they are probably of the free-radical type.[480] It has been shown that reduction of thiophene proceeds through butadiene and butene, not through 1-butanethiol or other sulfur compounds, that is, the sulfur is removed before the double bonds are reduced. This was demonstrated by isolation of the alkenes and the failure to isolate any potential sulfur-containing intermediates.[481]

OS IV, 638; V, 419; VI, 109, 581, 601. See also OS VII, 124, 476.

14-35 *Conversion of Sulfides to Organolithium Compounds*

LITHIO-DE-PHENYLTHIO-SUBSTITUTION

$$RSPh \xrightarrow[THF]{\text{Li napthalenide}} RLi$$

Sulfides can be cleaved, with a phenylthio group replaced by a lithium,[482] by treatment with lithium or lithium naphthalenide in THE[483] Good yields have been obtained with R = primary, secondary, or tertiary alkyl, or allylic,[484] and containing groups such as double bonds or halogens. Dilithio compounds can be made from compounds containing two separated SPh groups, but it is also possible to replace just one SPh from a compound with two such groups on a single carbon, to give an α-lithio sulfide.[485] The reaction has also been used to prepare α-lithio ethers and α-lithio organosilanes.[482] For some of these compounds, lithium 1-(dimethylamino)-naphthalenide is a better reagent than either Li or lithium naphthalenide.[486] The mechanism is presumably of the free-radical type.

Carbon as Leaving Group

14-36 *Decarboxylative Dimerization: The Kolbe Reaction*

DE-CARBOXYLIDE-COUPLING

$$2\ RCOO^- \xrightarrow{\text{electrolysis}} R\text{-}R$$

Electrolysis of carboxylate ions, which results in decarboxylation and combination of the resulting radicals, is called the *Kolbe reaction* or the *Kolbe electrosynthesis*.[487] It is used to prepare symmetrical RR, where R is straight or branched chained, except that little or no yield is obtained when there is a branching. The reaction is not successful for R = aryl. Many functional groups may be present, though many others inhibit the reaction.[487] Unsymmetrical RR′ have been made by coupling mixtures of acid salts.

A free-radical mechanism is involved:

$$RCOO^- \xrightarrow[\text{oxidation}]{\text{electrolytic}} RCOO\cdot \xrightarrow{-CO_2} R\cdot \longrightarrow R\text{-}R$$

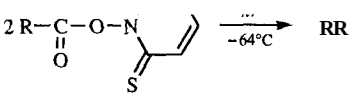
There is much evidence[488] for this mechanism, including side products (RH, alkenes) characteristic of free-radical intermediates and the fact that electrolysis of acetate ion in the presence of styrene caused some of the styrene to polymerize to polystyrene (such polymerizations can be initiated by free radicals, see p. 978). Other side products (ROH, RCOOR) are sometimes found; these stem from further oxidation of the radical R· to the carbocation R^+.[489]

When the reaction is conducted in the presence of 1,3-dienes, additive dimerization can occur:[490]

$$2\ RCOO + CH_2{=}CH{-}CH{=}CH_2 \longrightarrow RCH_2CH{=}CHCH_2CH_2CH{=}CHCH_2R$$

The radical R· adds to the conjugated system to give $RCH_2CH{=}CHCH_2\cdot$, which dimerizes. Another possible product is $RCH_2CH{=}CHCH_2R$, from coupling of the two kinds of radicals.[491]

In a nonelectrolytic reaction, which is limited to R = primary alkyl, the thiohydroxamic esters 29 give dimers when irradiated at —64°C in an argon atmosphere:[492]



29

In another nonelectrolytic process, arylacetic acids are converted to *vic*-diaryl compounds $2ArCR_2COOH \rightarrow ArCR_2CR_2Ar$ by treatment with sodium persulfate ($Na_2S_2O_8$) and a catalytic amount of $AgNO_3$.[493] Both of these reactions involve dimerization of free radicals. In still another process, electron-deficient aromatic acyl chlorides are dimerized to biaryls ($2\ ArCOCl \rightarrow ArAr$) by treatment with a disilane R_3SiSiR_3 and a palladium catalyst.[494]

OS III, 401; V, 445, 463; VII, 181.

14-37 *The Hunsdiecker Reaction*

BROMO-DE-CARBOXYLATION

$$RCOOAg + Br_2 \longrightarrow RBr + CO_2 + AgBr$$

Reaction of a silver salt of a carboxylic acid with bromine is called the *Hunsdiecker reaction*[495] and is a way of decreasing the length of a carbon chain by one unit.[496] The reaction is of wide scope, giving good results for *n*-alkyl R from 2 to 18 carbons and for many branched R too, producing primary, secondary, and tertiary bromides. Many functional groups may be present as long as they are not a substituted. The R group may also be aryl. However, if R contains unsaturation, the reaction seldom gives good results. Although bromine is the most often used halogen, chlorine and iodine have also been used.

When iodine is the reagent, the ratio between the reactants is very important and determines the products. A 1:1 ratio of salt to iodine gives the alkyl halide, as above. A 2:1 ratio, however, gives the ester RCOOR. This is called the *Simonini reaction* and is sometimes used to prepare carboxylic esters. The Simonini reaction can also be carried out with lead salts of acids.[497] A more convenient way to perform the Hunsdiecker reaction is by use of a mixture of the acid and mercuric oxide instead of the salt, since the silver salt must be very pure and dry and such pure silver salts are often not easy to prepare.[498]

Other methods for accomplishing the conversion RCOOH → RX are[499] (1) treatment of thallium(I) carboxylates[500] with bromine;[501] (2) treatment of carboxylic acids with lead tetraacetate and halide *ions* (Cl^-, Br", or 1~);[502] (3) reaction of the acids with lead tetraacetate and NCS, which gives tertiary and secondary chlorides in good yields but is not good for R — primary alkyl or phenyl;[503] (4) treatment of thiohydroxamic esters (24) with CCl_4, $BrCCl_3$ (which gives bromination), CHI3, or CH_2I_2 in the presence of a radical initiator;[504] (5) photolysis of benzophenone oxime esters of carboxylic acids in CCl_4 ($RCON{=}CPh_2 \rightarrow$ RC1).[505] Alkyl fluorides can be prepared in moderate to good yields by treating carboxylic acids RCOOH with XeF_2.[506] This method works best for R = primary and tertiary alkyl, and benzylic. Aromatic and vinylic acids do not react.

The mechanism of the Hundsdiecker reaction is believed to be as follows:

Step 1 $RCOOAg + X_2 \longrightarrow R-\underset{\underset{O}{\|}}{C}-O-X + AgX$

30

Step 2 $RC(=O)-O-X \longrightarrow RCOO\cdot + X\cdot$ (initiation)

Step 3 $RCOO\cdot \longrightarrow R\cdot + CO_2$

Step 4 $R\cdot + RCOOX \longrightarrow RX + RCOO\cdot$ (propagation)

etc.

The first step is not a free-radical process, and its actual mechanism is not known.[507] Compound 30 is an acyl hypohalite and is presumed to be an intermediate, though it has never been isolated from the reaction mixture. Among the evidence for the mechanism is that optical activity at R is lost (except when a neighboring bromine atom is present, see p. 899); if R is neopentyl, there is no rearrangement, which would certainly happen with a carbocation; and the side products, notably RR, are consistent with a free-radical mechanism. There is evidence that the Simonini

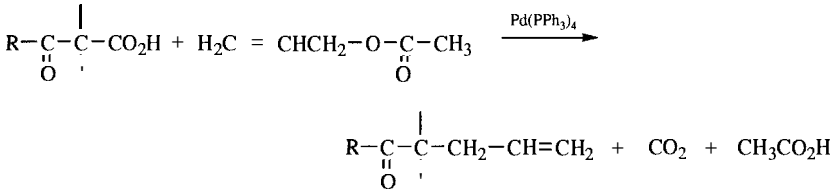
reaction involves the same mechanism as the Hunsdiecker reaction but that the alkyl halide formed then reacts with excess RCOOAg **(10-26)** to give the ester.[508] See also **19-12.**

A related reaction reacts the sodium salt of an alkylsulfonic acid with thionyl chloride at 100°C, to give the alkyl chloride.[509]

OS **III,** 578; V, 126; VI, 179; 75, 124. See also OS VI, 403.

14-38 *Decarboxylatlve Allylation*

ALLYL-DE-CARBOXYLATION



The COOH group of a P-keto acid is replaced by an allylic group when the acid is treated with an allylic acetate and a palladium catalyst at room temperature.[510] The reaction is successful for various substituted allylic groups. The less highly substituted end of the allylic group forms the new bond. Thus, both $CH_2{=}CHCHMeOAc$ and $MeCH{=}CHCH_2OAc$ gave $(R)O{=}C{-}\underset{|}{\overset{|}{C}}{-}CH_2CH{=}CHMe$ as the product.

14-39 *Decarbonylation of Aldehydes and Acyl Halides*

CARBONYL-EXTRUSION

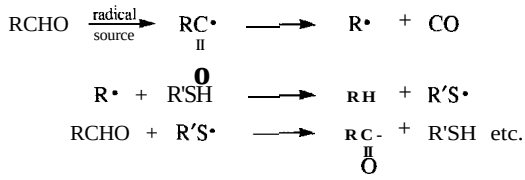
Aldehydes, both aliphatic and aromatic, can be decarbonylated[511] by heating with chlorotris(triphenylphosphir.e)rhodium[512] or other catalysts such as palladium.[513] The compound $RhCl(Ph_3P)_3$ is often called *Wilkinson's catalyst.*[514] In an older reaction, aliphatic (but not aromatic) aldehydes are decarbonylated by heating with di-*tert*-peroxide or other peroxides,[515] usually in a solution containing a hydrogen donor, such as a thiol. The reaction has also been initiated with light, and thermally (without an initiator) by heating at ~ 500°C.

Wilkinson's catalyst has also been reported to decarbonylate aromatic acyl halides at 180°C (ArCOX → ArX).[516] This reaction has been carried out with acyl iodides,[517] bromides, and chlorides. Aliphatic acyl halides that lack an a hydrogen also give this reaction,[518] but if an α hydrogen is present, elimination takes place instead **(17-16).** Aromatic acyl cyanides give aryl cyanides (ArCOCN → ArCN).[519] Aromatic acyl chlorides and cyanides can also be decarbonylated with palladium catalysts.[520]

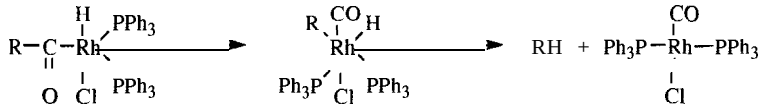
It is possible to decarbonylate acyl halides in another way, to give alkanes (RCOCl —• RH). This is done by heating the substrate with tripropylsilane Pr_3SiH in

the presence of *tert*-butyl peroxide.[521] Yields are good for R = primary or secondary alkyl and poor for R = tertiary alkyl or benzylic. There is no reaction when R = aryl. (See also the decarbonylation ArCOCl → ArAr mentioned in 14-36.)

The mechanism of the peroxide- or light-induced reaction seems to be as follows (in the presence of thiols):[522]



The reaction of aldehydes with Wilkinson's catalyst goes through complexes of the form 26 and 27, which have been trapped.[523] The reaction has been shown to give retention of configuration at a chiral R;[524] and deuterium labeling demonstrates that the reaction is intramolecular: RCOD give RD.[525] Free radicals are not involved.[526] The mechanism with acyl halides appears to be more complicated.[527]



26 27

For aldehyde decarbonylation by an electrophilic mechanism, see 11-37.

[124] There is evidence (unusually high amounts of multiply chlorinated products) that under certain conditions in the reaction of RH with Cl_2, the products of the second propagation step ($RX + X\cdot$) are enclosed within a solvent cage. See Skell, P.S.; Baxter III, H.N. *J. Am. Chem. Soc,* ***1985,*** *107,* 2823; Raner, K.D.; Lusztyk, J.; Ingold, K.U. *J. Am. Chem. Soc,* ***1988,*** *110,* 3519; Tanko, J.M.; Anderson III, FE. *J. [128] It has been reported that the reaction of F atoms with CH_4 at 25 K takes place with practically zero activation energy: Johnson, G.L.; Andrews, L. *J. Am. Chem. Soc,* ***1980,*** *102,* 5736.

[129] For F_2, the following initiation step is possible: $F_2 + RH \rightarrow R\cdot + F\cdot + HF$ (first demonstrated by Miller, Jr., W.T.; Koch Jr., S.D.; McLafferty, F.W. *J. Am. Chem. Soc,* ***1956,*** *78,* 4992). The parameter *AH* for this reaction is equal to the small positive value of 5 kcal mol^{-1} (21 kJ mol^{-1}). The possibility of this reaction (which does not require an initiator) explains why fluorination can take place without uv light (which would otherwise be needed to furnish the 38 kcal mol^{-1} (159 kJ mol^{-1}) necessary to break the F—F bond). Once the reaction has been initiated, the large amount of energy given off by the propagation steps is ample to cleave additional F_2 molecules. Indeed, it is the magnitude of this energy that is responsible for the cleavage of carbon chains by F_2

CHAPTER 15

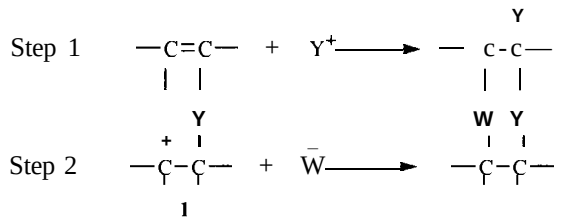
Addition to Carbon-Carbon Multiple Bonds

There are basically four ways in which addition to a double or triple bond can take place. Three of these are two-step processes, with initial attack by a nucleophile, an electrophile, or a free radical. The second step consists of combination of the resulting intermediate with, respectively, a positive species, a negative species, or a neutral entity. In the fourth type of mechanism, attack at the two carbon atoms of the double or triple bond is simultaneous. Which of the four mechanisms is operating in any given case is determined by the nature of the substrate, the reagent, and the reaction conditions. Some of the reactions in this chapter can take place by all four mechanistic types.

MECHANISMS

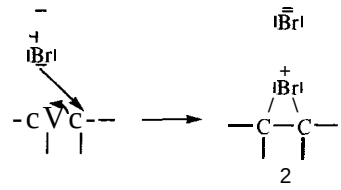
Electrophilic Addition[1]

In this mechanism, a positive species approaches the double or triple bond and in the first step forms a bond by converting the *n* pair of electrons into a a pair:



The IUPAC designation for this mechanism is A_E+A_N (or A_H+A_N if $Y^+=H^+$). As in electrophilic substitution (p. 676), Y need not actually be a positive ion but can be the positive end of a dipole or an induced dipole, with the negative part breaking off either during the first step or shortly after. The second step is a combination of 1 with a species carrying an electron pair and often bearing a negative charge. This step is the same as the second step of the S_N1 mechanism. Not all electrophilic additions follow the simple mechanism given above. In many brominations it is fairly certain

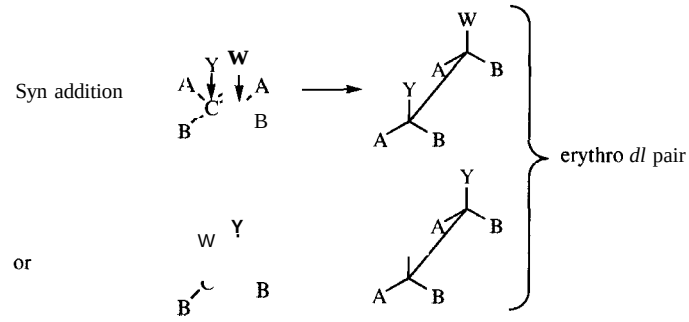
that 1, if formed at all, very rapidly cyclizes to a bromonium ion (2):



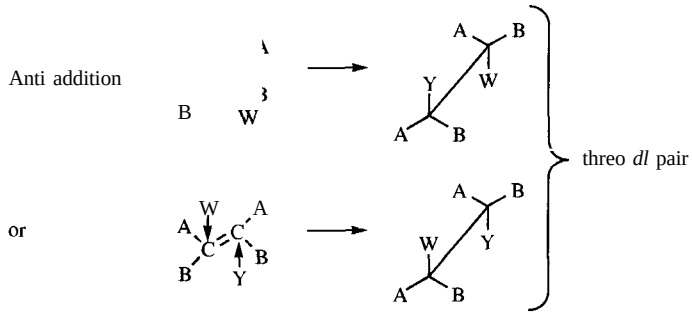
2

This intermediate is similar to those encountered in the neighboring-group mechanism of nucleophilic substitution (see p. 404). The attack of $\bar{W}$ on an intermediate like 2 is an S_N2 step. Whether the intermediate is 1 or 2, the mechanism is called Ad_E2 (electrophilic addition, bimolecular).

In investigating the mechanism of addition to a double bond, perhaps the most useful type of information is the stereochemistry of the reaction.[2] The two carbons of the double bond and the four atoms immediately attached to them are all in a plane (p. 8); there are thus three possibilities. Both Y and W may enter from the same side of the plane, in which case the addition is stereospecific and syn; they may enter from opposite sides for stereospecific anti addition; or the reaction may be nonstereospecific. In order to determine which of these possibilities is occurring in a given reaction, the following type of experiment is often done: YW is added to the cis and trans isomers of an alkene of the form ABC=CBA. We may use the cis alkene as an example. If the addition is syn, the product will be the erythro *dl* pair, because each carbon has a 50% chance of being attacked by Y:

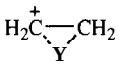


On the other hand, if the addition is anti, the threo *dl* pair will be formed:



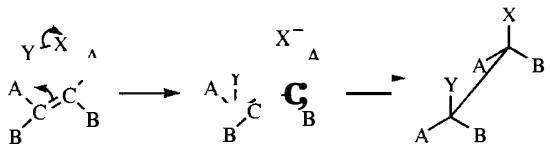
Of course, the trans isomer will give the opposite results: the threo pair if the addition is syn and the erythro pair if it is anti. The threo and erythro isomers have different physical properties. In the special case where Y = W (as in the addition of Br_2), the "erythro pair"is a meso compound. In addition to triple-bond compounds of the type AC≡CA, syn addition results in a cis alkene and anti addition in a trans alkene. By the definition given on page 166 addition to triple bonds cannot be stereospecific, though it can be, and often is, stereoselective.

It is easily seen that in reactions involving cyclic intermediates like 2 addition must be anti, since the second step is an S_N2 step and must occur from the backside. It is not so easy to predict the stereochemistry for reactions involving 1. If 1 has a relatively long life, the addition should be nonstereospecific, since there will be free rotation about the single bond. On the other hand, there may be some factor that maintains the configuration, in which case W may come in from the same side or the opposite side, depending on the circumstances. For example, the positive charge might be stabilized by an attraction for Y that does not involve a full bond:



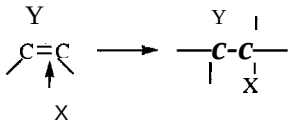
3

The second group would then come in anti. A circumstance that would favor syn addition would be the formation of an ion pair after the addition of Y:[3]



Since X is already on the same side of the plane as Y, collapse of the ion pair leads to syn addition.

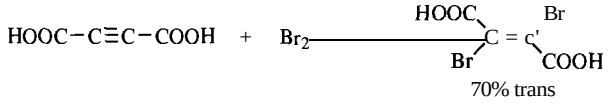
Another possibility is that anti addition might, at least in some cases, be caused by the operation of a mechanism in which attack by W and Y are essentially simultaneous but from opposite sides:



This mechanism, called the Ad_E3 mechanism (*termolecular addition,* IUPAC A_NA_E),[4] has the disadvantage that three molecules must come together in the transition state. However, it is the reverse of the E2 mechanism for elimination, for which the transition state is known to possess this geometry (p. 1300).

There is much evidence that when the attack is by Br^+ (or a carrier of it), the bromonium ion (2) is often an intermediate and the addition is anti. As long ago as 1911, McKenzie and Fischer[5] independently showed that treatment of maleic acid with bromine gave the *dl* pair of 2,3-dibromosuccinic acid, while fumaric acid (the

trans isomer) gave the meso compound. Many similar experiments have been performed since with similar results. For triple bonds, stereoselective anti addition was shown even earlier. Bromination of dicarboxyacetylene gave 70% of the trans isomer.[6]



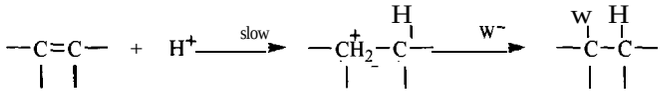
70% trans

There is other evidence for mechanisms involving 2. We have already mentioned (p. 407) that bromonium ions have been isolated in stable solutions in nucleophilic substitution reactions involving bromine as a neighboring group. Such ions have also been isolated in reactions involving addition of a Br^+ species to a double bond.[7] The following is further evidence. If the two bromines approach the double bond from opposite sides, it is very unlikely that they could come from the same bromine molecule. This means that if the reaction is performed in the presence of nucleophiles, some of these will compete in the second step with the bromide liberated from the bromine. It has been found, indeed, that treatment of ethylene with bromine in the presence of chloride ions gives some 1-chloro-2-bromoethane along with the dibromoethane.[8] Similar results are found when the reaction is carried out in the presence of water **(15-39)** or of other nucleophiles.[9] *Ab initio* MO studies show that 2 is more stable than its open isomer 1 (Y = Br).[10] There is evidence that formation of 2 is reversible.[11]

However, a number of examples have been found where addition of bromine is not stereospecifically anti. For example, the addition of Br_2 to *cis*- and *trans*-\-phenylpropenes in CCl_4 was nonstereospecific.[12] Furthermore, the stereospecificity of bromine addition to stilbene depends on the dielectric constant of the solvent. In solvents of low dielectric constant, the addition was 90-100% anti, but with an increase in dielectric constant, the reaction became less stereospecific, until, at a dielectric constant of ~ 35, the addition was completely nonstereospecific.[13] Likewise in the case of triple bonds, stereoselective anti addition was found in bromination of 3-hexyne, but both cis and trans products were obtained in bromination of phenylacetylene.[14] These results indicate that a bromonium ion is not formed where the open cation can be stabilized in other ways (e.g., addition of Br^+ to 1 -phenylpropene gives the ion $PhC^+HCHBrCH_3$, which is a relatively stable benzylic cation) and that there is probably a spectrum of mechanisms between complete bromonium ion (2, no rotation) formation and completely open-cation (1, free rotation) formation, with partially bridged bromonium ions (3, restricted rotation) in between.[15] We have previously seen cases (e.g., p. 415) where cations require more stabilization from outside sources as they become intrinsically less stable themselves.[16] Further evidence for the open cation mechanism where aryl stabilization is present was reported in an isotope effect study of addition of Br_2 to ArCH=CHCHAr' (Ar = *p*-nitrophenyl, Ar' = *p*-tolyl). The ^{14}C isotope effect for one of the double bond carbons (the one closer to the NO_2 group) was considerably larger than for the other one.[17]

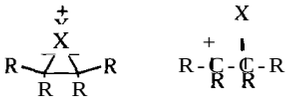
Attack by Cl^+,[18] I^+,[19] and RS^+[20] is similar to that by Br^+; there is a spectrum of mechanisms between cyclic intermediates and open cations. As might be expected from our discussion in Chapter 10 (p. 407), iodonium ions compete with open carbocations more effectively than bromonium ions, while chloronium ions compete less effectively. There is kinetic and spectral evidence that at least in some cases, for example in the addition of Br_2 or IC1, the electrophile forms a *n* complex with the alkene before a covalent bond is formed.[21]

When the electrophile is a proton,[22] a cyclic intermediate is not possible, and the mechanism is the simple A_H+A_N process shown before



This is an A-S_E2 mechanism (p. 466). There is a great deal of evidence[23] for it, including:

1. The reaction is general acid, not specific acid catalyzed, implying rate-determining proton transfer from the acid to the double bond.[24]
2. The existence of open carbocation intermediates is supported by the contrast in the pattern of alkyl substituent effects[25] with that found in brominations, where cyclic intermediates are involved. In the latter case substitution of alkyl groups on $H_2C=CH_2$ causes a cumulative rate acceleration until all four

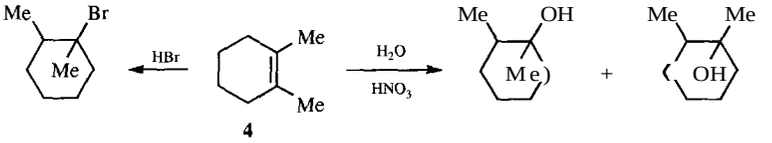


hydrogens have been replaced by alkyl groups, because each group helps to stabilize the positive charge.[26] In addition of HX, the effect is not cumulative. Replacement of the two hydrogens on one carbon causes great rate increases (primary → secondary → tertiary carbocation), but additional substitution on the other carbon produces little or no acceleration.[27] This is evidence for open cations when a proton is the electrophile.[28]

3. Open carbocations are prone to rearrange (Chapter 18). Many rearrangements have been found to accompany additions of HX and H_2O.[29]

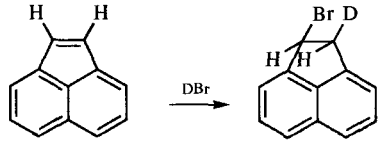
It may also be recalled that vinylic ethers react with proton donors in a similar manner (see **10-6).**

The stereochemistry of HX addition is varied. Examples are known of predominant syn, anti, and nonstereoselective addition. It was found that treatment of 1,2-dimethylcyclohexene (4) with HBr gave predominant anti addition,[30] while addition of water to 4 gave equal amounts of the cis and trans alcohols:[31]



4

On the other hand, addition of DBr to acenaphthylene (5) and to indene and 1-phenylpropene gave predominant syn addition.[32]



5

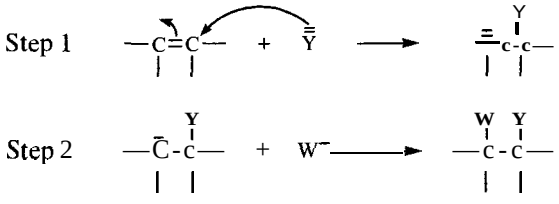
In fact, it has been shown that the stereoselectivity of HCl addition can be controlled by changing the reaction conditions. Addition of HCl to 4 in CH_2Cl_2 at $-98°C$ gave predominantly syn addition, while in ethyl ether at 0°C, the addition was mostly anti.[33]

Addition of HX to triple bonds has the same mechanism, though the intermediate in this case is a vinylic cation:[34]

In all these cases (except for the Ad_E3 mechanism), we have assumed that formation of the intermediate (1, 2, or 3) is the slow step and attack by the nucleophile on the intermediate is rapid, and this is probably true in most cases. However, some additions have been found in which the second step is rate determining.[35]

Nucleophilic Addition[36]

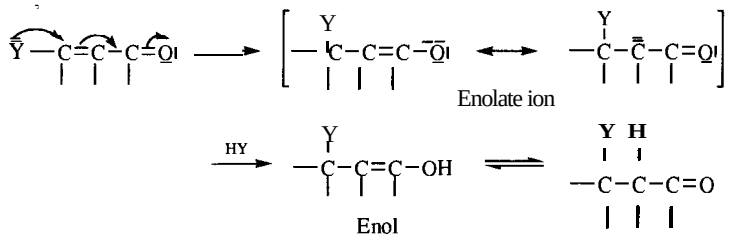
In the first step of nucleophilic addition a nucleophile brings its pair of electrons to one carbon atom of the double or triple bond, creating a carbanion. The second step is combination of this carbanion with a positive species:



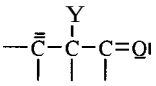
This mechanism is the same as the simple electrophilic one shown on page 970 except that the charges are reversed (IUPAC A_N+A_E or A_N+A_H). When the alkene contains a good leaving group (as defined for nucleophilic substitution), substitution is a side reaction (this is nucleophilic substitution at a vinylic substrate, see p. 428).

In the special case of addition of HY to a substrate of the form —C=C—Z, where Z = CHO, COR[37] (including quinones[38]), COOR, $CONH_2$, CN, NO_2, SOR, SO_2R,[39] and so on, addition nearly always follows a nucleophilic mechanism,[40] with Y~

bonding with the carbon *away* from the Z group, for example,



Protonation of the enolate ion is chiefly at the oxygen, which is more negative than the carbon, but this produces the enol, which tautomerizes. So, although the net result of the reaction is addition to a carbon-carbon double bond, the *mechanism* is 1,4 nucleophilic addition to the C=C–C=O (or similar) system and is thus very similar to the mechanism of addition to carbon–oxygen double and similar bonds (see Chapter 16). When Z is CN or a C=O group, it is also possible for Y" to attack at *this* carbon, and this reaction sometimes competes. When it happens, it is called 1,2 addition. 1,4 Addition to these substrates is also known as *conjugate addition.* The Y^- ion almost never attacks at the 3 position, since the resulting carbanion would have no resonance stabilization:[41]

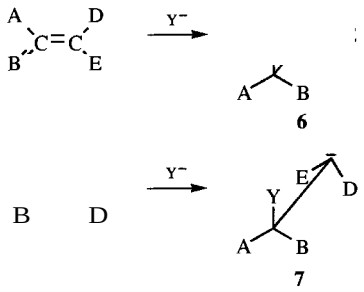


An important substrate of this type is acrylonitrile, and 1,4 addition to it is called *cyanoethylation* because the Y is cyanoethylated:

$$H_2C{=}CH{-}CN + HY \longrightarrow Y{-}CH_2{-}CH_2{-}CN$$

With any substrate, when Y is an ion of the type $Z{-}\bar{C}R_2$ (Z is as defined above; R may be alkyl, aryl, hydrogen, or another Z), the reaction is called the *Michael reaction* (see **15-21).** In this book, we will call all other reactions that follow this mechanism *Michael-type additions.* Systems of the type C=C–C=C–Z can give 1,2, 1,4, or 1,6 addition.[42] Michael-type reactions are reversible, and compounds of the type YCH_2CH_2Z can often be decomposed to YH and $CH_2{=}CHZ$ by heating, either with or without alkali.

If the mechanism for nucleophilic addition is the simple carbanion mechanism outlined on page 975, the addition should be nonstereospecific, though it might well be stereoselective (see p. 166 for the distinction). For example, the (*E*) and (Z) forms of an alkene ABC=CDE would give 6 and 7:



If the carbanion has even a short lifetime, 6 and 7 will assume the most favorable conformation before the attack of W. This is of course the same for both, and when W attacks, the same product will result from each. This will be one of two possible diastereomers, so the reaction will be stereoselective; but since the cis and trans isomers do not give rise to different isomers, it will not be stereospecific. Unfortunately, this prediction has not been tested on open-chain alkenes. Except for Michael-type substrates, the stereochemistry of nucleophilic addition to double bonds has been studied only in cyclic systems, where only the cis isomer exists. In these cases, the reaction has been shown to be stereoselective with syn addition reported in some cases[43] and anti addition in others.[44] When the reaction is performed on a Michael-type substrate, C=C–Z, the hydrogen does not arrive at the carbon directly but only through a tautomeric equilibrium. The product naturally assumes the most thermodynamically stable configuration, without relation to the direction of original attack of Y. In one such case (the addition of EtOD and of Me_3CSD to *trans*-MeCH=CHCOOEt) predominant anti addition was found; there is evidence that the stereoselectivity here results from the final protonation of the enolate, and not from the initial attack.[45] For obvious reasons, additions to triple bonds cannot be stereospecific. As with electrophilic additions, nucleophilic additions to triple bonds are usually stereoselective and anti,[46] though syn addition[47] and nonstereoselective addition[48] have also been reported.

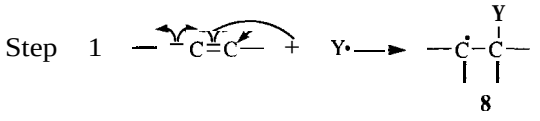
Free-Radical Addition

The mechanism of free-radical addition[49] follows the pattern discussed in Chapter 14 (pp. 894-895). The method of principal component analysis has been used to analyze polar and enthalpic effect in radical addition reactions.[50] A radical is generated by

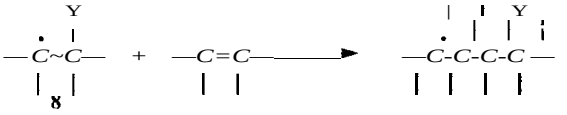
$$YW \xrightarrow[\text{dissociation}]{h\nu \text{ or spontaneous}} Y\cdot + W\cdot$$

$$R\cdot \text{ (from some other source)} + YW \longrightarrow RW + Y\cdot$$

Propagation then occurs by

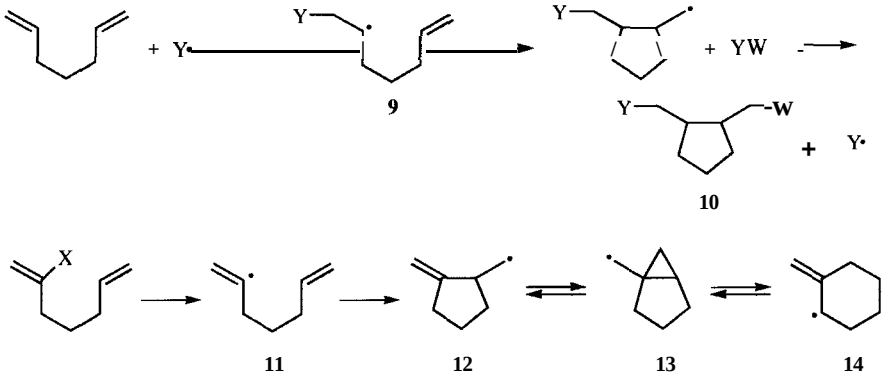


Step 2 is an abstraction, so W is nearly always univalent, either hydrogen or halogen (p. 900). Termination of the chain can occur in any of the ways discussed in Chapter 14. If 8 adds to another alkene molecule, a dimer is formed. This can add to



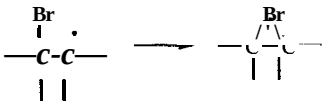
still another, and chains, long or short, may be built up. This is the mechanism of free-radical polymerization. Short polymeric molecules (called *telomers*), formed in this manner, are often troublesome side products in free-radical addition reactions.

When free radicals are added to 1,5- or 1,6-dienes, the initially formed radical (9) can add intramolecularly to the other bond, leading to a cyclic product (10).[51] When the radical is generated from an precursor that gives vinyl radical 11, however, cyclization leads to 12, which is in equilibrium with cyclopropylcarbinyl radical 13 via a 5-exo-trig reaction.[52] A 6-endo-trig reaction leads to 14, but unless there are perturbing substituent effects, however, cyclopropanation should be the major process.



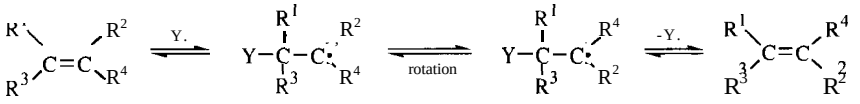
Radicals of the type 9, generated in other ways, also undergo these cyclizations. Both five- and six-membered rings can be formed in these reactions (see p. 985).

The free-radical addition mechanism just outlined predicts that the addition should be nonstereospecific, at least if 8 has any but an extremely short lifetime. However, the reactions may be stereoselective, for reasons similar to those discussed for nucleophilic addition on page 976. Not all free-radical additions have been found to be stereoselective, but many are. For example, addition of HBr to 1-bromocyclohexene gave only *cis*- 1,2-dibromocyclohexane and none of the trans isomer (anti addition),[53] and propyne (at -78 to -60°C) gave only *cis*- 1-bromopropene (anti addition).[54] However, stereospecificity has been found only in a few cases. Selectivity was observed in radical cyclization reactions of functionalized alkenes, which proceeded via a trans ring closure.[55] The most important case is probably addition of HBr to 2-bromo-2-butene under free-radical conditions at - 80°C. Under these conditions, the cis isomer gave 92% of the meso product, while the trans isomer gave mostly the *dl* pair.[56] This stereospecificity disappeared at room temperature, where both alkenes gave the same mixture of products (about 78% of the *dl* pair and 22% of the meso compound), so the addition was still stereoselective but no longer stereospecific. The stereospecificity at low temperatures is probably caused by a stabilization of the intermediate radical through the formation of a bridged bromine radical, of the type mentioned on page 899:



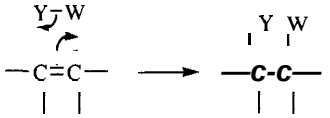
This species is similar to the bromonium ion that is responsible for stereospecific anti addition in the electrophilic mechanism. Further evidence for the existence of such bridged radicals was obtained by addition of Br· to alkenes at 77 K. The ESR spectra of the resulting species were consistent with bridged structures.[57]

For many radicals, step 1 (C=C+Y· → ·C—C—Y) is reversible. In such cases, free radicals can cause cis → trans isomerization of a double bond by the pathway.[58]



Cyclic Mechanisms

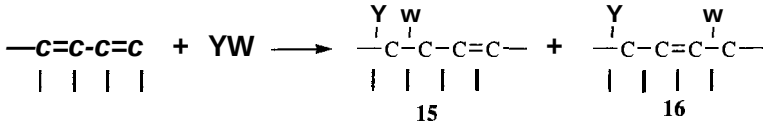
There are some addition reactions where the initial attack is not at one carbon of the double bond, but both carbons are attacked simultaneously. Some of these are four-center mechanisms, which follow this pattern:



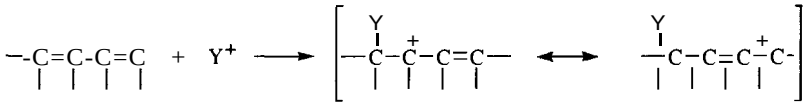
In others, there is a five- or a six-membered transition state. In these cases, the addition to the double or triple bond must be syn. The most important reaction of this type is the Diels–Alder reaction **(15-58).**

Addition to Conjugated Systems

When electrophilic addition is carried out on a compound with two double bonds in conjugation, a 1,2-addition product (15) is often obtained, but in most cases there is also a 1,4-addition product (16), often in larger yield:[59]

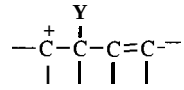


If the diene is unsymmetrical, there may be two 1,2-addition products. The competition between two types of addition product comes about because the carbocation resulting from attack by Y^+ is a resonance hybrid, with partial positive charges at the 2 and 4 positions:

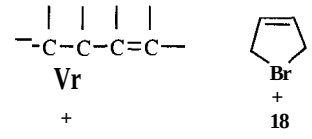


W^- may then attack either position. The original attack of Y^+ is always at the end of the conjugated system because an attack at a middle carbon would give a cation

unstabilized by resonance:



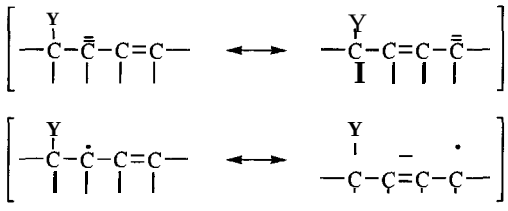
In the case of electrophiles like Br^+, which can form cyclic intermediates, both 1,2- and 1,4-addition products can be rationalized as stemming from an intermediate like 17. Direct nucleophilic attack by W~ would give the 1,2 product, while the 1,4 product could be formed by attack at the 4 position, by an S_N2' type mechanism (see p. 422). Intermediates like 18 have been postulated but ruled out for Br and Cl by the observation that chlorination or bromination of butadiene gives trans 1,4



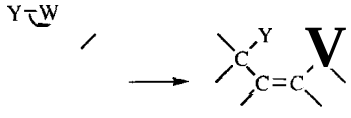
17 18

products.[60] If an ion like 18 were the intermediate, the 1,4 products would have to have the cis configuration.

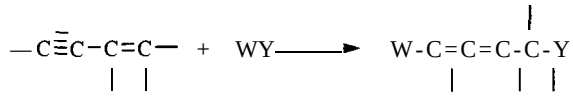
In most cases, more 1,4- than 1,2-addition product is obtained. This may be a consequence of thermodynamic control of products, as against kinetic. In most cases, under the reaction conditions, 15 is converted to a mixture of 15 and 16, which is richer in 16. That is, either isomer gives the same mixture of both, which contains more 16. It was found that at low temperatures, butadiene and HO gave only 20-25% 1,4 adduct, while at high temperatures, where attainment of equilibrium is more likely, the mixture contained 75% 1,4 product.[61] 1,2 Addition predominated over 1,4 in the reaction between DC1 and 1,3-pentadiene, where the intermediate was the symmetrical (except for the D label) $H_3CHC{-}\dot{C}H{-}CHCH_2D$.[62] Ion pairs were invoked to explain this result, since a free ion would be expected to be attacked by Cl~ equally well at both positions, except for the very small isotope effect.



Addition to conjugated systems can also be accomplished by any of the other three mechanisms. In each case, there is competition between 1,2 and 1,4 addition. In the case of nucleophilic or free-radical attack,[63] the intermediates are resonance hybrids and behave like the intermediate from electrophilic attack. Dienes can give 1,4 addition by a cyclic mechanism in this way:



Other conjugated systems, including trienes, enynes, diynes, and so on, have been studied much less but behave similarly. 1,4 Addition to enynes is an important way of making allenes:



Radical addition to conjugated systems is an important part of chain propagation reactions. The rate constants for addition of cyclohexyl radical to conjugated amides have been measured, and shown to be faster than addition to styrene.[64] In additions to $RCH{=}C(CN)_2$ systems, where the R group has a chiral center, the Felkin–Ahn rule (p. 148) is followed and the reaction proceeds with high selectivity.[65] Addition of some radicals, such as $(Me_3Si)_3Si\cdot$, is reversible and this can lead to poor selectivity or isomerization.[66]

ORIENTATION AND REACTIVITY

Reactivity

As with electrophilic aromatic substitution (Chapter 11), electron-donating groups increase the reactivity of a double bond toward electrophilic addition and electron-withdrawing groups decrease it. This is illustrated in Tables 15.1 and 15.2.[67] As a further illustration it may be mentioned that the reactivity toward electrophilic addition of a group of alkenes increased in the order $CCl_3CH{=}CH_2 < Cl_2CHCH{=}CH_2 < ClCH_2CH{=}CH_2 < CH_3CH_2{=}CH_2$.[68] For nucleophilic addition the situation is reversed. These reactions are best carried out on substrates containing three or four electron-withdrawing groups, two of the most common being $F_2C{=}CF_2$[69] and $(NC)_2C{=}C(CN)_2$.[70] The effect of substituents is so great that it is possible to make the statement that *simple alkenes do not react by the nucleophilic mechanism, and polyhalo or polycyano alkenes do not generally react by the electrophilic mechanism?*[1] There are some reagents that attack only as nucleophiles (e.g., ammonia) and these add only to substrates susceptible to nucleophilic attack. Other reagents attack

TABLE 15.1 Relative Reactivity of Some Alkenes Toward Bromine in Acetic Acid at 24°C

Alkene	Relative Rate
$PhCH{=}CH_2$	Very fast
PhCH=CHPh	18
$CH_2{=}CHCH_2Cl$	1.6
$CH_2{=}CHCH_2Br$	1.0
PhCH=CHBr	0.11
$CH_2{=}CHBr$	0.0011

TABLE 15.2 Relative Reactivity of Some Alkenes Toward Bromine in Methanol

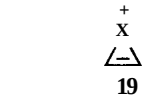
Alkene	Relative Rate
CH_2=CH2	3.0 x 10^1
$CH_3CH_2CH=CH_2$	2.9 x 10^3
cis-$CH_3CH_2CH=CHCH_3$	1.3 x 10^5
$(CH_3)_2C=C(CH_3)_2$	2.8 x 10^7

only as electrophiles, and, for example, $F_2C=CF_2$ does not react with these. In still other cases, the same reagent reacts with a simple alkene by the electrophilic mechanism and with a polyhalo alkene by a nucleophilic mechanism. For example, Cl_2 and HF are normally electrophilic reagents, but it has been shown that Cl_2 adds to $(NC)_2C=CHCN$ with initial attack by Cl^-,[72] and that HF adds to $F_2C=CClF$ with initial attack by F^-.[73] Compounds that have a double bond conjugated with a Z group (as defined on p. 975) nearly always react by a nucleophilic mechanism.[74] These are actually 1,4 additions, as discussed on page XXX. A number of studies have been made of the relative activating abilities of various Z groups.[75] On the basis of these studies, the following order of decreasing activating ability has been suggested: Z = NO_2, COAr, CHO, COR, SO_2Ar, CN, COOR, SOAr, $CONH_2$, CONHR.[76]

It seems obvious that electron-withdrawing groups enhance nucleophilic addition and inhibit electrophilic addition because they lower the electron density of the double bond. Addition of electrophilic radicals to electron rich alkenes has been reported,[77] so the reaction is possible in some cases. This is probably true, and yet similar reasoning does not always apply to a comparison between double and triple bonds.[78] There is a higher concentration of electrons between the carbons of a triple bond than in a double bond, and yet triple bonds are *less* subject to electrophilic attack and *more* subject to nucleophilic attack than double bonds.[79] This statement is not universally true, but it does hold in most cases. In compounds containing both double and triple bonds (nonconjugated), bromine, an electrophilic reagent, always adds to the double bond.[80] In fact, all reagents that form bridged intermediates like 2 react faster with double than with triple bonds. On the other hand, addition of electrophilic H^+ (acid-catalyzed hydration, **15-3;** addition of hydrogen halides, **15-**2) takes place at about the same rates for alkenes as for corresponding alkynes.[81] Furthermore, the presence of electron-withdrawing groups lowers the alkene/alkyne rate ratio. For example, while styrene $PhCH=CH_2$ was brominated 3000 times faster than PhC≡CH, the addition of a second phenyl group (PhCH=CHPh vs. PhC≡CPh) lowered the rate ratio to about 250.[82] In the case of *trans*-MeOOCCH=CHCOOMe versus MeOOCC≡CCOOMe, the triple bond compound was actually brominated faster.[83]

Still, it is true that in general triple bonds are more susceptible to nucleophilic and less to elcctrophilic attack than double bonds, in spite of their higher electron density. One explanation is that the electrons in the triple bond are held more tightly

because of the smaller carbon-carbon distance; it is thus harder for an attacking electrophile to pull out a pair. There is evidence from far-UV spectra to support this conclusion.[84] Another possible explanation has to do with the availability of the unfilled orbital in the alkyne. It has been shown that a n^* orbital of bent alkynes (such as cyclooctyne) has a lower energy than the n^* orbital of alkenes, and it has been suggested[85] that linear alkynes can achieve a bent structure in their transition states when reacting with an electrophile. Where electrophilic addition involves

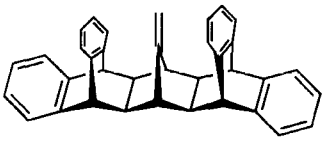


19 **20**

bridged-ion intermediates, those arising from triple bonds (19) are more strained than the corresponding 20 and furthermore are antiaromatic systems (see p. 58), which 20 are not. This may be a reason why electrophilic addition by such electrophiles as Br, I, SR, and so on, is slower for triple than for double bonds.[86] As might be expected, triple bonds connected to a Z group (C≡C—Z) undergo nucleophilic addition especially well.[87]

Although alkyl groups in general increase the rates of electrophilic addition, we have already mentioned (p. 974) that there is a different pattern depending on whether the intermediate is a bridged ion or an open carbocation. For brominations and other electrophilic additions in which the first step of the mechanism is rate determining, the rates for substituted alkenes correlate well with the ionization potentials of the alkenes, which means that steric effects are not important.[88] Where the second step is rate determining [e.g., oxymercuration (15-3), hydroboration (15-17)], steric effects are important.[88]

Free-radical additions can occur with any type of substrate. The determining factor is the presence of a free-radical attacking species. Some reagents (e.g., HBr, RSH) attack by ionic mechanisms if no initiator is present, but in the presence of a free-radical initiator, the mechanism changes and the addition is of the free-radical type. Nucleophilic radicals (see p. 896) behave like nucleophiles in that the rate is increased by the presence of electron-withdrawing groups in the substrate. The reverse is true for electrophilic radicals.[89] However, nucleophilic radicals react with alkynes more slowly than with the corresponding alkenes,[90] which is contrary to what might have been expected.[91]



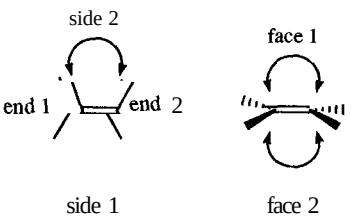
21

Steric influences are important in some cases. In catalytic hydrogenation, where the substrate must be adsorbed onto the catalyst surface, the reaction becomes more difficult with increasing substitution. The hydrocarbon 21, in which the double bond is entombed between the benzene rings, does not react with Br_2, H_2SO_4, O3, BH3, $:CBr_2$, or other reagents that react with most double bonds.[92] A similarly inactive

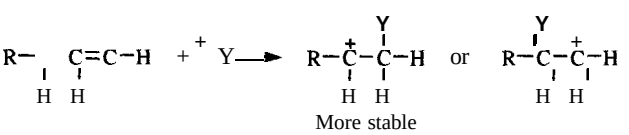
compound is tetra-*tert*-butylallene $(t\text{-Bu})_2C{=}C{=}C(t\text{-Bu})_2$, which is inert to Br_2, Cl_2, O_3, and catalytic hydrogenation.[93]

Orientation

When an unsymmetrical reagent is added to an unsymmetrical substrate, the question arises: Which side of the reagent goes to which side of the double or triple bond? The terms side and face are arbitrary, and a simple guide is shown to help understand the arguments used here. For electrophilic attack, the answer is given by

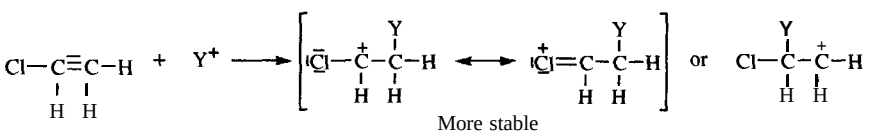


Markovnikov's rule: The positive portion of the reagent goes to the side of the double or triple bond that has more hydrogens.[94] A number of explanations have been suggested for this regioselectivity, but the most probable is that Y^+ adds to that side that will give the more stable carbocation. This premise has been examined by core electron spectroscopy and by theoretical analysis.[95] Thus, when an alkyl group is present, secondary carbocations are more stable than primary:



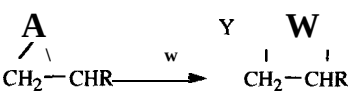
More stable

We may ask: How does Y^+ "know" which side will give the more stable carbocation? As in the similar case of electrophilic aromatic substitution (p. 681), we invoke the Hammond postulate and say that the lower energy carbocation is preceded by the lower energy transition state. Markovnikov's rule also applies for halogen substituents because the halogen stabilizes the carbocation by resonance:



More stable

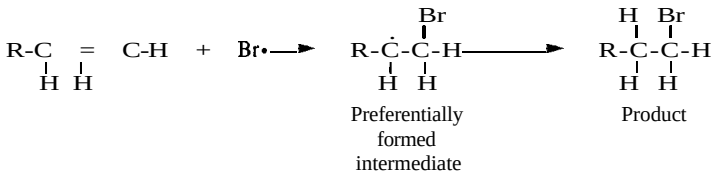
Markovnikov's rule is also usually followed where bromonium ions or other three-membered rings are intermediates.[96] This means that in these cases attack by W must resemble the S_N1 rather than the S_N2 mechanism (see p. 461), though the overall stereospecific anti addition in these reactions means that the nucleophilic substitution step is taking place with inversion of configuration.



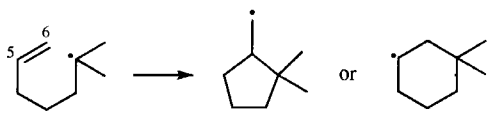
Alkenes containing strong electron-withdrawing groups may violate Markovnikov's rule. For example, attack at the Markovnikov position of $Me_3N^+-CH=CH_2$ would give an ion with positive charges on adjacent atoms. The compound $CF_3CH=CH_2$ has been reported to give electrophilic addition with acids in an anti-Markovnikov direction, but it has been shown[97] that, when treated with acids, this compound does not give simple electrophilic addition at all; the apparently anti-Markovnikov products are formed by other pathways.

For nucleophilic addition the direction of attack has been studied very little, except for Michael-type addition, with compounds of the type C=C–Z. Here the negative part of the reagent almost always attacks regioselectively at the carbon that does not carry the Z (see p. 976).

In free-radical addition,[98] the main effect seems to be steric.[99] All substrates $CH_2=CHX$ are preferentially attacked at the CH_2, regardless of the identity of X or of the attacking radical. With a reagent such as HBr, this means that the addition is anti-Markovnikov:



Thus the observed orientation in both kinds of HBr addition (Markovnikov electrophilic and anti-Markovnikov free radical) is caused by formation of the secondary intermediate. In the electrophilic case, it forms because it is more stable than the primary; in the free-radical case because it is sterically preferred. The stability order of the free-radical intermediates is also usually in the same direction: $3° > 2° > 1°$ (p. 241), but this factor is apparently less important than the steric factor. Internal alkenes with no groups present to stabilize the radical usually give an approximately 1:1 mixture.

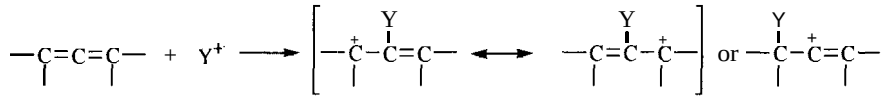


Favored

In *intramolecular* additions of radicals containing a 5,6 double bond,[51] both five- and six-membered rings can be formed, but in most cases[100] the five-membered rings are greatly preferred kinetically, even (as in the case shown) where five-membered ring closure means generating a primary radical and six-membered ring closure a secondary radical. This phenomenon may be caused by more favorable entropy factors leading to a five-membered ring, as well as by stereoelectronic factors, but other explanations have also been offered.[101] Similar behavior is found when the double bond is in other positions (from the 3,4 to the 7,8 position). In each case the smaller ring (exo-trig addition) is preferred to the larger (endo-trig

addition)[102] (see the Baldwin rules, p. 282). However, when a radical that is unsaturated in the 5,6 position contains an alkyl group in the 5 position, formation of the six-membered ring is generally favored.[103]

For conjugated dienes, attack by a positive ion, a negative ion, or a free radical is almost always at the *end* of the conjugated system, since in each case this gives an intermediate stabilized by resonance. In the case of an unsymmetrical diene, the more stable ion is formed. For example, isoprene $CH_2{=}CMeCH{=}CH_2$, treated with HCl gives only $Me_2CClCH{=}CH_2$ and $Me_2C{=}CHCH_2Cl$, with none of the product arising from attack at the other end. The compound $PhCH{=}CHCH{=}CH_2$ gives only $PhCH{=}CHCHClCH_3$ since it is the only one of the eight possible products that has a double bond in conjugation with the ring and that results from attack by H^+ at an end of the conjugated system.

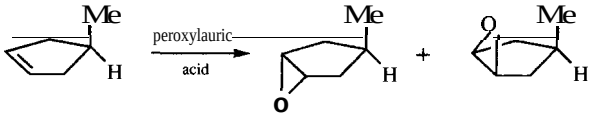


When allenes are attacked by electrophilic reagents,[104] Markovnikov's rule would predict that the attack should be at the end of the system, since there are no hydrogens in the middle. Attack at the center gives a carbocation stabilized by resonance, but not immediately. In order for such stabilization to be in effect the three *p* orbitals must be parallel, and it requires a rotation about the C–C bond for this to happen.[105] Therefore, the stability of the allylic cation has no effect on the transition state, which still has a geometry similar to that of the original allene (p. 133). Probably because of this, attack on the unsubstituted $CH_2{=}C{=}CH_2$ is most often at the end carbon, to give a vinylic cation, though center attack has also been reported. However, as alkyl or aryl groups are substituted on the allene carbons, attack at the middle carbon becomes more favorable because the resulting cation is stabilized by the alkyl or aryl groups (it is now a secondary, tertiary, or benzylic cation). For example, allenes of the form $RCH{=}C{=}CH_2$ are still attacked most often at the end, but with $RCH{=}C{=}CHR'$ center attack is more prevalent. Tetramethylallene is also attacked predominantly at the center carbon.[106] Free radicals[107] attack allenes most often at the end,[108] though attack at the middle has also been reported.[109] As with electrophilic attack and for the same reason, the stability of the allylic radical has no effect on the transition state of the reaction between a free radical and an allene. Again, as with electrophilic attack, the presence of alkyl groups increases the extent of attack by a radical at the middle carbon.[110]

Stereochemical Orientation

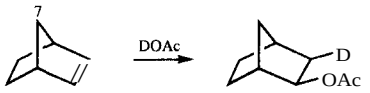
It has already been pointed out that some additions are syn, with both groups, approaching from the same side, and that others are anti, with the groups approaching from opposite sides of the double or triple bond. For cyclic compounds, there are further aspects of steric orientation. In syn addition to an unsymmetrical cyclic alkene, the two groups can come in from the more-hindered face or from the

less-hindered face of the double bond. The rule is that syn addition is usually, though not always, from the less-hindered face. For example, epoxidation of 4-methylcyclopentene gave 76% addition from the less-hindered and 24% from the more-hindered face.[111]

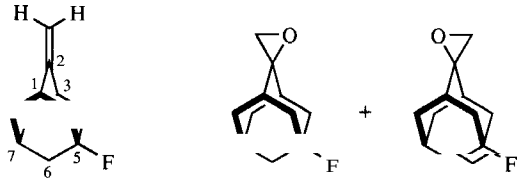


76% 24%

In anti addition to a cyclic substrate, the initial attack by the electrophile is also from the less-hindered face. However, many (though not all) electrophilic additions to norbornene and similar strained bicycloalkenes are syn additions.[112] In these cases attack is always from the exo side, for example,[113]



unless the exo side is blocked by substituents in the 7 position, in which case endo attack may predominate; for example, 7,7-dimethylnorbornene undergoes syn-endo epoxidation (15-48) and hydroboration[114] (15-16). However, addition of DCl and F_3CCOOD to, and oxymercuration (15-2) of, 7,7-dimethylnorbornene proceeds syn–exo in spite of the methyl groups in the 7 position.[115] Similarly, free-radical additions to norbornene and similar molecules are often syn-exo, though anti additions and endo attacks are also known.[116]



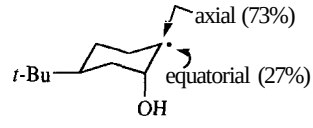
22 23 24

Ratio 66:34

Electronic effects can also play a part in determining which face is attacked. In the adamantane derivative (22), steric effects are about the same for each face of the double bond. Yet epoxidation, dibromocarbene attack (15-62), and hydroboration (15-16) all predominantly take place from the face that is syn to the electron-withdrawing fluorine.[117] In the case shown, about twice as much 23 was formed, compared to 24. Similar results have been obtained on other substrates:[118] groups that are electron-withdrawing by the field effect (-7) direct attack from the syn face; +/ groups from the anti face, for both electrophilic and nucleophilic attack. These results are attributed[119] to hyperconjugation: For the adamantane case, there is overlap between the σ^* orbital of the newly forming bond (between the attacking species and C-2 in 22) and the filled σ orbitals of the C_α–C_β bonds on the opposite

side. This is called the *Cieplak effect.* The $LiAlH_4$ reduction of 2-axial methyl or methoxy cyclohexanones supports Cieplak's proposal.[120] In addition reactions of methanol to norbornanones, however, little evidence was found to support the Cieplak effect.[121] The four possible bonds are C-3—C-4 and C-1—C-9 on the syn side and C-3—C-10 and C-1—C-8 on the anti side. The preferred pathway is the one where the incoming group has the more electron-rich bonds on the side *opposite* to it (these are the ones it overlaps with). Since the electron-withdrawing F has its greatest effect on the bonds closest to it, the C-1—C-8 and C-3—C-10 bonds are more electron rich, and the group comes in on the face syn to the F.

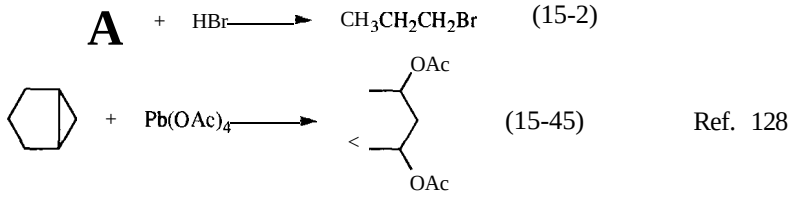
It has been mentioned that additions of Br_2 and HOBr are often anti because of formation of bromonium ions and that free-radical addition of HBr is also anti. When the substrate in any of these additions is a cyclohexene, the addition is not only anti but the initially formed product is conformationally specific too, being mostly diaxial.[122] This is so because diaxial opening of the three-membered ring preserves a maximum coplanarity of the participating centers in the transition state; indeed, on opening, epoxides also give diaxial products.[123] However, the initial diaxial product may then pass over to the diequatorial conformer unless other groups on the ring render the latter less stable than the former. In free-radical additions to cyclohexenes in which cyclic intermediates are not involved, the initial attack by the radical is also usually from the axial direction,[124] resulting in a diaxial initial product if the overall addition is anti. The direction from which unsymmetrical radicals attack has also been studied.[125] For example, when the radical 25 adds to a double bond it preferentially does so anti to the OH group, leading to a diaxial trans product.[125]



25

Addition to Cyclopropane Rings[126]

We have previously seen (p. 181) that in some respects, cyclopropane rings resemble double bonds.[127] It is not surprising, therefore, that cyclopropanes undergo addition reactions analogous to those undergone by double-bond compounds, resulting in the opening of the three-membered rings, as in the two examples shown where pertinent reaction numbers are in parentheses.



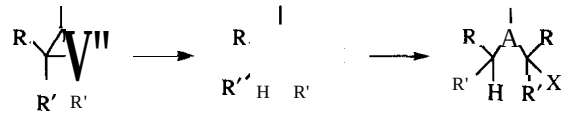
Other examples are discussed at 15-3, 15-15, and 15-61.

Additions to cyclopropanes can take place by any of the four mechanisms already discussed in this chapter, but the most important type involves electrophilic attack.[129] For substituted cyclopropanes, these reactions usually follow Markovnikov's rule, though exceptions are known and the degree of regioselectivity is often small. The application of Markovnikov's rule to these substrates can be illustrated by the reaction of 1,1,2-trimethylcyclopropane with HX.[130] The rule predicts that the electrophile (in this case H^+) goes to the carbon with the most hydrogens and the

nucleophile goes to the carbon that can best stabilize a positive charge (in this case the tertiary rather than the secondary carbon). The stereochemistry of the reaction can be investigated at two positions: the one that becomes connected to the electrophile and the one that becomes connected to the nucleophile. The results at the former position are mixed. Additions have been found to take place with 100% retention,[131] 100% inversion,[132] and with mixtures of retention and inversion.[133] At the carbon that becomes connected to the nucleophile the result is usually inversion, though retention has also been found,[134] and elimination, rearrangement, and racemization processes often compete, indicating that in many cases a positively charged carbon is generated at this position.

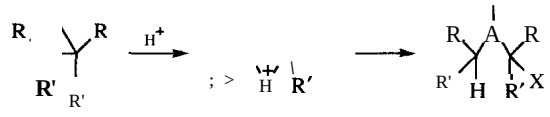
At least three mechanisms have been proposed for electrophilic addition (these mechanisms are shown for attack by HX, but analogous mechanisms can be written for other electrophiles).

Mechanism *a*



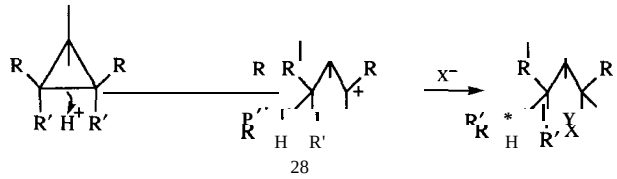
26

Mechanism *b*



27

Mechanism *c*

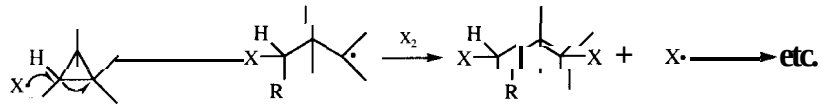


28

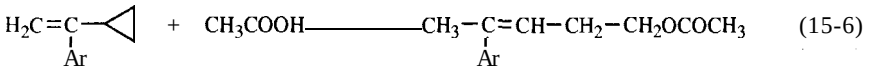
Mechanism *a* involves a corner-protonated cyclopropane (**26**);[135] we have already seen examples of such ions in the 2-norbornyl and 7-norbornenyl cations (pp. 409, 414). Mechanism *b* involves an edge-protonated cyclopropane (27). Mechanism *c* consists of a one-step S_E2-type attack by H^+ to give the classical cation 28, which

then reacts with the nucleophile. Although the three mechanisms as we have drawn them show retention of configuration at the carbon that becomes attached to the proton, mechanisms *a* and *c* at least can also result in inversion at this carbon. Unfortunately, the present available evidence does not allow us unequivocally to select any of these as the exclusive mechanism in all cases. Matters are complicated by the possibility that more than one edge-protonated cyclopropane is involved, at least in some cases. There is strong evidence for mechanism *b* with the electrophiles Br^+ and Cl^+;[136] and for mechanism *a* with D^+ and Hg^{2+}.[137] *Ab initio* studies show that the corner-protonated 26 is slightly more stable ($\sim$1.4 kcal mol^{-1}, 6 kJ mol^{-1}) than the edge-protonated **27**.[138] There is some evidence against mechanism *c*.[139]

Free-radical additions to cyclopropanes have been studied much less, but it is known that Br_2 and Cl_2 add to cyclopropanes by a free-radical mechanism in the presence of UV light. The addition follows Markovnikov's rule, with the initial radical attacking the least-substituted carbon and the second group going to the most-substituted position. Several investigations have shown that the reaction is stereospecific at one carbon, taking place with inversion there, but nonstereospecific at the other carbon.[140] A mechanism that accounts for this behavior is[141]



In some cases, conjugate addition has been performed on systems where a double bond is "conjugated" with a cyclopropyl ring. An example is[142]



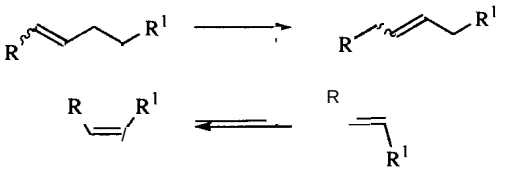
(15-6)

REACTIONS

Reactions are classified by type of reagent. Isomerization of double and triple bonds is followed by examination of all reactions where hydrogen adds to one side of the double or triple bond.

Isomerization of Double and Triple Bonds

5-1 *Isomerization*



There are several reagents that lead to isomerization of a double bond to form a new alkene. Allyl decyl ether ($CH_2{=}CHCH_2OC_{10}H_{21}$) was isomerized to 1-decyloxy-1-propene ($CH_3CH{=}CHOC_{10}H_{21}$) by treatment with $NaHFe(CO)_4$.[143] Many of these reactions were discussed in 12-2.

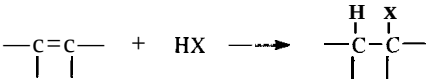
Isomerization of (*E/Z*) isomers is another important transformation. Isomerization of (*E*) and (Z-) conjugated amides is effected photochemically[144] (photoisomerization[145]). There is a rather high energy barrier for the excited state required for (*E/Z*) isomerization.[146] Isomerization of the C=C units in dienes is also induced photochemically.[147] Isomerization of cyclic alkenes is more difficult but cyclooctene is isomerized photochemically.[148] Conjugated aldehydes have been isomerized using thiourea in DMF.[149]

Reactions in Which Hydrogen Adds to One Side

A. *Halogen on the Other Side*

15-2 *Addition of Hydrogen Halides*

HYDRO-HALO-ADDITION



Any of the four hydrogen halides can be added to double bonds.[150] The compounds HI, HBr, and HF[151] add at room temperature. The addition of HC1 is more difficult and usually requires heat,[22] although HC1 adds easily in the presence of silica gel.[152] The reaction has been carried out with a large variety of double-bond compounds, including conjugated systems, where both 1,2 and 1,4 addition are possible. A convenient method for the addition of HF involves the use of a polyhydrogen fluoride-pyridine solution.[153] When the substrate is mixed with this solution in a solvent such as THF at 0°C, alkyl fluorides are obtained in moderate-to-high yields.

The addition of hydrogen halides to simple alkenes, in the absence of peroxides, takes place by an electrophilic mechanism, and the orientation is in accord with Markovnikov's rule.[154] When peroxides are added, the addition of HBr occurs by a free-radical mechanism and the orientation is anti-Markovnikov (p. 985).[155] It must be emphasized that this is true only for HBr. Free-radical addition of HF and HI has never been observed, even in the presence of peroxides, and of HC1 only rarely. In the rare cases where free-radical addition of HC1 was noted, the orientation was still Markovnikov, presumably because the more stable *product* was formed.[156] Free-radical addition of HF, HI, and HC1 is energetically unfavorable (see the discussions on pp. 900, 910). It has often been found that anti-Markovnikov addition of HBr takes place even when peroxides have not been added. This happens because the substrate alkenes absorb oxygen from the air, forming small amounts of peroxides

(14-8). Markovnikov addition can be ensured by rigorous purification of the substrate, but in practice this is not easy to achieve, and it is more common to add inhibitors (e.g., phenols or quinones), which suppress the free-radical pathway. The presence of free-radical precursors such as peroxides does not inhibit the ionic mechanism, but the radical reaction, being a chain process, is much more rapid than the electrophilic reaction. In most cases, it is possible to control the mechanism (and hence the orientation) by adding peroxides to achieve complete free-radical addition, or inhibitors to achieve complete electrophilic addition, though there are some cases where the ionic mechanism is fast enough to compete with the free-radical mechanism and complete control cannot be attained. Markovnikov addition of HBr, HC1, and HI has also been accomplished, in high yields, by the use of phase transfer catalysis.[157] For alternative methods of adding HBr (or HI) with anti-Markovnikov orientation, see **12-28.**

It is also possible to add 1[158] or 2 mol of any of the four hydrogen halides to triple bonds.

$$-C\equiv C- \xrightarrow{HX} -CH=CX- \xrightarrow{HX} -CH_2-CX_2-$$

Markovnikov's rule ensures that *gem*-dihalides and not *vic*-dihalides are the products of the addition of 2 mol.

Chlorotrimethylsilane can be added to alkenes to give alkyl chlorides. 1-Hexene reacts with Me_3SiCl in water to give 2-chlorohexane.[159] Treatment of an alkene with KHF_2 and SiF_4 leads to the alkyl fluoride.[160]

The HX compounds are electrophilic reagents, and many polyhalo and polycyano alkenes, (e.g., $Cl_2C=CHCl$) do not react with them at all in the absence of free-radical conditions. When such reactions do occur, however, they take place by a nucleophilic addition mechanism, (i.e., initial attack is by X^-). This type of mechanism also occurs with Michael-type substrates C=C–Z,[161] where the orientation is always such that the halogen goes to the carbon that does not bear the Z, so the product is of the form X–C–CH–Z, even in the presence of free-radical initiators. Hydrogen iodide adds 1,4 to conjugated dienes in the gas phase by a pericyclic mechanism:[162]

HX can be added to ketenes[163] to give acyl halides:

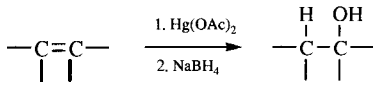
$$-\underset{|}{C} = C=O + HX \longrightarrow -\overset{H}{\underset{X}{C}}-\underset{|}{C}=O$$

OS I, 166; **II,** 137, 336; **III,** 576; IV, 238, 543; VI, 273; **VII,** 59; 76, 263.

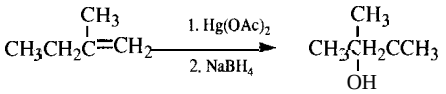
B. *Oxygen on the Other Side*

15-3 *Hydration of Double bonds*

HYDRO-HYDROXY-ADDITION



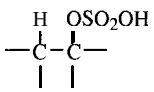
Alkenes can be hydrated quickly under mild conditions in high yields without rearrangement products by the use of *oxymercuration* (addition of oxygen and mercury)[164] followed by *in situ* treatment with sodium borohydride[165] (12-23). For example, 2-methyl-1-butene treated with mercuric acetate,[166] followed by $NaBH_4$, gave 2-methyl-2-butanol:



90%

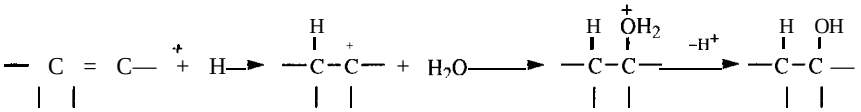
This method, which is applicable to mono-, di-, tri-, and tetraalkyl as well as phenyl-substituted alkenes, gives almost complete Markovnikov addition. Hydroxy, methoxy, acetoxy, halo, and other groups may be present in the substrate without, in general, causing difficulties.[167] When two double bonds are present in the same molecule, the use of ultrasound allows oxymercuration of the less-substituted one without affecting the other.[168] A related reaction treats an alkene with zinc borohydride on silica gel to give a 35:65 mixture of secondary:primary alcohols.[169]

Double bonds can also be hydrated by treatment with water and an acid catalyst. The most common catalyst is sulfuric acid, but other acids, such as nitric or perchloric can also be used. The mechanism is electrophilic and begins with attack by a proton (see p. 974). The negative attacking species may be HSO_4^- (or similar ion in the case of other acids) to give the initial product 29 which can be isolated, but under the conditions of the reaction, is usually hydrolyzed to the alcohol (10-4).



29

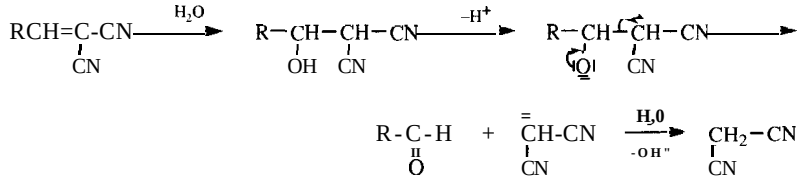
However, the conjugate base of the acid is not the only possible species that attacks the initial carbocation. The attack can also be by water:



When the reaction proceeds by this pathway, 29 and similar intermediates are not involved and the mechanism is exactly (by the principle of microscopic reversibility)

the reverse of El elimination of alcohols (**17-1**).[170] It is likely that the mechanism involves both pathways. The initial carbocation occasionally rearranges to a more stable one. For example, hydration of $CH_2{=}CHCH(CH_3)_2$ gives $CH_3CH_2COH(CH_3)_2$. With ordinary alkenes the addition predominantly follows Markovnikov's rule. Another method for Markovnikov addition of water consists of simultaneously adding an oxidizing agent (O_2) and a reducing agent (either Et_3SiH [171] or a secondary alcohol such as 2-propanol[172]) to the alkene in the presence of a cobalt-complex catalyst. No rearrangement is observed with this method. The corresponding alkane and ketone are usually side products.

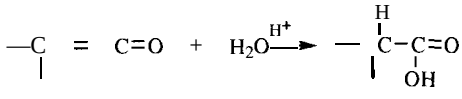
Water can be added indirectly, with anti-Markovnikov orientation, by treatment of the alkene with a 1:1 mixture of $PhCH_2NEt_3^+BH_4^-$ and Me_3SiCl, followed by addition of an aqueous solution of K_2CO_3.[173] Reaction of alkenes with $Ti(BH_4)_3$, and then aqueous K_2CO_3 also leads to the anti-Markovnikov alcohol.[174] For another method of anti-Markovnikov hydration, see **15-16.** With substrates of the type C=C–Z (Z is as defined on p. 975) the product is almost always HO–C–CH–Z and the mechanism is usually nucleophilic,[175] though electrophilic addition gives the same product[176] since a cation CH–C–Z would be destabilized by the positive charges (full or partial) on two adjacent atoms. However, the other product, HC–CH(OH)Z, was obtained by treatment of the substrate with O_2, $PhSiH_3$, and a manganese-complex catalyst.[177] When the substrate is of the type $RCH{=}CZZ'$, addition of water may result in cleavage of the adduct, to give an aldehyde and CH_2ZZ', for example,[178]



The cleavage step is an example of **12-39.**

Alkenes react with PhO_2BH and a niobium catalyst, followed by oxidation with $NaOO^-$, to give the alcohol,[179] and Cp_2TiCl_4 can also be used.[180] Reaction with $HSiCl_3$ and a chiral palladium catalyst, followed by reaction with KF and hydrogen peroxide, leads to the alcohol with high asymmetric induction.[181] Alkenes react with molecular oxygen in the presence of a cobalt porphyrin catalyst, and reduction with $P(OMe)_3$ leads to the secondary alcohol.[182] This procedure has also been used to hydrate conjugated dienes,[183] although conjugated dienes are seldom hydrated.

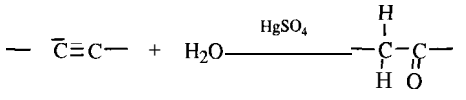
The addition of water to enol ethers causes hydrolysis to aldehydes or ketones (10-6). Ketenes add water to give carboxylic acids in a reaction catalyzed by acids:[184]



OS IV, 555, 560; VI, 766. Also see OS V, 818.

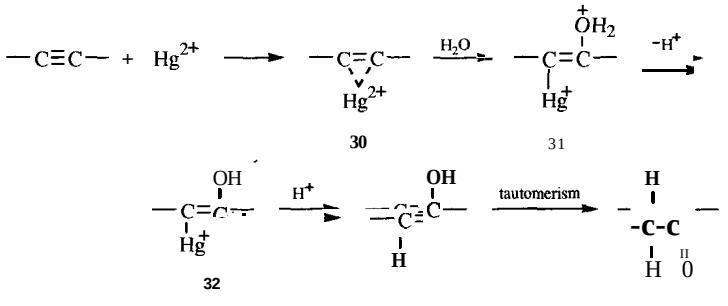
15-4 *Hydration of Triple Bonds*

DIHYDRO-OXO-BIADDITION



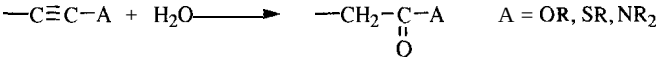
The hydration of triple bonds is generally carried out with mercuric ion salts (often the sulfate or acetate) as catalysts.[185] Mercuric oxide in the presence of an acid is also a common reagent. Since the addition follows Markovnikov's rule, only acetylene gives an aldehyde. All other triple-bond compounds give ketones (for a method of reversing the orientation for terminal alkynes, see 15-16). With alkynes of the form RC≡CH methyl ketones are formed almost exclusively, but with RC≡CR' both possible products are usually obtained. The reaction can be conveniently carried out with a catalyst prepared by impregnating mercuric oxide onto Nafion-H (a superacidic perfluorinated resinsulfonic acid).[186]

The first step of the mechanism is formation of a complex (30) (ions like Hg^{2+} form complexes with alkynes, p. 102). Water then attacks in an S_N2 type process to give the intermediate 31,



which loses a proton to give 32. Hydrolysis of 32 (an example of 12-31) gives the enol, which tautomerizes to the product. A spectrum of the enol was detected by flash photolysis when phenylacetylene was hydrated photolytically.[187]

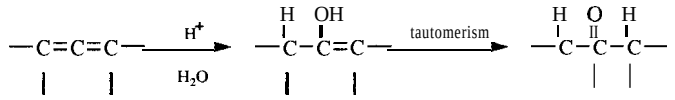
Carboxylic esters, thiol esters, and amides can be made, respectively, by acid-catalyzed hydration of acetylenic ethers, thioethers,[188] and ynamines, without a mercuric catalyst:[189]



This is ordinary electrophilic addition, with rate-determining protonation as the first step.[190] Certain other alkynes have also been hydrated to ketones with strong acids in the absence of mercuric salts.[191] Simple alkynes can also be converted to ketones by heating with formic acid, without a catalyst.[192] Lactones have been prepared from

trimethylsilyl alkenes containing an hydroxyl unit elsewhere in the molecule, when reacted with molecular oxygen, $CuCl_2$, and a palladium catalyst.[193]

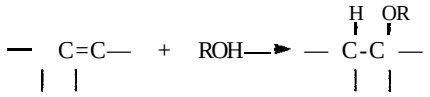
Allenes can also be hydrolyzed to ketones, with an acid catalyst.[194]



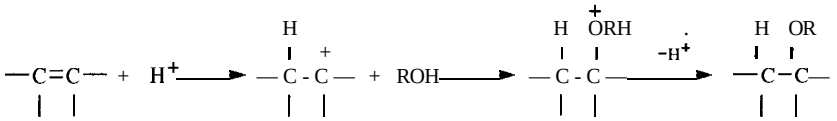
OS III, 22; IV, 13; V, 1024.

15-5 *Addition of Alcohols and Phenols*

HYDRO-ALKOXY-ADDITION

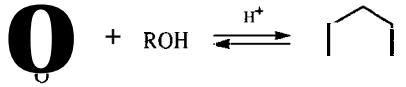


The addition of alcohols and phenols to double bonds is catalyzed by acids or bases. When the reactions are acid catalyzed, the mechanism is electrophilic, with H^+ as the attacking species. The resulting carbocation combines with a molecule of alcohol:



The addition, therefore, follows Markovnikov's rule. Primary alcohols give better results than secondary, and tertiary alcohols are very inactive. This is a convenient method for the preparation of tertiary ethers by the use of a suitable alkene such as $Me_2C{=}CH_2$. Alcohols add intramolecularly to alkenes to generate cyclic ethers, often bearing a hydroxyl unit as well.[195] This addition can be promoted by a palladium catalyst, with migration of the double bond in the final product.[196] Rhenium compounds also facilitate this cyclization reaction to form functionalized tetrahydrofurans.[197]

For those substrates more susceptible to nucleophilic attack (e.g., polyhalo alkenes and alkenes of the type C=C–Z), it is better to carry out the reaction in basic solution, where the attacking species is RO^-.[198] The reactions with C=C–Z are of the Michael type, and OR goes to the side away from the Z. Since triple bonds are more susceptible to nucleophilic attack than double bonds, it might be expected that bases would catalyze addition to triple bonds particularly well. This is the case, and enol ethers and acetals can be produced by this reaction.[199] Because enol ethers are more susceptible than triple bonds to electrophilic attack, the addition of alcohols to enol ethers can also be catalyzed by acids.[200] One utilization of this reaction involves the compound dihydropyran



33 34

(33), which is often used to protect the OH groups of primary and secondary[201] alcohols and phenols.[202] The tetrahydropyranyl acetal formed by this reaction (34) is stable to bases, Grignard reagents, $LiAlH_4$, and oxidizing agents, any of which can be used to react with functional groups located within the R group. When the reactions are completed, 34 is easily cleaved by treatment with dilute acids (10-6). The addition of alcohols to enol ethers is also catalyzed by $CoCl_2$.[203]

In base-catalyzed addition to triple bonds, the rate falls in going from a primary to a tertiary alcohol, and phenols require more severe conditions. Other catalysts, namely, BF_3 and mercuric salts, have also been used in addition of ROH to triple bonds.

Alcohols can be added to certain double-bond compounds (cyclohexenes, cycloheptenes) photochemically[204] in the presence of a photosensitizer such as benzene. The mechanism is electrophilic and Markovnikov orientation is found. The alkenes react in their first excited triplet states.[205]

The oxymercuration-demercuration procedure mentioned in **15-3** can be adapted to the preparation of ethers (Markovnikov orientation) if the oxymercuration is carried out in an alcohol (ROH) as solvent,[206] for example, 2-methyl-1-butene in ethanol gives $EtMe_2COEt$.[207] Primary alcohols give good yields when mercuric acetate is used, but for secondary and tertiary alcohols it is necessary to use mercuric trifluoroacetate.[208] However, even with this reagent the method fails where the product would be a ditertiary ether. Alkynes generally give acetals. If the oxymercuration is carried out in the presence of a hydroperoxide instead of an alcohol, the product (after demercuration with $NaBH_4$) is an alkyl peroxide (peroxy-mercuration).[209] This can be done intramolecularly.[210]

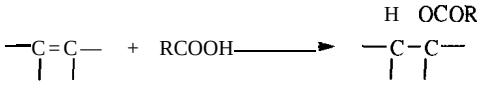
Both alcohols and phenols add to ketenes to give carboxylic esters ($R_2C{=}C{=}O + ROH \rightarrow R_2CHCO_2R$).[211] This has been done intramolecularly (with the ketene end of the molecule generated and used *in situ)* to form medium- and large-ring lactones.[212] In the presence of a strong acid, ketene reacts with aldehydes or ketones (in their enol forms) to give enol acetates.

Alcohols can also add to alkenes in a different way (see **15-28).**

OS III, 371, 774, 813; **IV,** 184, 558; **VI,** 916; **VII, 66,** 160, 304, 334, 381; **VIII,** 204, 254; **IX,** 472.

15-6 *Addition of Carboxylic Acids*

HYDRO-ACYLOXY-ADDITION



Carboxylic esters are produced by the addition of carboxylic acids to alkenes, a reaction that is usually acid catalyzed (by proton or Lewis acids[213]) and similar in mechanism to **15-5.** Since Markovnikov's rule is followed, hard-to-get esters of tertiary alcohols can be prepared from alkenes of the form $R_2C{=}CHR$.[214] A combination of V_2O_5 and trifluoroacetic acid converts alkenes to trifluoroacetate

esters.[215] When a carboxylic acid that contains a double bond in the chain is treated with a strong acid, the addition occurs internally and the product is a *y*- and/or a 8-lactone, regardless of the original position of the double bond in the chain, since strong acids catalyze double-bond shifts (12-2).[216] The double bond always migrates (also see **15-1)** to a position favorable for the reaction, whether this has to be toward or away from the carboxyl group. Carboxylic esters have also been prepared by the acyloxymercuration-demercuration of alkenes (similar to the procedures mentioned in **15-3** and **15-4**).[217] Addition of carboxylic acids to alkenes to form esters or lactones is catalyzed by palladium compounds.[218] Thallium acetate also promotes this cyclization reaction.[219]

Triple bonds can give enol esters or acylals when treated with carboxylic acids. Mercuric salts are usually catalysts,[220] and vinylic mercury compounds $-\overset{|}{\underset{HgX}{C}}=C-OCOR$ are intermediates.[221] Terminal alkynes RC≡CH react with CO_2, a secondary amine R'_2NH, and a ruthenium-complex catalyst, to give enol carbamates $RCH=CHOC(=O)NR$.[222] This reaction has also been performed intramolecularly, to produce unsaturated lactones.[223] With ketenes, carboxylic acids give anhydrides[224] and acetic anhydride is prepared industrially in this manner [$CH_2=C=O + MeCO_2H \rightarrow (MeC=O)_2O$]. Carboxylic esters can also be obtained by the addition to alkenes of diacyl peroxides.[225] These reactions are catalyzed by copper and are free-radical processes.

OS **III,** 853; IV, 261, 417, 444; V, 852, 863; **VII,** 30, 411. Also see OS I, 317.

C. *Sulfur on the Other Side*

15-7 *Addition of H_2S and Thiols*

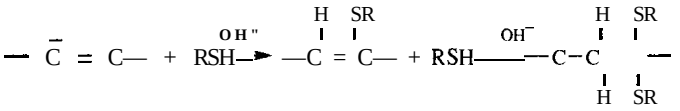
HYDRO-ALKYLTHIO-ADDITION

$$-C=C- + RSH \longrightarrow -\overset{H}{C}-\overset{SR}{C}-$$

Hydrogen sulfide and thiols add to alkenes by electrophilic, nucleophilic, or free-radical mechanisms.[226] In the absence of initiators the addition to simple alkenes is by an electrophilic mechanism, similar to that in **15-5,** and Markovnikov's rule is followed. However, this reaction is usually very slow and often cannot be done or requires very severe conditions unless a proton or Lewis acid catalyst is used. For example, the reaction can be performed in concentrated H_2SO_4[227] or together with $AlCl_3$.[228] In the presence of free-radical initiators, H_2S and thiols add to double and triple bonds by a free-radical mechanism and the orientation is anti-Markovnikov.[229] In fact, the orientation can be used as a diagnostic tool to indicate which mechanism is operating. Free-radical addition can be done with H_2S, RSH (R may be primary, secondary, or tertiary), ArSH, or RCOSH.[230] The R group may contain various functional groups. The alkenes may be terminal, internal, contain branching, be cyclic, and have various functional groups including OH, COOH, COOR, NO_2,

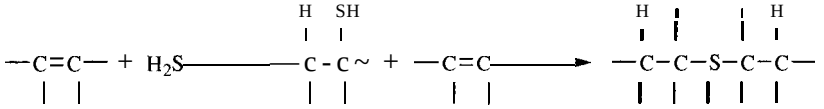
RSO_2, and so on. Addition of Ph_3SiSH to terminal alkenes under radical conditions also leads to the primary thiol.[231] With alkynes it is possible to add 1 or 2 mols of RSH.

When thiols are added to substrates susceptible to nucleophilic attack, bases catalyze the reaction and the mechanism is nucleophilic. These substrates may be of the Michael type[232] or may be polyhalo alkenes or alkynes.[199] As with the free-radical mechanism, alkynes can give either vinylic thioethers or dithioacetals:



Thiols add to alkenes under photochemical conditions to form thioethers, and the reaction can be done intramolecularly to give cyclic thioethers.[233] Thiols also add to alkynes and with a palladium catalyst, vinyl sulfides can be formed.[234] Selenium compounds (RSeH) add in a similar manner.[235]

By any mechanism, the initial product of addition of H_2S to a double bond is a thiol, which is capable of adding to a second molecule of alkene, so that sulfides are often produced:



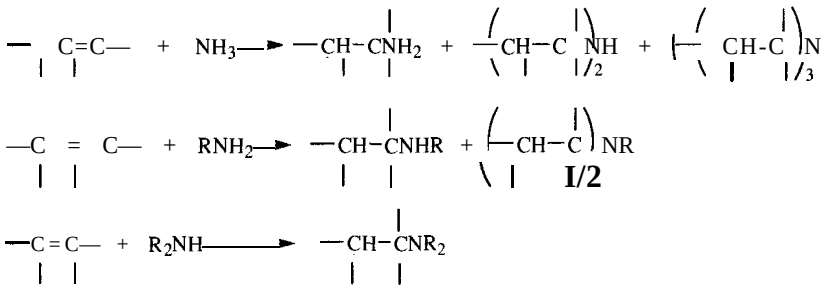
As with alcohols, ketenes add thiols to give thiol esters ($R_2C{=}C{=}O + RSH \rightarrow R_2CHCOSR$).

OS III, 458; IV, 669; VIII, 302. See also OS VIII, 458.

D. *Nitrogen on the Other Side*

15-8 *Addition of Ammonia and Amines*

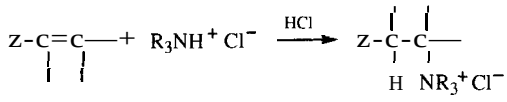
HYDRO-AMINO-ADDITION



Ammonia and primary and secondary amines add to alkenes *that are susceptible* to nucleophilic attack.[236] Since ammonia and amines are much weaker acids than

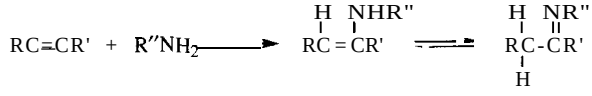
water, alcohols, and thiols (see **15-3, 15-5, 15-7)** and since acids could hardly catalyze the reaction (because they would turn NH_3 into NH_4^+), this reaction does not occur by an electrophilic mechanism and so gives very low yields, if any, with ordinary alkenes, unless extreme conditions are used (e.g., 178–200°C, 800–1000 atm, and the presence of metallic Na, for the reaction between NH3 and ethylene[237]). Ammonia gives three possible products, since the initial product is a primary amine, which may add to a second molecule of alkene, and so on. Similarly, primary amines give both secondary and tertiary products. In practice it is usually possible to control which product predominates. The mechanism is nearly always nucleophilic, and the reaction is generally performed on polyhalo alkenes,[238] Michael-type substrates,[239] and alkynes.[240] As expected, on Michael-type substrates the nitrogen goes to the carbon that does not carry the Z. With substrates of the form RCH=CZZ', the same type of cleavage of the adduct can take place as in **15-3**.[241] Ammonia adds to alkenes photochemically.[242] Reaction of a secondary amine with butyllithium generates an amide base, which can add intramolecularly to an alkene to form a pyrrolidine.[243]

Other nitrogen compounds, among them hydroxylamine, hydrazines, and amides (15-9), also add to alkenes. Even with amines, basic catalysts are sometimes used, so that RNH^- or R_2N^- is the actual nucleophile. Tertiary amines (except those that are too bulky) add to Michael-type substrates in a reaction that is catalyzed by acids like HC1 or HNO_3 to give the corresponding quaternary ammonium salts.[244]

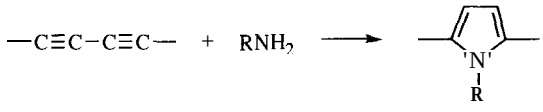


The tertiary amine can be aliphatic, cycloalkyl, or heterocyclic (including pyridine).

Primary amines add to triple bonds[245] to give enamines that have a hydrogen on the nitrogen and (analogously to enols) tautomerize to the more stable imines:

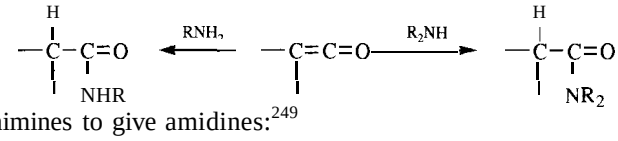


These are often stable enough for isolation.[246] When ammonia is used instead of a primary amine, the corresponding $RH_2C{-}\overset{\overset{NH}{\|}}{C}{-}R'$ is not stable enough for isolation, but polymerizes. Ammonia and primary amines (aliphatic and aromatic) add to conjugated diynes to give pyrroles:[247]

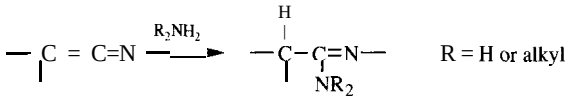


This is not 1,4 but 1,2 addition twice.

Primary and secondary amines add to ketenes to give, respectively, N-substituted and N,N-disubstituted amides:[248]

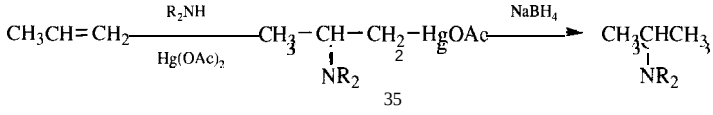


and to ketenimines to give amidines:[249]



Secondary amines can be added to certain nonactivated alkenes if palladium(II) complexes are used as catalysts.[250] The complexation lowers the electron density of the double bond, facilitating nucleophilic attack.[251] Markovnikov orientation is observed and the addition is anti.[252] An intramolecular addition to an alkyne unit in the presence of a palladium compound, generated a tetrahydropyridine,[253] and a related addition to an allene is known.[254] Amines add to allenes in the presence of a catalytic amount of CuBr[255] or palladium compounds.[256] Molybdenum complexes have also been used in the addition of aniline to alkenes.[257] Reduction of nitro compounds in the presence of rhodium catalysts, in the presence of alkenes, CO and H_2, leads to an amine unit adding to the alkene moiety.[258] An intramolecular addition of an amine unit to an alkene to form a pyrrolidine was reported using a lanthanide reagent.[259]

Ammonia can be added to double bonds (even ordinary double bonds) in an indirect manner by the use of hydroboration **(15-16)** followed by treatment with NH_2Cl or NH_2OSO_2OH **(12-29).** This produces a primary amine with anti-Markovnikov orientation. An indirect way of adding a primary or secondary amine to a double bond consists of aminomercuration followed by reduction (see **15-3** for the analogous oxymercuration-demercuration procedure), for example,[260]



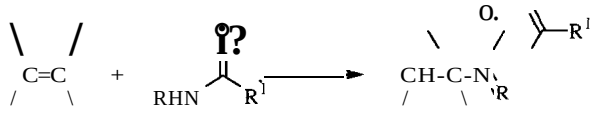
35

The addition of a secondary amine (shown above) produces a tertiary amine, while addition of a primary amine gives a secondary amine. The overall orientation follows Markovnikov's rule. For conversion of **35** to other products, see **15-52.**

OS **I,** 196; **HI,** 91, 93, 244, 258; **IV,** 146, 205; **V,** 39, 575, 929; **VI,** 75, 943; **VIII**, 188, 190, 536. See also OS VI, 932.

15-9 *Addition of Amides*

HYDRO-AMIDO-ADDITION



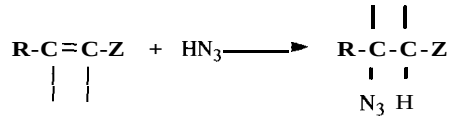
Under certain conditions, amides can add directly to alkenes to form N-alkylated amides. 3-Pentenamide was cyclized to 5-methyl-2-pyrrolidinone by treatment with trifluorosulfonic acid.[261] Acylhydrazine derivatives also cyclized in the presence of hypervalent iodine reagents to give lactams.[262] When a carbamate was treated with Bu_3SnH, and AIBN, addition to an alkene led to a bicyclic lactam.[263]

The reaction can be done intramolecularly. N-Benzyl pent-4-ynamide reacted with tetrabutylammonium fluoride to an alkylidene lactam.[264] Similar addition of a tosylamide-alkene, with a palladium catalyst, led to a vinyl *N*-tosyl pyrrolidine.[265] Similar cyclization reactions occur with tosylamide-alkynes.[266]

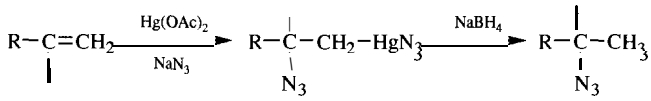
Imides can also add to alkenes or alkynes. Ethyl 2-propynoate reacted with phthalimide, in the presence of a palladium catalyst, to give ethyl 2-phthalimido-2-propenoate.[267]

15-10 *Addition of Hydrazoic Acid*

HYDRO-AZIDO-ADDITION



Hydrazoic acid can be added to certain Michael-type substrates (Z is as defined on p. 975) to give (3-azido compounds.[268] The reaction apparently fails if R is phenyl. Ammonia also adds to enol ethers $CH_2{=}CHOR$ to give $CH_3{-}CH(OR)N_3$, and to silyl enol ethers,[269] but it does not add to ordinary alkenes unless a Lewis acid catalyst, such as $TiCl_4$, is used, in which case good yields of azide can be obtained.[269] Ammonia can also be added indirectly to ordinary alkenes by azidomercuration, followed by demercuration,[270] analogous to the similar procedures mentioned in

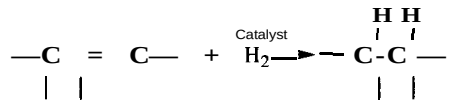


15-3, 15-5, 15-6, and 15-8. The method can be applied to terminal alkenes or strained cycloalkenes (e.g., norbornene) but fails for unstrained internal alkenes.

E. *Hydrogen on Both Sides*

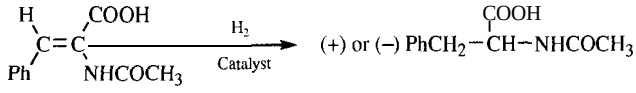
15-11 *Hydrogenation of Double and Triple Bonds*[111]

DIHYDRO-ADDITION



Most carbon-carbon double bonds, whether substituted by electron-donating or

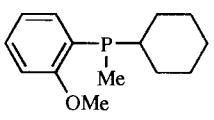
electron-withdrawing substituents, can be catalytically hydrogenated, usually in quantitative or near-quantitative yields.[272] Almost all known alkenes added hydrogen at temperatures between 0-275°C. Many functional groups may be present in the molecule, (e.g., OH, COOH, NH_2, CHO, COR, COOR, or CN). Some of these groups are also susceptible to catalytic reduction, but it is usually possible to find conditions under which double bonds can be reduced selectively (see Table 19.2).[273] The catalysts used can be divided into two broad classes, both of which mainly consist of transition metals and their compounds: (1) catalysts insoluble in the reaction medium *(heterogeneous catalysts).* Among the most effective are Raney nickel,[274] palladium-on-charcoal (perhaps the most common), $NaBH_4$ reduced nickel[275] (also called nickel boride), platinum metal or its oxide, rhodium, ruthenium, and zinc oxide,[276] and (2) catalysts soluble in the reaction medium *(homogeneous catalysts).*[211] The most important is chlorotris(triphenylphosphine)-rhodium $[RhCl(Ph_3P)_3$,[278] *Wilkinson's catalyst],*[219] which catalyzes the hydrogenation of many alkenyl compounds without disturbing such groups as COOR, NO_2, CN, or COR present in the same molecule.[280] Even unsaturated aldehydes can be reduced to saturated aldehydes,[281] although in this case decarbonylation (14-39) may be a side reaction. Among other homogeneous catalysts are chlorotris(triphenylphosphine)hydridoruthenium(II), $(Ph_3P)_3RuClH$,[282] which is specific for terminal double bonds (other double bonds are hydrogenated slowly or not at all), and pentacyanocobaltate(II), $Co(CN)_5^{3-}$, which is effective for double and triple bonds only when they are part of conjugated systems (the conjugation may be with C=C, C=O, or an aromatic ring).[283] Colloidal palladium has also been used as a catalyst.[284] Homogeneous catalysts often have the advantages of better catalyst reproducibility and better selectivity. They are also less susceptible to catalyst poisoning[285] (heterogeneous catalysts are usually poisoned by small amounts of sulfur, often found in rubber stoppers, or by sulfur-containing compounds such as thiols and sulfides).[286] On the other hand, heterogeneous catalysts are usually easier to separate from the reaction mixture.



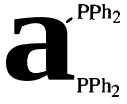
36 37

Optically active homogeneous (as well as heterogeneous) catalysts have been used to achieve partially asymmetric (enantioselective) hydrogenations of certain prochiral substrates.[287] For example,[288] hydrogenation of 31 with a suitable catalyst gives (+) or (—) 37 (depending on which enantiomer of the catalyst is used) with an ee as high as 96%.[289] Prochiral substrates that give such high optical yields generally contain functional groups similar to those in **36**.[290] The catalyst in such cases[291] is usually a ruthenium- or rhodium-phosphine in which the phosphine is optically active either because of an asymmetric phosphorus atom, (e.g., 38),[292] or because of a chiral group connected to the phosphorus, (e.g., 39).[293] Chiral complexes[294] using other chiral additives have been formed with rhodium catalysts to achieve good-

to-excellent asymmetric induction during the hydrogenation.[295] Other types of



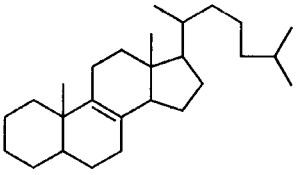
38



39

catalysts,[296] for example, titanocenes with chiral cyclopentadienyl ligands, have given enantioselective hydrogenation of alkenes that lack functional groups such as COOH or NHCOCH3, for example, 2-phenyl-1-butene.[297] Enantioselective reduction of certain alkenes has also been achieved by reducing with baker's yeast.[298] Hydrogenation with Ni_2B on borohydride exchange resin (BER) has also been used.[299] Chiral poisoning has been used as a strategy for asymmetric catalysis.[300]

Hydrogenations in most cases are carried out at room temperature and just above atmospheric pressure, but some double bonds are more resistant and require higher temperatures and pressures. The resistance is usually a function of increasing substitution and is presumably caused by steric factors. Trisubstituted double bonds require, say, 25°C and 100 atm, while tetrasubstituted double bonds may require 275°C and 1000 atm. Among the double bonds most difficult to hydrogenate



40

or which cannot be hydrogenated at all are those common to two rings, as in steroid 40. Hydrogenations, even at about atmospheric pressure, are ordinarily performed in a special hydrogenator, but this is not always necessary. Both the catalyst and the hydrogen can be generated *in situ*, by treatment of H_2PtCl_6 or $RhCl_3$ with $NaBH_4$;[301] ordinary glassware can then be used. The great variety of catalysts available often allows an investigator to find one that is highly selective. For example, the catalyst Pd(salen), where bis(solicylidene)ethylenediamine is salen, encapsulated in zeolites permitted the catalytic hydrogenation of 1-hexene in the presence of cyclohexene.[302] It has been shown that the pressure of the reaction can influence enantioselectivity in asymmetric catalytic hydrogenations.[303]

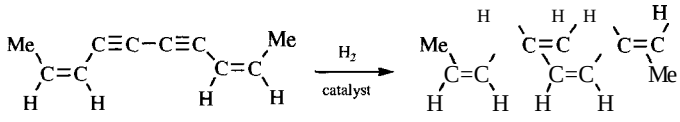
Triple bonds can be reduced, either by catalytic hydrogenation or by the other methods mentioned in the following two sections. The comparative reactivity of triple and double bonds depends on the catalyst. With most catalysts, (e.g., Pd) triple bonds are hydrogenated more easily, and therefore it is possible to add just 1 mol of hydrogen and reduce a triple bond to a double bond (usually a stereoselective syn addition) or to reduce a triple bond without affecting a double bond present in the same molecule.[304] A particularly good catalyst for this purpose is the Lindlar catalyst ($Pd\text{-}CaCO_3$—PbO).[305] An alternative catalyst used for selective hydrogena-

tion to cis-alkenes is palladium on barium sulfate ($BaSO_4$) catalyst, poisoned with quinoline (sometimes called the *Rosenmund catalyst*).[306]

An indirect method[307] of double-bond reduction involves hydrolysis of boranes (prepared by 15-16). Trialkylboranes can be hydrolyzed by refluxing with carboxylic acids,[308] while monoalkylboranes RBH2 can be hydrolyzed with base.[309] Triple bonds can be similarly reduced, to cis alkenes.[310]

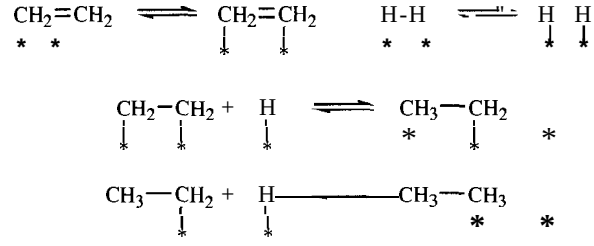
Conjugated dienes can add hydrogen by 1,2 or 1,4 addition. Selective 1,4 addition can be achieved by hydrogenation in the presence of carbon monoxide, with bis(cyclopentadienyl)chromium as catalyst.[311] With allenes[312] catalytic hydrogenation usually reduces both double bonds.

Most catalytic reductions of double or triple bonds, whether heterogeneous or homogeneous, have been shown to be syn, with the hydrogens entering from the less-hindered side of the molecule.[313] Stereospecificity can be investigated only for tetrasubstituted alkenes (except when the reagent is D_2), which are the hardest to hydrogenate, but the results of these investigations show that the addition is usually 80–100% syn, though some of the anti addition product is normally also found and in some cases predominates. Catalytic hydrogenation of alkynes is nearly always stereoselective, giving the cis alkene (usually at least 80%), even when it is thermodynamically less stable. For example, 41 gave 42, even though the steric hindrance is such that a planar molecule is impossible.[314] This is thus a useful method for preparing cis alkenes.[315] However, when steric hindrance is too great, the



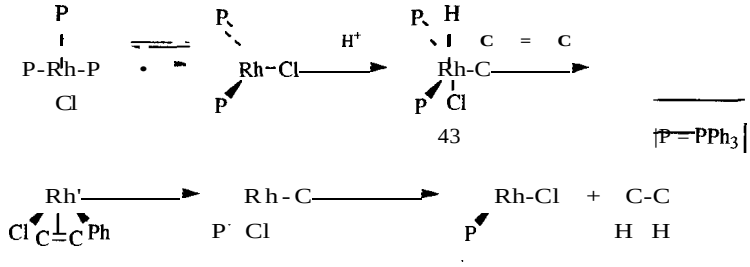
41 42

trans alkene may be formed. One factor that complicates the study of the stereochemistry of heterogeneous catalytic hydrogenation is that exchange of hydrogens takes place, as can be shown by hydrogenation with deuterium.[316] Thus deuterogenation of ethylene produced all the possible deuterated ethylenes and ethanes (even C_2H_6), as well as HD.[317] With 2-butene, it was found that double-bond migration, cis-trans isomerization, and even exchange of hydrogen with groups not on the double bond could occur (e.g., $C_4H_2D_8$ and C_4HD_9 were detected on treatment of *cis*-2-butene with deuterium and a catalyst).[318] Indeed, *alkanes* have been found to exchange with deuterium over a catalyst,[319] and even without deuterium(e.g., $CH_4+CD_4 \rightarrow CHD_3+CH_3D$ in the gas phase, with a catalyst). All this makes it difficult to investigate the stereochemistry of heterogeneous catalytic hydrogenation.



The mechanism of the heterogeneous catalytic hydrogenation of double bonds is not thoroughly understood because it is a very difficult reaction to study.[320] Because the reaction is heterogeneous, kinetic data, though easy to obtain (measurement of decreasing hydrogen pressure), are difficult to interpret. Furthermore, there are the difficulties caused by the aforementioned hydrogen exchange. The currently accepted mechanism for the common two-phase reaction was originally proposed in 1934.[321] According to this, the alkene is adsorbed onto the surface of the metal, though the nature of the actual bonding is unknown,[322] despite many attempts to elucidate it.[323] The metallic site is usually indicated by an asterisk. For steric reasons it is apparent that adsorption of the alkene takes place with its less-hindered side attached to the catalyst surface. The fact that addition of hydrogen is generally also from the less-hindered side indicates that the hydrogen too is probably adsorbed on the catalyst surface before it reacts with the alkene. It is likely that the H_2 molecule is cleaved to hydrogen atoms in the act of being adsorbed. It has been shown that platinum catalyzes homolytic cleavage of hydrogen molecules.[324] In the second step, one of the adsorbed hydrogen atoms becomes attached to a carbon atom, creating in effect, an alkyl radical (which is still bound to the catalyst though only by one bond) and two vacant catalyst sites. Finally, another hydrogen atom (not necessarily the one originally connected to the first hydrogen) combines with the radical to give the reaction product, freed from the catalyst surface, and two more vacant sites. All the various side reactions, including hydrogen exchange and isomerism, can be explained by this type of process.[325] Although this mechanism is satisfactory as far as it goes,[326] there are still questions it does not answer, among them questions[327] involving the nature of the asterisk, the nature of the bonding, and the differences caused by the differing nature of each catalyst.[328]

The mechanism of homogeneous hydrogenation[329] catalyzed by $RhCl(Ph_3P)_3$[330] involves reaction of the catalyst with hydrogen to form a metal hydride $(PPh_3)_2RhH_2Cl$ (43), which rapidly transfers two hydrogen atoms to the alkene.



44

The intermediate 43 can be isolated. If a mixture of H_2 and D_2 is used, the product contains only dideuterated and nondeuterated compounds; no monodeuterated products are found, indicating that (unlike the case of heterogeneous catalysis) H_2 or D_2 has been added to one alkene molecule and that no exchange takes place.[330] Although conversion of 44 to the products takes place in two steps,[331] the addition of H_2 to the double bond is syn.

The occurrence of hydrogen exchange and double-bond migration in heterogeneous catalytic hydrogenation means that the hydrogenation does not necessarily

take place by straightforward addition of two hydrogen atoms at the site of the original double bond. Consequently, this method is not synthetically useful for adding D_2 to a double or triple bond in a regioselective or stereospecific manner. However, this objective can be achieved (with syn addition) by a homogeneous catalytic hydrogenation, which usually adds D_2 without scrambling[332] or by the use of one of the diimide methods (15-12).[345] Deuterium can also be regioselectively added by the hydroboration-reduction procedure previously mentioned.

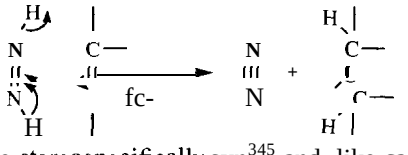
Reductions of double and triple bonds are found at OS I, 101, 311; II, 191, 491; III, 385, 794; IV, 298, 304, 408; V, 16, 96, 277; VI, 68, 459; VII, 226, 287; VIII, 420. 609; IX, 169, 533.

Catalysts and apparatus for hydrogenation are found at OS I, 61, 463; II, 142; III, 176, 181, 685; V, 880.

15-12 *Other Reductions of Double and Triple Bonds*

Although catalytic hydrogenation is the method most often used, double bonds can be reduced by other reagents, as well. Among these are sodium in ethanol, sodium and *tert*-butyl alcohol in HMPA,[333] lithium and aliphatic amines (see also 15-14),[334] zinc and acids, sodium hypophosphate and Pd-C,[335] $(EtO)_3SiH$–$Pd(OAc)_2$,[336] trifluoroacetic acid and triethylsilane (Et_3SiH),[337] and hydroxylamine and ethyl acetate.[338] However, metallic hydrides, such as lithium aluminum hydride and sodium borohydride, do not in general reduce carbon-carbon double bonds, although this can be done in special cases where the double bond is polar, as in 1,1-diarylethenes[339] and in enamines.[340]

In the above-mentioned reactions with hydrazine and hydroxylamine, the actual reducing species is diimide (NH=NH), which is formed from N_2H_4 by the oxidizing agent and from NH_2OH by the ethyl acetate.[341] The rate of this reaction has been studied.[342] Although both the syn and anti forms of diimide are produced, only the syn form reduces the double bond,[343] at least in part by a cyclic mechanism:[344]



The addition is therefore stereospecifically syn[345] and, like catalytic hydrogenation, generally takes place from the less-hindered side of a double bond, though not much discrimination in this respect is observed where the difference in bulk effects is small.[346] Diimide reductions are most successful with symmetrical multiple bonds (C=C, C≡C, N=N) and are not useful for those inherently polar (C≡N, C=N, C=O, etc.). Diimide is not stable enough for isolation at ordinary temperatures, though it has been prepared[347] as a yellow solid at −196°C.

Triple bonds can also be selectively reduced to double bonds with DIBAL-H,[348] with activated zinc (see **12-36**),[349] with hydrogen and Bi_2B–borohydride exchange resin,[350] or (internal triple bonds only) with alkali metals (Na, Li) in liquid ammonia or a low-molecular-weight amine.[351] Terminal alkynes are not reduced by the Na–NH_3 procedure because they are converted to acetylide ions under these conditions. However, terminal triple bonds can be reduced to double bonds by the

addition to the $Na–NH_3$ solution of $(NH_4)_2SO_4$, which liberates the free ethynyl group.[352] The reaction of a terminal alkyne with lithium naphthalenide and $NiCl_2$ effectively reduced the alkyne unit (i.e. $PhC{\equiv}CH \rightarrow PhCH_2CH_3$).[353] This reagent is also effect for the reduction of simple alkenes.[354] A mixture of $NaBH_4$ and $BiCl_3$ also reduced certain alkenes[355] and an alkyne unit was reduced to an alkene, in the presence of a phenylthio group elsewhere in the molecule, using $Cp_2Zr(H)Cl$.[356]

Reduction of just one double bond of an allene, to give an alkene, has been accomplished by treatment with $Na\text{-}NH_3$[357] or with DIBAL-H,[358] and by hydrogenation with $RhCl(PPh_3)_3$ as catalyst.[359]

When double bonds are reduced by lithium in ammonia or amines, the mechanism is similar to that of the Birch reduction (**15-14**).[360] The reduction with trifluoroacetic acid and Et_3SiH has an ionic mechanism, with H^+ coming in from the acid and H^- from the silane.[248] In accord with this mechanism, the reaction can be applied only to those alkenes that when protonated can form a tertiary carbocation or one stabilized in some other way (e.g., by a OR substitution).[361] It has been shown, by the detection of CIDNP, that reduction of α-methylstyrene by hydridopentacarbonylmanganese(I) $HMn(CO)_5$ involves free-radical addition.[362]

Catalytic hydrogenation of triple bonds and the reaction with DIBAL-H usually give the cis alkene **(15-11).** Most of the other methods of triple-bond reduction lead to the more thermodynamically stable trans alkene. However, this is not the case with the method involving hydrolysis of boranes or with the reductions with activated zinc, hydrazine, or NH_2OSO_3H, which also give the cis products.

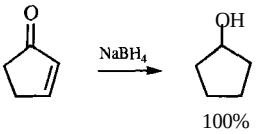
The inertness of ordinary double bonds toward metallic hydrides is quite useful, since it permits reduction of, say, a carbonyl or nitro group, without disturbing a double bond in the same molecule (see Chapter 19 for a discussion of selectivity in reduction reactions). Sodium in liquid ammonia also does not reduce ordinary double bonds,[363] although it does reduce alkynes, allenes, conjugated dienes,[364] and aromatic rings **(15-14).**

Another hydrogenation method is called *transfer hydrogenation.*[365] In this method, the hydrogen comes from another organic molecule, which is itself oxidized. A transition metal catalyst, heterogeneous or homogeneous, is frequently employed. A common reducing agent is cyclohexene, which, when a palladium catalyst is used, is oxidized to benzene, losing 2 mol of hydrogen.

Reductions of double and triple bonds are found at OS **III,** 586, 742; **IV,** 136, 302, 887; V, 281, 993; **VII,** 524.

15-13 *Reduction of The Double or Triple Bonds of Conjugated Systems*

In certain cases,[366] metallic hydride reagents may also reduce double bonds in conjugation with C=O bonds, as well as reducing the C=O bonds, for example,[367]

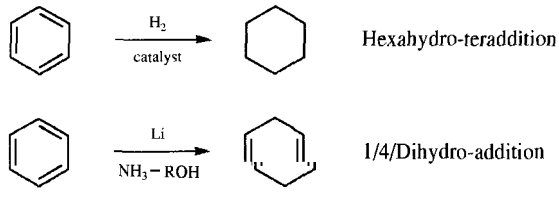


100%

$NaBH_4$ has a greater tendency than $LiAlH_4$ to effect this double reduction, though even with $NaBH_4$ the product of single reduction (of the C=O bond) is usually formed in larger amount than the doubly reduced product. The $LiAlH_4$ gives significant double reduction only in cinnamyl systems, (e.g., with PhCH=CHCOOH).[368] Asymmetric catalytic hydrogenation has been reported for conjugated carboxylic acids[369] and conjugated ketones.[370]

Reduction of only the C=C bond of conjugated C=C–C=O and C=C–C≡N systems[371] has been achieved by many reducing agents,[372] a few of which are H_2 and a Rh catalyst,[373] $PhSiH_3$ and a nickel catalyst[374] or CuCl,[375] $PhSiH_3$–$Mo(CO)_6$,[376] $NaBH_4$–$BiCl_3$,[377] borohydride exchange resin, (BER)–$CuSO_4$,[378] SmI_2,[379] and catecholborane.[380] See **16-23** for methods of reducing C=O bonds in the presence of conjugated C=C bonds. The C=C unit of conjugated aldehydes has been reduced using $AlMe_3$ with a catalytic amount of CuBr[381] and with ammonium formate/Pd–C.[382] Selective reduction of the C=C unit in conjugated ketones was accomplished with $Na_2S_2O_4$ in aqueous dioxane, and nonconjugated alkenes were not reduced.[383] Lithium aluminiun hidride also reduces the double bonds of allylic alcohols[384] and $NaBH_4$ in MeOH-THF[385] or $NaCNBH_3$ on a zeolite[386] reduces α,β-unsaturated nitro compounds to nitroalkanes. Baker's yeast reduces conjugated nitro compounds to nitroalkanes[387] and the C=C unit of conjugated ketones.[388] Furthermore, both $LiAlH_4$ and $NaBH_4$, as well as NaH, reduce ordinary alkenes and alkynes when complexed with transition metal salts, such as $FeCl_2$ or $CoBr_2$.[389] The C=C unit proximal to the carbonyl in dienyl amides is selectively reduced with $NaBH_4$/I_2.[390] Silanes can be effective for the reduction of the C=C unit in conjugated systems in the presence of copper species.[391]

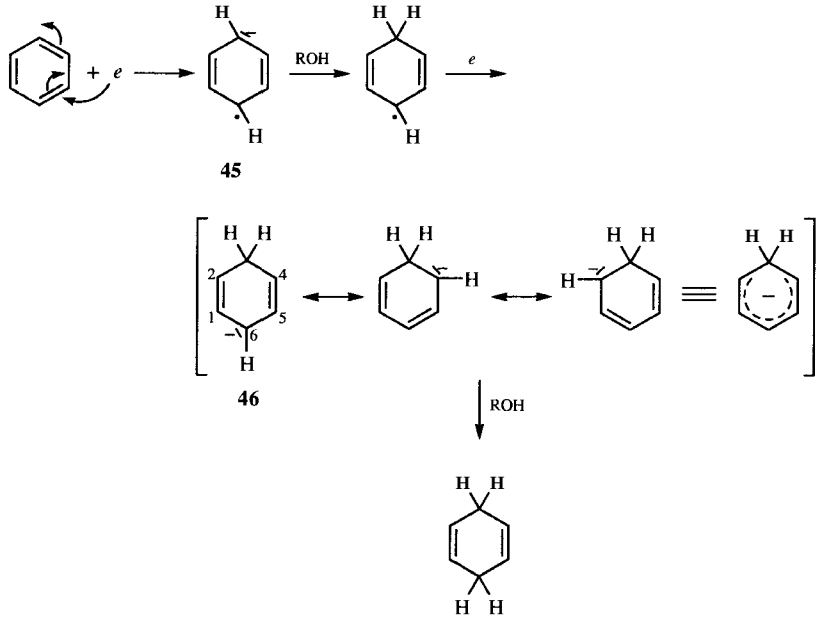
15-14 *Hydrogenation of Aromatic Rings*



Aromatic rings can be reduced by catalytic hydrogenation,[392] but higher temperatures (100-200°C) are required than for ordinary double bonds.[393] Though the reaction is usually carried out with heterogeneous catalysts, homogeneous catalysts have also been used; conditions are much milder with these.[394] Mild conditions are also successful in hydrogenations with phase-transfer catalysts.[395] Many functional groups, such as OH, O^-, COOH, COOR, and NH_2, do not interfere with the reaction, but some groups may be preferentially reduced. Among these are CH_2OH groups, which undergo hydrogenolysis to CH_3 **(10-81).** Phenols may be reduced to cyclohexanones, presumably through the enol. Heterocyclic compounds are often reduced. Thus furan gives tetrahydrofuran. With benzene rings it is usually impossible to stop the reaction after only one or two bonds have been reduced,

since alkenes are more easily reduced than aromatic rings.[396] Thus, 1 mol of benzene, treated with 1 mol of hydrogen, gives no cyclohexadiene or cyclohexene but $\frac{1}{3}$ mol of cyclohexane and $\frac{2}{3}$ mol of recovered benzene. This is not true for all aromatic systems. With anthracene, for example, it is easy to stop after only the 9,10-bond has been reduced (see p. 49). Hydrogenation of phenol derivatives can lead to conjugated cyclohexenones.[397]

When aromatic rings are reduced by lithium (or potassium or sodium) in liquid ammonia (such reductions are known as *dissolving metal reductions),* usually in the presence of an alcohol (often ethyl, isopropyl, or terf-butyl alcohol), 1,4 addition of hydrogen takes place and nonconjugated cyclohexadienes are produced.[398] This reaction is called the *Birch reduction.*[399] Heterocycles such as pyrroles[400] and furans[401] can be reduced using Birch reduction. Ammonia obtained commercially often has iron salts as impurities that lower the yield in the Birch reduction. Therefore, it is often necessary to distill the ammonia. When substituted aromatic compounds are subjected to the Birch reduction, electron-donating groups such as alkyl or alkoxyl decrease the rate of the reaction and are generally found on the nonreduced positions of the product. For example, anisole gives 1-methoxy-1,4-cyclohexadiene, not 3-methoxy-l,4-cyclohexadiene. On the other hand, electron-withdrawing groups such as COOH or $CONH_2$ increase the reaction rate and are found on the reduced positions of the product.[402] The regioselectivity of the reaction has been examined.[403] The mechanism involves solvated electrons,[404] which are transferred from the metal to the solvent, and hence to the ring:[405]



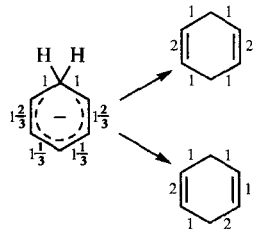
The sodium becomes oxidized to Na^+ and creates a radical ion (**45**).[406] There is a great deal of evidence from ESR spectra for these species.[407] The radical ion accepts

a proton from the alcohol to give a radical, which is reduced to a carbanion by another sodium atom. Finally, 46 accepts another proton. Thus the function of the alcohol is to supply protons, since with most substrates ammonia is not acidic enough for this purpose. In the absence of the alcohol, products arising from dimerization of 45 are frequently obtained. There is evidence[408] at least with some substrates, (e.g., biphenyl) that the radical ion corresponding to 45 is converted to the carbanion corresponding to 46 by a different pathway, in which the order of the steps is reversed: first a second electron is gained to give a dianion,[406] which then acquires a proton, producing the intermediate corresponding to 46.

Indium metal reduces the pyridine ring in quinoline in aqueou sethanol solution.[409] Samarium iodide (SmI_2) reduces pyridine in aqueous THF[410] and phenol in MeOH/KOH.[411]

Ordinary alkenes are usually unaffected by Birch-reduction conditions, and double bonds may be present in the molecule if they are not conjugated with the ring. However, phenylated alkenes, internal alkynes (p. 1009), and conjugated alkenes (with C=C or C=O) are reduced under these conditions.

Note that 46 is a resonance hybrid; that is we can write the two additional canonical forms shown. The question therefore arises: Why does the carbanion pick up a proton at the 6 position to give the 1,4-diene? Why not at the 2 position to give the 1,3-diene?[412] An answer to this question has been proposed by Hine,[413] who has suggested that this case is an illustration of the operation of the *principle of least motion.*[413] According to this principle, "those elementary reactions will be favored that involve the least change in atomic position and electronic configuration."[413] The principle can be applied to the case at hand in the following manner (simplified): The VB bond orders (p. 32) for the six carbon-carbon bonds (on the assumption that each of the three forms contributes equally) are (going around the ring) $1\frac{2}{3}$, 1, 1, $1\frac{2}{3}$, $1\frac{1}{3}$, and $1\frac{1}{3}$. When the carbanion is converted to the diene, these bond orders change as follows:



It can be seen that the two bonds whose bond order is 1 are unchanged in the two products, but for the other four bonds there is a change. If the 1,4-diene is formed, the change is $\frac{1}{3}+\frac{1}{3}+\frac{1}{3}+\frac{1}{3}$, while formation of the 1,3-diene requires a change of $\frac{1}{3}+\frac{2}{3}+\frac{2}{3}+\frac{1}{3}$. Since a greater change is required to form the 1,3-diene, the principle of least motion predicts formation of the 1,4-diene. This may not be the only factor, because the ^{13}C NMR spectrum of 46 shows that the 6 position has a somewhat greater electron density than the 2 position, which presumably would make the former more attractive to a proton.[414]

Reduction of aromatic rings with lithium[415] or calcium[416] in amines (instead of ammonia—called *Benkeser reduction)* proceeds further and cyclohexenes are obtained. It is thus possible to reduce a benzene ring, by proper choice of reagent, so that one, two, or all three double bonds are reduced.[417] Lithium triethylborohydride ($LiBEt_3H$) has also been used, to reduce pyridine derivatives to piperidine derivatives.[418]

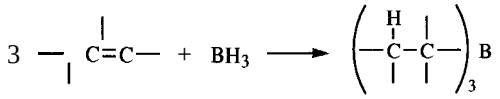
OS I, 99, 499; II, 566; HI, 278, 742; IV, 313, 887, 903; V, 398, 400, 467, 591, 670, 743, 989; VI, 371, 395, 461, 731, 852, 856, 996; VII, 249.

15-15 *Reductive Cleavage of Cyclopropanes*

Cyclopropanes can be cleaved by catalytic hydrogenolysis.[419] Among the catalysts used have been Ni, Pd, and Pt. The reaction can often be run under mild conditions.[420] Certain cyclopropane rings, especially cyclopropyl ketones and aryl-substituted cyclopropanes,[421] can be reductively cleaved by an alkali metal (generally Na or Li) in liquid ammonia.[422] Similar reduction has been accomplished photochemically in the presence of $LiClO_4$.[423]

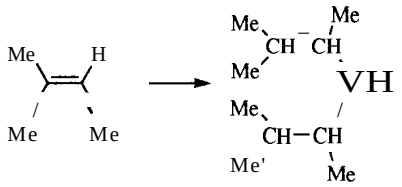
F. *A Metal on the Other Side*

15-16 *Hydroboration*



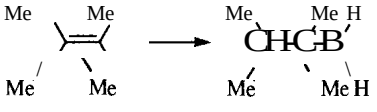
When alkenes are treated with borane[424] in ether solvents, BH_3 adds across the double bond.[425] Borane cannot be prepared as a stable pure compound[426] (it dimerizes to diborane B_2H_6), but it is commercially available in the form of complexes with THF, Me_2S,[427] phosphines, or tertiary amines. The alkenes can be treated with a solution of one of these complexes ($THF{-}BH_3$ reacts at 0°C and is the most convenient to use; $R_3N{-}BH_3$ generally require temperatures of $\sim 100°C$; however, the latter can be prepared as air stable liquids or solids, while the former can only be used as relatively dilute solutions in THF and are decomposed by moisture in air) or with a mixture of $NaBH_4$ and BF_3 etherate, which generates borane *in situ*.[428] Ordinarily, the process cannot be stopped with the addition of one molecule of BH_3 because the resulting RBH_2 adds to another molecule of alkene to give R_2BH, which in turn adds to a third alkene molecule, so that the isolated product is a trialkylborane (R_3B). The reaction can be performed on alkenes with one to four substituents, including cyclic alkenes, but when the alkene is moderately hindered, the product *is* the dialkylborane R_2BH or even the monalkylborane RBH_2.[429] For example, 47 (*disiamylborane*) and 48 (*thexylborane*)[430] have been

prepared in this manner. Monoalkylboranes (RBH_2) (which can be prepared from hindered alkenes, as above) and dialkylboranes (R_2BH) also add to alkenes, to give



Disiamylborane

47

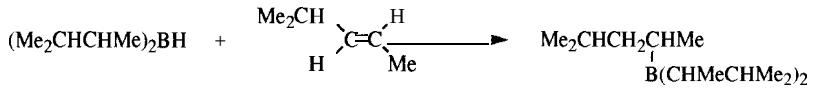


48

Thexylborane

the mixed trialkylboranes RR'_2B and $R_2R'B$, respectively. Surprisingly, when methylborane (MeBH2),[431] which is not a bulky molecule, adds to alkenes in the solvent THF, the reaction can be stopped with one addition to give the dialkylboranes (RMeBH).[432] Reaction of this with a second alkene produces the trialkylborane (RR'MeB).[433] Other monoalkylboranes, *i*-$PrBH_2$, *n*-$BuBH_2$, *s*-$BuBH_2$, and *t*-$BuBH_2$, behave similarly with internal alkenes, but not with alkenes of the type RCH=CH2.[434]

In all cases, the boron goes to the side of the double bond that has more hydrogens, whether the substituents are aryl or alkyl.[435] This actually follows Markovnikov's rule, since boron is more positive than hydrogen. However, the regioselectivity is caused mostly by steric factors, though electronic factors also play a part. Studies of the effect of ring substituents on rates and on the direction of attack in hydroboration of substituted styrenes showed that the attack by boron has electrophilic character.[436] When both sides of the double bond are monosubstituted or both disubstituted, about equal amounts of each isomer are obtained. However, it is possible in such cases to make the addition regioselective by the use of a large attacking molecule. For example, treatment of *i*-PrCH=CHMe with borane gave 57% of product with boron on the methyl-bearing carbon and 43% of the other, while treatment with 47 gave 95% 45 and only 5% of the other isomer.[437]

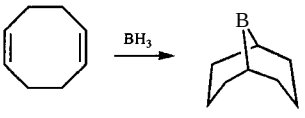


47

(95%)

49

Another reagent with high regioselectivity is 9-borabicyclo[3.3.1]nonane (9-BBN), which is prepared by hydroboration of 1,5-cyclooctadiene:[438]



9-BBN

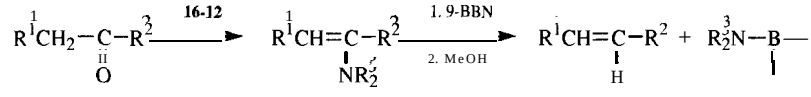
The 9-BBN has the advantage that it is stable in air. Borane is quite unselective and attacks all sorts of double bonds. Disiamylborane, 9-BBN, and similar molecules are

far more selective and preferentially attack less-hindered bonds, so it is often possible to hydroborate one double bond in a molecule and leave others unaffected or to hydroborate one alkene in the presence of a less reactive alkene.[439] For example, 1-pentene can be removed from a mixture of 1- and 2-pentenes, and a cis alkene can be selectively hydroborated in a mixture of the cis and trans isomers.

A hydroboration reagent with greater regioselectivity than BH_3 (for terminal alkenes or those of the form $R_2C{=}CHR$) is monochloroborane[440] BH_2Cl coordinated with dimethyl sulfide (the hydroboration product is a dialkylchloroborane, R_2BCl).[441] For example, 1-hexene gave 94% of the anti-Markovnikov product with BH3-THF, but 99.2% with $BH_2Cl{-}SMe_2$. Treatment of alkenes with dichloroborane-dimethyl sulfide ($BHCl_2{-}SMe_2$) in the presence of BF3[442] or with BCl_3 and Me_3SiH[443] gives alkyldichloroboranes ($RBCl_2$).

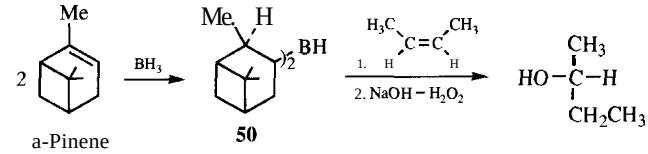
An important use of the hydroboration reaction is that alkylboranes, when oxidized with H_2O_2 and NaOH, are converted to alcohols **(12-26).** This is therefore an indirect way of adding H_2O across a double bond in an anti-Markovnikov manner. However, boranes undergo many other reactions as well. Among other things, they react with α-halo carbonyl compounds to give alkylated products (10-**109),** with α,β-unsaturated carbonyl compounds to give Michael-type addition of R and H **(15-25),** with CO to give alcohols and ketones **(18-23-18-24);** they can be reduced with carboxylic acids, providing an indirect method for reduction of double bonds **(15-11),** or they can be oxidized with chromic acid or pyridinium chlorochromate to give ketone[444] or aldehydes (from terminal alkenes),[445] dimerized with A_8No_3 and NaOH **(14-32),** isomerized **(18-11),** or converted to amines **(12-29)** or halides **(12-28).** They are thus useful intermediates for the preparation of a wide variety of compounds.

Such functional groups as OR, OH, NH_2, SMe, halogen, and COOR may be present in the molecule,[446] but not groups that are reducible by borane. Hydroboration of enamines with 9-BBN provides an indirect method for reducing an aldehyde or ketone to an alkene, for example.[447]



Enamines can also be converted to amino alcohols via hydroboration.[448] Alleneboranes react with aldehydes to give alkyne-alcohols.[449]

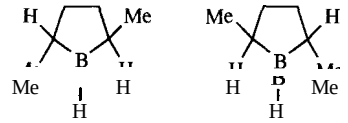
Use of the reagent diisopinocampheylborane 50 (prepared by treating optically active α-pinene with BH_3) results in enantioselective hydroboration-oxidation.[450] Since both (+) and (—) α-pinene are readily available, both enantiomers can be prepared. Alcohols with optical purities as high as 98% have been obtained in this



a-Pinene
Optically active

Optically active

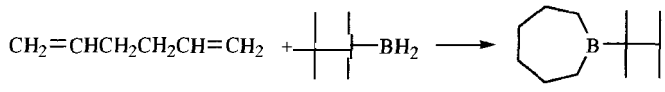
way.[451] However, 50 does not give good results with even moderately hindered alkenes; a better reagent for these compounds is isopinocampheylborane[452] though optical yields are lower. Limonylborane,[453] 2- and 4-dicaranylboranes,[454] a myrtanylborane,[455] and dilongifolylborane[456] have also been used. Other new asymmetric boranes have also been developed. The chiral cyclic boranes *trans*-2,15-dimethylborolanes (51 and 52) also add enantioselectively to alkenes (except



51 (*R, R*) **52** (*S, S*)

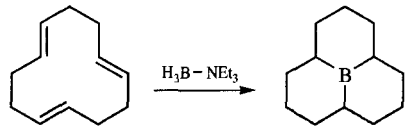
alkenes of the form $RR'C{=}CH_2$) to give boranes of high optical purity.[457] When chiral boranes are added to trisubstituted alkenes of the form RR'C=CHR", two new chiral centers are created, and, with 51 or 52, only one of the four possible diastereomers is predominantly produced, in yields >90%.[457] This has been called *double-asymmetric synthesis*.[458]

The double bonds in a conjugated diene are hydroborated separately, that is, there is no 1,4 addition. However, it is not easy to hydroborate just one of a conjugated system, since conjugated double bonds are less reactive than isolated ones. Thexylborane[430] (**48**) is particularly useful for achieving the cyclic hydroboration of dienes, conjugated or nonconjugated, as in the formation of 53.[459]



48 **53**

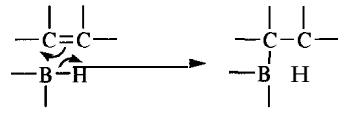
Rings of five, six, or seven members can be formed in this way. Similar cyclization can also be accomplished with other monoalkylboranes and, in some instances, with BH_3 itself.[460] One example is the formation of 9-BBN, shown above. Another is conversion of 1,5,9-cyclododecatriene to perhydro-9*b*-boraphenalene:[461]



Triple bonds[462] can be monohydroborated to give vinylic boranes, which can be reduced with carboxylic acids to cis alkenes or oxidized and hydrolyzed to aldehydes or ketones. Terminal alkynes give aldehydes by this method, in contrast to the mercuric or acid-catalyzed addition of water discussed at 15-4. However, terminal alkynes give vinylic boranes[463] (and hence aldehydes) only when treated with a hindered borane such as 47, 48, or catecholborane (p. 798),[464] or with $BHBr_2{-}SMe2$.[465] The reaction between terminal alkynes and BH_3 produces 1,1-

dibora compounds, which can be oxidized either to primary alcohols (with $NaOH–H_2O_2$) or to carboxylic acids (with *m*- chloroperoxybenzoic acid).[466] Double bonds can be hydroborated in the presence of triple bonds if the reagent is 9-BBN.[467] On the other hand, dimesitylborane selectively hydroborates triple bonds in the presence of double bonds.[468] Furthermore, it is often possible to hydroborate selectively one particular double bond of a nonconjugated diene.[469] A triple bond can be hydroborated in the presence of a ketone, and treatment with acetic acid reduces the C≡C unit to a cis- alkene (see 15-12).[470] When the reagent is catecholborane, hydroboration is catalyzed by rhodium complexes,[471] such as Wilkinson's catalyst,[472] by SmI_2,[473] or lanthanide reagents.[474] Enantioselective hydroboration-oxidation has been achieved by the use of optically active rhodium complexes.[475]

For most substrates, the addition in hydroboration is stereospecific and syn, with attack taking place from the less-hindered side.[476] The mechanism[477] may be a cyclic four-center one:[478]

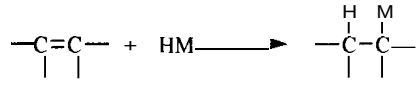


When the substrate is an allylic alcohol or amine, the addition is generally anti,[479] though the stereoselectivity can be changed to syn by the use of catecholborane and the rhodium complexes mentioned above.[480] Because the mechanism is different, use of this procedure can result in a change in regioselectivity as well, [e.g., styrene $PhCH{=}CH_2$ gave $PhCH(OH)CH_3$].[481]

OS **VI,** 719, 852, 919, 943; **VII,** 164, 339, 402, 427; **VIII,** 532.

15-17 *Other Hydrometalation*

HYDRO-METALLO-ADDITION



Metal hydrides of Groups 13 (IIIA) and 14 (IVA) of the periodic table (e.g., AlH_3, GaH_3) as well as many of their alkyl and aryl derivatives (e.g., R_2AlH, Ar_3SnH) add to double bonds to give organometallic compounds.[482] The hydroboration reaction **(15-16)** is the most important example, but other important metals in this reaction are aluminum,[483] tin,[484] and zirconium (a Group 4(IVB) metal).[485] Some of these reactions are uncatalyzed, but in other cases various types of catalyst have been used.[486] Hydrozirconation is most commonly carried out with Cp_2ZrHCl,[487] known as *Schwartz's reagent.* The mechanism with Group 13 (IIIA) hydrides seems to be electrophilic (or four-centered pericyclic with some electrophilic characteristics) while with Group 14 (IVA) hydrides a mechanism involving free radicals seems more likely. Dialkylmagnesium reagents have been obtained by adding MgH_2 to

double bonds.[488] The compound RMgX can be added to an alkene $R'CH{=}CH_2$ to give $R'CH_2CH_2MgX$, with $TiCl_4$ as a catalyst.[489] With some reagents triple bonds[490] can add 1 or 2mol for example, [491]

$$RCECH \xrightarrow{R_2AlH} RC{=}CH{-}AlR'_2 \xrightarrow{R_2AlH} RCH_2CH(AlR'_2){-}AlR'_2$$

When 2 mol are added, electrophilic addition generally gives 1,1-dimetallic products (as with hydroboration), while free-radical addition usually gives the 1,2-dimetallic products.

OS **VII,** 456; **VIII,** 268, 295, 507. See also OS **VIII,** 277, 381.

G. *Carbon on the Other Side*

15-18 Addition of Alkanes

HYDRO-ALKYL-ADDITION

$$-C{=}C- + RH \longrightarrow -\overset{H}{\underset{|}{C}}-\overset{R}{\underset{|}{C}}-$$

There are two important ways of adding alkanes to alkenes—the thermal method and the acid-catalysis method.[492] Both give chiefly mixtures, and neither is useful for the preparation of relatively pure compounds in reasonable yields. However, both are useful industrially. In the thermal method, the reactants are heated to high temperatures ($\sim$ 500°C) at high pressures (150–300 atm) without a catalyst. As an example, propane and ethylene gave 55.5% isopentane, 7.3% hexanes, 10.1% heptanes, and 7.4% alkenes.[493] The mechanism is undoubtedly of a free-radical type and can be illustrated by one possible sequence in the reaction between propane and ethylene:

Step 1 $CH_3CH_2CH_3 + CH_2{=}CH_2 \xrightarrow{\Delta} CH3\text{-}\dot{C}H\text{-}CH3 + CH_3CH_2\cdot$

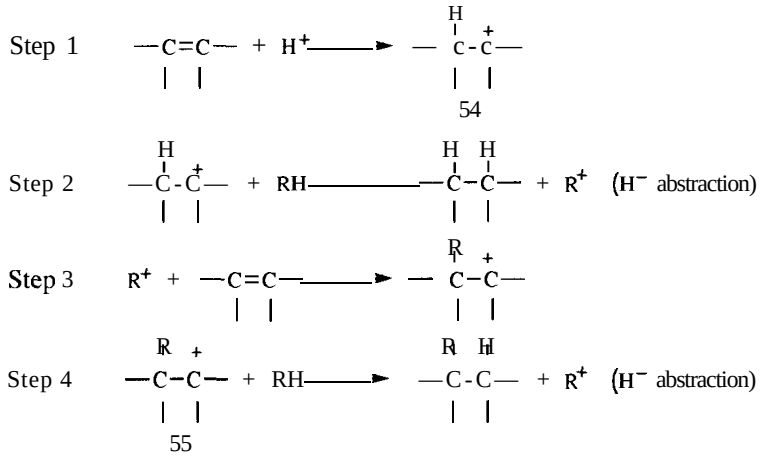
Step 2 $CH3\text{-}\dot{C}H\text{-}CH3 + CH_2{=}CH_2 \longrightarrow (CH_3)_2CHCH_2CH_2\cdot$

Step 3 $(CH_3)_2CHCH_2CH_2\cdot + CH_3CH_2CH_3 \longrightarrow (CH_3)_2CHCH_2CH_3 + CH_3\dot{C}HCH_3$

There is kinetic evidence that the initiation takes place primarily by steps like 1, which are called *symproportionation* steps (the opposite of disproportionation, p. 246).[494]

In the acid-catalysis method, a proton or Lewis acid is used as the catalyst and the reaction is carried out at temperatures between —30 and 100°C. This is a Friedel-Crafts process with a carbocation mechanism[495] (illustrated for a proton acid

catalyst):

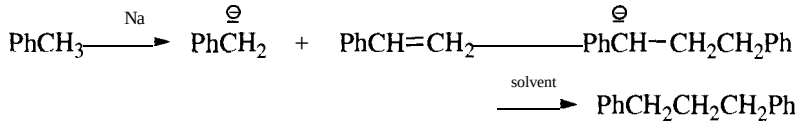


54

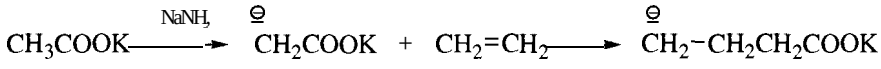
55

Compound **55** often rearranges before it abstracts a hydride ion, explaining, for example, why the principal product from the reaction between isobutane and ethylene is 2,3-dimethylbutane. It is also possible for 54 (or **55)** instead of abstracting a hydride ion, to add to another mole of alkene, so that not only rearrangement products but also dimeric and polymeric products are frequent. If the tri- or tetrasubstituted alkenes are treated with Me_4Si, HC1, and $AlCl_3$, they become protonated to give a tertiary carbocation, which reacts with the Me_4Si to give a product that is the result of addition of H and Me to the original alkene.[496] (For a free-radical hydro-methyl-addition, see **15-26.)** Addition a cation to a vinyl bromide, generated from an α-ethoxy-lactam with trifluoroacetic acid, generated a ketone.[497]

The reaction can also be base catalyzed, in which case there is nucleophilic addition and a carbanion mechanism.[498] Carbanions most often used are those stabilized by one or more α-aryl groups. For example, toluene adds to styrene in the presence of sodium to give 1,3-diphenylpropane:[499]



Conjugated dienes give 1,4 addition.[500] This reaction has also been performed with salts of carboxylic acids in what amounts to a method of alkylation of carboxylic acids (see also 10-96).[501]



Silanes (R_3SiH) also add to alkenes to form a new alkyl silane ($R_3Si{-}R'$) in the presence of a hyponitrite.[502] Silanes add to dienes with a palladium catalyst, and asymmetric induction is achieved by using a binapthyl additive.[503]

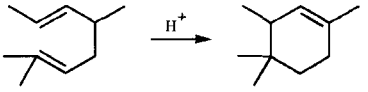
OS I, 229; IV, 665; **VII,** 479.

15-19 Addition of Alkenes and/or Alkynes to Alkenes and/or Alkynes

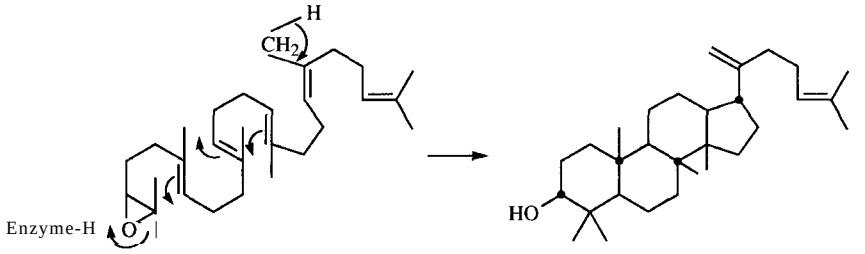
HYDRO-ALKENYL-ADDITION

$$CH_2{=}CH_2 + CH_2{=}CH_2 \xrightarrow{H^+} CH_2{=}CHCH_2CH_3$$

With certain substrates, alkenes can be dimerized by acid catalysts, so that the product is a dimer that contains one double bond.[504] This reaction is more often carried out internally, for example,

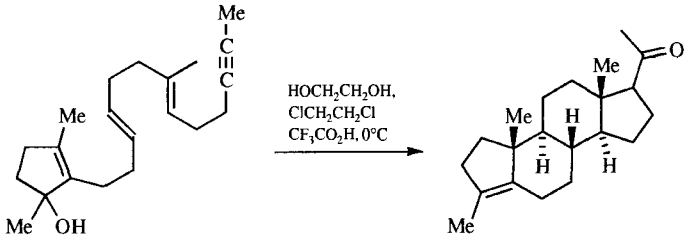


Processes of this kind are important in the biosynthesis of steroids and tetra- and pentacyclic terpenes. For example, squalene 2,3-oxide is converted by enzymatic catalysis to dammaradienol.



Squalene 2,3-oxide Dammaradienol

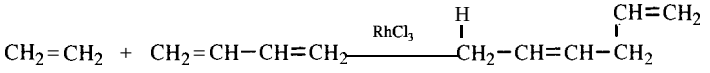
The squalene → lanosterol biosynthesis (which is a key step in the biosynthesis of cholesterol) is similar. The idea that the biosynthesis of such compounds involves this type of multiple ring closing was proposed in 1955 and is known as the *Stork–Eschenmoser hypothesis.*[505] Such reactions can also be carried out in the laboratory, without enzymes.[506] By putting cation-stabilizing groups at positions at which positive charges develop, Johnson and co-workers have been able to close as many as four rings stereoselectively and in high yield, in one operation/[507] An example is [508]



Lewis acids can be used to initiate this cyclization.[509] Cyclization to a tricyclic systems that included formation of a dihydropyran ring was reported using mercuric

bis(trifluorosulfonate) as an initiator.[510] A radical cyclization approach to polyene cyclization using a seleno-ester anchor gave a tetracyclic system.[511] A cyclization using an epoxide anchor to form a bicyclic molecule has also been reported.[512]

The addition of alkenes to alkenes[513] can also be accomplished by bases[514] as well as by the use of catalyst systems[515] consisting of nickel complexes and alkylaluminum compounds (known as *Ziegler catalysts),*[516] rhodium catalysts,[517] and other transition metal catalysts, including iron.[518] These and similar catalysts also catalyze the 1,4 addition of alkenes to conjugated dienes,[519] for example,

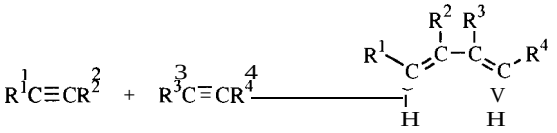


and the dimerization of 1,3-butadienes to octatrienes.[520] Ethylene adds to alkenes to form a new alkene in the presence of a nickel catalyst[521] or a zirconium catalyst,[522] to alkynes in the presence of a ruthenium catalyst[523] to form a diene, and allenes add to alkynes to give a diene with a titanium catalyst.[524]

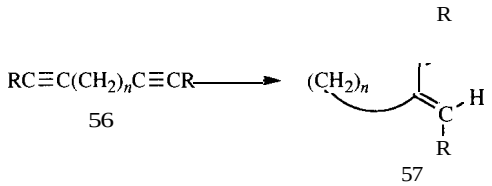
In the presence of cuprous chloride and ammonium chloride, acetylene adds to another molecule of itself to give vinylacetylene.

This type of alkyne dimerization is also catalyzed by certain nickel complexes, as well as other catalysts[525] and has been carried out internally to convert diynes to large-ring cycloalkynes with an exocyclic double bond.[526]

In another type of alkyne, dimerization is the reductive coupling in which two molecules of alkyne, the same or different, give a 1,3-diene[527]



In this method, one alkyne is treated with Schwartz's reagent (see 15-17) to produce a vinylic zirconium intermediate. Addition of MeLi or MeMgBr, followed by the second alkyne, gives another intermediate, which, when treated with aqueous acid, gives the diene in moderate-to-good yields. The stereoisomer shown is the one formed in usually close to 100% purity. If the second intermediate is treated with I_2 instead of aqueous acid, the 1,4-diiodo-1,3-diene is obtained instead, in comparable yield and isomeric purity. This reaction can also be done intramolecularly: Diynes 56 can be cyclized to *(E, E)* exocyclic dienes 57 by treatment with a zirconium complex.[528]



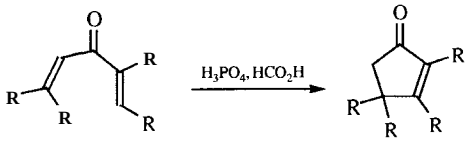
56 57

Rings of four, five, and six members were obtained in high yield; seven-membered rings in lower yield. When the reaction is applied to enynes, compounds similar to 57 but with only one double bond are obtained.[529]

In another reductive coupling, substituted alkenes (CH_2=CHY; Y = R, COOMe, OAc, CN, etc.) can be dimerized to substituted alkanes ($CH_3CHYCHYCH_3$) by photolysis in an H_2 atmosphere, using Hg as a photosensitizer.[530] Still another procedure involves palladium-catalyzed addition of vinylic halides to triple bonds to give 1,3-dienes.[531]

Alkenes and alkynes can also add to each other to give cyclic products in other ways (see **15-61** and **15-63).** The first exclusive exo-dig carbocyclization was reported using $HfCl_4$ as a catalyst.[532] Alkynes also add to alkenes for form rings in the presence of a palladium catalyst[533] or a zirconium catalyst.[534] Carbocyclization of an alkene unit to another alkene unit was reported using an yttrium catalyst[535] and alkenes add to alkynes to give cyclic compounds with titanium catalysts.[536]

An important cyclization procedure involves acid-catalyzed addition of diene-ketones such as 58, where one conjugated alkene adds to the other conjugated alkene to form cyclopentenones (59). This is called the *Nazarov cyclization.*[537] Cyclization can also give the nonconjugated five-membered ring.[538]



58 59

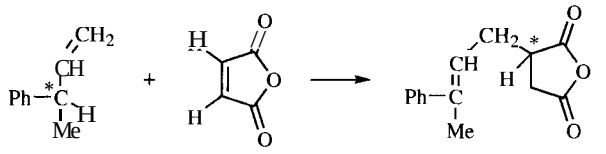
OS **VIII,** 190, 381, 505; **IX,** 310.

15-20 *The Ene Synthesis*

HYDROALLYL-ADDITION

Alkenes can add to double bonds in a reaction different from those discussed in **15-19,** which, however, is still formally the addition of RH to a double bond. This is called the *ene reaction* or the *ene synthesis.*[539] For the reaction to proceed without a catalyst, one of the components must be a reactive dienophile (see **15-58** for a definition of this word) such as maleic anhydride, but the other (which supplies the hydrogen) may be a simple alkene such as propene. Cyclopropene has also been used.[540] The reaction is compatible with a variety of functional groups that can be appended to the ene and dienophile.[541] N,N-Diallyl amides give an ene cyclization, for example.[542] The ene reaction is known with fullerene (see p. 70) derivatives.[543] There has been much discussion of the mechanism of this reaction, and both

concerted pericyclic (as shown above) and stepwise mechanisms have been



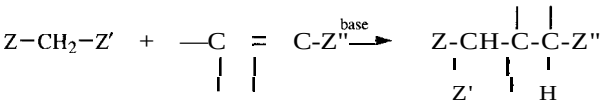
60

suggested. A retro-ene reaction is known with allylic dithiocarbonates.[544] The reaction between maleic anhydride and optically active $PhCHMeCH{=}CH_2$ gave an optically active product (**60**),[545] which is strong evidence for a concerted rather than a stepwise mechanism.[546] The reaction can be highly stereoselective.[547] The reaction can be extended to less-reactive enophiles by the use of Lewis acid catalysts, especially alkylaluminum halides.[548] Titanium catalysts,[549] $Sc(OTf)_3$,[550] $LiClO_4$[551] have also been used. The Lewis acid catalyzed reaction probably has a stepwise mechanism.[552] The ene reaction has also been mediated on certain resins.[553] The carbonyl-ene reaction is also very useful, and often gives synthetically useful yields of products when catalyzed by Lewis acids,[554] including asymmetric catalysts.[555] Scandium triflate[556] has been used to catalyze this reaction. Carbonyl ene cyclization has been reported on silica gel at high pressure (15 kbar).[557] Ene reactions with imines are also known.[558]

OS IV, 766; V, 459. See also OS **VIII,** 427.

15-21 *The Michael Reaction*

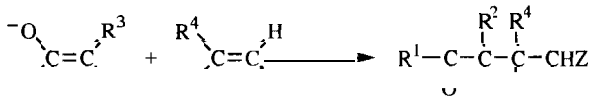
HYDRO-BIS(ETHOXYCARBONYL)METHYL-ADDITION, AND SO ON



Compounds containing electron-withdrawing groups (Z is defined on p. 975) add, in the presence of bases, to alkenes of the form C=C–Z (including quinones). This is called the *Michael reaction* and involves conjugate addition.[559] The base removes the acidic proton, and then the mechanism is as outlined on page 975. The reaction has been carried out with malonates, cyanoacetates, acetoacetates, other β-keto esters, and compounds of the form ZCH_3, ZCH_2R, $ZCHR_2$, and ZCHRZ', including carboxylic esters, ketones, aldehydes, nitriles, nitro compounds,[560] and sulfones, as well as other compounds with relatively acidic hydrogens, such as indenes and fluorenes. The aggregation state of nitrile anions plays an important role in 1,2 versus 1,4 addition to conjugated ketones.[561] These reagents do not add to ordinary double bonds, except in the presence of free-radical initiators **(15-28).** 1,2 Addition (to the C=O or C=N group) often competes and sometimes predominates (16-**41**).[562] In particular, α,β-unsaturated *aldehydes* seldom give 1,4 addition.[563] The Michael reaction has traditionally been performed in protic solvents, with catalytic amounts of base,[564] but more recently better yields with fewer side reactions have

been obtained in some cases by using an equimolar amount of base to convert the nucleophile to its enolate form *(preformed enolate).* In particular, preformed enolates are often used where stereoselective reactions are desired.[565] Transition metal compounds such as $CeCl_3$[566] or $Yb(OTf)_3$[567] also induce the reaction, as does Y-zeolite.[568] Palladium catalysts lead to Michael addition of aryl halides.[569] Water-promoted Michael additions have also been reported.[570]

In a Michael reaction with suitably different R groups, two new chiral centers are created:



Enolate Substrate

Thus the product in such cases can exist as two pairs of enantiomers.[571] In a diastereoselective process, one of the two pairs is formed exclusively or predominantly as a racemic mixture. Many such examples have been reported.[449] In many of these cases, both the enolate and substrate can exist as (Z) or (*E*) isomers. With enolates derived from ketones or carboxylic esters, (*E*) enolates gave the syn pair of enantiomers (p. 146), while (Z) enolates gave the anti pair.[572] Addition of chiral additives to the reaction, such as proline derivatives,[573] or (—)-sparteine[574] lead to product formation with good-to-excellent asymmetric induction. Ultrasound has also been used to promote asymmetric Michael reactions.[575] Intramolecular versions of Michael addition are well known.[576]

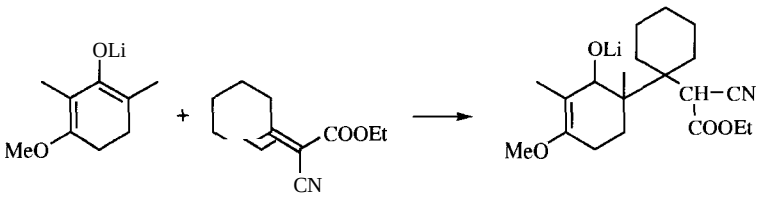
When either or both of the reaction components has a chiral substituent, the reaction can be enantioselective (only one of the four diastereomers formed predominantly), and this has been accomplished a number of times.[577] Enantioselective addition has also been achieved by the use of a chiral catalyst[578] and by using optically active enamines instead of enolates.[579] Chiral imines have also been used.[580]

Other nucleophiles add to conjugated systems to give Michael-type products. Aniline derivatives add to conjugated aldehydes in the presence of a catalytic amount of DBU (p. 488).[581] Amines add to conjugated esters in the presence of $InCl_3$,[582] $La(OTf)_3$,[583] or $YTb(OTf)_3$ at 3 kbar,[584] for example, to give P-amino esters. This reaction can be initiated photochemically.[585] An intramolecular addition of an amine unit to a conjugated ketone in the presence of a palladium catalyst, or photochemically, led to cyclic amines.[586] Amines add to conjugated thio-lactams.[587] Chiral imines add in a highly stereoselective manner.[588] Lactams have been shown to add to conjugated esters in the presence of $Si(OEt)_4$ and CsF.[589] Thioaryl moieties can be added in the presence of Yb.[590]

Mannich bases (see 16-15) and β-halo carbonyl compounds can also be used as substrates; these are converted to the C=C–Z compounds *in situ* by the base (16-15, 17-12).[591] Substrates of this kind are especially useful in cases where the C=C–Z compound is unstable. The reaction of C=C–Z compounds with enamines (12-18) can also be considered a Michael reaction. Michael reactions are reversible.

When the substrate contains *gem*- Z groups, (e.g., 62), bulky groups can be added, if the reaction is carried out under aprotic conditions. For example, addition of

enolate 61 to 62 gave 63 in which two adjacent quaternary centers have been formed.[592]

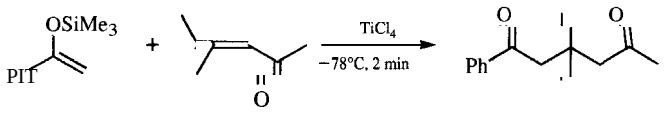


61 62 63 (68%)

In certain cases, Michael reactions can take place under acidic conditions.[593] Michael-type addition of radicals to conjugated carbonyl compounds is also known.[594] Radical addition can be catalyzed by $Yb(OTf)_3$,[595] but radicals add under standard conditions as well, even intramolecularly.[596] Electrochemical-initiated Michael additions are known, and aryl halides add in the presence of $NiBr_2$.[597]

Michael reactions are sometimes applied to substrates of the type C≡C–Z, where the co-products are conjugated systems of the type C=C–Z.[598] Indeed, because of the greater susceptibility of triple bonds to nucleophilic attack, it is even possible for nonactivated alkynes (e.g., acetylene), to be substrates in this reaction.[599]

In a closely related reaction, silyl enol ethers add to α,β-unsaturated ketones and esters when catalyzed[600] by $TiCl_4$, for example,[601]



The compound $InCl_3$ also catalyzes this reaction.[602] Aluminum compounds also catalyze this reaction[603] and the reaction has been done in neat tri-n- propylaluminum.[604] A solid-state version of the reaction used alumina·$ZnCl_2$.[605] This reaction, also, has been performed diastereoselectively.[606] Allylic silanes $R_2C{=}CHCH_2$-$SiMe_3$ can be used instead of silyl enol ethers (the *Sakurai reaction*).[607] Similarly, silyl ketene acetals, $RCH{=}C(OMe)OSiMe_3$, add to conjugated ketones to give 5-keto esters, in $MeNO_2$ as solvent,.[608]

OS I, 272; II, 200; III, 286; IV, 630, 652, 662, 776; V, 486, 1135; VI, 31, 648, 666, 940; VII, 50, 363, 368, 414, 443; VIII, 87, 210, 219, 444, 467; IX, 526. See also OS VIII, 148.

15-22 *Addition of Organometallics to Double and Triple Bonds Not Conjugated to Carbonyls*

HYDRO-ALKYL-ADDITION

Neither Grignard reagents nor lithium dialkylcopper reagents generally add to ordinary C=C double bonds.[609] An exception is the reaction of $(PhMe_2Si)_2$-Cu(CN)Li to 8-oxabicyclo[3.2. l]oct-2-ene derivatives.[610] Grignard reagents usually add only to double bonds susceptible to nucleophilic attack (e.g., fluoroalkenes and tetracyanoethylene.[611] However, active Grignard reagents (benzylic, allylic) also add to the double bonds of allylic amines,[612] and of allylic and homoallylic alcohols,[613] as well as to the triple bonds of propargyl alcohols and certain other alkynols.[614] Grignard reagents also add to alkynes in the presence of $MnCl_2$ at 100°C[615] and to alkenes in the presence of zirconium catalysts.[616] It is likely that cyclic intermediates are involved in these cases, in which the magnesium coordinates with the hetero atom. Organolithium reagents (primary, secondary. and tertiary alkyl and in some cases aryl) also add to the double and triple bonds of allylic and propargylic alcohols[617] (in this case tetramethylethylenediamine is a catalyst) and to certain other alkenes containing hetero groups such as OR, NR_2, or SR. Allylic, benzylic, and tertiary alkyl Grignard reagents also add to 1-alkenes and strained internal alkenes, (e.g., norbornene) if the reaction is carried out not in ether but in a hydrocarbon solvent such as pentane or in the alkene itself as solvent, heated, under pressure if necessary, to 60–130°C.[618] Yields are variable. *Intramolecular* addition of RMgX to completely unactivated double and triple bonds has been demonstrated,[619] for example, refluxing of 6-chloro-1-heptene with Mg for 5 h gave, after hydrolysis, an 88% yield of 1,2-dimethylcyclopentane.[620]

Organolithium reagents containing an alkene or alkyne unit cyclize at low temperatures and quenching with methanol replaces the new C–Li bond with C–H. Cyclization occurs with both alkynes[621] and alkenes.[622] Alkyllithium and alkenyllithium derivatives containing an ester moiety can be cyclized.[623] Tandem cyclization are possible with dienes and en-ynes to form more than one ring,[624] including bicyclic compounds.[625] The organolithium reagents can contain heteroatoms such as nitrogen elsewhere in the molecule, and the organolithium species can be generated from an intermediate organotin derivative.[626] Enolate anions can add to allylic sulfides, forming β-lactams in some cases.[627]

Unactivated alkenes can react with other organometallic compounds under certain conditions. Trimethylaluminum reacts with 4-methyl-1-pentene, in the presence of Cl_2ZrCp_2, for example, and subsequent reaction with molecular oxygen leads to 2(*R*),4-dimethyl-1-pentanol in good yield and 74% ee.[628] These reagents also add to alkynes.[629] Ruthenium catalysts have been used to add allylic alcohols to alkynes.[630] Samarium iodide (SmI2) induces cyclization of a halide moiety to an alkyne unit[631] or an alkene unit[632] to form cyclized products. Copper complexes can catalyze similar cyclization to alkenes, even when an ester unit is present in the molecule.[633] Vinyl halides add to allylic amines in the presence of Ni(cod)2, where cod is 1,5-cylooctadiene, followed by reduction with sodium borohydride.[634] Organomanganese reagents add to alkenes.[635] Manganese triacetate $[Mn(OAc)_3$, in the presence of cupric acetate, facilitates intramolecular cyclization of a halide unit to an alkene.[636]

Grignard reagents add to the C=C unit of $(MeO)_2CRCH{=}CH{-}R$ moieties to give a 3-alkyl substituted ketone in the presence of a nickel catalyst.[637]

When a chiral additive is used, this reaction proceeds with good enantioselectivity.

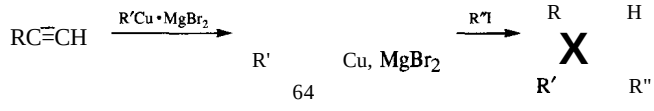
Alkynes react with indium reagents such as $(allyl)_3In_2I_3$ to form dienes (allyl substituted alkenes from the alkyne).[638] Allyltin reagents add to alkynes in a similar manner in the presence of $ZrCl_4$.[639] Alkylzinc reagents add to alkynes to give substituted alkenes in the presence of a palladium catalyst.[640]

15-23 *The Addition of Two Alkyl Groups to an Alkyne*

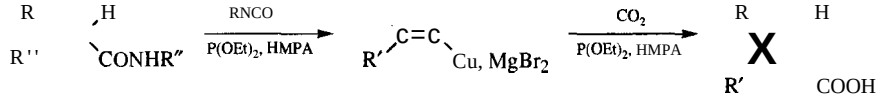
DIALKYL-ADDITION

$$RC{\equiv}CH + R'Cu{\cdot}MgBr_2 + R''I \xrightarrow[\text{ether—HPMA}]{(EtO)_2P} \underset{R'}{}\!\!\!\!\underset{R''}{}$$

Two different alkyl groups can be added to a terminal alkyne[641] in one laboratory step by treatment with an alkylcopper-magnesium bromide reagent (called *Normant reagents)*[642] and an alkyl iodide in ether–HMPA containing triethyl phosphite.[643] The groups add stereoselectively syn. The reaction, which has been applied to primary[644] R′ and to primary, allylic, benzylic, vinylic, and α-alkoxyalkyl R′, involves initial addition of the alkylcopper reagent,[645] followed by a coupling reaction (10-94):

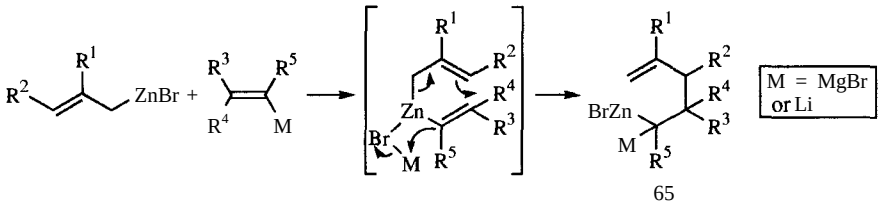


Acetylene itself (R = H) undergoes the reaction with R_2CuLi instead of the Normant reagent.[646] The use of R′ containing functional groups has been reported.[647] If the alkyl iodide is omitted, the vinylic copper intermediate 64 can be converted



to a carboxylic acid by the addition of CO_2 (see 16-34) or to an amide by the addition of an isocyanate, in either case in the presence of HMPA and a catalytic amount of triethyl phosphite.[648] The use of I_2 results in a vinylic iodide.[649]

Similar reactions, in which two alkyl groups are added to a triple bond, have been carried out with trialkylalanes R_3Al, with zirconium complexes as catalysts.[650]



65

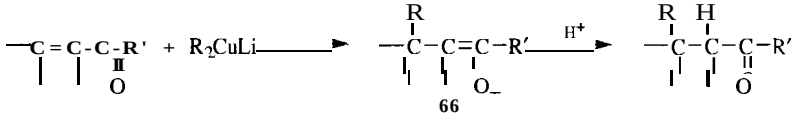
Ally] ethers and iodobenzene have also been added using a zirconium complex.[651] Similarly, allyl ethers and allyl chlorides have been added.[652]

Allylic zinc bromides add to vinylic Grignard and lithium reagents to give the *gem*-dimetallo compounds 65. The two metallo groups can be separately reacted with various nucleophiles.[653]

OS **VII,** 236, 245, 290.

15-24 *1,4 Addition of Organometallic Compounds to Activated Double Bonds*

HYDRO-ALKYL-ADDITION



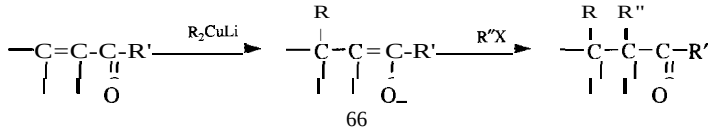
66

Lithium dialkylcopper reagents (see **10-94)** add to α,β-unsaturated aldehydes[654] and ketones (R' = H, R, Ar) to give conjugate addition products[655] in a reaction closely related to the Michael reaction. α,β-Unsaturated esters are less reactive,[656] and the corresponding acids do not react at all. The R group can be primary alkyl, vinylic, or aryl. If Me_3SiCl is present, the reaction takes place much faster and with higher yields; in this case the product is the silyl enol ether of **66** (see **12-22**).[657] The use of Me_3SiCl also permits good yields with allylic R groups.[658] Conjugated alkynyl-ketones also react via 1,4 addition to give substituted alkenyl-ketones.[659]

Various functional groups such as OH and unconjugated C=O groups may be present in the substrate.[660] Conjugated sulfones are also good substrates.[661] A characteristic of the reaction is that only one of the R groups of R_2CuLi adds to the substrate; the other is wasted. This can be a limitation where the precursor (RLi or RCu, see **12-33)** is expensive or available in limited amounts. The difficulty can be overcome by using one of the mixed reagents R(R'C≡C)CuLi,[662] R(O—*t*-Bu)CuLi,[663] or R(PhS)CuLi,[664] each of which transfers only the R group. These reagents are easily prepared by the reaction of RLi with R′C≡CCu (R′ = *n*-Pr or *t*-Bu), *t*-BuOCu, or PhSCu, respectively. A further advantage of the mixed reagents is that good yields of addition product are achieved when R is tertiary, so that use of one of them permits the introduction of a tertiary alkyl group. The mixed reagents R(CN)CuLi[665] (prepared from RLi and CuCN) and $R_2Cu(CN)Li_2$[666] also selectively transfer the R group.[667] The reaction has also been carried out with α,β-acetylenic ketones, esters, and nitriles.[668] Conjugate addition to α,β-unsaturated and acetylenic acids and esters, as well as ketones, can be achieved by the use of the coordinated reagents $RCu{\cdot}BF_3$ (R = primary).[669] Alkylcopper compounds RCu (R = primary or secondary alkyl) have also been used with tetramethylethylenediamine and Me_3SiCl to give silyl enol ethers from αβ-unsaturated ketones in high yield.[670] Amine units have been transferred in this manner to give amino-esters. N-Boc-2-lithiopyrrolidine, for example, reacted with CuCN and LiCl to give a cuprate, that reacted with methyl acrylate to give *N*-Boc-2-(2-carboxymethylethyl)pyrrolidine.[671]

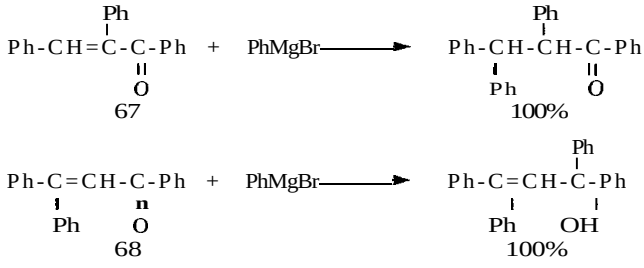
Related compounds have been generated from $BocRNCH_2SnR'_3$ and *s*-butyllithium/CuCN which also added to conjugated ketones.[672] Other amino-cuprates are known to give conjugate addition reactions.[673]

There is generally little or no competition from 1,2 addition (to the C=O). However, when R is allylic, 1,4 addition is observed with some substrates and 1,2 addition with others.[674] The compound R_2CuLi also add to α,β-unsaturated sulfones[675] but not to simple αβ-unsaturated nitriles.[676] Organocopper reagents RCu (as well as certain R_2CuLi) add to αβ-unsaturated and acetylenic sulfoxides.[677]



66

Usually, after an enolate ion is generated from an αβ-unsaturated ketone, it is converted to the β-alkylated product as shown above. But it is often possible to have the enolate react with some other electrophile *(tandem vicinal difunctionalization*), in some cases at the O and in other cases at the C.[678] For example, if an alkyl halide R′X is present (R′ = primary alkyl or allylic), and the solvent is 1,2-dimethoxyethane, the enolate (66) can be alkylated directly.[679] Thus, by this method, both the a and β positions of a ketone are alkylated in one synthetic operation (see also **15-23).**



67 100%

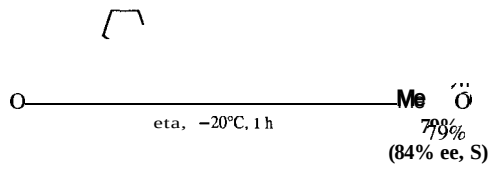
68 100%

Grignard reagents also add to these substrates, but with these reagents, 1,2 addition may seriously compete:[680] The product is often controlled by steric factors. Thus 67 with phenylmagnesium bromide gives 100% 1,4 addition, while 68 gives 100% 1,2 addition. In general, substitution at the carbonyl group increases 1,4 addition, while substitution at the double bond increases 1,2 addition. In most cases, both products are obtained, but α,β-unsaturated *aldehydes* nearly always give exclusive 1,2 addition when treated with Grignard reagents. However, the extent of 1,4 addition of Grignard reagents can be increased by the use of a copper ion catalyst, for example, CuCl, $Cu(OAc)_2$.[681] Grignard reagents mixed with $CeCl_3$ generates a reactive species that gives primarily 1,4 addition.[682] It is likely that alkylcopper reagents, formed from RMgX and Cu^+ (cupric acetate is reduced to cuprous ion by excess RMgX), are the actual attacking species in these cases.[655] Alkyllithium reagents,[683] treated with compounds of the form $C{=}C{-}COCH_3$ and $C{=}C{-}COOC_2H_5$, gave only 1,2 addition,[684] but 1,4 addition was achieved with esters of the form C=C—COOAr, where Ar was a bulky group such as *2,6-di-tert-*

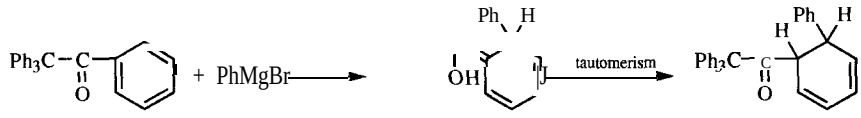
butyl-4-methoxyphenyl.[685] Also, alkyllithium reagents can be made to give 1,4 addition with α,β-unsaturated ketones[686] and aldehydes[687] if the reactions are conducted in the presence of HMPA. Among alkyllithium reagents that have been found to add 1,4 in this manner are 2-lithio-1,3-dithianes (see 10-107).[688] Lithium-halogen exchange (12-20) generates an organolithium species that adds intramolecularly to conjugated esters to give cyclic and bicyclic products.[689] 1,4 Addition of alkyllithium reagents to α,β-unsaturated aldehydes can also be achieved by converting the aldehyde to a benzothiazole derivative (masking the aldehyde function),[690] from which the aldehyde group can be regenerated. When some conjugated acids are added to *n*-butyllithium, the conjugate addition product was isolated in good yield.[691]

An alkynyl group can be added to the double bond of an α,β-unsaturated ketone by use of the diethylalkynylalane reagents $Et_2AlC{\equiv}CR$.[692] In a similar manner, the alkenyl reagents $R_2AlCH{=}CR$ transfer an alkenyl group.[693] Trialkylalanes R_3Al also add 1,4 to such ketones in the presence of nickel acetylacetonate.[694] Also used for 1,4 addition to these ketones are alkyl- and arylmanganese chlorides, catalyzed by CuCl (this reagent is successful for α,β-unsaturated aldehydes and esters also),[695] arylpalladium compounds,[696] and arylmercury compounds with phase-transfer catalysts.[697] Diethylzinc adds to conjugated nitro compounds in the presence of a catalytic amount of $Cu(OTf)_2$ and a BINOL additive to give the conjugate addition product with modest% ee.[698] The chiral bis-phosphine called *chiraphos* has also been used.[699] Reaction of alkyl iodides with Zn/CuI with ultrasound generates an organometallic that adds to conjugated esters.[700] Diarylzinc compounds (prepared with the aid of ultrasound) in the presence of nickel acetylacetonate, undergo 1,4 addition not only to α,β-unsaturated ketones, but also to α,β-unsaturated aldehydes.[701] Mixed alkylzinc compounds also add to conjugated systems.[702] An allyl group can be added, to α,β-unsaturated carboxylic esters, amides and nitriles, with $CH_2{=}CH\text{-}CH_2SiMe_3$ and F^- ion (see 15-45).[703] This reagent gave better results than lithium diallylcuprate. Functionalized allylic groups can be added to terminal alkynes with allylic halides, zinc, and ultrasound, to give 1,4-dienes.[704] An aryl group can be added to a triple bond with an aryl iodide and a $Pd{-}HCOOH{-}R_3N$ catalyst.[705] A reagent formed from $Me_3Ti{\cdot}MeLi$ adds a methyl group to conjugated ketones.[706]

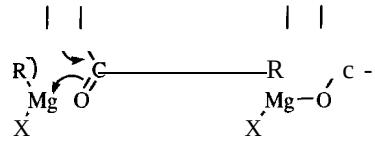
As with the Michael reaction (15-21) the 1,4 addition of organometallic compounds has been performed diastereoselectively[707] and enantioselectively.[708] The influence of solvent and additives on yield and selectivity has been examined.[709] The use of chiral ligands with MgI_2/I_2 and Bu_3SnI gave conjugate addition products with α,β-unsaturated amides with good %ee.[710] Chiral templates have also been used with Grignard reagents, directly[711] and in the presence of $AlMe_2Cl$.[712] An example is the conjugated addition ofdimethyl cuprate in the presence of the chiral ligand shown.[713]



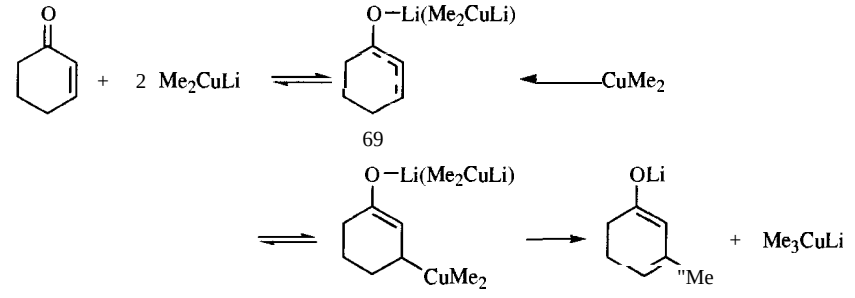
In certain cases, Grignard reagents add 1,4 to *aromatic* systems, for example,[714]



Such cyclohexadienes are easily oxidizable to benzenes (often by atmospheric oxygen), so this reaction becomes a method of alkylating and arylating suitably substituted (usually hindered) aryl ketones. A similar reaction has been reported for aromatic nitro compounds where 1,3,5-trinitrobenzene reacts with excess methylmagnesium halide to give 2,4,6-trinitro-l,3,5-trimethylcyclohexane.[715] Both Grignard and R_2CuLi reagents[716] have also been added to systems of the form $C{\equiv}C{-}C{=}O$.[717]



The mechanisms of most of these reactions are not well known. The 1,4-uncatalyzed Grignard reaction has been postulated to proceed by the cyclic mechanism shown, but there is evidence against it.[718] The R_2CuLi[719] and copper-catalyzed Grignard additions may involve a number of mechanisms, since the actual attacking species and substrates are so diverse.[720] A free-radical mechanism of some type (perhaps SET) has been suggested[721] though the fact that retention of configuration at R has been demonstrated in several cases rules out a completely free R· radical.[722] For simple α,β-unsaturated ketones, such as 2-cyclohexenone, and Me_2CuLi, there is evidence[723] for this mechanism:



69

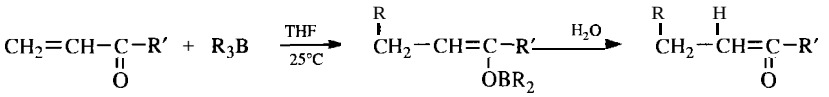
69 is a *d,n** complex, with bonding between copper, as a base supplying a pair of *d* electrons, and the enone as a Lewis acid using the π^* orbital of the allylic system.[723] The ^{13}C NMR spectrum of an intermediate similar to 69 has been reported.[724] The addition of R_3Al takes place by a free-radical mechanism.[694]

For the addition of organocopper reagents to alkynes and conjugated dienes, see 15-23.

OS IV, 93; V, 762; VI, 442, 666, 762, 786; VIII, 112, 257, 277, 479; IX, 328, 350, 640.

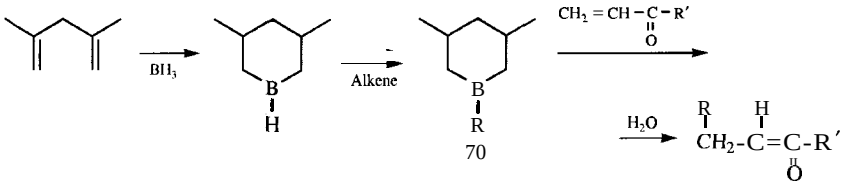
15-25 *The Addition of Boranes to Activated Double Bonds*

HYDRO-ALKYL-ADDITION (OVERALL TRANSFORMATION)



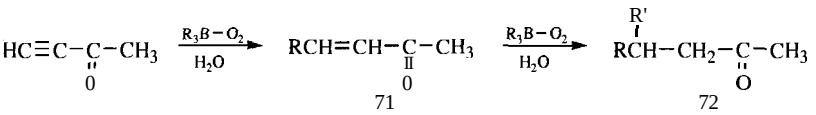
R'H, Me

Trialkylboranes rapidly add to the double bonds of acrolein, methyl vinyl ketone, and certain of their derivatives in THF at 25°C to give enol borinates, which can be hydrolyzed to aldehydes or ketones.[725] The water may be present from the beginning, so the reaction can be run in one laboratory step. Since the boranes can be prepared from alkenes (15-16), this reaction provides a means of lengthening a carbon chain by three or four carbons, respectively. Compounds containing a terminal alkyl group, such as crotonaldehyde ($CH_3CH{=}CHCHO$) and 3-penten-2-one, fail to react under these conditions, as does acrylonitrile, but these compounds can be induced to react by the slow and controlled addition of O_2 or by initiation with peroxides or UV light.[726] A disadvantage is that only one of the three R groups



70

of R_3B adds to the substrate, so that the other two are wasted. This difficulty is overcome by the use of a |3-alkyl borinate such as 70,[727] which can be prepared as shown. Compound 70 (R = *tert*-butyl) can be made by treatment of 70 (R = OMe) with *t*-BuLi. The use of this reagent permits *tert*-butyl groups to be added. (3-1-Alkenyl-9-BBN compounds β-RCH=CR′-9-BBN (prepared by treatment of alkynes with 9-BBN or of RCH=CR'Li with β-methoxy-9-BBN[728]) add to methyl vinyl ketones to give, after hydrolysis, y,5-unsaturated ketones,[729] though β-R-9-BBN, where R = a saturated group, are not useful here, because the R group of these reagents does not preferentially add to the substrate.[726] The corresponding (3-1-alkynyl-9-BBN compounds also give the reaction.[730] Like the three substrates mentioned above, 3-butyn-2-one fails to react in the absence of air but undergoes the reaction when exposed to a slow stream of air:[731]



71 72

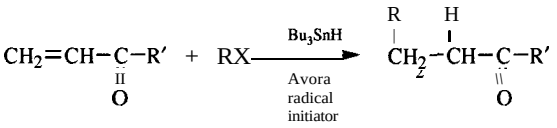
Since the product, 71, is an α,β-unsaturated ketone, it can be made to react with another BR_3, the same or different, to produce a wide variety of ketones (72).

Vinyl boranes add to conjugated ketones in the presence of a rhodium catalyst (with high asymmetric induction in the presence of BINAP).[732] Alkynyl-boranes also add to conjugated ketones, in the presence of BF_3.[733]

The fact that these reactions are catalyzed by free-radical initiators and inhibited by galvinoxyl (a free-radical inhibitor)[734] indicates that free-radical mechanisms are involved.

15-26 *The Addition of Tin and Mercury Hydrides to Activated Double Bonds*

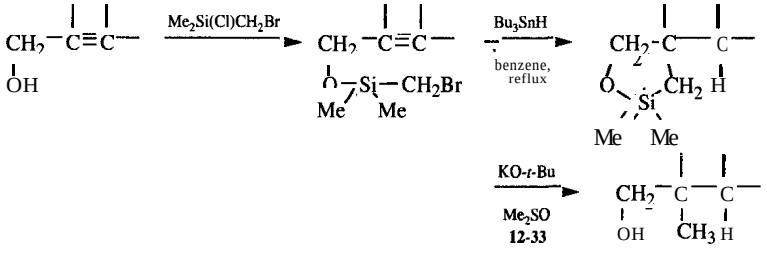
HYDRO-ALKYL-ADDITION



In a reaction similar to **15-25,** alkyl groups can be added to alkenes activated by such groups as COR', COOR', CN, and even Ph.[735] In the method illustrated above, the R group comes from an alkyl halide (R = primary, secondary, or tertiary alkyl; X = Br or I) and the hydrogen from the tin hydride. Organomercury hydrides (RHgH), generated *in situ* from RHgX and $NaBH_4$, can also be used.[736] When the tin method is used, Bu_3SnH can also be generated in a similar way, from R_3SnX and $NaBH_4$. The tin method has a broader scope (e.g., it can be used on $CH_2{=}CCl_2$), but the mercury method uses milder reaction conditions. Like **15-25,** these additions have free-radical mechanisms. The reaction has been used for free-radical cyclizations of the type discussed on page 978.[737] Such cyclizations normally give predominant formation of 15-membered rings, but large rings (11–20 members) have also been synthesized by this reaction.[738]

Free-radical addition of an aryl group and a hydrogen has been achieved by treatment of activated alkenes with a diazonium salt and $TiCl_3$.[739]

In a related reaction, a methylgroup and a hydrogen can be added indirectly to the double bond of an otherwise unactivated allylic alcohol in this manner:[740]

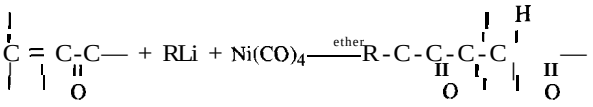


This procedure has been used to introduce angular methyl groups (methyl groups at the bridgeheads of fused rings).[741]

OS **VII,** 105.

15-27 *Acylation of Activated Double Bonds and of Triple Bonds*

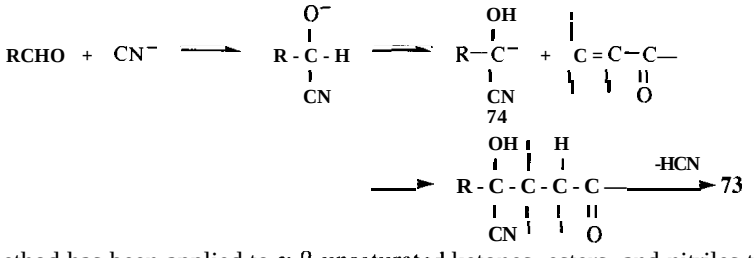
HYDRO-ACYL-ADDITION



73

An acyl group can be introduced into the 4 position of an α,β-unsaturated ketone by treatment with an organolithium compound and nickel carbonyl.[742] The product is a 1,4-diketone (73). The R group may be aryl or primary alkyl. The reaction can also be applied to alkynes, which need not be activated, in which case 2 mol add and the product is also a 1,4-diketone, (e.g., $R'C{\equiv}CH \rightarrow RCOCHR'CH_2COR$.[743] In a different procedure, α,β-unsaturated ketones and aldehydes are acylated by treatment at −110°C with $R_2(CN)CuLi_2$ and CO. This method is successful for R = primary, secondary, and tertiary alkyl.[744] For secondary and tertiary groups, R(CN)CuLi (which does not waste an R group) can be used instead.[745]

Another method involves treatment with an aldehyde and cyanide ion (see **16-51**) in a polar aprotic solvent such as DMF or Me_2SO.[746]



This method has been applied to α,β-unsaturated ketones, esters, and nitriles to give the corresponding 1,4-diketones, γ-keto esters, and γ-keto nitriles, respectively (see also **16-54**). The ion **74** is a synthon for the unavailable $R^{\theta}C{=}O$ anion (see also p. 553); it is a masked $R^{\theta}C{=}O$ anion. Other masked carbanions that have been used in this reaction are the $RC^{\theta}(CN)NR$ ion,[747] the $EtSC^{\theta}RSOEt$ ion[748] (see p. 553), the $CH_2{=}C^{\theta}OEt$ ion,[749] $CH_2{=}C(OEt)Cu_2Li$,[750] $CH_2{=}CMe(SiMe_3)$,[750] and the $RC^{\theta}(OCHMeOEt)CN$ ion[751] (see p. 557). In the last case, best results are obtained when R is a vinylic group. Anions of 1,3-dithianes (**10-107**) do not give 1,4 addition to these substrates (except in the presence of HMPA, see **15-24**) but add 1,2 to the C=O group instead (**16-41**).

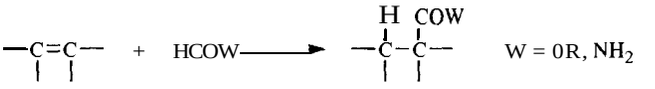
In another procedure, acyl radicals derived from phenyl selenoesters ArCOSePh (by treatment of them with Bu_3SnH) add to α,β-unsaturated esters and nitriles to give γ-keto esters and γ-keto nitriles, respectively.[752]

OS **VI,** 866; **VIII,** 620.

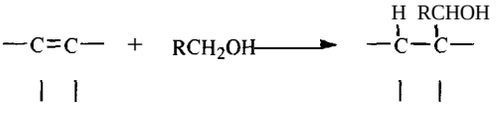
15-28 *Addition of Alcohols, Amines, Carboxylic Esters, Aldehydes, and so on*

HYDRO-ACYL-ADDITION, AND SO ON

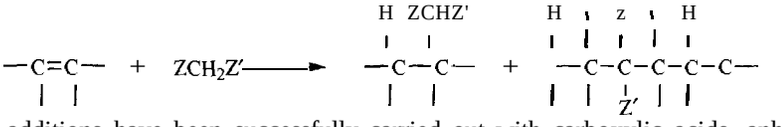
Aldehydes, formates, primary, and secondary alcohols, amines, ethers, alkyl halides, compounds of the type Z—CH2—Z′, and a few other compounds add to double bonds in the presence of free-radical initiators.[753] This is formally the addition of RH to a double bond, but the "R" is not just any carbon but one connected to an oxygen or a nitrogen, a halogen, or to two Z groups (defined as on p. 548). The addition of aldehydes is illustrated above. Formates and formamides[754] add similarly:



Alcohols, ethers, amines, and alkyl halides add as follows (shown for alcohols):

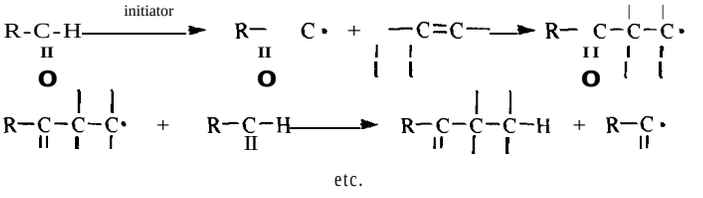


The ZCH2Z′ compounds react at the carbon bearing the active hydrogen:[755]



Similar additions have been successfully carried out with carboxylic acids, anhydrides,[756] acyl halides, carboxylic esters, nitriles, and other types of compounds.[757]

These reactions are not successful when the alkene contains electron-withdrawing groups such as halo or carbonyl groups. A free-radical initiator is required,[758] usually peroxides or UV light. The mechanism is illustrated for aldehydes but is similar for the other compounds:



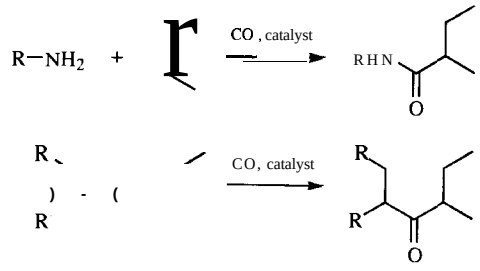
Polymers are often side products. Photochemical addition of aldehyde to conjugated C=C units can be efficient when a triplet sensitizer (p. 316) such as benzophenone is used.[759]

Similar reactions have been carried out on acetylene.[760] Aldehydes add to alkynes in the presence of a rhodium catalyst to give conjugated ketones.[761] In a cyclic version of the addition of aldehydes, 4-pentenal was converted to cyclopentanone with a rhodium-complex catalyst.[762] In the presence of a palladium catalyst, a tosylamide group added to an alkene unit to generate *N*-tosylpyrrolidine derivatives.[763]

OS IV, 430; V, 93; VI, 587, 615.

15-29 *Carbonylation of double and Triple Bonds*

ALKYL OR AMINO-CARBONYL-ADDITION



In the presence of certain metal catalysts, alkenes and alkynes can be carbonylated or carboxylated. An intramolecular carbonylation converted an alkene-alkyne to a bicyclic conjugated ketone.[764] Reaction of a molecule containing an amine and an alkene unit was carboxylated with CO in the presence of a palladium catalyst to give a lactam.[765] A similar reaction with a molecule containing an amine and an alkyne also generated a lactam, in the presence of CO and a rhodium catalyst.[766]

15-30 *Hydrocarboxylation*

HYDRO-CARBOXY-ADDITION

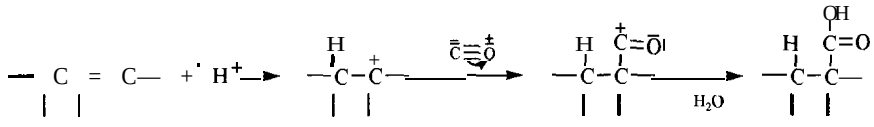
The acid-catalyzed hydrocarboxylation of alkenes (the *Koch reaction)* can be performed in a number of ways.[767] In one method, the alkene is treated with carbon monoxide and water at 100-350°C and 500-1000 atm pressure with a mineral-acid catalyst. However, the reaction can also be performed under milder conditions. If the alkene is first treated with CO and catalyst, and then water is added, the reaction can be accomplished at 0-50°C and 1-100 atm. If formic acid is used as the source of both the CO and the water, the reaction can be carried out at room temperature and atmospheric pressure.[768] The formic acid procedure is called the *Koch-Haaf reaction* (the Koch-Haaf reaction can also be applied to alcohols, see **10-113).** Nearly all alkenes can be hydrocarboxylated by one or more of these procedures. However, conjugated dienes are polymerized instead. Hydrocarboxylation can also be accomplished under mild conditions (160°C and 50 atm) by the use of nickel carbonyl as catalyst. This is more often applied to triple bonds to give α,β-unsaturated acids, in which cases the conditions are milder still. Acid catalysts are used along with the nickel carbonyl, but basic catalysts can also be employed.[769] Other metallic salts and complexes, for example, bis(triphenylphosphine)palladium dichloride, $(Ph_3P)_2PdCl_2$,[770] have also been used. This has been done enantioselectively, with moderate-to-high optical yields, by the use of an optically active palladium-complex catalyst.[771] Dienes react with Cp_2TiCl_2/RMgCl and then with Me_2NCOCl to give amides.[772] In the presence of formic acid, CO, and palladium

acids can similarly be formed.[773] Alkenes also react with $Fe(CO)_5$ and CO to give carboxylic acids.[774]

Triple bonds give unsaturated acids and saturated dicarboxylic acids when treated with carbon dioxide and an electrically reduced nickel complex catalyst.[775] Alkynes also react with $NaHFe(CO)_4$, followed by $CuCl_2{\cdot}2\ H_2O$, to give alkenyl-acid derivatives.[776] A related reaction with CO and palladium catalysts in the presence of $SnCl_2$ also leads to conjugated acid derivatives.[777]

With any method, if the alkene contains a functional group such as OH, NH_2, or $CONH_2$, the corresponding lactone (10-23), lactam (10-57), or cyclic imide may be the product.[778] Amines add to allenes, in the presence of CO and a palladium catalyst, to form conjugated amides.[779] Hept-6-en-2-one reacts with $Cp_2Ti(PMe_3)_2$, in the presence of C, to give a bicyclic lactone, for example.[780] When 2-allylphenol reacts with CO/H_2, in the presence of a palladium catalyst, the product is also a bicyclic lactone.[781] Allylic alcohols generate lactones in the presence of CO and a ruthenium catalyst.[782] Benzylic alcohols add to alkynes in the presence of rhodium catalysts and CO to give lactones.[783]

When acid catalysts are employed, in the absence of nickel carbonyl, the mechanism[784] involves initial attack by a proton, followed by attack of the resulting carbocation on carbon monoxide to give an acyl cation, which, with water, gives the product:



Therefore, Markovnikov's rule is followed, and carbon skeleton rearrangements and double-bond isomerizations (prior to attack by CO) are frequent.

For the nickel carbonyl reaction, the addition is syn for both alkenes and alkynes.[785] The following is the accepted mechanism:[785]

Step 1 $Ni(CO)_4 \longrightarrow Ni(CO)_3 + CO$

Step 2 $-C{=}C- + Ni(CO)_3 \longrightarrow -C(-Ni(CO)_3)-C-$

Step 3 $-C(-Ni(CO)_3)-C- + H^+ \longrightarrow -C(H)-C(-Ni(CO)_3)-$

Step 4 $-C(H)-C(-Ni(CO)_3)- \longrightarrow -C(H)-C(-C(=O)-Ni(CO)_2)-$

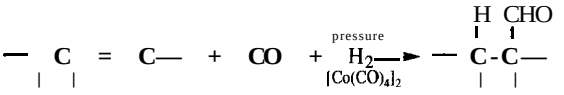
Step 5 $-C(H)-C(-C(=O)-Ni(CO)_2)- \xrightarrow{H_2O} -C(H)-C(-C(=O)-OH)-$

Step 3 is an electrophilic substitution. The principal step of the mechanism, step 4, is a rearrangement.

In either the acid catalysis or the nickel carbonyl (or other metallic catalyst) method, if alcohols, thiols, amines, etc. are used instead of water, the product is the corresponding ester, thiol ester, or amide, instead of the carboxylic acid.

15-31 *Hydroformylation*

HYDRO-FORMYL-ADDITION



Alkenes can be hydroformylated[786] by treatment with carbon monoxide and hydrogen over a catalyst. The most common catalysts are cobalt carbonyls and rhodium complexes [e.g., hydridocarbonyltris(triphenylphosphine)rhodium],[787] but other transition metal compounds have also been used. Cobalt catalysts are less active than the rhodium type, and catalysts of other metals are less active still.[788] Commercially, this is called the *oxo process*, but it can be carried out in the laboratory in an ordinary hydrogenation apparatus. The order of reactivity is straigh t-chain terminal alkenes > straight-chain internal alkenes > branched-chain alkenes. With terminal alkenes, for example, the aldehyde unit is formed on both the primary and secondary carbon, but proper choice of catalyst and additive leads to selectivity for the secondary product[789] or primary product.[790] Conjugated dienes give dialdehydes when rhodium catalysts are used[791] but saturated monoaldehydes (the second double bond is reduced) with cobalt carbonyls. The 1,4- and 1,5-dienes may give cyclic ketones.[792] Many functional groups (e.g., OH, CHO, COOR, CN) can be present in the molecule, though halogens usually interfere. Cyclization to prolinal derivatives has been reported with allylic amines.[793] Hydroformylation of triple bonds proceeds very slowly, and few examples have been reported.[794] Good yields for hydroformylation have been reported using rhodium catalysts in the presence of certain other additives.[795] Among the side reactions are the aldol reaction (16-38), acetal formation, the Tishchenko reaction (19-61), and polymerization. Stereoselective syn addition has been reported.[796] Asymmetric hydroformylation has been accomplished with a chiral catalyst,[797] and in the presence of chiral additives.[798]

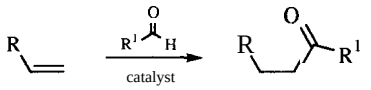
When dicobalt octacarbonyl, $[Co(CO)_4]_2$, is the catalyst, the species that actually adds to the double bond is tricarbonylhydrocobalt, $HCo(CO)_3$.[799] Carbonylation, $RCo(CO)_3 + CO \rightarrow RCo(CO)_4$, takes place, followed by a rearrangement and a reduction of the C—Co bond, similar to steps 4 and 5 of the nickel carbonyl mechanism shown in 15-30. The reducing agent in the reduction step is tetracarbonylhydrocobalt $HCo(CO)_4$,[800] or, under some conditions, H_2.[801] When $HCo(CO)_4$ was the agent used to hydroformylate styrene, the observation of CIDNP indicated that the mechanism is different, and involves free radicals.[802] Alcohols can be obtained by allowing the reduction to continue after all the carbon monoxide is

used up. It has been shown[803] that the formation of alcohols is a second step, occurring after the formation of aldehydes, and that $HCo(CO)_3$ is the reducing agent.

OS VI, 338.

15-32 *Addition of Aldehydes*

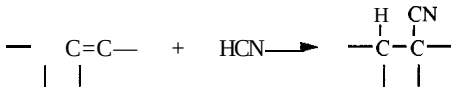
ALKYL-CARBONYL-ADDITION



In the presence of metal catalysts such as rhodium compounds,[804] aldehydes can add directly to alkenes to form ketones. The reaction of ω-alkenyl aldehydes with rhodium catalyst leads to cyclic ketones,[805] with high enantioselectivity if chiral ligands are employed. Aldehydes also add to vinyl esters in the presence of hyponitrites and thioglycolates.[806]

15-33 *Addition of HCN*

HYDRO-CYANO-ADDITION



Ordinary alkenes do not react with HCN, but polyhalo alkenes and alkenes of the form C=C–Z add HCN to give nitriles.[807] The reaction is therefore a nucleophilic addition and is base catalyzed. When Z is COR or, more especially, CHO, 1,2 addition **(16-52)** is an important competing reaction and may be the only reaction. Triple bonds react very well when catalyzed by an aqueous solution of CuCl, NH4C1, and HC1 or by Ni or Pd compounds.[808] The HCN can be generated *in situ* from acetone cyanohydrin (see **16-51),** avoiding the use of the poisonous HCN.[809] We can add 1 or 2 mol of HCN to a triple bond, since the initial product is a Michael-type substrate. Acrylonitrile is commercially prepared this way, by the addition of HCN to acetylene. Alkylaluminum cyanides (e.g., Et_2AlCN) or mixtures of HCN and trialkylalanes R_3Al are especially good reagents for conjugate addition of HCN[810] to α,β-unsaturated ketones and α,β-unsaturated acyl halides. Hydrogen cyanide can be added to ordinary alkenes in the presence of dicobalt octacarbonyl[811] or certain other transition metal compounds.[812] An indirect method for the addition of HCN to ordinary alkenes uses an isocyanide RNC and Schwartz's reagent (see **15-17**); this method gives anti-Markovnikov addition.[813] *tert*-Butyl isocyanide and $TiCl_4$ have been used to add HCN to C=C–Z alkenes.[814] Pretreatment with NaI/Me_3SiCl followed by CuCN converts alkynes to vinyl nitriles.[815]

OS I, 451; II, 498; **III,** 615; IV, 392, 393, 804; V, 239, 572; VI, 14.

For addition of ArH, see **11-12** (Friedel-Crafts alkylation).

15-34 *Addition of Silanes*

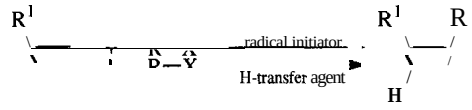
SILYL-HYDRO-ADDITION

Dienes react with zirconium compounds and silanes to produce cyclic compounds in which the silyl group has also added to one C=C unit.[816] Other catalysts such as $Cp_2Y[CH(TMS)_2]$ also allow silanes to add to alkenes, with high anti-Markovnikov selectivity.[817] Silanes add to alkynes in the presence of BEt_3 to give the corresponding vinyl silane.[818] Rhodium compounds allow silanes to add to enamides to give the α-silylamide.[819] Allylsilanes add to certain allylic alcohols in the presence of Me_3SiOTf, via a S_N2' like reaction, to give dienes.[820] Silanes also add to alkenes under radical conditions (using AIBN) with high anti-Markovnikov selectivity.[821]

Vinyl silanes add to conjugated carbonyl compounds in the presence of a ruthenium catalyst.[822]

15-35 *Radical Addition*[*23]

ALKYL-HYDRO-ADDITION



Radical addition to alkenes is usually difficult, except when addition occurs to conjugated carbonyl compounds (15-21). An important exception involves radicals bearing a heteroatom α to the carbon bearing the radical center. These radical are much more stable and can add to alkenes, usually with anti-Markovnikov orientation, as in the radical induced addition of HBr to alkenes (**15-2**).[824] Examples of this type of reaction include the use of alcohol-, ester-,[825] amino-, and aldehyde-stabilized radicals.[324] The radical generated from $(EtO)_2POCH_2Br$ adds to alkenes to generate a new phosphonate ester.[826] Other radicals can add to alkenes. The rate constant for the addition of methyl radicals to alkenes has been studied,[827] and the rate of radical additions to alkenes in general has also been studied.[828] Alkynes are generally less reactive than alkenes in radical coupling reactions.[829] Nonradical nucleophiles usually react faster with alkynes than with alkenes, however.[830]

15-36 *Radical Cyclization*[831]

ALKYL-HYDRO-ADDITION

ω-Haloalkenes generate radicals upon treatment with reagents such as AIBN, or under photolysis conditions,[832] and the radical carbon adds to the alkene to form cyclic compounds.[833] A mixture of a Grignard reagent and $CoCl_2$ has also been used to initiate aryl radical cyclizations.[834] A hydrogen-transfer agent[835] is usually required to quench the radical reaction, and reduction of the halogen may be faster than the cyclization process. Radical rearrangements can also diminish the yield of the desired product.[836] Given a choice between a larger and a smaller ring, radical cyclization generally gives the smaller ring,[837] but not always.[838] Electrochemically generated radicals also cyclize.[839]

Both phenylthio and phenylseleno groups can be used as "leaving groups" for radical cyclization, where sulfur or selenium atom transfer leads to formation of the radical. Radical cyclization reaction often proceeds with high diastereoselectivity and high asymmetric induction when chiral precursors are used. Internal alkynes are good substrates for radical cyclization,[840] but terminal alkynes tend to give mixtures of *exo:endo-dig* products (p. 282).[841] N-alkenyl pyridinium salts, with ortho-halogen substituents generate the aryl radical with Bu_3SnH/AIBN, which cyclizes on the pedant alkene unit.[842] Cyclization of vinyl radicals[843] and allenyl radicals[844] are also well known. Ring expansion during radical cyclization is possible when the terminal intermediate is a cyclobutylcarbinyl radical.[845] In radical cyclization to form large rings, 1,5- and 1,9-hydrogen atom abstractions can pose a problem[846]

Radical cyclization is compatible with the presence of other functional groups. Treatment of $XCH_2CON(R)-C(R^1)=CH_2$ derivatives (X = Cl, Br, I) with Ph3SnH and AIBN led to formation of a lactam via radical cyclization.[847] Cyclization of *N*-iodoethyl-5-vinyl-2-pyrrolidinone led to the corresponding bicyclic lactam,[848] and there are other examples of radical cyclization with molecules containing a lactam unit[849] or an amide unit.[850] Radical cyclization occurs with enamines as well.[851] Photochemical irradiation of *N,N*-diallyl acrylamide leads to formation of a lactam ring, and in this case thiophenol was added to generate the phenylthio derivative.[852] Phenylseleno N-allylamines lead to cyclic amines.[853] ω-Iodo acrylate esters cyclize to form lactones.[854]

Acyl radicals can be generated and they cyclize in the usual manner. A polyene-cyclization reaction generated four rings, initiating the sequence by treatment of a phenylseleno ester with Bu_3SnH/AIBN to form the acyl radical, which added to the first alkene unit.[855] The newly formed carbon radical added to the next alkene, and so on. Acyl radicals generated from Ts(R)NCOSePh derivatives cyclize to form lactams.[856]

The attacking radical need not always be at carbon. Amidyl radical are known and give cyclization reactions.[857] Aminyl radical cyclizations have been reported.[858] Oxygen radical can be generated under photochemical conditions, and they add to alkenes in a normal manner.[859]

In cases where hydrogen atom transfer gives primarily reduced products, Bu_3Sn-$SnBu_3$ under photochemical generates the radical that can cyclize, but a halogen atom transfer agent such as iodoethane is usually present (see 15-44).

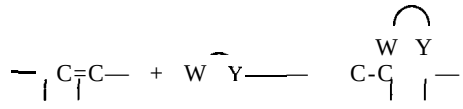
The compound ArX can be added across double bonds, in a free-radical process, by treatment of alkenes with diazonium salts, although Meerwein arylation (substi-

tution) (14-18) competes.[860] This addition can be either 1,2 or 1,4 with conjugated dienes.[861] Addition of ArX can also be accomplished by treatment with an arylmercury halide ArHgX in the presence of CuX_2, LiX, and a palladium compound catalyst, usually Li_2PdCl_4.[862] In this case also, substitution (14-19) is a side reaction. Yields of addition product are increased by increasing the concentration of CuX_2. Palladium compounds also catalyze the addition of allylic halides to alkynes.[863]

Radicals are known to open cyclopropane derivatives, although high dilution techniques are often required. The three-membered ring is opened as the new ring forms, generating a new methyl group.[864]

Reactions in Which Hydrogen Adds to Neither Side

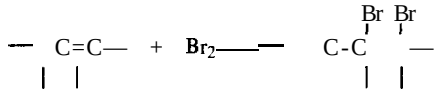
Some of these reactions are *cycloadditions* (Reactions **15-48**, **15-49**, 15-53, and 15-56-15-64). In such cases addition to the multiple bond closes a ring:



A. *Halogen on One or Both Sides*

15-37 *Halogenation of Double and Triple Bonds (Addition of Halogen, Halogen)*

DIHALO-ADDITION



Most double bonds are easily halogenated[865] with bromine, chlorine, or interhalogen compounds.[866] Substitution can compete with addition in some cases.[867] Iodination has also been accomplished, but the reaction is slower.[868] Under free-radical conditions, iodination proceeds more easily.[869] However, *vic*-diiodides are generally unstable and tend to revert to iodine and the alkene. The order of activity for some of the reagents is $BrCl > ICl$[870] $> Br_2 > IBr > I_2$.[871] Mixed halogenations have also been achieved by other methods. Mixtures of Br_2 and Cl_2 have been used to give bromochlorination,[872] as has tetrabutylammonium dichlorobromate (Bu_4NBrCl_2);[873] iodochlorination has been achieved with $KICl_2$,[874] $CuCl_2$, and either I_2, HI, or CdI_2; iodofluorination[875] with mixtures of AgF and I_2;[876] and mixtures of N-bromo amides in anhydrous HF give bromofluorination.[877] Bromo-, iodo-, and chlorofluorination have also been achieved by treatment of the substrate with a solution of Br_2, I_2, or an N-halo amide in polyhydrogen fluoride-pyridine;[878] while

addition of I along with Br, Cl, or F has been accomplished with the reagent bis(pyridine)iodo(I) tetrafluoroborate, $I(Py)_2BF_4$, and Br^-, Cl^-, or F^-, respectively.[879] This reaction (which is also successful for triple bonds[880]) can be extended to addition of I and other nucleophiles (e.g., NCO, OH, OAc, and NO_2).[879]

Under ordinary conditions fluorine itself is too reactive to give simple addition; it attacks other bonds and mixtures are obtained.[881] However, F_2 has been successfully added to certain double bonds in an inert solvent at low temperatures (−78°C), usually by diluting the F_2 gas with Ar or N_2.[882] Addition of fluorine has also been accomplished with other reagents (e.g., *p*-Tol— IF_2/Et_3N·5 HF)[883] and a mixture of PbO_2 and SF_4.[884]

The reaction with bromine is very rapid and is easily carried out at room temperature, although the reaction is reversible under some conditions. In the case of bromine, an alkene·Br_2 complex has been detected in at least one case.[887] Bromine is often used as a test, qualitative or quantitative, for unsaturation.[888] The vast majority of double bonds can be successfully brominated. Even when aldehyde, ketone, amine, so on functions are present in the molecule, they do not interfere, since the reaction with double bonds is faster.

Several other reagents add Cl_2 to double bonds, among them Me_3SiCl–MnO_2,[889] $NaClO_2$/Mn(acac)$_2$/moist Al_2O_3,[890] $BnNEt_3MnO_4$/Me_3SiCl,[891] and $KMnO_4$–oxalyl chloride.[892] A convenient reagent for the addition of Br_2 to a double bond on a small scale is the commercially available pyridinium bromide perbromide $C_5H_5NH^+Br_3^-$.[893] A mixture of decylNMe_3MnO_4 and Me_3SiBr is also an effective reagent.[894] Either Br_2 or Cl_2 can also be added with $CuBr_2$ or $CuCl_2$ in the presence of a compound such as acetonitrile, methanol, or triphenylphosphine.[895]

The mechanism is usually electrophilic (see p. 972), but when free-radical initiators (or UV light) are present, addition can occur by a free-radical mechanism.[896] Once Br· or Cl· radicals are formed, however, substitution may compete (**14-1** and 14-2). This is especially important when the alkene has allylic hydrogens. Under free-radical conditions (UV light) bromine or chlorine adds to the benzene ring to give, respectively, hexabromo- and hexachlorocyclohexane. These are mixtures of stereoisomers (see p. 161).[897]

Conjugated systems give both 1,2 and 1,4 addition.[897] Triple bonds add bromine, though generally more slowly than double bonds (see p. 981). Molecules that contain both double and triple bonds are preferentially attacked at the double bond. Bromine (2 mol) can be added to triple bonds to give tetrabromo products. There is evidence that the addition of the first mole of bromine to a triple bond may take place by a nucleophilic mechanism.[898] Iodine on Al_2O_3 adds to triple bonds to give good yields of 1,2-diiodoalkenes.[899] A mixture of $NaBO_3$ and NaBr adds two bromine atoms across a triple bond.[900] With allenes it is easy to stop the reaction after only 1 mol has added, to give X—C—CX=C.[901] Addition of halogen to ketenes gives α-halo acyl halides, but the yields are not good.

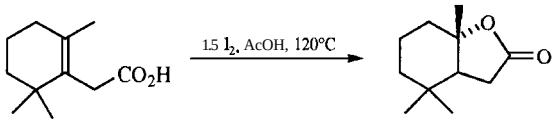
15-38 *Halolactonization and Halolactamization*

HALO-ALKOXYLATION

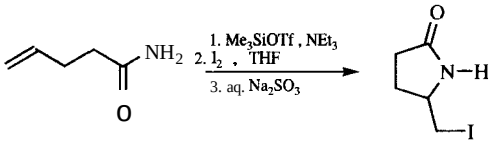
An internal example of the addition of X and OCOR is called *halolactonization.*[902] A typical example is[903]



The most common version of this reaction is known as *iodolactonization*,[904] but bromo lactones and, to a lesser extent, chloro lactones, have also been prepared. In general, addition of the halogen to an alkenyl acid, as shown, leads to the halolactone. Other reagents include $I^+(collidine)_2PF_6^-$,[905] KI/sodium persulfate.[906] Thallium reagents, along with the halogen, have also been used.[907] When done in the presence of a chiral titanium reagent, I_2, and CuO, lactones are formed with good enantioselectivity.[908]

In the case of γ,δ-unsaturated acids, five-membered rings (γ-lactones) are predominantly formed (as shown above; note that Markovnikov's rule is followed), but six-membered and even four-membered lactones have also been made by this procedure. There is a *gem*- dimethyl effect that favors formation of 7–11 membered ring lactones by this procedure.[909]

Formation of halo-lactams by a similar procedure is difficult, but the problems have been overcome. Formation of a triflate followed by treatment with iodine leads to the iodo-lactam, for example[910]

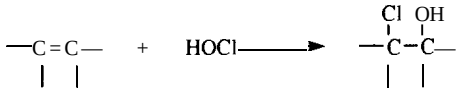


A related cyclization of N-sulfonyl-amino-alkenes and NBS gave the bromo-lactam,[911] and a dichloro-*N,N*-bisallylamide was converted to a dichloro-lactam with $FeCl_2$.[912]

OS IX, 516

15-39 *Addition of Hypohalous Acids and Hypohalites (Addition of Halogen, Oxygen)*

HYDROXY-CHLORO-ADDITION, AND SO ON[913]



The compounds HOCl, HOBr, and HOI can be added to alkenes[914] to produce halohydrins.[915] Both HOBr and HOCl are often generated *in situ* by the reaction between H_2O and Br_2 or Cl_2, respectively. The HOI compound, generated from I_2 and H_2O, also adds to double bonds, if the reaction is carried out in tetramethylene sulfone–$CHCl_3$[916] or if an oxidizing agent such as HIO_3 is present.[917] Iodine and cerium sulfate in aqueous acetonitrile also generates iodohydrins,[918] as does $NaIO_4$ with sodium bisulfite.[919] The HOF compound has also been added, but this reagent is difficult to prepare in a pure state and *detonations occur.*[920] The HOBr compound can also be conveniently added by the use of a reagent consisting of an N-bromo amide (e.g., NBS or *N*-bromoacetamide) and a small amount of water in a solvent such as Me_2SO or dioxane.[921] An especially powerful reagent for HOCl addition is fen-butyl hydroperoxide (or di-*tert*-butyl peroxide) along with $TiCl_4$. This reaction is generally complete within 15 min at -78°C.[922] Chlorohydrins can be conveniently prepared by treatment of the alkene with Chloramine T ($TsNCl^-Na^+$)[923] in acetone-water.[924] The HOI compound can be added by treatment of alkenes with periodic acid and $NaHSO_3$.[925]

The mechanism of HOX addition is electrophilic, with initial attack by the positive halogen end of the HOX dipole. Following Markovnikov's rule, the positive halogen goes to the side of the double bond that has more hydrogens. The resulting carbocation (or bromonium or iodonium ion) reacts with OH^- or H_2O to give the product. If the substrate is treated with Br_2 or Cl_2 (or another source of positive halogen such as NBS) in an alcohol or a carboxylic acid solvent, it is possible to obtain, directly $X-\overset{|}{C}-\overset{|}{C}-OR$ or $X-\overset{|}{C}-\overset{|}{C}-OCOR$, respectively (see also **15-46**).[926] Even the weak nucleophile $CF_3SO_2O^-$ can participate in the second step: The addition of Cl_2 or Br_2 to alkenes in the presence of this ion resulted in the formation of some β-haloalkyl triflates.[927] There is evidence that the mechanism with Cl_2 and H_2O is different from that with HOCl.[928] Both HOCl and HOBr can be added to triple bonds to give dihalo carbonyl compounds $-CX_2-CO-$.

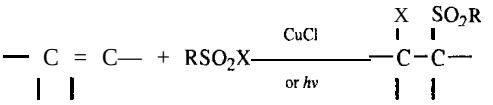
tert-Butyl hypochlorite (Me_3COCl), hypobromite, and hypoiodite[929] add to double bonds to give halogenated *tert*-butyl ethers, $X-C-C-OCMe_3$. This is a convenient method for the preparation of tertiary ethers. Iodine and ethanol convert some alkenes to iodo-ethers.[930] When Me_3COCl or Me_3COBr is added to alkenes in the presence of excess ROH, the ether produced is $X-\overset{|}{C}-\overset{|}{C}-OR$.[931] Vinylic ethers give β-halo acetals.[932] A mixture of Cl_2 and SO_3 at -78°C converts alkenes to 2-chloro chlorosulfates ($ClCHRCHROSO_2Cl$), which are stable compounds.[933] Chlorine acetate [solutions of which are prepared by treating Cl_2 with $Hg(OAc)_2$ in an appropriate solvent] adds to alkenes to give acetoxy chlorides.[934] Acetoxy fluorides have been obtained by treatment of alkenes with CH3COOF.[935]

For a method of iodoacetyl addition, see **15-46.**

OS I, 158; **IV,** 130, 157; **VI,** 184, 361, 560; **VII,** 164; **VIII, 5, 9.**

15-40 *Addition of Sulfur Compounds (Addition of Halogen, Sulfur)*

ALKYLSULFONYL-CHLORO-ADDITION, AND SO ON[936]

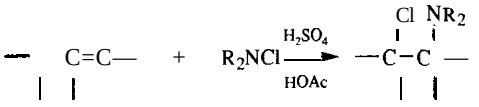


Sulfonyl halides add to double bonds, to give P-halo sulfones, in the presence of free-radical initiators or UV light. A particularly good catalyst is cuprous chloride.[937] Triple bonds behave similarly, to give β-halo-α,β-unsaturated sulfones.[938] In a similar reaction, sulfenyl chlorides, RSC1, give P-halo thioethers.[939] The latter may be free-radical or electrophilic additions, depending on conditions. The addition of MeS and Cl has also been accomplished by treating the alkene with Me_3SiCl and Me_2SO.[940] The use of Me_3SiBr and Me_2SO does not give this result; dibromides **(15-37)** are formed instead. β-Iodo thiocyanates can be prepared from alkenes by treatment with I_2 and isothiocyanatotributylstannane (Bu_3SnNCS).[941] Bromothiocyanation can be accomplished with Br_2 and thallium(I) thiocyanate.[942] β-Halo disulfides, formed by addition of arenethiosulfenyl chlorides to double-bond compounds, are easily converted to thiiranes by treatment with sodium amide or sodium sulfide.[943]

OS **VIII,** 212. See also OS **VII,** 251.

15-41 *Addition of Halogen and an Amino Group (Addition of Halogen, Nitrogen)*

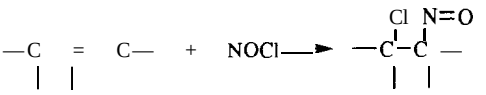
DIALKYLAMINO-CHLORO-ADDITION



The groups R_2N and Cl can be added directly to alkenes, allenes, conjugated dienes, and alkynes, by treatment with dialkyl-*N*-chloroamines and acids.[944] These are free-radical additions, with initial attack by the $R_2NH^{\cdot+}$ radical ion.[945] N-Halo amides (RCONHX) add RCONH and X to double bonds under the influence of UV light or chromous chloride.[946] Amines add to allenes in the presence of a palladium catalyst.[947]

15-42 *Addition of NOX and NO_2X (Addition of Halogen, Nitrogen)*

NITROSO-CHLORO-ADDITION



There are three possible products when NOCl is added to alkenes.[948] The initial product is always the p-halo nitroso compound, but these are stable only if the carbon bearing the nitrogen has no hydrogen. If it has, the nitroso compound tautomerizes to the *oxime*:

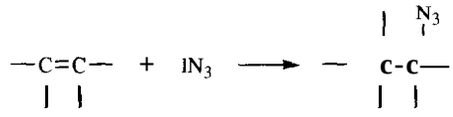
With some alkenes, the initial P-halo nitroso compound is oxidized by the NOCl to a P-halo nitro compound.[949] Many functional groups can be present without interference (e.g., COOH, COOR, CN, OR). The mechanism in most cases is probably simple electrophilic addition, and the addition is usually anti, though syn addition has been reported in some cases.[950] Markovnikov's rule is followed, the positive NO going to the carbon that has more hydrogens.

Nitryl chloride (NO_2Cl) also adds to alkenes, to give P-halo nitro compounds, but this is a free-radical process. The NO_2 goes to the less-substituted carbon.[951] Nitryl chloride also adds to triple bonds to give the expected 1-nitro-2-chloro alkenes.[952] The compound FNO_2 can be added to alkenes[953] by treatment with HF in HNO_3[954] or by addition of the alkene to a solution of nitronium tetrafluoroborate ($NO_2^+BF_4^-$, see **11-2)** in 70% polyhydrogen fluoride-pyridine solution[955] (see also **15-37).**

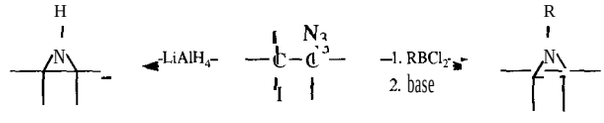
OS **IV,** 711; **V,** 266, 863.

15-43 *Addition of XN_3 (Addition of Halogen, Nitrogen)*

AZIDO-IODO-ADDITION



The addition of iodine azide to double bonds gives p-iodo azides.[956] The addition is stereospecific and anti, suggesting that the mechanism involves a cyclic iodonium ion intermediate.[957] The reaction has been performed on many double-bond compounds, including allenes[958] and α,β-unsaturated ketones. Similar reactions can be performed with BrN_3[959] and ClN_3. 1,4 Addition has been found with acyclic conjugated dienes.[960] In the case of BrN_3, both electrophilic and free-radical mechanisms are important,[961] while with ClN_3 the additions are chiefly free radical.[962] The compound IN_3 also adds to triple bonds to give β-iodo-α,β-unsaturated azides.[963]



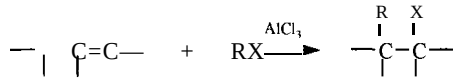
β-Iodo azides can be reduced to aziridines with $LiAlH_4$[964] or converted to N-alkyl- or N-arylaziridines by treatment with an alkyl- or aryldichloroborane fol-

lowed by a base.[965] In both cases the azide is first reduced to the corresponding amine (primary or secondary, respectively) and ring closure (10-44) follows.

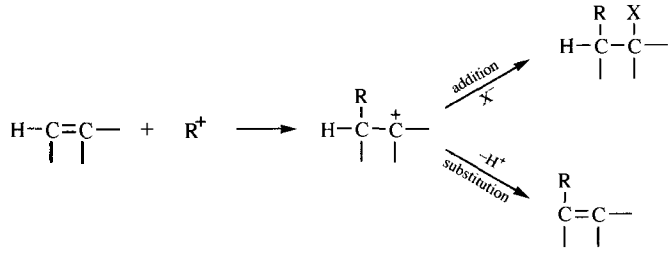
OS VI, 893.

15-44 *Addition of Alkyl Halides (Addition of Halogen, Carbon)*

ALKYL-HALO-ADDITION[654]

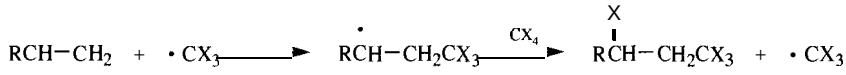


Alkyl halides can be added to alkenes in the presence of a Friedel–Crafts catalyst, most often $AlCl_3$.[966] The yields are best for tertiary R. Secondary R can also be used, but primary R give rearrangement products (as with 11-12). Methyl and ethyl halides, which cannot rearrange, give no reaction at all. The attacking species is the carbocation formed from the alkyl halide and the catalyst (see **11-12**).[967] The addition therefore follows Markovnikov's rule, with the cation going to the carbon with more hydrogens. Substitution is a side reaction, arising from loss of hydrogen from the carbocation formed when the original carbocation attacks the double bond:



Conjugated dienes can add 1,4.[968] Triple bonds also undergo the reaction, to give vinylic halides.[969]

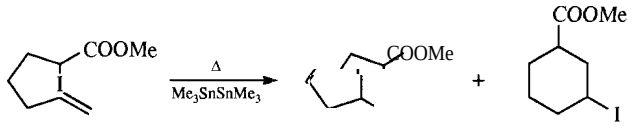
The compounds CCl_4, $BrCCl_3$, ICF_3, and similar simple polyhalo alkanes add to alkenes in good yield.[970] These are free-radical additions and require initiation, for example,[971] by peroxides, metal halides (e.g., $FeCl_2$, CuCl),[972] or UV light. The initial attack is by the carbon, and it goes to the carbon with more hydrogens, as in most free-radical attack:



This type of polyhalo alkane adds to halogenated alkenes in the presence of $AlCl_3$ by an electrophilic mechanism. This is called the *Prins reaction* (not to be confused with the other Prins reaction, 16-53).[973]

α-Iodolactone add to alkenes in the presence of BEt_3/O_2 to give the addition product.[974] Other α-iodoesters add under similar conditions to give the lactone.[975] Iodoesters also add to alkenes in the presence of BEt_3 to give iodo-esters that have not cyclized.[976]

A variant of the free-radical addition method has been used for ring closure. For example, treatment of 75 with the free-radical initiator hexamethylditin gave a mixture of *cis*- and *trans*-*76*, with a small amount of *cis*- and *trans*-**77** (total yield 83%).[977] The reaction has been performed with α-iodo esters, ketones, and malonates.



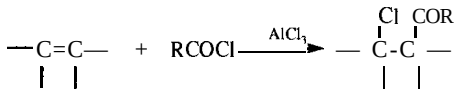
75 cis and trans 76 cis and trans **77**

For another method of adding R and I to a triple bond, see 15-23.

OS II, 312; IV, 727; V, 1076; VI, 21; VII, 290.

15-45 *Addition of Acyl Halides (Addition of Halogen, Carbon)*

ACYL-HALO-ADDITION



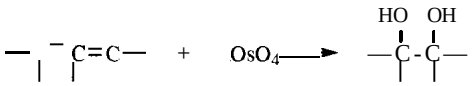
Acyl halides have been added to many alkenes, in the presence of Friedel–Crafts catalysts. The reaction has been applied to straight-chain, branched, and cyclic alkenes, but to very few containing functional groups, other than halogen.[978] The mechanism is similar to that of 15-44, and, as in that case, substitution competes (12-14). Increasing temperature favors substitution,[979] and good yields of addition products can be achieved if the temperature is kept under 0°C. The reaction usually fails with conjugated dienes, since polymerization predominates.[980] Iodo acetates have been formed from alkenes using iodine, $Pb(OAc)_2$ in acetic acid.[981] The reaction can be performed on triple-bond compounds, producing compounds of the form RCO—C=C—Cl.[982] *A fanny l* group and a halogen can be added to triple bonds by treatment with N,N-disubstituted formamides and $POCl_3$ (Vilsmeier conditions, see 11-15).[983]

OS IV, 186; VI, 883; VIII, 254.

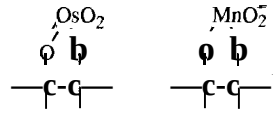
B. *Oxygen, Nitrogen, or Sulfur on One or Both Sides*

15-46 *Hydroxylation (Addition of Oxygen, Oxygen)*

DIHYDROXY-ADDITION



There are many reagents that add two OH groups to a double bond.[984] Osmium tetroxide (OsO_4)[985] and alkaline $KMnO_4$[986] give syn addition from the less-hindered side of the double bond. Less substituted double bonds are oxidized more rapidly than more substituted alkenes.[987] Osmium tetroxide adds rather slowly but almost quantitatively. The cyclic ester (78) is an intermediate and can be isolated,[988] but usually decomposed

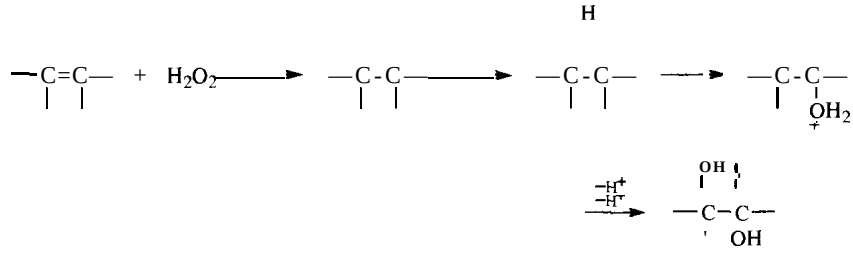


78 79

in solution, with sodium sufite in ethanol or other reagents. Bases catalyze the reaction by coordinating with the ester. The chief drawback to this reaction is that OsO_4 is expensive and highly toxic, so that its use has been limited to small-scale preparations of scarce materials. However, the same result (syn addition) can be accomplished more economically by the use of H_2O_2, with O_sO_4 present in catalytic amounts.[989] tert-Butyl hydroperoxide in alkaline solution,[990] *N*-methylmorpholine-*N*-oxide (NMO),[991] and $K_3Fe(CN)_6$ [992] have been substituted for H_2O_2 in this procedure. Another method uses polymer-bound OsO_4 [993] and OsO_4 has been microencapsulated and shown to give the diol in the presence of NMO.[994]

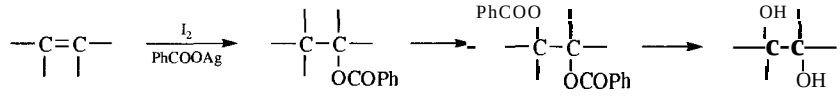
Potassium permanganate is a strong oxidizing agent and can oxidize the glycols[995] that are the products of this reaction (see 19-7 and 19-10). In acid and neutral solution it always does so; hence it is not feasible to prepare glycols in this manner. Glycols can be prepared with alkaline[996] permanganate, but the conditions must be mild. Even so, yields are seldom ~ 50%, though they can be improved with phase-transfer catalysis[997] or increased stirring.[998] The use of ultrasound with permanganate dihydroxylation has resulted in good yields of the diol.[999] There has been much speculation that, as with OsO_4, cyclic esters (79) are intermediates, and there is evidence for them.[1000] This reaction is the basis of the *Baeyer test* for the presence of double bonds.

Anti hydroxylation can be achieved by treatment with H_2O_2 and formic acid. In this case, epoxidation (15-48) occurs first, followed by an S_N2 reaction, which results in overall anti addition:



The same result can be achieved in one step with *m*-chloroperoxybenzoic acid and water.[1001] Overall anti addition can also be achieved by the method of Prévost. In

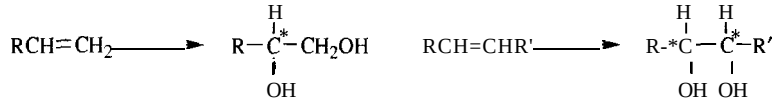
this method, the alkene is treated with iodine and silver benzoate in a 1:2 molar ratio. The initial addition is anti and results in a β-halo benzoate (80). These can be isolated, and this represents a method of addition of IOCOPh. However, under the normal reaction conditions, the iodine is replaced by a second PhCOO group. This is a nucleophilic substitution reaction, and it operates by the neighboring-group mechanism (p. 403), so the groups are still anti:



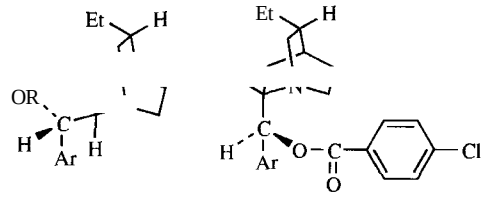
80

Hydrolysis of the ester does not change the configuration. Woodward's method is similar, but results in overall syn hydroxylation.[1002] The alkene is treated with iodine and silver acetate in a 1:1 molar ratio in acetic acid containing water. Here again, the initial product is a (3-halo ester; the addition is anti and a nucleophilic replacement of the iodine occurs. However, in the presence of water, neighboring-group participation is prevented or greatly decreased by solvation of the ester function, and the mechanism is the normal S_N2 process,[1003] so the monoacetate is syn and hydrolysis gives the glycol that is the product of overall syn addition. Although the Woodward method results in overall syn addition, the product may be different from that with OsO_4 or $KMnO_4$, since the overall syn process is from the more hindered side of the alkene.[1004] Both the Prevost and the Woodward methods[1005] have also been carried out in high yields with thallium(I) acetate and thallium(I) benzoate instead of the silver carboxylates.[1006]

With suitable substrates, addition of two OH groups creates either one or two new chiral centers:

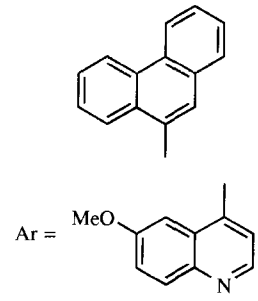


Addition to alkenes of the form RCH=CH2 has been made enantioselective, and addition to RCH=CHR'both diastereoselective[1007] enantioselective,[1008] by using optically active amines, such as 81, 82 (derivatives of the naturally occurring quinine



81
9′-Phenanthryl ether of dihydroquinidine

82
Dihydroquinine *p*-chlorobenzoate



and quinuclidine),[1009] along with OsO_4, in what is called *Sharpless asymmetric dihydroxylation*.[1010] Other chiral ligands[1011] have also been used, as well as polymer-[1012] and silica-bound[1013] *Cinchona* alkaloids. These amines bind to the OsO_4 *in situ* as chiral ligands, causing it to add asymmetrically.[1014] This has been done both with the stoichiometric and with the catalytic method.[1015] The catalytic method has been extended to conjugated dienes, which give tetrahydroxy products diastereoselectively,[1016] and to conjugated ketones.[1017] Asymmetric dihydroxylation has also been reported with chiral alkenes.[1018]

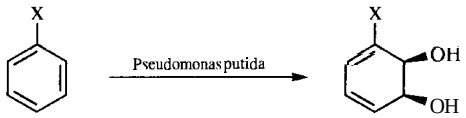
Ligands 81 and 82 not only cause enantioselective addition, but also accelerate the reaction, so that they may be useful even where enantioselective addition is not required.[1019] Although 81 and 82 are not enantiomers, they give enantioselective addition to a given alkene in the opposite sense; for example, styrene predominantly gave the *(R)* diol with 81, and the (S) diol with 82.[1020] Enantioselective and diastereoselective addition have also been achieved by using preformed derivatives of OsO_4, already containing chiral ligands,[1021] and by the use of OsO_4 on alkenes that have a chiral group elsewhere in the molecule.[1022]

Alkenes can also be oxidized with metallic acetates such as lead tetraacetate[1023] or thallium(III) acetate[1024] to give bis-acetates of glycols.[1025] Oxidizing agents such as benzoquinone, MnO_2, or $O2$, along with palladium acetate, have been used to convert conjugated dienes to l,4-diacetoxy-2-alkenes (1,4 addition).[1026]

OS II, 307; III, 217; IV, 317; V, 647; VI, 196, 342, 348;IX, 251, 383.

15-47 *Dihydroxylation of Aromatic Rings*

DIHYDROXY-ADDITION

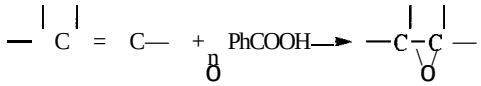


One π-bond of an aromatic ring can be converted to a cyclohexadiene 1,2-diol by reaction with enzymes associated with *P. putida*.[1027] A variety of substituted aromatic compounds can be oxidized, including bromobenzene, chlorobenzene,[1028] and toluene.[1029] In these latter cases, introduction of the hydroxyl groups generates a chiral molecule that can be used as a template for asymmetric syntheses.[1030]

OS 76, 77

15-48 *Epoxidation (Addition of Oxygen, Oxygen)*

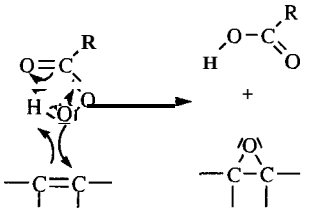
EPI-OXY-ADDITION



Alkenes can be epoxidized with any of a number of peroxyacids,[1031] of which *m*-chloroperoxybenzoic has been the most often used. The reaction, called the

Prilezhaev reaction, has wide utility.[1032] Alkyl, aryl, hydroxyl, ester, and other groups may be present, though not amino groups, since these are affected by the reagent. Electron-donating groups increase the rate, and the reaction is particularly rapid with tetraalkyl alkenes. Conditions are mild and yields are high. Other peroxyacids, especially peroxyacetic and peroxybenzoic, are also used; trifluoroperoxyacetic acid[1033] and 3,15-dinitroperoxybenzoic acid[1034] are particularly reactive ones.

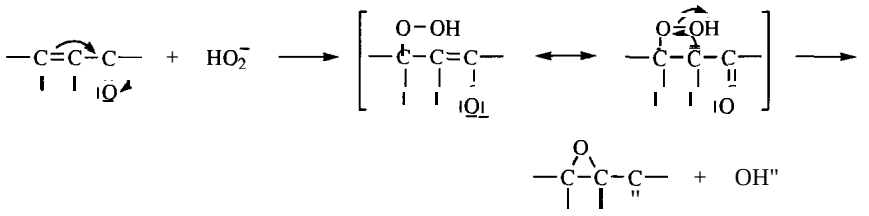
The following one-step mechanism[1035] was proposed by Bartlett:[1036]



Evidence for this mechanism is as follows:[1037] (1) The reaction is second order. If ionization were the rate-determining step, it would be first order in peroxyacid. (2) The reaction readily takes place in nonpolar solvents, where formation of ions is inhibited. (3) Measurements of the effect on the reaction rate of changes in the substrate structure show that there is no carbocation character in the transition state.[1038] (4) The addition is stereospecific (i.e., a trans alkene gives a trans epoxide and a cis alkene a cis epoxide) even in cases where electron-donating substituents would stabilize a hypothetical carbocation intermediate. However, where there is an OH group in the allylic or homoallylic position, the stereospecificity diminishes or disappears, with both cis and trans isomers giving predominantly or exclusively the product where the incoming oxygen is syn to the OH group. This probably indicates a transition state in which there is hydrogen bonding between the OH group and the peroxy acid.[1039]

Conjugated dienes can be epoxidized (1,2 addition), though the reaction is slower than for corresponding alkenes, but α,β-unsaturated ketones do not generally give epoxides when treated with peroxyacids.[1040] Conjugated ketones are oxidized to epoxy-ketones with DBU (p. 488) and *tert*-butyl hydroperoxide,[1041] with $NaBO_3$ and tetrahexylammonium hydrogen sulfate, [1042] $KF–Al_2O_3$/*tert*- butyl hydroperoxide,[1043] and treatment with diethylzinc, O_2, in the presence of a chiral amino-alcohol, gives the epoxy-ketone with high enantioselectivity.[1044] A Yb–BINOL complex, with r-BuOOH led to epoxidation of conjugated ketones with high asymmetric induction,[1045] as did a mixture of NaOCl and a *Cinchona* alkaloid.[1046] However, α,β-unsaturated esters react normally, to give glycidic esters.[1047] When a carbonyl group is in the molecule but not conjugated with the double bond, the Baeyer-Villiger reaction (18-19) may compete. Allenes[1048] are converted by peroxyacids to allene oxides[1049] or spiro dioxides, both of which species can in certain cases be isolated[1050] but more often are unstable under the reaction conditions and react further to give other products.[1051]

α,β-Unsaturated ketones (including quinones), aldehydes, and sulfones can be epoxidized with alkaline H_2O_2.[1052] This is a nucleophilic addition by a Michael-type mechanism, involving attack by HO_2^- :[1053]



α,β-Unsaturated carboxylic acids can be epoxidized with H_2O_2 and heteropoly acids,[1054] and α,β-unsaturated esters, amides, and sulfones with *t*- BuOOH and an alkyllithium in THF.[1055] Epoxides can also be prepared by treating alkenes with oxygen or with an alkyl peroxide,[1056] catalyzed by a complex of a transition metal such as V, Mo, Ti, or Co.[1057] The reaction with oxygen, which can also be carried out without a catalyst, is probably a free-radical process.[1058]

Allylic alcohols can be converted to epoxy-alcohols with tert-butylhydroperoxide on molecular sieves,[1059] or with peroxy acids.[1060] Epoxidation of allylic alcohols can also be done with high enantioselectivity. In the *Sharpless asymmetric epoxidation,*[1061] allylic alcohols are converted to optically active epoxides in better than 90% ee, by treatment with *t*-BuOOH, titanium tetraisopropoxide and optically active diethyl tartrate.[1062] The $Ti(OCHMe_2)_4$ and diethyl tartrate can be present in catalytic amounts (15-10mol %) if molecular sieves are present.[1063] Polymer-supported catalysts have also been reported.[1064] Since both (+) and (-) diethyl tartrate are readily available, and the reaction is stereospecific, either enantiomer of the product can be prepared. The method has been successful for a wide range of primary allylic alcohols, where the double bond is mono-, di-, tri-, and tetrasubstituted.[1065] This procedure, in which an optically active catalyst is used to induce asymmetry, has proved to be one of the most important methods of asymmetric synthesis, and has been used to prepare a large number of optically active natural products and other compounds. The mechanism of the Sharpless epoxidation is believed to involve attack on the substrate by a compound[1066] formed from the titanium alkoxide and the diethyl tartrate to produce a complex that also contains the substrate and the *t*-BuOOH.[1067]

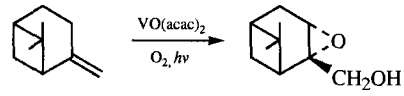
Ordinary alkenes (without an allylic OH group) have been enantioselectively epoxidized with sodium hypochlorite (commercial bleach) and an optically active manganese-complex catalyst.[1068] Variations of this oxidation use a manganese–salen complex with various oxidizing agents, in what is called the *Jacobsen-Katsuki reaction}*[069] Manganese porphyrin complexes have also been used.[1070] Cobalt complexes give similar results.[1071] A related epoxidation reaction used an iron complex with molecular oxygen and isopropanal.[1072] Nonracemic epoxides can be prepared from racemic epoxides with salen cobalt(II) catalysts following a modified procedure for kinetic resolution.[1073]

Many other reagents for converting alkenes to epoxides,[1074] including H_2O_2 and DCC,[1075] Oxone®,[1076] VO(*O*-isopropyl)$_3$ in liquid CO_2,[1077] polymer-supported cobalt (II) acetate and O2,[1078] and dimethyl dioxirane.[1079] This reagent is rather versatile, and converts methylene oxiranes to spiro-epoxides.[1080] One problem with dimethyloxirane is C—H insertion reactions rather than epoxidation.[1081] Magnesium monoperoxyphthalate[1082] is commercially available, and has been shown to be a good substitute for *m*-chloroperoxybenzoic acid in a number of reactions.[1083]

Oxirene

It would be useful if triple bonds could be similarly epoxidized to give oxirenes. However, oxirenes are not stable compounds.[1084] Two of them have been trapped in solid argon matrices at very low temperatures, but they decayed on warming to 35 K.[1085] Oxirenes probably form in the reaction,[1086] but react further before they can be isolated. Note that oxirenes bear the same relationship to cyclobutadiene that furan does to benzene and may therefore be expected to be antiaromatic (see p. 58).

In a different type of reaction, alkenes are photooxygenated (with singlet O_2, see 14-8) in the presence of a Ti, V, or Mo complex to give epoxy alcohols formally derived from allylic hydroxylation followed by epoxidation, for example,[1087]



67%

Thiiranes can be prepared directly from alkenes using specialized reagents.[1088]

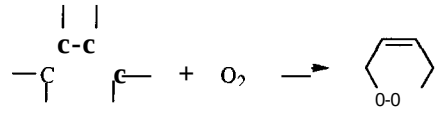
15-49 *Photooxidation of Dienes (Addition of Oxygen, Oxygen)*

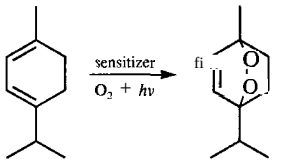
(2 + 4)*OC,OC-CYCLO*-PEROXY-1/4/ADDITION



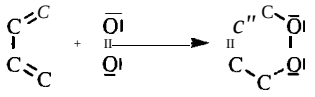
83

Conjugated dienes react with oxygen under the influence of light to give cyclic peroxides (83).[1089] The reaction has mostly[1090] been applied to cyclic dienes.[109] The scope extends to certain aromatic compounds such as phenanthrene.[1092] Besides those dienes and aromatic rings that can be photooxidized directly, there is a larger group that give the reaction in the presence of a photosensitizer such as eosin (see

p. 316). Among these is α-terpinene, which is converted to ascaridole:

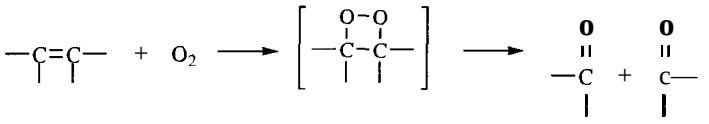


As in **14-8,** it is not the ground-state oxygen (the triplet), that reacts, but the excited singlet state,[1093] so the reaction is actually a Diels–Alder reaction (see **15-58)** with singlet oxygen as dienophile:[1094]



Like **15-58,** this reaction is reversible.

We have previously discussed the reaction of singlet oxygen with double-bond compounds to give

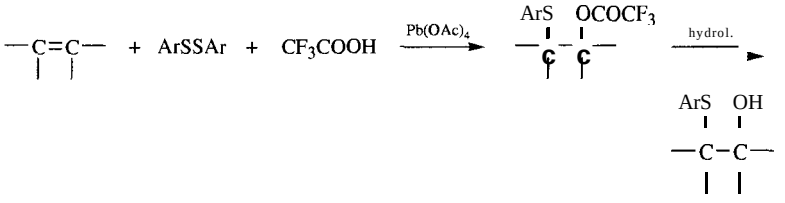


84

hydroperoxides (14-8), but singlet oxygen can also react with double bonds in another way to give a dioxetane intermediate (**84**)[1095], which usually cleaves to aldehydes or ketones[1096] but has been isolated.[1097] Both the six-membered cyclic peroxides 76[1098] and the four-membered **84**[1099] have been formed from oxygenation reactions that do not involve singlet oxygen. If 84 are desired, better reagents[1100] are triphenyl phosphite ozonide, $(PhO)_3PO_3$, and triethylsilyl hydrotrioxide, Et_3-SiOOOH, though yields are not high.[1101]

15-50 *Hydroxysulfenylation (Addition of Oxygen, Sulfur)*

HYDROXY-ARYLTHIO-ADDITION (OVERALL TRANSFORMATION)



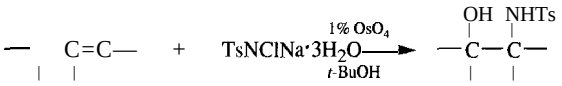
A hydroxy and an arylthio group can be added to a double bond by treatment with an aryl disulfide and lead tetraacetate in the presence of trifluoroacetic acid.[1102] Manganese and copper acetates have been used instead of $Pb(OAc)_4$.[1103] Addition of the groups OH and RSO has been achieved by treatment of alkenes with O_2 and a thiol (RSH).[1104] Two RS groups were added, to give *vic*- dithiols, by treatment of the alkene with a disulfide RSSR and BF_3–etherate.[1105] This reaction has been carried

out internally.[1106] In a similar manner, reaction of alkenes with ceric ammonium nitrate, diphenyl diselenide in methanol leads to vicinally substituted phenylselenyl methyl ethers.[1107] Dimethyl diselenide adds to alkenes to form vicinal bis(methylselenyl) compounds, in the presence of tin tetrachloride.[1108]

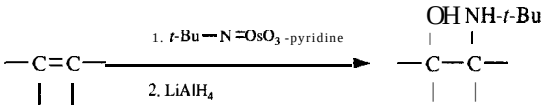
Halo-ethers can be formed by the reaction of alkenyl alcohols with various reagents. Hept-6-en-1-ol reacts with $(collidine)_2I^+PF_6^-$, for example, to form 2-iodomethyl-1-oxacycloheptane.[1109]

15-51 *Oxyamination (Addition of Oxygen, Nitrogen)*

TOSYLAMINO-HYDROXY-ADDITION



N-Tosylated β-hydroxy alkylamines (which can be easily hydrolyzed to (3-hydroxyamines[1110]) can be prepared[1111] by treatment of alkenes with the trihydrate of Chloramine-T[923] and a catalytic amount of OsO_4. In some cases yields can be improved by the use of phase-transfer catalysis.[1112] The reaction has been carried out enantioselectively.[1113] In another procedure, certain β-hydroxy secondary alkylamines can be prepared by treatment of alkenes with the osmium compounds



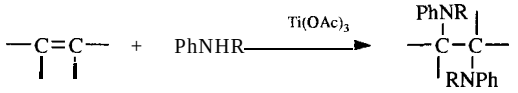
t-Bu–N=OsO_3, followed by reductive cleavage with $LiAlH_4$ of the initially formed osmic esters.[1114] It is presumed that Ts–N=OsO_3 is an intermediate in the Chloramine-T reaction. Another oxyamination reaction involves treatment of a palladium complex of the alkene with a secondary or primary amine, followed by lead tetraacetate or another oxidant.[1115]

P-Amino alcohols can be prepared by treatment of an alkene with a reagent prepared from HgO and HBF_4 along with aniline to give an aminomercurial compound PhHN–C–C–$HgBF_4$ (aminomercuration; see 15-7), which is hydrolyzed to PhHN–C–C–OH.[1116] The use of an alcohol instead of water gives the corresponding amino ether.

OS **VII,** 223, 375.

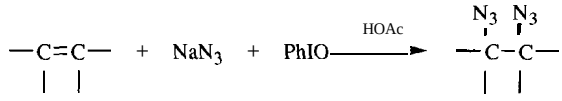
15-52 *Diamination (Addition of Nitrogen, Nitrogen)*

DI(ALKYLARYLAMINO)-ADDITION



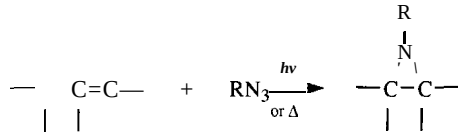
Primary (R = H) and secondary aromatic amines react with alkenes in the presence of thallium(III) acetate to give *vic*- diamines in good yields.[1117] The reaction is not successful for primary aliphatic amines. In another procedure, alkenes can be diaminated by treatment with the osmium compounds R_2NOsO_2 and R_3NOsO (R = *t*-Bu),[1118] analogous to the osmium compound mentioned at **15-51.** The palladium-promoted method of **15-51** has also been extended to diamination.[1119] Alkenes can also be diaminated[1120] indirectly by treatment of the aminomercurial compound mentioned in **15-51** with a primary or secondary aromatic amine.[1121]

Two azido groups can be added to double bonds by treatment with sodium azide and iodosobenzene in acetic acid.[1122]

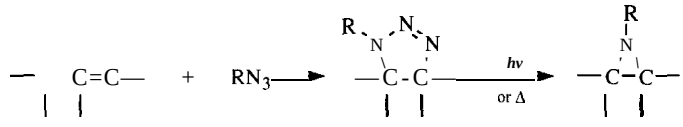


15-53 *Formation of Aziridines (Addition of Nitrogen, Nitrogen)*

EPI-ARYLIMINO-ADDITION, AND SO ON



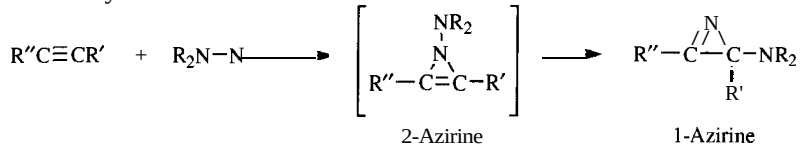
Aziridines can be prepared directly from double-bond compounds by photolysis or thermolysis of a mixture of the substrate and an azide.[1123] The reaction has been carried out with R = aryl, cyano, EtOOC, and RSO_2, as well as other groups. The reaction can take place by at least two pathways. In one, the azide is converted to a nitrene, which adds to the double bond in a manner analogous to that of carbene addition **(15-62).** Reaction of $NsONHCO_2Et$/ CuO [Ns = *N*(*p*-toluenesulfonyl-inimo)] and a conjugated ketone, for example, leads to the *N*-carboethoxy aziridine derivative.[1124] Calcium oxide has also been used to generate the nitrene.[1125] Other specialized reagents have also been used.[1126]



Triazoline

In the other pathway a 1,3 dipolar addition **(15-57)** takes place to give a triazoline (which can be isolated), followed by extrusion of nitrogen **(17-57).** Evidence for the nitrene pathway is most compelling for R = acyl groups. As discussed on pages 253, singlet nitrenes add stereospecifically while triplet nitrenes do not. Diphenyl sulfimide (Ph_2SNH) converts Michael-type substrates to the corresponding aziridines.[1127] Aminonitrenes (R_2NN) have been shown to add to triple bonds to give 1-azirines, which arise from rearrangement of the initially formed 2-

azirines.[1128] Like oxirenes (see **15-48),** 2-azirines are unstable, probably because of antiaromaticity.



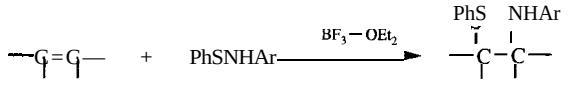
An alternative preparation of aziridines reacts an alkene with iodine and chloramine-T (see p. 1056) generating the corresponding *N*-tosyl aziridine.[1129] Bromamine-T ($TsNBr^-Na^+$) has been used in a similar manner.[1130] Diazoalkanes react with imines to give aziridines.[1131] Another useful reagent is NsN=IPh, which reacts with alkenes in the presence of rhodium compounds[1132] or $Cu(OTf)_2$[1133] to give N–Ns aziridines. Manganese salen catalysts have also been used with this reagent.[1134]

Nitrenes can also add to aromatic rings to give ring-expansion products analogous to those mentioned in **15-62**.[1135]

OS VI, 56.

15-54 *Aminosulfenylation (Addition of Nitrogen, Sulfur)*

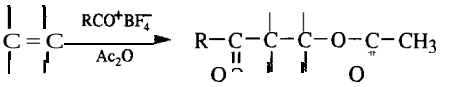
ARYLAMINO-ARYLTHIO-ADDITION



An amino group and an arylthio group can be added to a double bond by treatment with a sulfenanilide (PhSNHAr) in the presence of BF_3–etherate.[1136] The addition is anti, and the mechanism probably involves a thiiranium ion.[1137] In another aminosulfenylation procedure, the substrate is treated with dimethyl(methylthio)sulfonium fluoroborate ($MeSSMe_2BF_4^-$) and ammonia or an amine,[1138] the latter acting as a nucleophile. This reaction was extended to other nucleophiles:[1139] N_3^-,[1140] NO_2^-, CN^-, OH^-, and OAc^- to give MeS–C–C–A, where A = N_3, NO_2, CN, OH, and OAc, respectively. An RS (R = alkyl or aryl) and an NHCOMe group have been added in an electrochemical procedure.[1141]

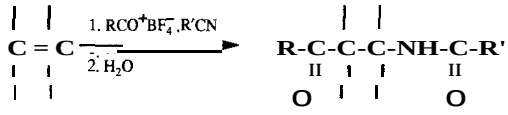
15-55 *Acylacyloxylation and Acylamidation (Addition of Oxygen, Carbon, or Nitrogen, Carbon)*

ACYL-ACYLOXY-ADDITION



An acyl and an acyloxy group can be added to a double bond by treatment with an acyl fluoroborate and acetic anhydride.[1142] As expected, the addition follows

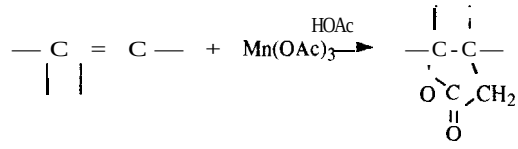
Markovnikov's rule, with the electrophile Ac^+ going to the carbon with more hydrogens. In an analogous reaction, an acyl and an amido group can be added, if a nitrile is used in place of the anhydride:



85

Similarly, halo-acetoxylation is known.[1143] This reaction has also been carried out on triple bonds, to give the unsaturated analogs of 85 (syn addition).[1144]

15-56 *The Conversion of Alkenes to γ-Lactones (Addition of Oxygen, Carbon)*



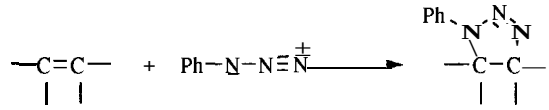
This reaction is clearly related to forming esters and lactones by reaction of carboxylic acids with alkenes (15-6), but the manganese reagent leads to differences. Alkenes react with manganese(III) acetate to give γ-lactones.[1145] The mechanism is probably free radical, involving addition of $\cdot CH_2COOH$ to the double bond. Ultrasound improves the efficiency of the reaction.[1146] In a related reaction, cyclohexene reacted with $MeO_2CCH_2CO_2K$ and $Mn(OAc)_3$ to give an α-carbomethoxy bicyclic lactone.[1147] The use of dimethyl malonate and ultrasound in this reaction gave the same type of product.[1148] Lactone formation has also been accomplished by treatment of alkenes with α-bromo carboxylic acids in the presence of benzoyl peroxide as catalyst,[1149] and with alkylidene chromium pentacarbonyl complexes.[1150] Alkenes can also be converted to γ-lactones by indirect routes.[1151]

An intramolecular variation of this reaction is known, involving amides, which generates a lactam.[1152]

OS **VII,** 400.

For addition of aldehydes and ketones, see the Prins reaction **(16-53),** and Reactions **16-63** and **16-64.**

15-57 *1,3-Dipolar Addition (Addition of Oxygen, Nitrogen, Carbon)*



Azides add to double bonds to give triazolines. This is one example of a large group of reactions ([3 + 2]-cycloadditions) in which five-membered heterocyclic compounds are prepared by addition of 1,3-dipolar compounds to double bonds (see Table 15.3).[1153] These are compounds that have a sequence of three atoms A—B—C,

TABLE 15.3 Some Common **1,3-Dipolar** Compounds

[c]See Ref. 1156.
[d]See Ref. 1157.

of which a has a sextet of electrons in the outer shell and c has an octet with at least one unshared pair. The reaction can then be formulated as

Since compounds with six electrons in the outer shell of an atom are usually not stable, the A—B—C system is actually one canonical form of a resonance hybrid, for which at least one other form can be drawn (see Table 15.3). 1,3-Dipolar compounds can be divided into two main types:

1. Those in which the dipolar canonical form has a double bond on the sextet atom and the other canonical form has a triple bond on that atom:

$$\bar{A}-B=\overset{+}{C}- \longleftrightarrow \bar{A}-B\equiv\overset{+}{C}-$$

If we limit ourselves to the first row of the periodic table, B can only be nitrogen, C can be carbon or nitrogen, and A can be carbon, oxygen, or

nitrogen; hence there are six types. Among these are azides (A=B=C=N), illustrated above, and diazoalkanes.

2. Those in which the dipolar canonical form has a single bond on the sextet atom and the other form has a double bond:

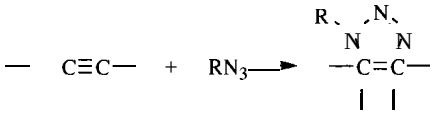
$$\bar{\underline{A}}\text{-}\underline{B}\text{-}\overset{+}{C}— \longleftrightarrow \bar{\underline{A}}\text{-}B=\overset{+}{C}—$$

Here B can be nitrogen or oxygen, and A and C can be nitrogen, oxygen, or carbon, but there are only 12 types, since, for example, N—N—C is only another form of C—N—N. Examples are shown in Table 15.3.

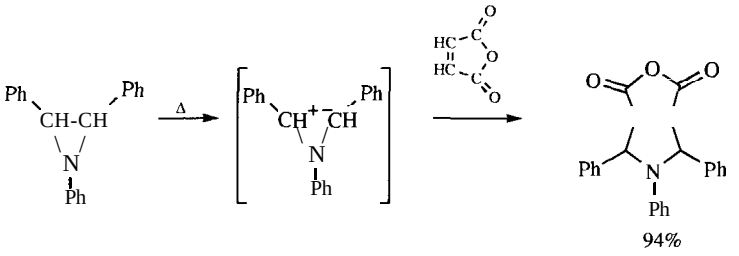
Of the 18 systems, some of which are unstable and must be generated *in situ*,[1158] the reaction has been accomplished for at least 15, though not in all cases with a carbon-carbon double bond (the reaction also can be carried out with other double bonds[1159]). Not all alkenes undergo 1,3-dipolar addition equally well. The reaction is most successful for those that are good dienophiles in the Diels–Alder reaction (**15-58**). The addition is stereospecific and syn, and the mechanism is probably a one-step concerted process, as illustrated above.[1160] In-plane aromaticity has been invoked for these dipolar cycloadditions.[1161] As expected for this type of mechanism, the rates do not vary much with changes in solvent.[1162] There are no simple rules covering orientation in 1,3-dipolar additions. Regioselectivities are complicated but have been explained by MO treatments.[1163] When the 1,3-dipolar compound is a thiocarbonyl ylid ($R_2C{=}S^+{-}{}^-CH_2$) the addition has been shown to be nonstereospecific with certain substrates (though stereospecific with others), indicating a nonsynchronous mechanism in these cases, and in fact, a di-ionic intermediate (see mechanism *c* on p. 1078) has been trapped in one such case.[1164]

There are many cases where the [3 + 2]-cycloaddition leads to cycloadducts with high enantioselectivity.[1165] Conjugated dienes generally give exclusive 1,2 addition, though 1,4 addition (a 3 + 4 cycloaddition) has been reported.[1166]

Carbon-carbon triple bonds can also undergo 1,3-dipolar addition.[1167] For example, azides give triazoles:



The 1,3-dipolar reagent can in some cases be generated by the *in situ* opening of a suitable three-membered ring system. For example, aziridines can add to activated double bonds to give pyrrolidines, for example,[1168]



94%

Aziridines also add to C≡C triple bonds as well as to other unsaturated linkages, including C=O, C=N, and C≡N.[1169] In some of these reactions it is a C–N bond of the aziridine that opens rather than the C–C bond.

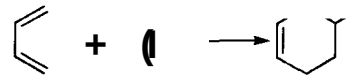
For other [3 + 2] cycloadditions, see **15-60.**

OS V, 957, 1124; **VI,** 592, 670; **VIII,** 231. Also see OS IV, 380.

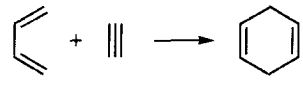
C. *Carbon on Both Sides.* *Reactions 15-58–15-64 are cycloaddition reactions.*[1170]

15-58 *The Diels–Alder Reaction*

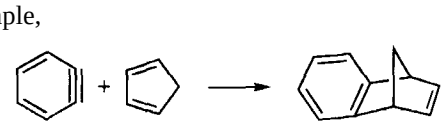
(2 + 4)*CYCLO*-ETHYLENE-1/4/ADDITION OR (4 + 2)*CYCLO*-[BUT-2-ENE-1,4-DIYL]-1/2/ADDITION, AND SO ON



In the *Diels–Alder reaction* a double bond adds 1,4 to a conjugated diene (a 2 + 4 cycloaddition),[1171] so the product is always a six-membered ring. The double-bond compound is called a *dienophile.* The reaction is easy and rapid and of very broad scope[1172] and reactivity of dienes and dienophiles can be predicted based on analysis of the HOMOs and LUMOs of these species.[1173] Ethylene and simple alkenes make poor dienophiles, although the reaction has been carried out with these compounds. Most dienophiles are of the form $-\overset{|}{C}=\overset{|}{C}-Z$ or, $Z-\overset{|}{C}=\overset{|}{C}-Z'$, where Z and Z' are CHO, COR,[1174] COOH, COOR, COCl, COAr, CN,[1175] NO_2,[1176] Ar, CH_2OH, CH_2Cl, CH_2NH_2, CH_2CN, CH_2COOH, halogen, $PO(OEt)_2$,[1177] or C=C. In the last case, the dienophile is itself a diene. When two dienes react, mixtures are quite possible. Thus, butadiene and isoprene ($CH_2=CH-CMe=CH_2$) gave all nine possible Diels–Alder adducts, as well as eight-membered rings and trimers.[1178] Particularly common dienophiles are maleic anhydride[1179] and quinones.[1180] Triple bond compounds (–C≡C–Z or Z–C≡C–Z′)



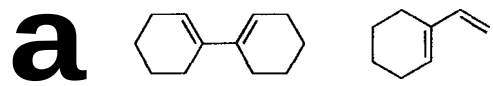
may be dienophiles,[1181] as may allenes, though allenes without activating groups are very poor dienophiles.[1182] Ketenes, however, do not undergo Diels–Alder reactions.[1183] Benzynes, although not isolable, act as dienophiles and can be trapped with dienes,[1184] for example,



86

The low reactivity of ethylene can be overcome by using phenyl vinyl sulfone $PhSO_2CH=CH_2$ instead.[1185] The $PhSO_2$ group can be easily removed with Na–Hg

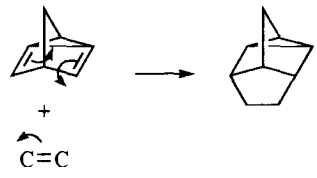
after the ring-closure reaction. Similarly, phenyl vinyl sulfoxide ($PhSOCH{=}CH_2$) can be used as a synthon for acetylene.[1186] In this case, PhSOH is lost from the sulfoxide product (17-11).



87 88 89

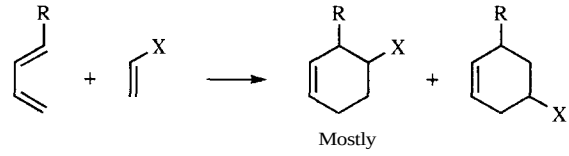
Dienes can be open-chain, inner-ring (e.g., 86), outer-ring[1187] (e.g., 87), across rings (e.g., 88), or inner-outer (e.g., 89), except that they may not be frozen into a transoid conformation (see p. 1064). They need no special activating groups, and nearly all conjugated dienes undergo the reaction with suitable dienophiles.[1188]

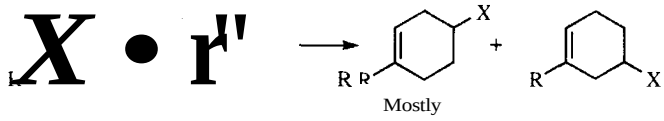
Aromatic compounds can also behave as dienes.[1189] Benzene is very unreactive toward dienophiles; very few dienophiles (one of them is benzyne) have been reported to give Diels–Alder adducts with it.[1190] Naphthalene and phenanthrene are also quite resistant, though naphthalene has given Diels-Alder addition at high pressures.[1191] However, anthracene and other compounds with at least three linear benzene rings give Diels-Alder reactions readily. The interesting compound triptycene can be prepared by a Diels-Alder reaction between benzyne and anthracene:[1192] For both all-carbon and hetero systems, the "diene" can be a conjugated enyne. If the geometry of the molecule is suitable, the diene can even be nonconjugated, for example,[1193]



This last reaction is known as the *homo-Diels–Alderreaction.*

When an unsymmetrical diene adds to an unsymmetrical dienophile, there are two regioisomeric products (not counting stereoisomers):



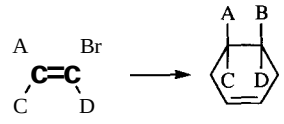


Although mixtures are often obtained, usually one predominates, the one indicated above. This regioselectivity, in which the "ortho" or "para" product is favored over

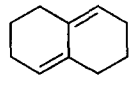
the "meta", has been explained by MO considerations.[1194] When X = NO_2, regioselectivity to give the "ortho" or "para" product was very high at room temperature. and this method, combined with subsequent removal of the NO_2 (see 10-87) has been used to perform regioselective Diels–Alder reactions.[1195]

The stereochemistry of the Diels–Alder reaction can be considered from several aspects:[1196]

1. With respect to the dienophile, the addition is stereospecifically syn, with very few exceptions.[1197] This means that groups that are cis in the alkene will be cis in the cyclohexene ring:



2. With respect to 1,4-disubstituted dienes, fewer cases have been investigated. but here too the reaction is stereospecific and syn. Thus, *trans,trans*-1,4-diphenylbutadiene gives *cis*- 1,4-diphenylcyclohexene derivatives.
3. The diene must be in the cisoid conformation. If it is frozen into the transoid conformation, as in 84, the reaction does not take place. The diene either must be frozen into the cisoid conformation or must be able to achieve it during the reaction.



90

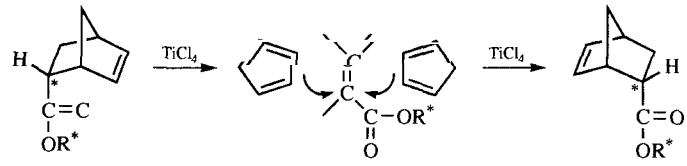
4. When the diene is cyclic, there are two possible ways in which addition can occur if the dienophile is not symmetrical. The larger side of the dienophile may be under the ring *(endo addition*), or it may be the smaller side *(exo addition):*

Endo addition Exo addition

Most of the time, the addition is predominantly endo; that is, the more bulk) side of the alkene is under the ring, and this is probably true for open-chain dienes also.[1198] However, exceptions are known, and in many cases mixtures of exo and endo addition products are found.[1199] It has been argued that facial selectivity is not due to torsional angle decompression.[1200]

5. As we have seen, the Diels-Alder reaction can be both stereoselective and regioselective.[1201] In some cases, the Diels-Alder reaction can be made enan-

tioselective.[1202] Solvent effects are important in such reactions.[1203] The role of reactant polarity on the course of the reaction has been examined.[1204] Most such work has used a chiral dienophile (e.g., 91) and an achiral diene,[1205] along with a Lewis acid catalyst (see below). In such cases addition of the diene to the two faces[1206] of 91 takes place at different rates, and 92 and 93 are formed in different amounts.[1207] In the case illustrated, hydrolysis of the product removes the chiral R group, making it a chiral auxiliary in this reaction. Asymmetric Diels–Alder reactions have also been carried out with achiral dienes and dienophiles, but with an optically active catalyst.[1208] Many chiral catalysts have been recently developed.[1209] In many cases, asymmetric Lewis acids form a chiral complex with the dienophile.[1210]



92 91 93

R = (+) or (-) phenylmethyl

Electron-donating substituents in the diene accelerate the reaction; electron-withdrawing groups retard it. For the dienophile it is just the reverse: donating groups decrease the rate, and withdrawing groups increase it. Cyclic dienes, in which the cisoid conformation is built in, usually react faster than the corresponding open-chain compounds, which have to achieve the cisoid conformation by rotation.[1211]

As should be apparent from the foregoing, many interesting compounds can be prepared by the Diels-Alder reaction, some of which would be hard to make in any other way. It has thus been exceedingly useful. Competing reactions are polymerization of the diene or dienophile, or both, and 1,2 cycloaddition (15-61). However, yields are usually quite high. No catalyst is needed, though it has been found that Lewis acids catalyze some Diels-Alder reactions,[1212] usually those in which Z in the dienophile is a C=O or C=N group. Br0nsted acids have also been used to accelerate the rate of the Diels-Alder reaction.[1213] A Lewis acid catalyst usually increases both the regioselectivity of the reaction (in the sense given above) and the extent of endo addition,[1214] and, in the case of enantioselective reactions, the extent of enantioselectivity. Lanthanum triflate, $La(OTf)_3$, has been reported as a reusable catalyst.[1215] Some Diels-Alder reactions can also be catalyzed by the addition of a stable cation radical, for example, tris(4-bromophenyl)aminium hexachloroantimonate ($Ar_3N\bullet^+SbCl_6^-$).[1216] Zirconocene-catalyzed cationic Diels-Alder reactions are known.[1217] Certain antibodies have been developed that catalyze Diels-Alder reactions.[1218] Photochemically induced Diels-Alder reactions are also known.[1219]

A number of other methods have been reported for the acceleration of Diels-Alder reactions,[1220] including the use of a microwave oven,[1221] ultrasound,[1222] 5 *M*

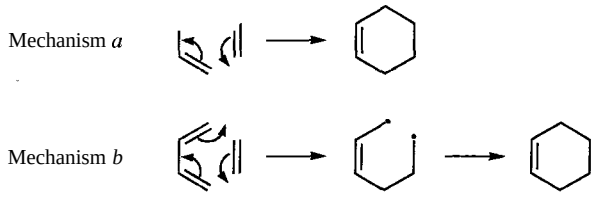
$LiClO_4$ in Et_2O as solvent,[1223] absorption of the reactants on chromatographic absorbents,[1224] via encapsulation techniques,[1225] and the use of an ultracentrifuge[1226] (one of several ways to achieve reaction at high pressures).[1227] One of the most common methods is to use water as a solvent or a cosolvent (a hydrophobic effect).[1228] The influence of hydrophobicity of reactants on the reaction has been examined[1229] as has micellular effects.[1230] The addition of HPO_4^- to an aqueous ethanol solution has also been shown to give an small rate enhancement.[1231] This appears to be the only case where an anion is responsible for a rate enhancement. The retro-Diels–Alder reaction has also been done in water.[1232] It has been shown that $InCl_3$ is an effective catalyst for aqueous Diels–Alder reactions,[1233] and there are other Lewis acid catalysts that are effective in water.[1234]

It is noted that the Diels–Alder reaction has been done with supercritical CO_2 as a solvent.[1235] Diels-Alder reactions on solid supports have also been reported,[1236] and zeolites have been used in conjunction with catalytic agents.[1237] Alumina has been used to promote Diels-Alder reactions.[1238]

Intramolecular versions of the Diels-Alder reaction are well known, and this is a powerful method for the synthesis of mono- and polycyclic compounds.[1239] There are many examples and variations. One interesting internal Diels-Alder reaction links the diene and dienophile by a C–O–SiR_2–C[1240] or a C–O–SiR_2–O–C[1241] linkage. Internal cyclization to give a bicyclic product is followed by cleavage of the O–Si unit to give a monocyclic alcohol.

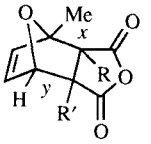
3-Sulfolene

The Diels-Alder reaction is usually reversible and has been used to protect double bonds.[1242] A convenient substitute for butadiene in the Diels-Alder reaction is the compound 3-sulfolene since the latter is a solid that is easy to handle while the former is gas.[1243] Butadiene is generated in situ by a reverse Diels-Alder reaction (see 17-20).



There are, broadly speaking, three possible mechanisms that have been considered for the uncatalyzed Diels-Alder reaction.[1244] In mechanism *a* there is a cyclic six-centered transition state and no intermediate. The reaction is concerted and occurs in one step. In mechanism *b*, one end of the diene fastens to one end of the dienophile first to give a diradical, and then, in a second step, the other ends become fastened. A diradical formed in this manner must be a singlet; that is, the

two unpaired electrons must have opposite spins, by an argument similar to that outlined on page 244. The third mechanism (c, not shown) is similar to mechanism *b*, but the initial bond and the subsequent bond are formed by movements of electron pairs and the intermediate is a di-ion. There have been many mechanistic investigations of the Diels–Alder reaction. The bulk of the evidence suggests that most Diels-Alder reactions take place by the one-step cyclic mechanism *a*,[1245] although it is possible that a diradical[1246] or even a di-ion[1247] mechanism may be taking place in some cases. The main evidence in support of mechanism *a* is as follows: (1) The reaction is stereospecific in both the diene and dienophile. A completely free diradical or di-ion probably would not be able to retain its configuration. (2) In general, the rates of Diels-Alder reactions depend very little on the nature of the solvent. This would rule out a di-ion intermediate because polar solvents increase the rates of reactions that develop charges in the transition state. (3) It was shown that, in the decomposition of 94, the isotope effect k_I/k_{II} was equal to 1.00 within experimental error.[1248] If bond *x* broke before bond *y*, there should



94

I: R = H, R' = D
II: R = D, R' = H

surely be a secondary isotope effect. This result strongly indicates that the bond breaking of *x* and *y* is simultaneous. This is the reverse of a Diels-Alder reaction, and by the principle of microscopic reversibility, the mechanism of the forward reaction should involve simultaneous formation of bonds *x* and *y*. Subsequently, a similar experiment was carried out on the forward reaction[1249] and the result was the same. There is also other evidence for mechanism a.[1250] However, the fact that the mechanism is concerted does not necessarily mean that it is synchronous. In the transition state of a synchronous reaction both new CT bonds would be formed to the same extent, but a Diels-Alder reaction with nonsymmetrical components might very well be nonsynchronous;[1251] that is, it could have a transition state in which one bond has been formed to a greater degree than the other.[1251,1252] A biradical mechanism has been proposed for some Diels-Alder reactions.[1253]

In another aspect of the mechanism, the effects of electron-donating and electron-withdrawing substituents (p. 1065) indicate that the diene is behaving as a nucleophile and the dienophile as an electrophile. However, this can be reversed. Perchlorocyclopentadiene reacts better with cyclopentene than with maleic anhydride and not at all with tetracyanoethylene, though the latter is normally the most reactive dienophile known. It is apparent, then, that this diene is the electrophile in its Diels-Alder reactions.[1254] Reactions of this type are said to proceed with *inverse electron demand}*[255]

We have emphasized that the Diels-Alder reaction generally takes place rapidly and conveniently. In sharp contrast, the apparently similar dimerization of alkenes to cyclobutanes **(15-61)** gives very poor results in most cases, except when

photochemically induced. Fukui, Woodward, and Hoffmann have shown that these contrasting results can be explained by the *principle of conservation of orbital symmetry,*[1256] which predicts that certain reactions are allowed and others forbidden. The orbital-symmetry rules (also called the Woodward-Hoffmann rules) apply *only to concerted reactions,* (e.g., mechanism *a)* and are based on the principle that reactions take place in such a way as to maintain maximum bonding throughout the course of the reaction. There are several ways of applying the orbital-symmetry principle to cycloaddition reactions, three of which are used more frequently than others.[1257] Of these three, we will discuss two: the frontier–orbital method and the Möbius-Hückel method. The third, called the correlation diagram method,[1258] is less convenient to apply than the other two.

The Frontier-Orbital Method[1259]

As applied to cycloaddition reactions the rule is that *reactions are allowed only when all overlaps between the HOMO of one reactant and the LUMO of the other are such that a positive lobe overlaps only with another positive lobe and a negative lobe only with another negative lobe.* We may recall that monoalkenes have two π molecular orbitals (p. 9) and that conjugated dienes have four (p. 36), as shown in Figure 15.1. A concerted cyclization of two monoalkenes (a 2 + 2 reaction) is not allowed because it would require that a positive lobe overlap with a negative lobe (Fig. 15.2). On the other hand, the Diels–Alder reaction (a 2 + 4 reaction) is allowed, whether considered from either direction (Fig. 15.3).

These considerations are reversed when the ring closures are photochemically induced since in such cases an electron is promoted to a vacant

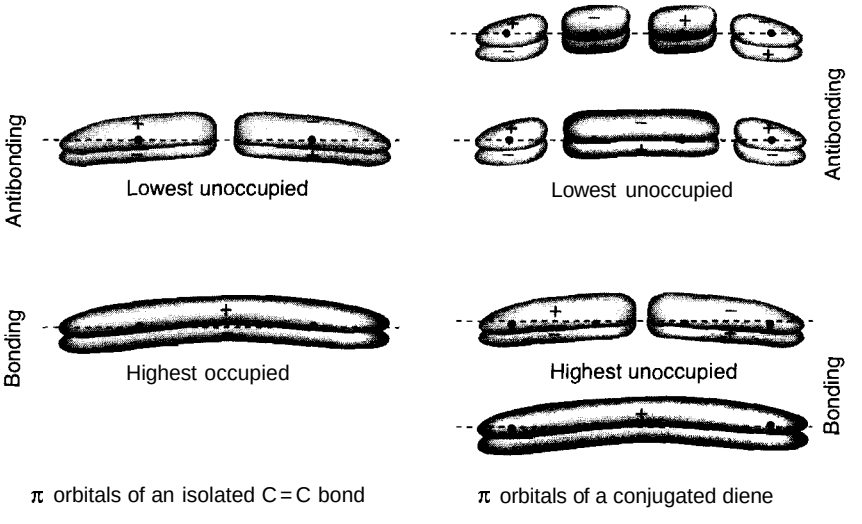


FIGURE 15.1 Schematic drawings of the *n* orbitals of an isolated C=C bond and a conjugated diene.

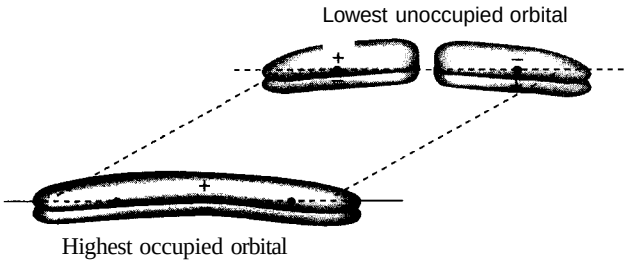

FIGURE 15.2 Overlap of orbitals in a thermal 2 + 2 cycloaddition.

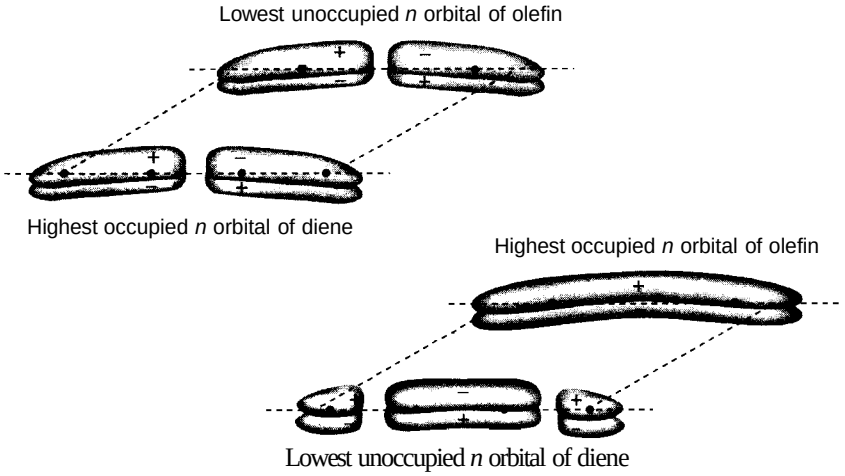

FIGURE 15.3 Two ways for orbitals to overlap in a thermal 2 + 4 cycloaddition.

orbital before the reaction occurs. Obviously, the 2 + 2 reaction is now allowed (Fig. 15.4) and the 2 + 4 reaction disallowed. The reverse reactions follow the same rules, by the principle of microscopic reversibility. In fact, Diels–Alder adducts are usually cleaved quite readily, while cyclobutanes, despite the additional strain, require more strenuous conditions.

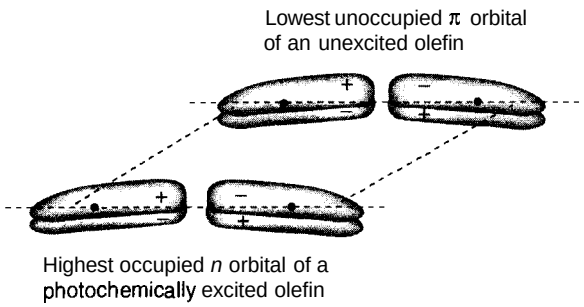

FIGURE 15.4 Overlap of orbitals in a photochemical 2 + 2 cycloaddition.

FIGURE 15.5 Some basis sets.

The Möbius–Hückel Method[1260]

In this method, the orbital symmetry rules are related to the Hückel aromaticity rule discussed in Chapter 2. Hückel's rule, which states that a cyclic system of electrons is aromatic (hence, stable) when it consists of $An + 2$ electrons, applies of course to molecules in their ground states. In applying the orbital symmetry principle, we are not concerned with ground states, but with transition states. In the present method, we do not examine the molecular orbitals themselves but rather the *p* orbitals before they overlap to form the MO. Such a set of *p* orbitals is called a *basis set* (Fig. 15.5). In investigating the possibility of a concerted reaction, we put the basis sets into the position they would occupy in the transition state. Figure 15.6 shows this for both the

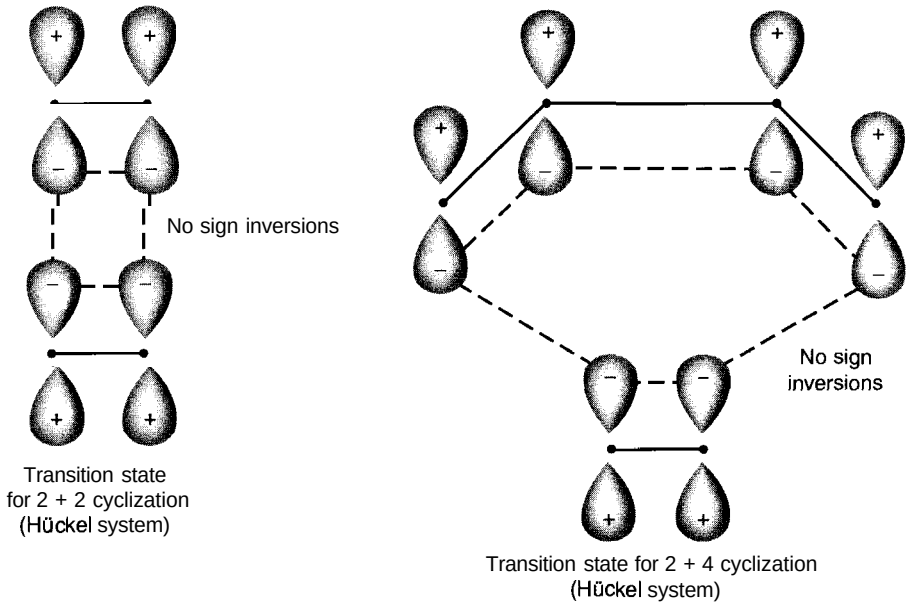

FIGURE 15.6 Transition states illustrating Hückel–Möbius rules for cycloaddition reactions.

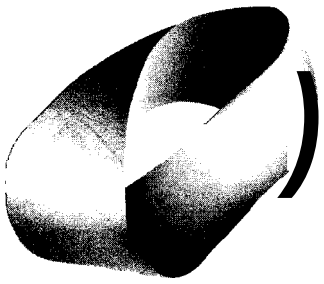

FIGURE 15.7 A Möbius strip. Such a strip is easily constructed by twisting a thin strip of paper 180° and fastening the ends together.

2 + 2 and the 2 + 4 ring closures. What we look for are *sign inversions.* In Figure 15.6, we can see that there are no sign inversions in either case. That is, the dashed line connects only lobes with a minus sign. Systems with *zero or an even number* of sign inversions are called *Hilckel systems.* Because they have no sign inversions, both of these systems are Hückel systems. Systems with *an odd number* of sign inversions are called *Mobius systems* (because of the similarity to the Mobius strip, which is a mathematical surface, shown in Fig. 15.7). Mobius systems do not enter into either of these reactions, but an example of such a system is shown on page 1430.

The rule may then be stated: *A thermal pericyclic reaction involving a Hiickel system is allowed only if the total number of electrons is 4n + 2. A thermal pericyclic reaction involving a Möbius system is allowed only if the total number of electrons is 4n.* For photochemical reactions these rules are reversed. Since both the 2 + 4 and 2 + 2 cycloadditions are Hiickel systems, the Möbius–Hückel method predicts that the 2 + 4 reaction, with 6 electrons, is thermally allowed, but the 2 + 2 reaction is not. One the other hand, the 2 + 2 reaction is allowed photochemically, while the 2 + 4 reaction is forbidden.

Note that both the 2 + 2 and 2 + 4 transition states are Hiickel systems no matter what basis sets we chose. For example, Figure 15.8 shows other basis sets we might have chosen. In every case there will be zero or an even number of sign inversions.

Thus, the frontier–orbital and Hückel-Möbius methods (and the correlation-diagram method as well) lead to the same conclusions: thermal 2 + 4 cycloadditions and photochemical 2 + 2 cycloadditions (and the reverse ring openings) are allowed, while photochemical 2 + 4 and thermal 2 + 2 ring closings (and openings) are forbidden.

Application of the same procedures to other ring closures shows that 4 + 4 and 2 + 6 ring closures and openings require photochemical induction while the 4 + 6 and 2 + 8 reactions can take place only thermally (see **15-52).** In general, cycloaddition reactions allowed thermally are those with *An* + 2 electrons, while those allowed photochemically have *An* electrons.

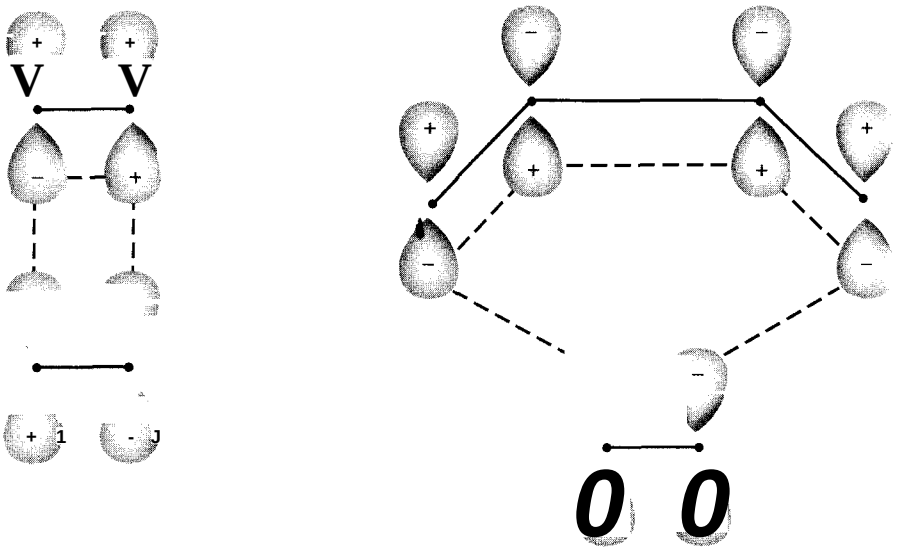

FIGURE 15.8 Transition states for 2 + 2 and 2 + 4 cyclizations involving other basis sets.

It must be emphasized once again that the rules apply only to cycloaddition reactions that take place by cyclic mechanisms, that is, where two s bonds are formed (or broken) at about the same time.[1261] The rule does not apply to cases where one bond is clearly formed (or broken) before the other. It must further be emphasized that the fact that the thermal Diels-Alder reaction (mechanism *a)* is allowed by the principle of conservation of orbital symmetry does not constitute proof that any given Diels-Alder reaction proceeds by this mechanism. The principle merely says the mechanism is allowed, not that it must go by this pathway. However, the principle does say that thermal 2 + 2 cycloadditions in which the molecules assume a face-to-face geometry cannot[1262] take place by a cyclic mechanism because their activation energies would be too high (however, see below). As we shall see (15-49), such reactions largely occur by two-step mechanisms. Similarly. 2 + 4 photochemical cycloadditions are also known, but the fact that they are not stereospecific indicates that they also take place by the two-step diradical mechanism (mechanism *b*).[1263]

In all of the above discussion, we have assumed that a given molecule forms both the new s bonds from the same face of the *n* system. This manner of bond formation, called *suprafacial,* is certainly most reasonable and almost always takes place. The subscript s is used to designate this geometry, and a normal Diels-Alder reaction would be called a $[_{\pi}2_{s}+_{\pi}4_{s}]$ cycloaddition (the subscript *n* indicates that *n* electrons are involved in the cycloaddition). However, we can conceive of another approach in which the newly forming bonds of the diene lie on *opposite* faces of the *n* system, that is, they point in opposite directions.

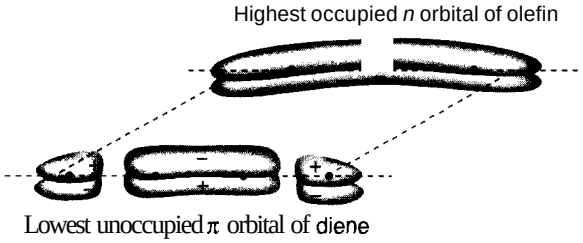

FIGURE 15.9 Overlap of orbitals in an antarafacial thermal 2+4 cycloaddition.

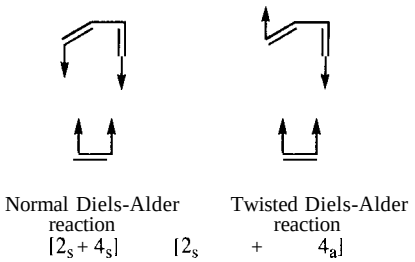
This type of orientation of the newly formed bonds is called *antarafacial*, and the reaction would be a $[_{\pi}2_s + {}_{\pi}4_a]$ cycloaddition (a stands for antarafacial). We can easily show by the frontier–orbital method that this reaction (and consequently the reverse ring-opening reactions) are thermally forbidden and photochemically allowed. Thus in order for a $[_{\pi}2_s + {}_{\pi}4_a]$ reaction to proceed, overlap between the highest occupied π orbital of the alkene and the lowest unoccupied *n* orbital of the diene would have to occur as shown in Figure 15.9, with a (+) lobe overlapping a (—) lobe. Since like signs are no longer overlapping, the thermal reaction is now forbidden.

Similarly, thermal $[_{\pi}2_a + \pi 4_s]$ and $[_{\pi}2_a + {}_{\pi}2_a]$ cyclizations are forbidden, while thermal $[_{\pi}2_a + {}_{\pi}4_a]$ and $[_{\pi}2_s + \pi 2_a]$ cyclizations are allowed, and these consi-



derations are reversed for the corresponding photochemical processes. Of course, an antarafacial approach is highly unlikely in a 2 + 4 cyclization,[1264] but larger ring closures could take place by such a pathway, and 2 + 2 thermal cyclizations, where the $[_{\pi}2_s + {}_{\pi}2_s]$ pathway is forbidden, can also do so in certain cases (see **15-61).** We therefore see that whether a given cycloaddition is allowed or forbidden depends on the geometry of approach of the two molecules involved.

Symmetry considerations have also been advanced to explain predominant endo addition.[1265] In the case of 2 + 4 addition of butadiene to itself, the approach can be exo or endo. It can be seen (Fig. 15.10) that whether the HOMO of the diene overlaps with the LUMO of the alkene or vice versa, the

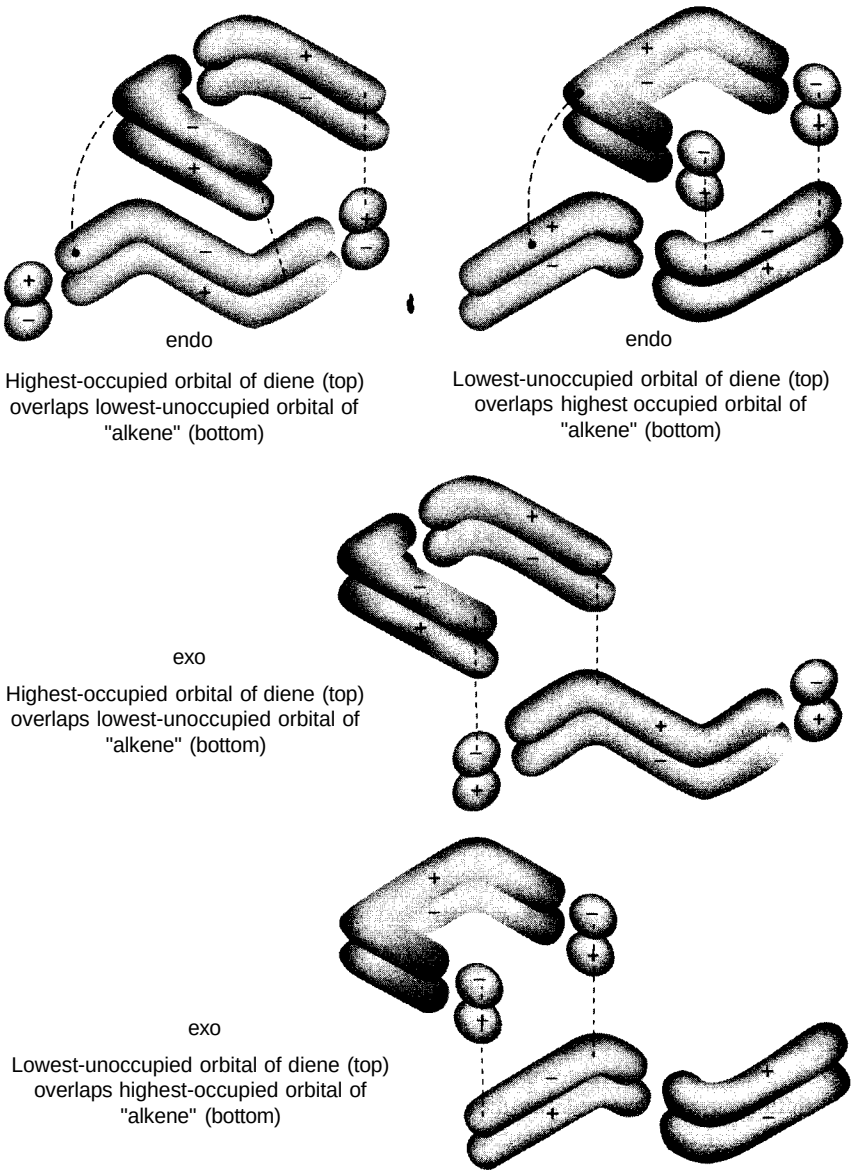


FIGURE 15.10 Overlap of orbitals in 2 + 4 cycloaddition of dienes.

endo orientation is stabilized by additional secondary overlap of orbitals[1266] of like sign (dashed lines between heavy dots). Addition from the exo direction has no such stabilization. Evidence for secondary orbital overlap as the cause of predominant endo orientation, at least in some cases, is that 4 + 6 cycloaddition is predicted by similar considerations to proceed with predominant exo orientation, and that is what is found.[1267] However, this

explanation does not account for endo orientation in cases where the dienophile does not possess additional *n* orbitals, and a number of alternative explanations have been offered.[1268]

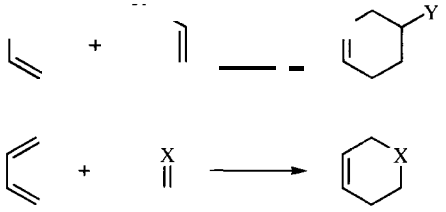
15-59 *Heteroatom Diels-Alder Reactions*



Carbon-carbon multiple bonds are not the only units that can participate in Diels-Alder reactions. Other double- and triple-bond compounds can be dienophiles and they give rise to heterocyclic compounds.[1269] Among these are N≡C–, –N=C–,[1270] -N=N-, O=N-,[1271] and -C=O compounds[1272] and, as we have seen (15-49), even molecular oxygen.

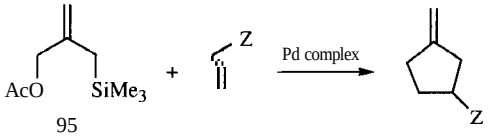
Azadienes undergo Diels-Alder reactions to form pyridine, dihydro- and tetrahydropyridine derivatives.[1273] N-Vinyl lactim ethers undergo Diels-Alder reactions with a limited set of dienophiles.[1274] Thioketones react with dienes to give Diels-Alder cycloadducts.[1275] The carbonyl group of lactams have also been shown to be a dienophile.[1276] Certain heterocyclic aromatic rings (among them furans)[1277] can also behave as dienes in the Diels-Alder reaction. Some hetero dienes that give the reaction are –C=C–C=O, O=C–C=O, and N=C–C=N.[1186]

Catalysts such as $Fe(BuEtCHCO_2)_3$ have been developed that are effective for the heteroatom Diels-Alder reaction.[1278] Indium trichloride ($InCl_3$) is a good catalyst for imino-Diels–Alder reactions.[1279] Hetero-Diels–Alder reactions involving carbonyls have been done in water.[1280] Ultrasound has been used to promote the Diels-Alder reactions of 1-azadienes.[1281]

Heteroatom Diels-Alder reactions that proceed with good to excellent asymmetric induction are well known.[1282] Chiral 1-aza-dienes have been developed as substrates, for example.[1283]

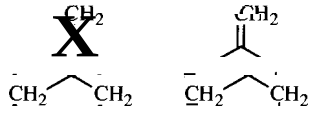
OS IV, 311; V, 60, 96. See also OS VII, 326.

15-60 *All-Carbon 3 + 2 Cycloadditions*[1284]



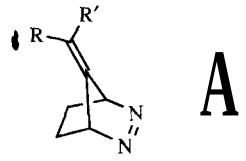
95

Several methods have been reported for the formation of cyclopentanes by 3 + 2 cycloadditions.[1285] One type involves reagents that produce intermediates 96 or 97.[1286] A synthetically useful example[1287] uses 2-[(trimethylsilyl)methyl]-2-propen-1-yl acetate (95), which is commercially available, and a palladium or other transition metal catalyst to generate 96 or 97, which adds to double bonds, to give, in



96 97

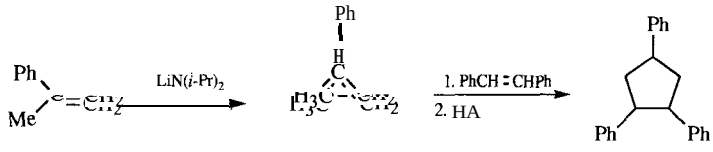
good yields, cyclopentanes with an exocyclic double bond. Similar or identical intermediates generated from bicyclo azo compounds 98 (see 17-36)[1288] or



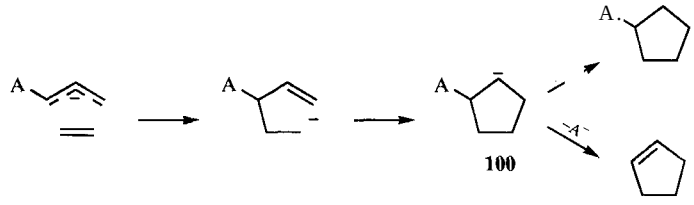
98 99

methylenecyclopropane 99[1289] also add to activated double bonds. With suitable substrates the addition can be enantioselective.[1290]

In a different type of procedure, 3 + 2 cycloadditions are performed with allylic anions. Such reactions are called 1,3-anionic cycloadditions.[1291] For example, α-methylstyrene adds to stilbene on treatment with the strong base lithium diisopropylamide.[1292]



The mechanism can be outlined as

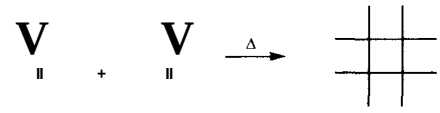


In the case above, 100 is protonated in the last step by the acid HA, but if the acid is omitted and a suitable nucleofuge is present, it may leave, resulting in a cyclopentene.[1293] In these cases the reagent is an allylic anion, but similar 3 + 2 cycloadditions involving allylic cations have also been reported.[1294]

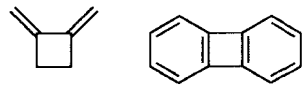
OS VIII, 173, 347.

15-61 *Dimerization of Alkenes*

(2 + 2)*CYCLO*-ETHYLENE-1/2/ADDITION



The thermal reaction between two molecules of alkene to give cyclobutane derivatives (a 2 + 2 cycloaddition) can be carried out where the alkenes are the same or different, but the reaction is not a general one for alkenes.[1295] Dimerization of like alkenes occurs with the following compounds: $F_2C{=}CX_2$ (X=F or Cl) and



101 Biphenylene

certain other fluorinated alkenes (though not $F_2C{=}CH_2$), allenes (to give derivatives of **101**),[1296] benzynes (to give biphenylene derivatives), activated alkenes (e.g., styrene, acrylonitrile, butadiene), and certain methylenecyclopropanes.[1297] Substituted ketenes can dimerize to give cyclobutenone derivatives, although ketene itself dimerizes in a different manner, to give an unsaturated β-lactone (**16-63**).[1298]

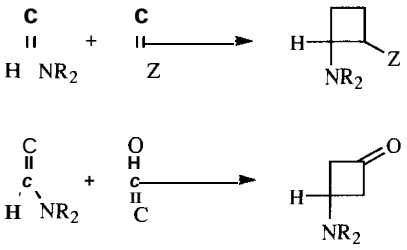
Ketenes react with many alkenes to give cyclobutanone derivatives[1299] and intermolecular cycloadditions are well known.[1300] A typical reaction is that of dimethylketene and ethene to give 2,2-dimethylcyclobutanone.[1301]

Me Me Me

Different alkenes combine as follows:

1. The compounds $F_2C{=}CX_2$ (X = F or Cl), especially $F_2C{=}CF_2$, form cyclobutanes with many alkenes. Compounds of this type even react with conjugated dienes to give four-membered rings rather than undergoing normal Diels–Alder reactions.[1302]
2. Allenes[1303] and ketenes[1304] react with activated alkenes and alkynes. Ketenes give 1,2 addition, even with conjugated dienes.[1305] Ketenes also add to unactivated alkenes if sufficiently long reaction times are used.[1306] Allenes and ketenes also add to each other.[1307]
3. Enamines[1308] form four-membered rings with Michael-type alkenes[1309] and ketenes.[1310] In both cases, only enamines from aldehydes give stable four-

membered rings:

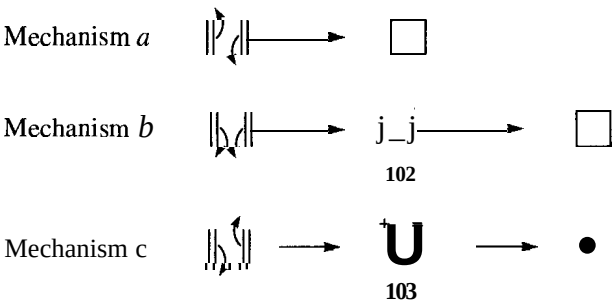


The reaction of enamines with ketenes can be conveniently carried out by generating the ketene *in situ* from an acyl halide and a tertiary amine.

4. Alkenes with electron-withdrawing groups may form cyclobutanes with alkenes containing electron-donating groups. The enamine reactions, mentioned above, are examples of this, but it has also been accomplished with tetracyanoethylene and similar molecules, which give substituted cyclobutanes when treated with alkenes of the form C=C–A, where A may be OR,[1311] SR (enol and thioenol ethers),[1312] cyclopropyl,[1313] or certain aryl groups.[1314]

Solvents are not necessary for 2 + 2 cycloadditions. They are usually carried out at 100–225°C under pressure, although the reactions in Group 4 (IV B) occur under milder conditions.

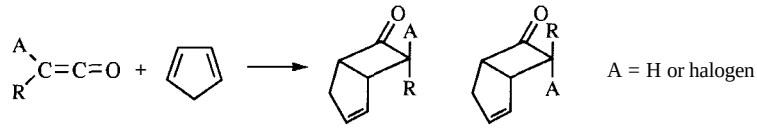
The reaction is similar to the Diels–Alder (in action, not in scope), and if dienes are involved, the latter reaction may compete, though most alkenes react with a diene either entirely by 1,2 or entirely by 1,4 addition. Three mechanisms can be proposed[1315] analogous to those proposed for the Diels–Alder reaction. Mechanism



a is a concerted pericyclic process, and mechanisms *b* and *c* are two-step reactions involving, respectively, a diradical (102) and a di-ion **(103)** intermediate. As in 15-58, a diradical intermediate must be a singlet. In searching for ways to tell which mechanism is operating in a given case, we would expect mechanism *c* to be sensitive to changes in solvent polarity, while mechanisms *a* and *b* should be insensitive. We would also expect mechanism *a* to be stereospecific, while mechanisms *b* and *c* probably would not be stereospecific, though if the second step of these processes takes place very rapidly, before **102** or **103** has a chance to rotate about the newly formed single bond, stereospecificity might be observed. Because of entropy

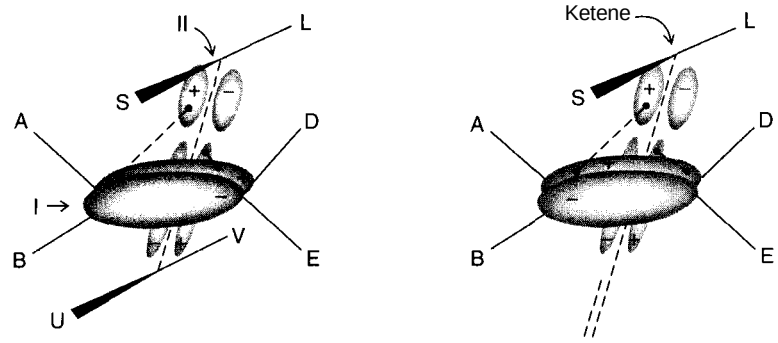
considerations such rapid ring closure might be more likely here than in a 2 + 4 cycloaddition.

There is evidence that the reactions can take place by all three mechanisms, depending on the structure of the reactants. A thermal $[_\pi 2_s + _\pi 2_s]$ mechanism is ruled out for most of these substrates by the orbital symmetry rules, but a $[_\pi 2_s + _\pi 2_a]$ mechanism is allowed (p. 1072), and there is much evidence that ketenes and certain other linear molecules[1316] in which the steric hindrance to such an approach is



endo 104 endo 105

minimal can and often do react by this mechanism. In a $[_\pi 2_s + _\pi 2_a]$ cycloaddition, the molecules must approach each other in such a way (Fig. 15.11*a*) that the (+) lobe of the HOMO of one molecule (I) overlaps with both (+) lobes of the LUMO of the other (II), even though these lobes are on opposite sides of the nodal plane of II. The geometry of this approach requires that the groups S and U of molecule II project *into* the plane of molecule I. This has not been found to happen for ordinary alkenes,[1317] but if molecule II is a ketene (Fig. 15.1 *b),* the group marked U is not present and the $[_\pi 2_s + _\pi 2_a]$ reaction can take place. Among the evidence[1318] for this mechanism[1319] is the following: (1) The reactions are stereospecific.[1320] (2) The isomer that forms is the *more-hindered one.* Thus methylketene plus cyclopentadiene gave only the endo product **(104,** A = H, R = CH_3).[1321] Even more remarkably, when haloalkyl ketenes RXC=C=O were treated with cyclopentadiene, the endo-exo ratio of the product (**104**, **105**, A = halogen) actually *increased* substantially when R was changed from Me to *i*-Pr to *t*-Bu![1322] One would expect preferential formation of the exo products **(105)** from $[_\pi 2_s + _\pi 2_s]$ cycloadditions where the molecules approach each other face-to-face, but a $[_\pi 2_s + _\pi 2_a]$ process leads to endo products because the ketene molecule (which for steric reasons would



(a) *(b)*

FIGURE 15.11 Orbital overlap in $_\pi 2_s + _\pi 2_a$, cycloaddition between *(a)* two alkene molecules and *(b)* a ketene and an alkene. S and L stand for small and large.

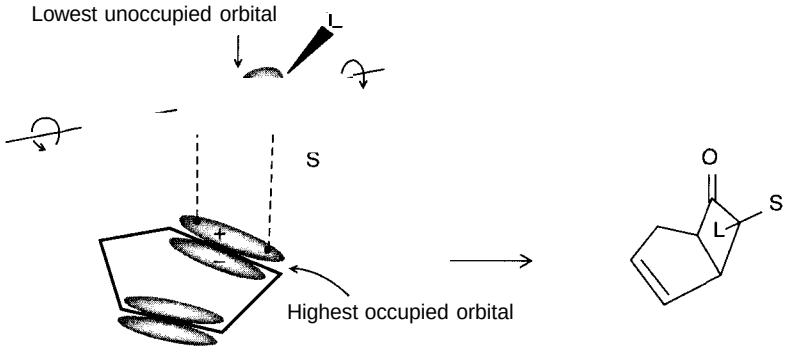


FIGURE 15.12 Orbital overlap in the reaction of a ketene with cyclopentadiene. The S and L stand for small and large.

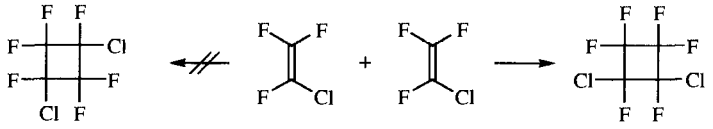
approach with its smaller group directed toward the alkene) must twist as shown in Fig. 15.12 (L = larger; S = smaller group) in order for the (+) lobes to interact and this swings the larger group into the endo position.[1323] The experimental results in which the amount of endo isomer increases with the increasing size of the R group would seem to be contrary to what would be expected from considerations of steric hindrance (we may call them *masochistic steric effects),* but they are just what is predicted for a $[\pi 2_s + \pi 2_a]$ reaction. (3) There is only moderate polar solvent acceleration.[1324] (4) The rate of the reaction is not very sensitive to the presence of electron-withdrawing or electron-donating substituents.[1325] Because cycloadditions involving allenes are often stereospecific, it has been suggested that these also take place by the $[\pi 2_s + \pi 2_a]$ mechanism,[1326] but the evidence in these cases is more consistent with the diradical mechanism ft.[1327]

The diradical mechanism *b* is most prominent in the reactions involving fluorinated alkenes.[1328] These reactions are generally not stereospecific[1329] and are insensitive to solvent effects. Further evidence that a diion is not involved is that head-to-head coupling is found when an unsymmetrical molecule is dimerized. Thus dimerization of $F_2C{=}CFCl$ gives **106,** not **107.** If one pair of electrons moved before the other, the positive end of one molecule would be expected to attack the negative end of the other.[1330]



The diion mechanism[1331] c has been reported for at least some of the reactions[1332] in categories 3 and 4,[1333] as well as some ketene dimerizations.[1334] For example, the rate of the reaction between l,2-bis(trifluoromethyl)-l,2-dicyanoethene and ethyl vinyl ether was strongly influenced by changes in solvent polarity.[1335] Some of these reactions are nonstereospecific, but others are stereospecific.[1336] As previously indicated, it is likely that in the latter cases the di-ionic

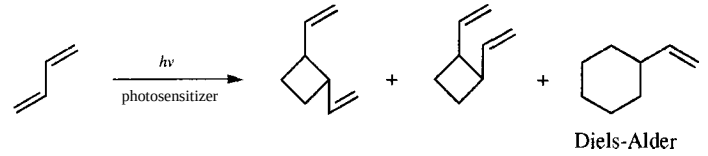
intermediate closes before rotation can take place. Such rapid ring closure is more likely for a diion than for a diradical because of the attraction between the opposite charges. Other evidence for the di-ion mechanism in these cases is that reaction rates are greatly dependent on the presence of electron-donating and electron-withdrawing groups and that it is possible to trap the di-ionic intermediates.

Whether a given alkene reacts by the diradical or di-ion mechanism depends, among other things, on the groups attached to it. For example, phenyl and vinyl groups at the a positions of **102** or **103** help to stabilize a diradical, while donors such as oxygen and nitrogen favor a di-ion (they stabilize the positively charged end).[1337] A table on page 451 of Ref. 960 shows which mechanism is more likely for 2 + 2 cycloadditions of various pairs of alkenes.

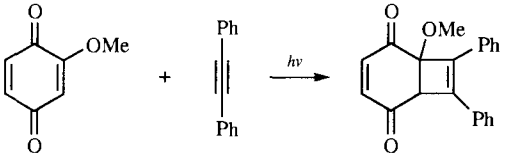
Thermal cleavage of cyclobutanes[1338] to give two alkene molecules *(cyclorever-sion*,[1339] the reverse of 2 + 2 cycloaddition) operates by the diradical mechanism, and the $[_{\sigma}2_{s} + _{CT}2_{a}]$ pathway has not been found[1340] (the subscripts σ indicate that σ bonds are involved in this reaction).

In some cases, double bonds add to triple bonds to give cyclobutenes, apparently at about the same rate that they add to double bonds. The addition of triple bonds to triple bonds would give cyclobutadienes, and this has not been observed, except where these rearrange before they can be isolated (see 15-63)[1341] or in the presence of a suitable coordination compound, so that the cyclobutadiene is produced in the form of a complex (p. 60).[1342]

Although thermal 2 + 2 cycloaddition reactions are essentially limited to the cases described above, many (though by no means all) double-bond compounds undergo such reactions *when photochemically excited* (either directly or by a photosensitizer, see p. 316), even if they are not in the above categories.[1343] Simple alkenes absorb in the far-UV (p. 310), which is difficult to reach experimentally, though this problem can sometimes be overcome by the use of suitable photosensitizers. The reaction has been applied to simple alkenes[1344] (especially to strained compounds such as cyclopropenes and cyclobutenes), but more often the double-bond compounds involved are conjugated dienes,[1345] α,β-unsaturated ketones,[1346] acids, or acid derivatives, or quinones, since these compounds, because they are conjugated, absorb at longer wavelengths (p. 310). Both dimerizations and mixed additions are common, some examples being (see also the example on p. 320):

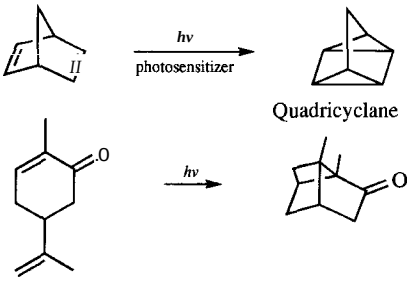


Ref. 1347



Ref. 1348

Photochemical 2 + 2 cycloadditions can also take place intramolecularly if a molecule has two double bonds that are properly oriented.[1349] The cyclization of the quinone dimer shown above is one example. Other examples are



Quadricyclane

Ref. 1350

Carvone

Carvonecamphor

Ref. 1351

It is obvious that many molecules can be constructed in this way that would be difficult to make by other procedures. However, attempted cyclizations of this kind are not always successful. In many cases, polymeric or other side products are obtained instead of the desired product.

It is possible that some of these photochemical cycloadditions take place by a $[_{\pi}2_s + _{\pi}2_s]$ mechanism, which is of course allowed by orbital symmetry; when and if they do, one of the molecules must be in the excited singlet state (S_1) and the other in the ground state.[1352] The nonphotosensitized dimerizations of *cis*- and *trans*-2-butene are stereospecific,[1353] making it likely that the $[_{\pi}2_s + _{\pi}2_s]$ mechanism is operating in these reactions. However, in most cases it is a triplet excited state that reacts with the ground-state molecule; in these cases the diradical (or in certain cases, the di-ionic) mechanism is taking place.[1354] In one intramolecular case, the intermediate diradical has been trapped.[1355] Photosensitized $2\pi + 2\pi$ cycloadditions almost always involve the triplet state, and hence a diradical (or di-ionic) mechanism.

The photochemical diradical mechanism is not quite the same as the thermal diradical mechanism. In the thermal mechanism, the initially formed diradical must be a singlet, but in the photochemical process a triplet excited state is adding to a ground state (which is of course a singlet). Thus, in order to conserve spin,[1356] the initially formed diradical must be a triplet; that is, the two electrons must have the same spin. Consequently, the second, or ring-closing, step of the mechanism cannot take place at once, because a new bond cannot form from a combination of two electrons with the same spin, and the diradical has a reasonably long lifetime before collisions with molecules in the environment allow a spin inversion to take place and the diradical to cyclize. We would therefore predict nonstereospecificity, and that is what is found.[1357] It has been believed that at least some 2 + 2 photocycloadditions take place by way of exciplex intermediates[1358] [an *exciplex*[1359] is an excited EDA complex (p. 102), which is dissociated in the ground state; in this case one double bond is the donor and the other is the acceptor], but there is evidence against this.[1360]

It has been found that certain 2 + 2 cycloadditions that do not occur thermally can be made to take place without photochemical initiation by the use of certain catalysts, usually transition metal compounds.[1361] Among the catalysts used are Lewis acids'[362] and phosphine-nickel complexes.[1363] Certain of the reverse cyclobutane ring openings can also be catalytically induced **(18-38).** The role of the catalyst is not certain and may be different in each case. One possibility is that the presence of the catalyst causes a forbidden reaction to become allowed, through coordination of the catalyst to the *n* or s bonds of the substrate.[1364] In such a case, the reaction would of course be a concerted $2_s + 2_s$ process. However, the available evidence is more consistent with nonconcerted mechanisms involving metal-carbon s-bonded intermediates, at least in most cases.[1365] For example, such an intermediate was isolated in the dimerization of norbornadiene, catalyzed by iridium complexes.[1366]

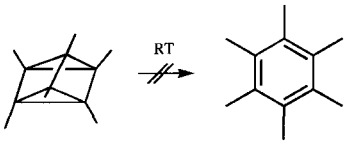
Thermal cycloadditions leading to four-membered rings can also take place between a cyclopropane ring and an alkene or alkyne[1367] bearing electron-withdrawing groups.[1368] These reactions are $_\pi 2 + {}_s 2$ cycloadditions. Ordinary cyclopropanes do not undergo the reaction, but it has been accomplished with strained systems such as bicyclo[1.1.0]butanes[1369] and bicyclo[2.1.0]pentanes. For example, bicyclo[2.1.0]pentane reacts with maleonitrile (or fumaronitrile) to give all three isomers of 2,3-dicyanonorbornane, as well as four other products.[1370] The lack of stereospecificity and the negligible effect of solvent on the rate indicate a diradical mechanism. Photochemical[1371] and metal-catalyzed[1372] $_\pi 2 + {}_s 2$ cycloadditions have also been reported.

In **15-58,** we used the principle of conservation of orbital symmetry to explain why certain reactions take place readily and others do not. The orbital symmetry principle can also explain why certain molecules are stable though highly strained. For example, quadricyclane and hexamethylprismane[1373] are thermodynamically much less stable (because much more strained) than their corresponding isomeric dienes, norbornadiene and hexamethylbicyclo[2.2.0]hexadiene (**108**).[1374] Yet the

Quadricyclane Norbornadiene Hexamethylprismane **108** (A Dewar benzene)

former two compounds can be kept indefinitely at room temperature (RT), although in the absence of orbital-symmetry considerations it is not easy to understand why the electrons simply do not move over to give the more stable diene isomers. The reason is that both these reactions involve the conversion of a cyclobutane ring to a pair of double bonds (a $_s 2 + {}_s 2$ process) and, as we have seen, a thermal process of this sort is forbidden by the Woodward-Hoffmann rules. The process is allowed photochemically, and we are not surprised to find that both quadricyclane and hexamethylprismane are photochemically converted to the respective dienes at RT or below.[1375] It is also possible to conceive of simple bond rearrangements whereby

hexamethylprismane is converted to hexamethylbenzene, which of course is far more



stable than either hexamethylprismane or **108.** It has been calculated that hexamethylbenzene is at least 90 kcal mol^{-1} (380 kJ mol^{-1}) more stable than hexamethylprismane. The fact that hexamethylprismane does not spontaneously undergo this reaction has prompted the observation[1376] that the prismane has "the aspect of an angry tiger unable to break out of a paper cage". However, a correlation diagram for this reaction1376 discloses that it too is a symmetry-forbidden process. All three of these "forbidden" reactions do take place when the compounds are heated, but the diradical mechanism is likely under these conditions.[1377]

Bicyclo[2.2.0]hexadienes and prismanes are *valence isomers* of benzenes.[1378] These compounds actually have the structures that were proposed for benzenes in the nineteenth century. Prismanes have the Ladenburg formula, and bicyclo[2.2.0]-hexadienes have the Dewar formula. Because of this bicyclo[2.2.0]hexadiene is often called Dewar benzene. On page 32 it was mentioned that Dewar formulas are canonical forms (though not very important) of benzenes. Yet, they also exist as separate compounds in which the positions of the nuclei are different from those of benzenes.

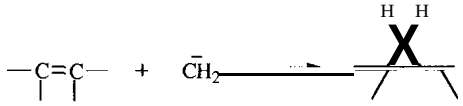
15-62 *The Addition of Carbenes and Carbenoids to Double and Triple Bonds*

fiPJ-METHYLENE-ADDITION



Carbenes and substituted carbenes add to double bonds to give cyclopropane derivatives ([1 + 2]-cycloaddition).[1379] Many derivatives of carbene (e.g., PhCH, ROCH)[1380] and $Me_2C{=}C$, and $C(CN)_2$, have been added to double bonds, but the reaction is most often performed with CH_2 itself, with halo and dihalocarbenes,[1381] and with carbalkoxycarbenes[1382] (generated from diazoacetic esters). Alkylcarbenes (HCR) have been added to alkenes,[1383] but more often these rearrange to give alkenes (p. 252). The carbene can be generated in any of the ways normally used (p. 249). However, most reactions in which a cyclopropane is formed by treatment of an alkene with a carbene "precursor" do not actually involve free carbene

intermediates. In some cases, it is certain that free carbenes are not involved, and in other cases there is doubt. Because of this, the term *carbene transfer* is often used to cover all reactions in which a double bond is converted to a cyclopropane, whether a carbene or a carbenoid (p. 250) is actually involved.

Carbene itself is extremely reactive and gives many side reactions, especially insertion reactions **(12-19),** which greatly reduce yields. When it is desired to add CH_2 for preparative purposes, free carbene is not used, but the Simmons-Smith procedure (p. 1088) or some other method that does not involve free carbenes is employed instead. Halocarbenes are less active than carbenes, and this reaction proceeds quite well, since insertion reactions do not interfere.[1384] The absolute rate constant for addition of selected alkoxychlorocarbene to butenes has been measured to range from 330 $M^{-1}s^{-1}$ to 1 x 10^4 $M^{-1}s^{-1}$.[1385] A few of the many ways[1386] in which halocarbenes or carbenoids are generated for this reaction are the following,[1387] most of which involve formal elimination (the first two steps of the S_N1cB mechanism, p. 448):

$$CH_2Cl_2 + RLi \longrightarrow CHCl$$

$$N_2CHBr \xrightarrow{h\nu} CHBr$$

$$CHCl_3 + OH^- \longrightarrow CCl_2$$

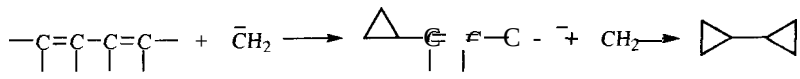
$$PhHgCCl_2Br \xrightarrow{\Delta} CCl_2 \qquad \text{Ref. 1388}$$

$$Me_3SnCF_3 + NaI \longrightarrow CF_2 \qquad \text{Ref. 1389}$$

$$Me_2CBr_2 \xrightarrow{\text{electrolysis}} Me_2C: \qquad \text{Ref. 1390}$$

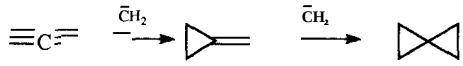
The reaction between $CHCl_3$ and OH^- is often carried out under phase-transfer conditions.[1391] It has been shown that the reaction between $PhCHCl_2$ and *t*-BuOK produces a carbenoid, but when the reaction is run in the presence of a crown ether, the free PhCCl is formed instead.[1392] Dihalocyclopropanes are very useful compounds[1393] that can be reduced to cyclopropanes, treated with magnesium or sodium to give allenes (18-3), or converted to a number of other products.

Alkenes of all types can be converted to cyclopropane derivatives by this reaction (though difficulty may be encountered with sterically hindered ones).[1394] Even tetracyanoethylene, which responds very poorly to electrophilic attack, gives cyclopropane derivatives with carbenes.[1395] Conjugated dienes give 1,2 addition:[1396]



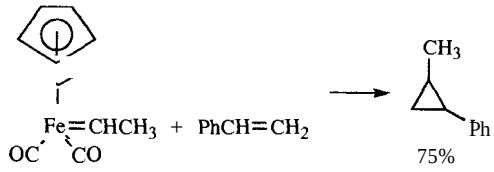
Addition of a second mole gives bicyclopropyl derivatives.[1397] 1,4 Addition is rare but has been reported in certain cases.[1398] Carbene adds to ketene to give cyclo-

propanone.[1399] Allenes react with carbenes to give cyclopropanes with exocyclic unsaturation:[1400]



A second mole gives spiropentanes. In fact, any size ring with an exocyclic double bond can be converted by a carbene to a spiro compound.[1401]

Free carbenes can also be avoided by using transition metal–carbene complexes $L_n M{=}CRR'$ (L = a ligand, M = a metal),[1402] which add the group CRR'to double bonds.[1403] An example is[1404]



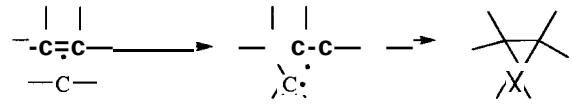
These complexes can be isolated in some cases; in others they are generated *in situ* from appropriate precursors, of which diazo compounds are among the most important. These compounds, including CH_2N_2 and other diazoalkanes, react with metals or metal salts (copper, palladium, and rhodium are most commonly used) to give the carbene complexes that add CRR' to double bonds.[1405] Ethyl α-diazoacetate reacts with styrene in the presence of bis(ferrocenyl) bis(imine), for example, to give ethyl 2-phenylcyclopropane-1-carboxylate.[1406] Optically active complexes have been used for enantioselective cyclopropane synthesis.[1407] Decomposition of diazoalkanes in the presence of chiral rhodium complexes leads to optically active cyclopropanes.[1408] An asymmetric, intramolecular cyclopropanation reaction has been reported that generates bicyclo[4.1.0]heptan-4-ones.[1409] In the presence of copper triflate[1410] or rhodium complexes,[1411] ethyl diazoacetate adds to imines to give aziridines.

Triple-bond compounds[1412] react with carbenes to give cyclopropenes, except that in the case of acetylene itself, the cyclopropenes first formed cannot be isolated because they rearrange to allenes.[1413] Cyclopropenones (p. 58) are obtained by hydrolysis of dihalocyclopropenes.[1414]

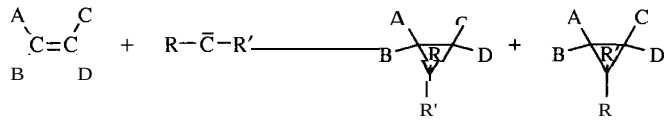
Most carbenes are electrophilic, and, in accord with this, electron-donating substituents on the alkene increase the rate of the reaction, and electron-withdrawing groups decrease it,[1415] though the range of relative rates is not very great.[1416] As discussed on page 252, carbenes in the singlet state (which is the most common state) react stereospecifically and syn,[1417] probably by a one-step mechanism,[1418] similar to mechanism *a* of 15-58 and 15-61:

Infrared spectra of a carbene and the cyclopropane product have been observed in an argon matrix at 12-45 K.[1419] Carbenes in the triplet state react nonstereospecifi-

cally,[1420] probably by a diradical mechanism, similar to mechanism *b* of 15-47 and 15-61:

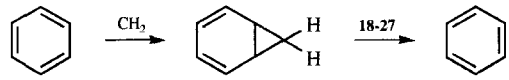


For carbenes or carbenoids of the type R—C—R′ there is another aspect of stereochemistry.[1421] When these species are added to all but symmetrical alkenes, two isomers are possible, even if the four groups originally on the double-bond carbons maintain their configurations:



Which isomer is predominantly formed depends on R, R', and on the method by which the carbene or carbenoid is generated. Most studies have been carried out on monosubstituted species (R' = H), and in these studies it is found that aryl groups generally prefer the more substituted side (syn addition) while carbethoxy groups usually show anti stereoselectivity. When R = halogen, free halocarbenes show little or no stereochemical preference, while halocarbenoids exhibit a preference for syn addition. Beyond this, it is difficult to make simple generalizations.

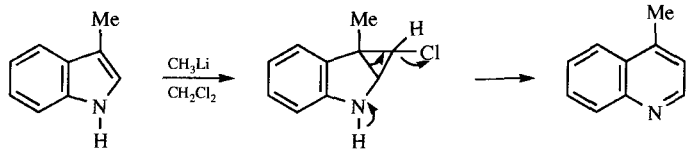
Carbenes are so reactive that they add to the "double bonds"of aromatic rings. The products are usually not stable and rearrange to give ring expansion. Carbene reacts with benzene to give cycloheptatriene:[1422]



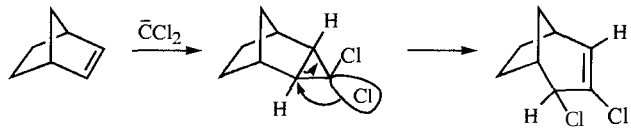
Norcaradiene

but not all carbenes are reactive enough to add to benzene. The norcaradiene intermediate cannot be isolated in this case (it undergoes an electrocyclic rearrangement, **18-27**),[1423] though certain substituted norcaradienes, for example, the product of addition of $C(CN)_2$ to benzene,[1424] have been isolated.[1425] With CH_2, insertion is a major side reaction, and, for example, benzene gives toluene as well as cycloheptatriene. A method of adding CH_2 to benzene rings without the use of free carbene is the catalytic decomposition of CH_2N_2 in the aromatic compound as solvent with CuCl or CuBr.[1426] By this method, better yields of cycloheptatrienes are obtained without insertion side products. Picosecond optical grating calorimetry has been used to investigate the photochemical decomposition of diazomethane in benzene, and it appears that a transient is formed that is consistent with a weak complex between singlet methylene and benzene.[1427] The compound CHC1 is active enough to add to benzene, but dihalocarbenes do not add to benzene or toluene, only to rings with greater electron density. Pyrroles and indoles can be expanded,

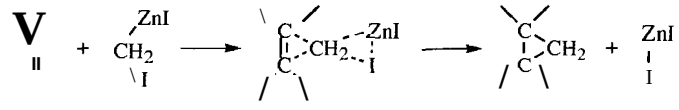
respectively, to pyridines and quinolines by treatment with halocarbenes,[1428] for example



In such cases, a side reaction that sometimes occurs is expansion of the *six-membered* ring. Ring expansion can occur even with nonaromatic compounds, when the driving force is supplied by relief of strain,[1429] for example



As previously mentioned, free carbene is not very useful for additions to double bonds since it gives too many side products. The *Simmons–Smithreaction* accomplishes the same result without a free carbene intermediate and without insertion side products.[1430] This procedure involves treatment of the double-bond compound with CH_2I_2 and a Zn—Cu couple and leads to cyclopropane derivatives in good yields.[1431] The Zn—Cu couple can be prepared in several ways,[1432] of which heating Zn dust with CuCl in ether under nitrogen[1433] is particularly convenient. The reaction has also been done with unactivated zinc and ultrasound.[1434] When $TiCl_4$ is used along with Zn and CuCl, CH_2I_2 can be replaced by the cheaper CH_2Br_2.[1435] The actual attacking species is an organozinc intermediate, probably $(ICH_2)_2Zn{\cdot}ZnI_2$. This intermediate is stable enough for solutions of it to be isolable.[1436] An X-ray crystallographic investigation of the intermediate, complexed with a diether, has been reported.[1437] The addition is stereospecifically syn, and a concerted mechanism[1438] is likely, perhaps[1439] Asymmetric induction is possible when chiral additives



are used.[1440] With the Simmons-Smith procedure, as with free carbenes, conjugated dienes give 1,2 addition,[1441] and allenes give methylenecyclopropanes or spiropentanes.

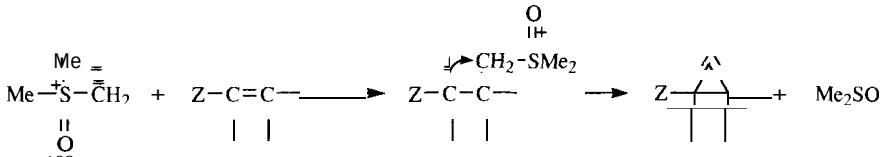
An alternative way of carrying out the Simmons-Smith reaction is by treatment of the substrate with CH_2I_2 or another dihalomethane and Et_2Zn in ether. This method can be adapted to the introduction of RCH and ArCH by the use of $RCHI_2$ or $ArCHI_2$ instead of the dihalomethane.[1442] In another method, CH_2I_2 or $MeCHI_2$ is used along with an alane R_3Al to transfer CH_2 or MeCH.[1443] For the conversion of enolates to cyclopropanols, CH_2I_2 has been used along with SmI_2.[1444]

Other cyclopropanation techniques have been developed. Treatment of an alkene with $ArCH(SnBu_3)OCO_2Me$ and $BF_3{\cdot}OEt_2$ leads to the cyclopropane with high cis

selectivity.[1445] Diodomethane in the presence of isopropylmagnesium chloride has been used to cyclopropanate allyl alcohols.[1446]

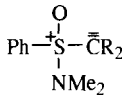
The Simmons–Smith reaction has been used as the basis of a method for the indirect a methylation of a ketone.[1447] The ketone (illustrated for cyclohexanone) is first converted to an enol ether, an enamine **(16-12)** or silyl enol ether (**12-22**)[1448] and cyclopropanation via the Simmons-Smith reaction is followed by hydrolysis to give a methylated ketone. A related procedure using diethylzinc and diiodomethane allows ketones to be chain extended by one carbon.[1449] In another variation, phenols can be ortho methylated in one laboratory step, by treatment with Et_2Zn and CH_2I_2.[1450]

Double-bond compounds that undergo the Michael reaction **(15-21)** can be converted to cyclopropane derivatives with sulfur ylids.[1451] Among the most common of these is dimethyloxosulfonium methylid (**109**),[1452] which is widely used to



109

transfer CH_2 to activated double bonds, but other sulfur ylids have also been used. Both CHR and CR_2 can be added in a similar manner with certain nitrogen-containing compounds. For example, ylids[1453] such as **110** add various groups to



110

activated double bonds.[1454] Similar reactions have been performed with phosphorus ylids,[1455] with pyridinium ylids,[1456] and with the compounds $(PhS)_3CLi$ and $Me_3Si(PhS)_2CLi$.[1457] The reactions with ylids are of course nucleophilic addition.

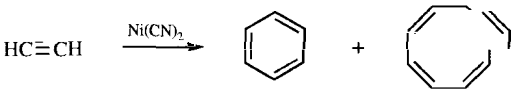
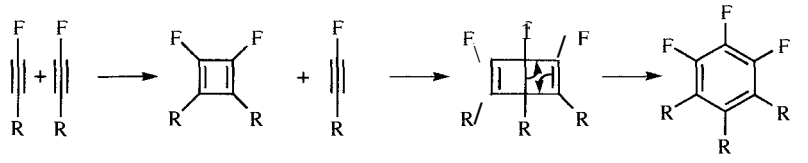
15-63 *Trimerization and Tetramerization of Alkynes*



When acetylene is heated with nickel cyanide, other Ni(II) or Ni(0) compounds, or similar catalysts, it gives benzene and cyclooctatetraene.[1458] It is possible to get more of either product by a proper choice of catalyst. Substituted acetylenes give substituted benzenes.[1459] This reaction has been used to prepare very crowded molecules. Diisopropylacetylene was trimerized over $CO_2(CO)_8$ and over $Hg[Co(CO)_4]_2$ to hexaisopropylbenzene.[1460] The six isopropyl groups are not free to rotate but are lined up perpendicular to the plane of the benzene ring. Highly substituted benzene derivatives have also been prepared using a rhodium complex.[1461] A triyne

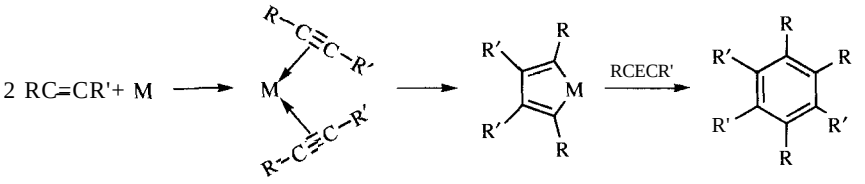
containing an N-tosyl unit was trimerized in the presence of $Mo(CO)_6$ to a tricyclic compound containing a benzene ring.[1462] Even more interesting was the *spontaneous* (no catalyst) trimerization of *t*-BuC≡CF to give 1,2,3-tri-*tert*-butyl-4,5,6-trifluorobenzene **(112),** the first time three adjacent tert-butyl groups had been put onto a benzene ring.[1463] The fact that this is a head-to-head joining makes the following sequence likely:



R = *tert*-butyl **111** **112**

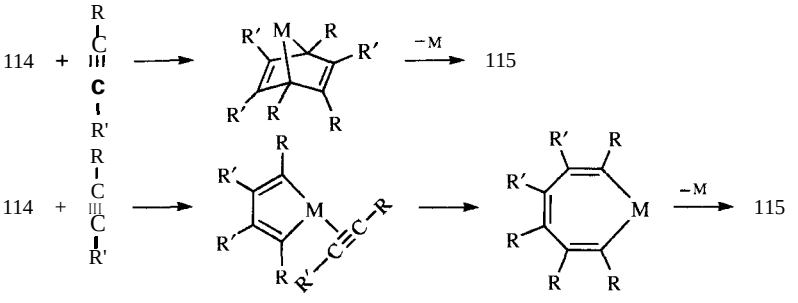
The fact that **111** (a Dewar benzene) was also isolated lends support to this scheme.[1464] Three equivalents of 3-hexyne trimerized to hexaethylbenzene at 200°C in the presence of SI_2Cl_6.[1465]

In contrast to the spontaneous reaction, the catalyzed process seldom gives the 1,2,3-trisubstituted benzene isomer from an acetylene RC=CH. The chief product is usually the 1,2,4-isomer, with lesser amounts of the 1,3,15-isomer also generally obtained, but little if any of the 1,2,3-isomer. The mechanism of the catalyzed



113 114 **115**

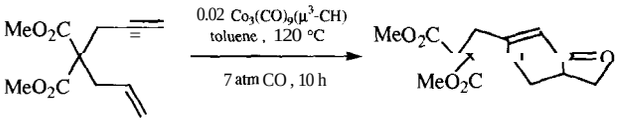
reaction to form benzenes[1466] is believed to go through a species **113** in which two molecules of alkyne coordinate with the metal, and another species **114,** a five-membered heterocyclic intermediate.[1467] Such intermediates (where M = Rh, Ir, or Ni) have been isolated and shown to give benzenes **(115)** when treated with alkynes.[1468] Note that this pathway accounts for the predominant formation of the 1,2,4-isomer. Two possibilities for the last step are a Diels–Alder reaction, and a ring expansion, each followed by extrusion of the metal:[1469]



In at least one case the mechanism is different, going through a cyclobutadiene-nickel complex (p. 60), which has been isolated.[1470]

When benzene, in the gas phase, was adsorbed onto a surface of 10% rhodium-on-alumina, the reverse reaction took place, and acetylene was formed.[1471]

The reaction of alkenes with alkenes or alkynes does not always produce an aromatic ring. An important variation of this reaction reacts dienes, diynes, or enynes with transition metals to form organometallic coordination complexes. In the presence of carbon monoxide, cyclopentenone derivatives are formed in what is known as the *Pauson-Khand reaction.*[1472] The reaction involves (1) formation of a hexacarbonyldicobalt-alkyne complex and (2) decomposition of the complex in the presence of an alkene.[1472] A typical example is[1473] Rhodium[1474] and tungsten[1475]



complexes have also been used for this reaction. The reaction can be promoted photochemically[1476] and the rate is enhanced by the presence of primary amines.[1477] Coordinating ligands also accelerate the reaction.[1478] Asymmetric Pauson-Khand reactions are known.[1479]

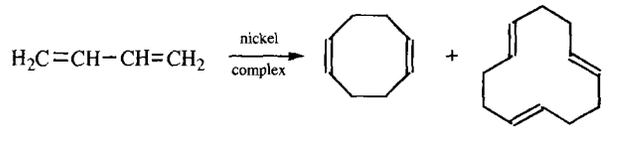
For addition of triple bonds to triple bonds, but not with ring formation, see **15-19.**

In a related reaction, heating ketones in the presence of $TlCl_3OTf$ leads to 1,3,5-trisubstituted arenes.[1480] Nitriles react with 2 mol of acetylene, in the presence of a cobalt catalyst, to give 2-substituted pyridines.[1481] Triketones fix nitrogen gas in the presence of $TiCl_4$ and lithium metal to form bicyclic pyrrole derivatives.[1482]

OS **VII,** 256; IX, 1.

15-64 *Other Cycloaddition Reactions*

CYCLO-[BUT-2-EN-1,4-DIYL]-1/4/ADDITION, AND SO ON



Conjugated dienes can be dimerized or trimerized at their 1,4 positions (formally, [4 + 4] and [4 + 4 + 4] cycloadditions) by treatment with certain complexes or other transition metal compounds.[1483] Thus butadiene gives 1,5-cyclooctadiene and 1,5,9-cyclododecatriene.[1484] The relative amount of each product can be controlled by use of the proper catalyst. For example, $Ni:P(OC_6H_4\text{–}o\text{-}Ph)_3$ gives predominant dimerization, while Ni(cyclooctadiene)$_2$ gives mostly trimerization. The products arise, not by direct 1,4 to 1,4 attack, but by stepwise mechanisms involving metal-alkene complexes.[1485]

As we saw in **15-58,** the Woodward-Hoffmann rules allow suprafacial concerted cycloadditions to take place thermally if the total number of electrons is $An + 2$ and

photochemically if the number is *An.* Furthermore, forbidden reactions become allowed if one molecule reacts antarafacially. It would thus seem that syntheses of many large rings could easily be achieved. However, when the newly formed ring is eight-membered or greater, concerted mechanisms, though allowed by orbital symmetry for the cases stated, become difficult to achieve because of the entropy factor (the two ends of one system must simultaneously encounter the two ends of the other), unless one or both components are cyclic, in which case the molecule has many fewer possible conformations. There have been a number of reports of cycloaddition reactions leading to eight-membered and larger rings, some thermally and some photochemically induced, but (apart from the dimerization and trimerization of butadienes mentioned above, which are known not to involve direct [4 + 4] or [4 + 4 + 4] cycloaddition) in most cases evidence is lacking to indicate whether they are concerted or stepwise processes. Some examples are

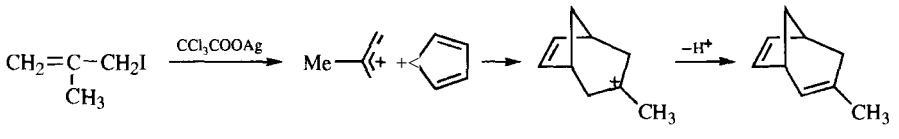
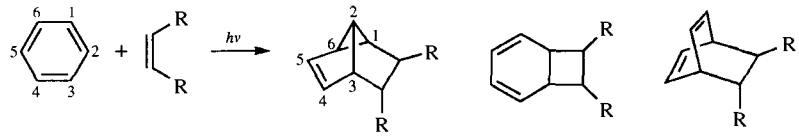
2 + 8 
Ref. 1488

4 + 6 
The suprafacial thermal addition of an allylic cation to a diene (a [3 + 4] cycloaddition) is allowed by the Woodward-Hoffmann rules (this reaction would be expected to follow the same rules as the Diels–Alder reaction[1490]). Such cycloadditions can be carried out[1491] by treatment of a diene with an allylic halide in the presence of a suitable silver salt, for example,[1492]



This reaction has even been carried out with benzene assuming the role of the diene.[1493]

Benzene rings can undergo photochemical cycloaddition with alkenes.[1494] The major product is usually the 1,3 addition product, **116** (in which a three-membered ring has also been formed), though some of the 1,2 product **(117)**



116 **117** **118**

(15-61) is sometimes formed as well. (Compound **117** is usually the main product where the alkene bears electron-withdrawing groups and the aromatic compound electron-donating groups, or vice versa.) The 1,4 product **(118)** is rarely formed. The reaction has also been run with benzenes substituted with alkyl, halo, OR, CN, and other groups, and with acyclic and cyclic alkenes bearing various groups.[1495]

A [2 + 2 + 2]-cycloaddition reaction is also known, facilitated by Ni(cod)2.[1496]

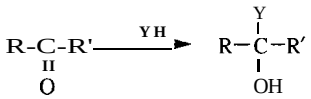
CHAPTER 16

Addition to Carbon-Hetero Multiple Bonds

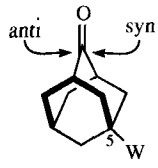
MECHANISM AND REACTIVITY

The reactions considered in this chapter involve addition to the carbon-oxygen, carbon–nitrogen, and carbon-sulfur double bonds and the carbon–nitrogen triple bond. The mechanistic study of these reactions is much simpler than that of the additions to carbon-carbon multiple bonds considered in Chapter 15.[1] Most of the questions that concerned us there either do not arise here or can be answered very simply. Since C=O, C=N, and C≡N bonds are strongly polar, with the carbon always the positive end (except for isocyanides, see p. 1251), there is never any doubt about the *orientation* of unsymmetrical addition to these bonds. Nucleophilic attacking species always go to the carbon and electrophilic ones to the oxygen or nitrogen. Additions to C=S bonds are much less common,[2] but in these cases the addition can be in the other direction.[3] For example, thiobenzophenone ($Ph_2C{=}S$), when treated with phenyllithium gives, after hydrolysis, benzhydryl phenyl sulfide (Ph_2CHSPh).[4] The *stereochemistry* of addition is not generally a factor because it is not normally possible to determine whether the addition is syn or anti. In addition of YH to a ketone, for example,



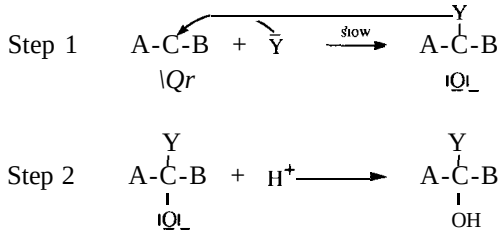
the product has a chiral carbon, but unless there is chirality in R or R' or YH is optically active, the product must be a racemic mixture and there is no way to tell from its steric nature whether the addition of Y and H was syn or anti. The same holds true for C=N and C=S bonds, since in none of these cases can chirality be present at the hetero atom. The stereochemistry of addition of a single YH to the carbon–nitrogen triple bond could be investigated, since the product can exist in (*E*) and (Z) forms (p. 139), but these reactions are not very important. Of course, if R or R' *is* chiral, a racemic mixture will not always arise and the stereochemistry of addition can be studied in such cases. Cram's rule (p. 147) allows us to predict the direction of attack of Y in many cases.[5] However, even in this type of study, the relative directions of attack of Y and H are not determined, but only the direction of attack of Y with respect to the rest of the substrate molecule.

On page 987, it was mentioned that electronic effects can play a part in determining which face of a carbon-carbon double bond is attacked. The same applies to additions to carbonyl groups. For example, in 5-substituted adamantanones:



electron-withdrawing ($-I$) groups W cause the attack to come from the syn face, while electron-donating groups cause it to come from the anti face.[6] In 5,6-disubstituted norborn-2-en-7-one systems, the carbonyl appears to tilt away from the π bond, with reduction occurring from the more hindered face.[7] An *ab initio* study of nucleophilic addition to 4-*tert*-butylcyclohexanones attempted to predict π-facial selectivity in that system.[8]

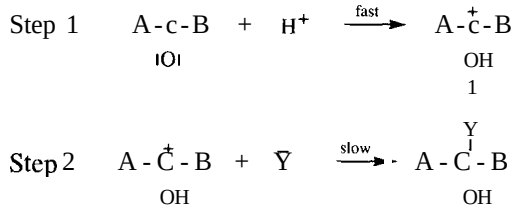
The mechanistic picture is further simplified by the fact that free-radical additions to carbon-hetero double bonds are rare.[9] The principal question remaining is which attacks first, the nucleophile or electrophile. In most cases it is the nucleophile that forms the first new bond to carbon, and these reactions are regarded as *nucleophilic additions*, which can be represented thus (for the C=O bond, analogously for the others):



The electrophile shown in step 2 is the proton. In almost all the reactions considered in this chapter, the electrophilic attacking atom is either hydrogen or carbon. It may be noted that step 1 is exactly the same as step 1 of the tetrahedral mechanism of nucleophilic substitution at a carbonyl carbon (p. 424), and it might be expected that substitution would compete with addition. However, this is seldom the case. When A and B are H, R, or Ar, the substrate is an aldehyde or ketone and these almost never undergo substitution, owing to the extremely poor nature of H, R, and Ar as leaving groups. For carboxylic acids and their derivatives (B = OH, OR, NH_2, etc.), addition is seldom found because these are much better leaving groups. It is thus the nature of A and B that determines whether a nucleophilic attack at a carbon-hetero multiple bond will lead to substitution or addition.

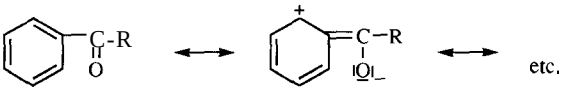
As is the case in the tetrahedral mechanism, it is also possible for the electrophilic species to attack first, in which case it goes to the heteroatom. This species is most

often a proton and the mechanism is



No matter which species attacks first, the rate-determining step is usually the one involving nucleophilic attack. It may be observed that many of these reactions can be catalyzed by both acids and bases.[10] Bases catalyze the reaction by converting a reagent of the form YH to the more powerful nucleophile Y^- (see p. 438). Acids catalyze it by converting the substrate to an ion (e.g., 1) in which the positive charge on the carbon is greatly increased, thus making it more attractive to nucleophilic attack. Similar catalysis can also be found with metallic ions, such as Ag^+, which act here as Lewis acids.[11] We have mentioned before (p. 223) that ions of type 1 are comparatively stable carbocations because the positive charge is spread by resonance.

Reactivity factors in additions to carbon-hetero multiple bonds are similar to those for the tetrahedral mechanism of nucleophilic substitution.[12] If A and/or B are electron-donating groups, rates are decreased. Electron-attracting substituents increase rates. This means that aldehydes are more reactive than ketones. Aryl groups are somewhat deactivating compared to alkyl, because of resonance that stabilizes the substrate molecule but is lost on going to the intermediate:

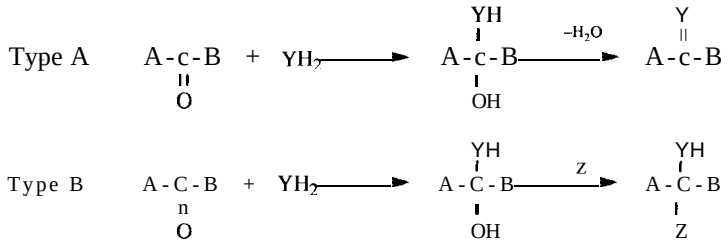


Double bonds in conjugation with the carbon-hetero multiple bond also lower addition rates, for similar reasons but, more important, may provide competition from 1,4 addition (p. 977). Steric factors are also quite important and contribute to the decreased reactivity of ketones compared with aldehydes. Highly hindered ketones like hexamethylacetone and dineopentyl ketone either do not undergo many of these reactions or require extreme conditions.

REACTIONS

Many of the reactions in this chapter are simple additions to carbon-hetero multiple bonds, with the reaction ending when the two groups have been added. But in many

other cases subsequent reactions take place. We shall meet a number of such reactions, but most are of two types:



In type *A*, the adduct loses water (or, in the case of addition to C=NH, ammonia, etc.), and the net result of the reaction is the substitution of C=Y for C=O (or C=NH, etc.). In type *B*, there is a rapid substitution, and the OH (or NH_2, etc.) is replaced by another group Z, which is often another YH moiety. This substitution is in most cases nucleophilic, since Y usually has an unshared pair and S_N1 reactions occur very well on this type of compound (see p. 434), even when the leaving group is as poor as OH or NH_2. In this chapter, we shall classify reactions according to what is initially adding to the carbon-hetero multiple bond, even if subsequent reactions take place so rapidly that it is not possible to isolate the initial adduct.

Most of the reactions considered in this chapter can be reversed. In many cases, we shall consider the reverse reactions with the forward ones, in the same section. The reverse of some of the other reactions are considered in other chapters. In still other cases, one of the reactions in this chapter is the reverse of another (e.g., 16-2 and 16-12). For reactions that are reversible, the principle of microscopic reversibility (p. 285) applies.

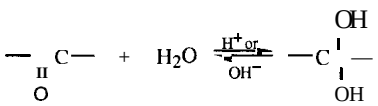
We shall discuss first reactions in which hydrogen or a metallic ion (or in one case phosphorus or sulfur) adds to the hetero atom, and then reactions in which carbon adds to the hetero atom. Within each group, the reactions are classified by the nature of the nucleophile. Additions to isocyanides, which are different in character, are treated at the end.

Reactions in Which Hydrogen or a Metallic Ion Adds to the Hetero Atom

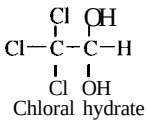
A. *Attack by OH (Addition of H_2O)*

16-1 *The Addition of Water to Aldehydes and Ketones: Formation of Hydrates*

O-HYDRO-*C*-HYDROXY-ADDITION



The adduct formed upon addition of water to an aldehyde or ketone is called a hydrate or *gem*-diol.[13] These compounds are usually stable only in water solution and decompose on distillation; that is the equilibrium shifts back toward the carbonyl compound. The position of the equilibrium is greatly dependent on the structure of the hydrate. Thus, formaldehyde in water at 20°C exists 99.99% in the hydrated form, while for acetaldehyde this figure is 58%, and for acetone the hydrate concentration is negligible.[14] It has been found, by exchange with ^{18}O, that the reaction with acetone is quite rapid when catalyzed by acid or base, but the equilibrium lies on the side of acetone and water.[15] Since methyl, a +/ group, inhibits hydrate formation, it may be expected that electron-attracting groups would have the opposite effect, and this is indeed the case. The hydrate of chloral[16] is a stable crystalline substance. In order for it to revert to chloral, OH^- or H_2O must leave; this is made difficult by the electron-withdrawing character of the Cl_3C group. Some other[17] polychlorinated and polyfluorinated aldehydes and ketones[18] and α-keto



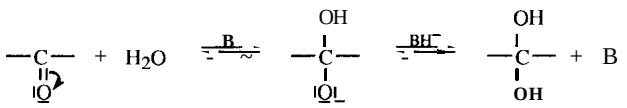
Chloral hydrate

Hydrate of cyclopropanone

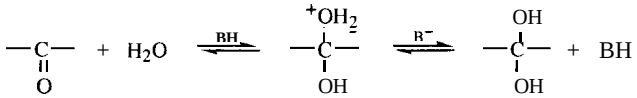
aldehydes also form stable hydrates, as do cyclopropanones.[19] In the last case,[20] formation of the hydrate relieves some of the / strain (p. 366) of the parent ketone.

The reaction is subject to both general-acid and general-base catalysis; the following mechanisms can be written for basic (B) and acidic (BH) catalysis, respectively:[21]

Mechanism a



Mechanism b



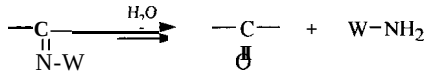
In mechanism *a*, as the H_2O attacks, the base pulls off a proton, and the net result is addition of OH^-. This can happen because the base is already hydrogen bonded to the H_2O molecule before the attack. In mechanism *b*, because HB is already hydrogen bonded to the oxygen of the carbonyl group, it gives up a proton to the oxygen as the water attacks. In this way, B and HB accelerate the reaction even beyond the extent that they form OH^- or H_3O^+ by reaction with water. Reactions in which the catalyst donates a proton to the electrophilic reagent (in this case the aldehyde or ketone) in one direction and removes it in the other are called class *e* reactions. Reactions in which the catalyst does the same to the nucleophilic reagent are called class *n* reactions.[22] Thus the acid-catalyzed process here is a class *e* reaction, while the base catalyzed process is a class *n* reaction.

For the reaction between ketones and H_2O_2, see **17-39.**

There are no OS references, but see OS **VIII,** 597, for the reverse reaction.

16-2 *Hydrolysis of the Carbon-Nitrogen Double Bond*

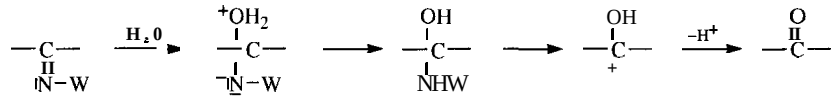
OXO-DE-ALKYLIMINO-BISUBSTITUTION, AND SO ON



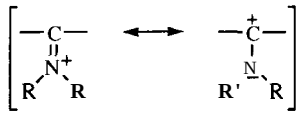
Compounds containing carbon–nitrogen double bonds can be hydrolyzed to the corresponding aldehydes or ketones. For imines (W = R or H) the hydrolysis is easy and can be carried out with water. When W = H, the imine is seldom stable enough for isolation, and hydrolysis usually occurs *in situ*, without isolation. The hydrolysis of Schiff bases (W = Ar) is more difficult and requires acid or basic catalysis. Oximes (W = OH), arylhydrazones (W = NHAr), and, most easily, semicarbazones ($W = NHCONH_2$) can also be hydrolyzed. Often a reactive aldehyde (e.g., formaldehyde) is added to combine with the liberated amine.

A number of other reagents[23] have been used to cleave C=N bonds, especially those not easily hydrolyzable with acidic or basic catalysts or which contain other functional groups that are attacked under these conditions. In particular, oximes have been converted to the corresponding aldehyde or ketone by treatment with, among other reagents, microwave irradiation on clay (Clayan),[24] on wet sodium periodate impregnated silica gel,[25] or in the presence of $BiCl_3$,[26] $CuCl_2$ in acetonitrile,[27] ozonolysis,[28] aqueous $NaHSO_3$,[29] $KMnO_4$–aqueous acetonitrile,[30] Amberlyst 15 and acetone,[31] alkaline H_2O_2,[32] and with $Me_3NH^+ CrO_3Cl^-$.[33] Tosylhydrazones can be hydrolyzed to the corresponding ketones with aqueous acetone and BF_3–etherate,[34] as well as with other reagents.[35] Dimethylhydrazones have been converted to ketones by heating with potassium carbonate in dimethyl sulfate,[36] or by microwave irradiation with $BiCl_3$ in aqueous THF.[37] Among other reagents that have been used to cleave C=N bonds are nitrous acid (as well as nitrosonium salts such as $NO^+BF_4^-$)[38] and ozone (see 19-9).[39]

The hydrolysis of carbon–nitrogen double bonds involves initial addition of water and elimination of a nitrogen moiety:

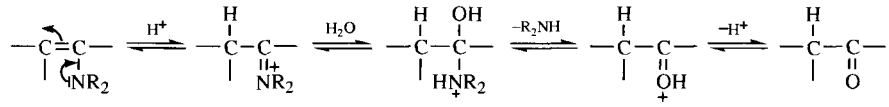


It is thus an example of reaction type A (p. 1175). The sequence shown is generalized.[40] In specific cases there are variations in the sequence of the steps, depending on acid or basic catalysis or other conditions.[41] Which step is rate determining also depends on acidity and on the nature of W and of the groups connected to the carbonyl.[42]



2

Iminium ions (2)[43] would be expected to undergo hydrolysis quite readily, since there is a contributing form with a positive charge on the carbon. Indeed, they react with water at room temperature.[44] Acid-catalyzed hydrolysis of enamines (the last step of the Stork reaction, **12-18)** involves conversion to iminium ions:[45]



The mechanism of enamine hydrolysis is thus similar to that of vinyl ether hydrolysis (10-6).

OS I, 217, 298, 318, 381; **II,** 49, 223, 234, 284, 310, 333, 395, 519, 522; **III,** 20, 172, 626, 818; IV, 120; V, 139, 277, 736, 758; VI, 1, 358, 640, 751, 901, 932; **VII,** 8; 65, 108, 183; 67, 33; 76, 23.

Related to this process is the hydrolysis of isocyanates or isothiocyanates[46] where addition of water to the carbon–nitrogen double bond would give an N-substituted carbamic acid (3). Such compounds are unstable and break down to carbon dioxide (or COS in the case of isothiocyanates) and the amine:

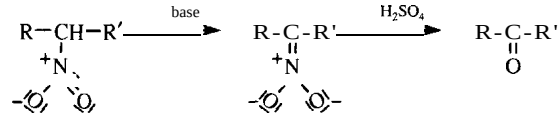
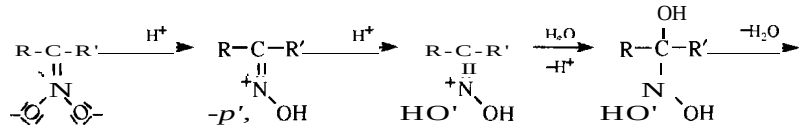
OS **II,** 24; IV, 819; V, 273; VI, 910.

16-3 *Hydrolysis of Aliphatic Nitro Compounds*

OXO-DE-HYDRO,NITRO-BISUBSTITUTION

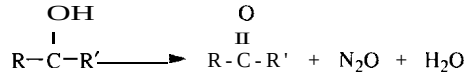


Primary or secondary aliphatic nitro compounds can be hydrolyzed, respectively, to aldehydes or ketones, by treatment of their conjugate bases with sulfuric acid. This is called the *Nef reaction.*[47] Tertiary aliphatic nitro compounds do not give the reaction because they cannot be converted to their conjugate bases. Like **16-2,** this reaction involves hydrolysis of a C=N double bond. A possible mechanism is[48]



Aci form of the nitro compound

4



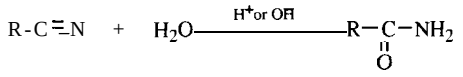
Intermediates of type 4 have been isolated in some cases.[49]

The conversion of nitro compounds to aldehydes or ketones has been carried out with better yields and fewer side reactions by several alternative methods. Among these are treatment of the nitro compound with tin complexes and $NaHSO_3$,[50] activated dry silica gel,[51] or 30% H_2O_2—K_2CO_3,[52] *t*-BuOOH and a catalyst,[53] or CAN.[54]

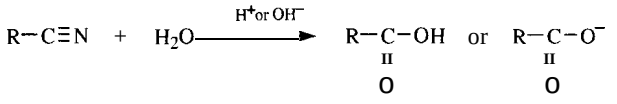
When *primary* nitro compounds are treated with sulfuric acid without previous conversion to the conjugate bases, they give carboxylic acids. Hydroxamic acids are intermediates and can be isolated, so that this is also a method for preparing them.[55] Both the Nef reaction and the hydroxamic acid process involve the aci form; the difference in products arises from higher acidity, for example, a difference in sulfuric acid concentration from 2 to 15.5 *M* changes the product from the aldehyde to the hydroxamic acid.[56] The mechanism of the hydroxamic acid reaction is not known with certainty, but if higher acidity is required, it may be that the protonated aci form of the nitro compound is further protonated.

OS VI, 648; VII, 414. See also OS IV, 573.

16-4 *Hydrolysis of Nitrites*



N,N-Dihydro-*C*-*oxo*-biaddition



Hydroxy,oxo-de-nitrilo-tersubstitution

Nitriles can be hydrolyzed to give either amides or carboxylic acids.[57] The amide is formed initially, but since amides are also hydrolyzed with acid or basic treatment, the carboxylic acid is the more common product. When the acid is desired.[58] the reagent of choice is aqueous NaOH containing $\sim$6–12% H_2O_2, though acid-catalyzed hydrolysis is also frequently carried out. A "dry" hydrolysis of nitriles has been reported.[59] However, there are a number of procedures for stopping at the amide stage,[60] among them the use of concentrated H_2SO_4; acetic acid and BF_3; H_2O_2 and OH^-;[61] two equivalents of chlorotrimethylsilane followed by H_2O,[62] heating on neutral alumina,[63] Oxone®,[64] and dry HC1 followed by H_2O. The same result can also be obtained by use of water and certain metal ions or complexes;[65] $Hg(OAc)_2$ in HOAc;[66] or 2-mercaptoethanol in a phosphate buffer.[67] Nitriles can be hydrolyzed to the carboxylic acids without disturbing carboxylic ester functions also present, by the use of tetrachloro- or tetrafluorophthalic acid.[68]

The hydrolysis of nitriles to carboxylic acids is one of the best methods for the preparation of these compounds. Nearly all nitriles give the reaction, with either acidic or basic catalysts. Hydrolysis of cyanohydrins, RCH(OH)CN, is usually carried out under acidic conditions, because basic solutions cause competing reversion of the cyanohydrin to the aldehyde and CN^-. However, cyanohydrins have been hydrolyzed under basic conditions with borax or alkaline borates.[69]

Thiocyanates can be converted to thiocarbamates, in a similar reaction:[70] $R{-}S{-}C{\equiv}N + H_2O \rightarrow R{-}S{-}CO{-}NH_2$. Hydrolysis of cyanamides gives amines,

produced by the breakdown of the unstable carbamic acid intermediates: $R_2NCN \rightarrow [R_2NCOOH] \rightarrow R_2NH$.

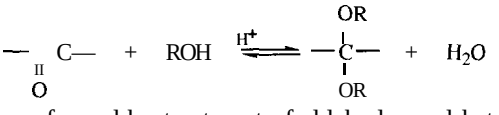
B. *Attack by OR (Addition of ROH)*

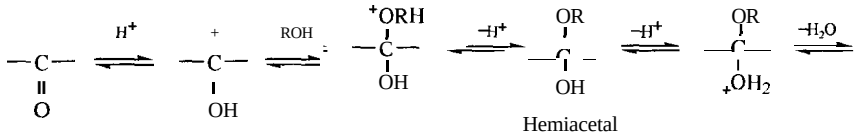
16-5 *The Addition of Alcohols and Thiols to Aldehydes and Ketones*

DIALKOXY-DE-OXO-BISUBSTITUTION
DITHIOALKYL-DE-OXO-BISUBSTITUTION

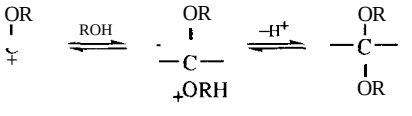


Acetals and ketals are formed by treatment of aldehydes and ketones, respectively, with alcohols in the presence of acid catalysts.[71] Lewis acids such as $TiCl_4$[72] can be used in conjunction with alcohols. Dioxolanes have been prepared in ethylene glycol using microwave irradiation and *p*-toluenesulfonic acid as a catalyst.[73] This reaction is reversible, and acetals and ketals can be hydrolyzed by treatment with acid (10-6). With small unbranched aldehydes the equilibrium lies to the right. If it is desired to prepare ketals, or acetals of larger molecules, the equilibrium must be shifted, usually by removal of water. This can be done by azeotropic distillation, ordinary distillation, or the use of a drying agent such as Al_2O_3 or a molecular sieve.[74] The reaction is not catalyzed in either direction by bases, so most acetals and ketals are quite stable to bases, though they are easily hydrolyzed by acids. This reaction is therefore a useful method of protection of aldehyde or ketone functions from attack by bases. The reaction is of wide scope. Most aldehydes are easily converted to acetals.[75] With ketones the process is more difficult, presumably for steric reasons, and the reaction often fails, though many ketals, especially from cyclic ketones, have been made in this manner.[76] Many functional groups may be present without being affected. Both 1,2- and 1,3-glycols form cyclic acetals and ketals (1,3-dioxolanes and 1,3-dioxanes, respectively), and these are often used to protect aldehydes and ketones.

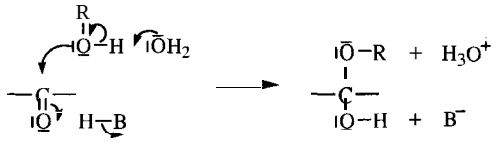
The mechanism, which involves initial formation of a *hemiacetal*,[71] is the reverse of that given for acetal hydrolysis (10-6):



Hemiacetal



In a study of the acid-catalyzed formation of the hemiacetal, Grunwald[78] has shown that the data best fit a mechanism in which the three steps shown here are actually all concerted; that is, the reaction is simultaneously catalyzed by acid and base, with water acting as the base:[79]



If the original aldehyde or ketone has an α hydrogen, it is possible for water to split out in that way and enol ethers can be prepared in this manner:

Similarly, treatment with an anhydride and a catalyst can give an enol ester.[80]

Hemiacetals themselves are no more stable than the corresponding hydrates (16-1). As with hydrates, hemiacetals of cyclopropanones[81] and of polychloro and polyfluoro aldehydes and ketones may be quite stable.

When acetals or ketals are treated with an alcohol of higher molecular weight than the one already there, it is possible to get a transacetalation (see 10-17). In another type of transacetalation, aldehydes or ketones can be converted to acetals or ketals by treatment with another acetal or ketal or with an ortho ester,[82] in the presence of an acid catalyst (shown for an ortho ester):

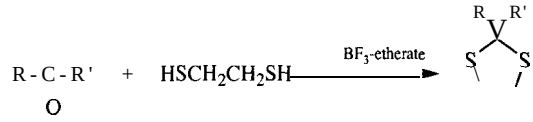
This method is especially useful for the conversion of ketones to ketals, since the direct reaction of a ketone with an alcohol often gives poor results. In another method, the substrate is treated with an alkoxysilane $ROSiMe_3$ in the presence of trimethylsilyl trifluoromethanesulfonate.[83]

1,4-Diketones give furans when treated with acids. This is actually an example of an intramolecular addition of an alcohol to a ketone, since it is the enol form that adds:

Similarly, 1,5-diketones give pyrans. Formic acid reacts with alcohols to give orthoformates.

Thiols add to aldehydes and ketones to give hemimercaptals and dithioacetals. Hemimercaptals are ordinarily unstable,[84] though they are more stable than the corresponding hemiacetals and can be isolated in certain cases.[85] Dithioacetals, like

acetals, are stable in the presence of bases, except that a strong base can remove the aldehyde proton, if there is one (see **10-107)**[86]**.** A common method for the protection of ketones involves treatment with ethanedithiol to give a cyclic dithioketal.[87] After subsequent reactions involving the R or R' group, the protecting group can then

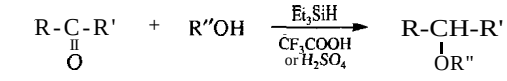


be removed by **10-6.** Alternatively, the dithioketal can be desulfurized with Raney nickel **(14-34),** giving the overall conversion $C{=}O \rightarrow CH_2$. Dithioacetals can also be prepared from aldehydes or ketones by treatment with thiols in the presence of $TiCl_4$,[88] $SiCl_4$,[89] with a disulfide (RSSR; R = alkyl or aryl),[90] or with methylthiotrimethylsilane ($MeSSiMe_3$).[91]

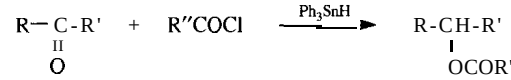
OS **I,** 1, 298, 364, 381; **II,** 137; **III,** 123, 387, 502, 536, 644, 731, 800; **IV,** 21, 479, 679; **V,** 5, 292, 303, 450, 539; **VI,** 567, 666, 954; **VII,** 59, 149, 168, 177, 241, 271, 297; **VIII,** 357. Also see OS **IV,** 558, 588; **V,** 25; **VIII,** 415.

16-6 *Reductive Alkylation of Alcohols*

C-HYDRO-*O*-ALKYL-ADDITION



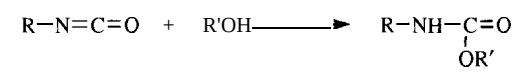
Aldehydes and ketones can be converted to ethers by treatment with an alcohol and triethylsilane in the presence of a strong acid[92] or by hydrogenation in alcoholic acid in the presence of platinum oxide.[93] The process can formally be regarded as addition of ROH to give a hemiacetal RR'C(OH)OR", followed by reduction of the OH. In this respect, it is similar to **16-14.** In a similar reaction, ketones can be converted to carboxylic esters (reductive acylation of ketones) by treatment with an acyl chloride and triphenyltin hydride.[94]



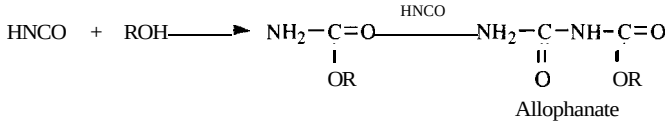
Ethers have also been prepared by the reductive dimerization of two molecules of an aldehyde or ketone (e.g., cyclohexanone → dicyclohexyl ether). This was accomplished by treatment of the substrate with a trialkylsilane and a catalyst.[95]

16-7 *The Addition of Alcohols to Isocyanates*

N-HYDRO-*C*-ALKOXY-ADDITION



Carbamates (substituted urethanes) are prepared when isocyanates are treated with alcohols. This is an excellent reaction, of wide scope, and gives good yields. Isocyanic acid HNCO gives unsubstituted carbamates. Addition of a second mole of HNCO gives *allophanates.*



Allophanate

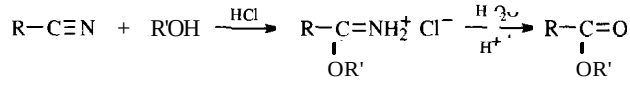
Polyurethanes are made by combining compounds with two NCO groups with compounds containing two OH groups. Isothiocyanates similarly give thiocarbamates (RNHCSOR'),[96] though they react slower than the corresponding isocyanates.

The details of the mechanism are poorly understood,[97] though the oxygen of the alcohol is certainly attacking the carbon of the isocyanate. Hydrogen bonding complicates the kinetic picture.[98] The addition of ROH to isocyanates can also be catalyzed by metallic compounds,[99] by light,[100] or, for tertiary ROH, by lithium alkoxides[101] or *n*-butyllithium.[102]

OS I, 140; V, 162; **VI,** 95, 226, 788, 795.

16-8 *Alcoholysis of Nitrites*

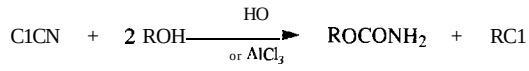
ALKOXY,OXO-DE-NITRILO-TERSUBSTITUTION



The addition of dry HC1 to a mixture of a nitrile and an alcohol in the absence of water leads to the hydrochloride salt of an imino ester (imino esters are also called imidates and imino ethers). This reaction is called the *Pinner synthesis.*[103] The salt can be converted to the free imino ester by treatment with a weak base such as sodium bicarbonate, or it can be hydrolyzed with water and an acid catalyst to the corresponding carboxylic ester. If the latter is desired, water may be present from the beginning, in which case aqueous HC1 can be used and the need for gaseous HC1 is eliminated. Imino esters can also be prepared from nitriles with basic catalysts.[104]

This reaction is of broad scope and is good for aliphatic, aromatic, and heterocyclic R and for nitriles with oxygen-containing functional groups. The application of the reaction to nitriles containing a carboxyl group constitutes a good method for the synthesis of mono esters of dicarboxylic acids with the desired group esterified and with no diester or diacid present.

Cyanogen chloride reacts with alcohols in the presence of an acid catalyst such as dry HC1 or $AlCl_3$ to give carbamates:[105]



The alcohol ROH can also be added to nitriles in another manner **(16-56).**

OS I, 5, 270; **II,** 284, 310; **IV,** 645; **VI,** 507; **VIII,** 415.

16-9 *The Formation of Xanthates*

S-METALLO-*C*-ALKOXY-ADDITION

$$S = C{=}S + ROH \xrightarrow{NaOH} RO{-}\underset{\underset{S}{\|}}{C}{-}S^{-}\,Na^{+}$$

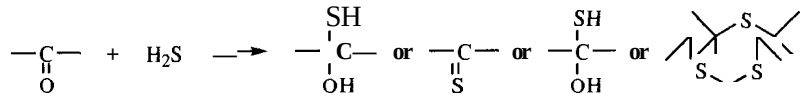
The addition of alcohols to carbon disulfide in the presence of a base produces xanthates.[106] The base is often OH^-, but in some cases better results can be obtained by using methylsulfinyl carbanion ($MeSOCH_2^-$).[107] If an alkyl halide RX is present, the xanthate ester ROCSSR' can be produced directly. In a similar manner, alkoxide ions add to CO_2 to give carbonate ester salts $ROCOO^-$.

OS V, 439; VI, 207, 418; VII, 139.

C. *Sulfur Nucleophiles*

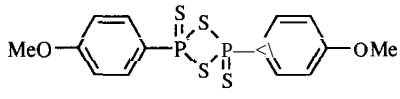
16-10 *The Addition of H_2S and Thiols to Carbonyl Compounds*

O-HYDRO-*C*-MERCAPTO-ADDITION[108]



5 **6** **7** **8**

The addition of H_2S to an aldehyde or ketone can result in a variety of products. The most usual product is the trithiane (8).[109] α-Hydroxy thiols (5) can be prepared from polychloro and polyfluoro aldehydes and ketones.[110] Apparently, compounds 5 are stable only when prepared from these compounds, and not even for all of them. Thioketones (6)[2] can be prepared from certain ketones, such as diaryl ketones, by treatment with H_2S and an acid catalyst, usually HC1. They are often unstable and tend to trimerize (to 8) or to react with air. Thioaldehydes[111] are even less stable and simple ones[112] apparently have never been isolated, though *t*-BuCHS has been prepared in solution, where it exists for several hours at 20°C.[113] A high-yield



9

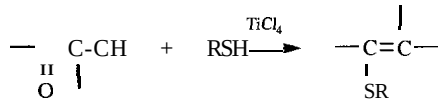
synthesis of thioketones involves treatment of acyclic[114] ketones with 2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane-2,4-disulfide (9) (known as *Lawesson's reagent*[115]).[116] Compound 9 also converts the C=O groups of amides and carboxylic esters[117] to C=S groups.[118] Similarly, $POCl_3$ followed by $S(TMS)_2$ converts lactams to thiolactams[119] and treatment with triflic anhydride and then H_2S converts amides to thioamides.[120] The compound H_2S–Me_3SiCl–$(i\text{-}Pr)_2NLi$ converts carboxylic esters to thiono esters.[121] Carboxylic acids (RCOOH) can be converted directly to dithiocarboxylic esters (RCSSR′),[122] in moderate yield, with P_4S_{10} and a primary alcohol R′OH.[123] Thioketones can also be prepared by

treatment of ketones with P_4S_{10}[124] or $CF_3SO_3SiMe_3/S(SiMe_3)_2$,[125] and from oximes or various types of hydrazone (overall conversion C=N⟶ C=S).[126]

Reagents are also available to convert thiocarbonyl compounds back to carbonyls.[127] Simple hydrolysis is the most common method for converting thiocarbonyls to carbonyls. Stirring thioketones with 4-nitrobenzaldehyde and a catalytic amount of TMSOTf gives the ketone.[128]

gem-Dithiols (7) are much more stable than the corresponding hydrates or α-hydroxy thiols.[129] They have been prepared by the treatment of ketones with H_2S under pressure[130] and under mild conditions with HC1 as a catalyst.[131] Thiols add to aldehydes and ketones to give hemimercaptals [C(OH)SR]and dithioacetals [$C(SR)_2$] (16-5).

If an aldehyde or ketone possesses an α hydrogen, it can be converted to the corresponding enol thioether by treatment with a thiol in the presence of $TiCl_4$:[132]

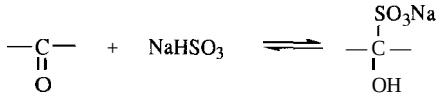


Aldehydes and ketones have been converted to sulfides by treatment with thiols and pyridine-borane, RCOR′+ R"SH → RR′CHSR′′,[133] in a reductive alkylation reaction, analogous to 16-6.

OS II, 610; IV, 927; VI, 109; VII, 124, 372. Also see OS III, 332; IV, 967; V, 780; VI, 556; VIII, 302.

16-11 *Formation of Bisulfite Addition Products*

O-HYDRO-*C*-SULFONATO-ADDITION



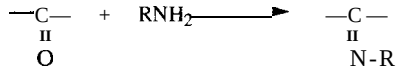
Bisulfite addition products are formed from aldehydes, methyl ketones, cyclic ketones (generally seven-membered and smaller rings), α-keto esters, and isocyanates, upon treatment with sodium bisulfite. Most other ketones do not undergo the reaction, probably for steric reasons. The reaction is reversible (by treatment of the addition product with either acid or base[134])[135] and is useful for the purification of the starting compounds, since the addition products are soluble in water and many of the impurities are not.[136]

OS I, 241, 336; III, 438; IV, 903; V, 437.

D. *Attack by NH_2, NHR, or NR_2 (Addition of NH_3, RNH_2, R_2NH)*

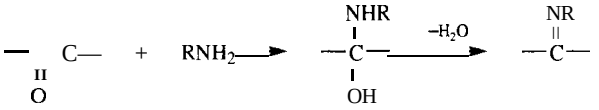
16-12 *The Addition of Amines to Aldehydes and Ketones*

ALKYLIMINO-DE-OXO-BISUBSTITUTION



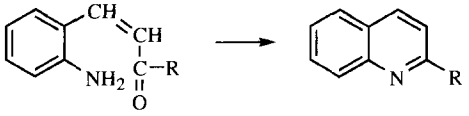
The addition of ammonia[137] to aldehydes or ketones does not generally give useful products. According to the pattern followed by analogous nucleophiles, the initial products would be expected to be *hemiaminals*,[138] but these compounds are generally unstable. Most imines with a hydrogen on the nitrogen spontaneously polymerize.[139]

In contrast to ammonia, primary, secondary, and tertiary amines can add to aldehydes[140] and ketones to give different kinds of products. Primary amines give imines.[141] Reduction of ω-azido ketones leads to the amino-ketones, which cyclizes to form a 2-substituted pyrroline.[142] Reduction of nitro-ketones in the presence of ruthenium compounds and CO also leads to 1-substituted pyrrolines.[143] In contrast to imines in which the nitrogen is attached to a hydrogen, these imines are stable enough for isolation. However, in some cases, especially with simple R groups, they rapidly decompose or polymerize unless there is at least one aryl group on the nitrogen or the carbon. When there is an aryl group, the compounds are quite stable. They are usually called *Schiff bases*, and this reaction is the best way to prepare them. The reaction is straightforward and proceeds in high yields. Even sterically hindered imines can be prepared.[144] Both imines and enamines (see below) have been prepared on clay with microwave irradiation.[145] The initial N-substituted hemiaminals[146] lose water to give the stable Schiff bases:



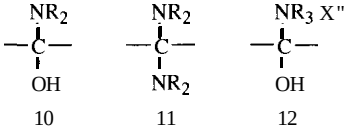
In general, ketones react more slowly than aldehydes, and higher temperatures and longer reaction times are often required.[147] In addition, the equilibrium must often be shifted, usually by removal of the water, either azeotropically by distillation, or with a drying agent such as $TiCl_4$,[148] or with a molecular sieve.[149]

The reaction is often used to effect ring closure.[150] The *Friedldnder quinoline synthesis*[151] is an example:



Pyrylium ions react with ammonia or primary amines to give pyridinium ions (see p. 447).[152]

When secondary amines are added to aldehydes or ketones, the initially formed N,N-disubstituted hemiaminals (14) cannot lose water in the same way, and it is possible to isolate them.[153] However, they are generally unstable, and under the reaction conditions usually react further. If no α hydrogen is present, 10 is converted



10 11 12

Aminal

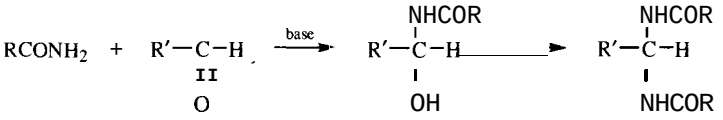
to the more stable *aminal* (**11**).[154] However, if an α hydrogen is present, water (from 10) or RNH_2 (from 11) can be lost in that direction to give an enamine:[155]

This is the most common method[156] for the preparation of enamines and usually takes place when an aldehyde or ketone containing an oc hydrogen is treated with a secondary amine. The water is usually removed azeotropically or with a drying agent,[157] but molecular sieves can also be used.[158] Stable primary enamines have also been prepared.[159] Enamino-ketones have been prepared from diketones and secondary amines using microwave irradiation on silica gel.[160] Secondary amine perchlorates react with aldehydes and ketones to give iminium salts (2, p. 1178).[161] Tertiary amines can only give salts (12).

OS I, 80, 355, 381; II, 31, 49, 65, 202, 231, 422; III, 95, 328, 329, 332, 358, 374, 513, 753, 827; IV, 210, 605, 638, 824; V, 191, 277, 533, 567, 627, 703, 716, 736, 758, 808, 941, 1070; VI, 5, 448, 474, 496, 520, 526, 592, 601, 818, 901, 1014; VII, 8, 135, 144, 473; VIII, 31, 132, 403, 451, 456, 493, 586, 597. Also see OS IV, 283, 464; VII, 197; VIII, 104, 112, 241.

16-13 *Addition of Amides to Aldehydes*

ALKYLAMIDO-DE-OXO-BISUBSTITUTION

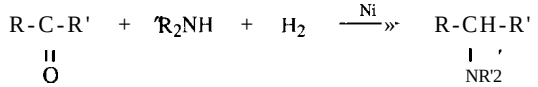


Amides can add to aldehydes in the presence of bases (so the nucleophile is actually $RCONH^-$) or acids to give acylated amino alcohols, which often react further to give alkylidene or arylidene bisamides.[162] If the R' group contains an oc hydrogen, water may split out.

Alternative procedures can be quite useful. Benzaldehyde reacts with $TsNH_2$, for example, at 160°C in the presence of $Si(OEt)_4$ to give the *N*-tosylimine, Ts–N=CHPh.[163] Reaction of aldehydes with $LiAl(NHBn)_4$ also give the corresponding *N*-benzylimine.[164]

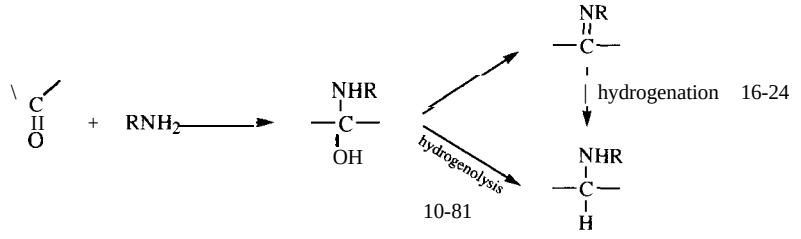
16-14 *Reductive Alkylation of Ammonia or Amines*

HYDRO,DIALKYLAMINO-DE-OXO-BISUBSTITUTION



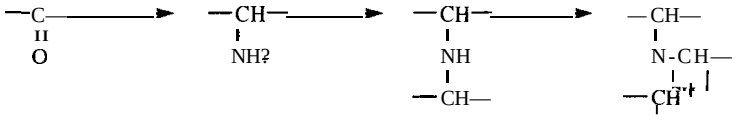
When an aldehyde or a ketone is treated with ammonia or a primary or secondary amine in the presence of hydrogen and a hydrogenation catalyst (heterogeneous or

homogeneous), *reductive alkylation* of ammonia or the amine (or *reductive amination* of the carbonyl compound) takes place.[165] The reaction can formally be regarded as occurring in the following manner (shown for a primary amine), which probably does correspond to the actual sequence of steps:[166]



For ammonia and primary amines there are two possible pathways, but when secondary amines are involved, only the hydrogenolysis pathway is possible. Other reducing agents[167] can be used instead of hydrogen and a catalyst, among them zinc and HC1, sodium cyanoborohydride ($NaBH_3CN$),[168] sodium triacetoxyborohydride,[169] sodium borohydride,[170] sodium borohydride in conjunction with $Ti(O\text{-}i\text{-}Pr)_4$,[171] borohydride-exchange resin,[172] and formic acid. When the last is used, the process is called the *Wallach reaction.* Conjugated aldehydes are converted to alkenyl-amines with the amine/silica gel followed by reduction with zinc borohydride.[173] In the particular case where primary or secondary amines are reductively methylated with formaldehyde and formic acid, the method is called the *Eschweiler–Clarke procedure.* It is possible to use ammonium (or amine) salts of formic acid,[174] or formamides, as a substitute for the Wallach conditions. This method is called the *Leuckart reaction*,[175] and in this case the products obtained are often the N-formyl derivatives of the amines instead of the free amines. Primary and secondary amines can be *N*-ethylated (e.g., ArNHR → ArNREt) by treatment with $NaBH_4$ in acetic acid.[176] Aldehydes react with aniline in the presence of Montmorillonite K10 clay and microwaves to give the amine.[177] Formaldehyde with formic acid converts secondary amines to the N-methyl derivative with microwave irradiation.[178]

When the reagent is ammonia, it is possible for the initial product to react again and for this product to react again, so that secondary and tertiary amines are usually obtained as side products:



Similarly, primary amines give tertiary as well as secondary amines. In order to minimize this, the aldehyde or ketone is treated with an excess of ammonia or primary amine (unless of course the higher amine is desired).

Primary amines have been prepared from many aldehydes with at least five carbons and from many ketones by treatment with ammonia and a reducing agent.

Smaller aldehydes are usually too reactive to permit isolation of the primary amine. Secondary amines have been prepared by both possible procedures: 2 mol of ammonia and 1 mol of aldehyde or ketone, and 1 mol of primary amine and 1 mol of carbonyl compound, the latter method being better for all but aromatic aldehydes. Tertiary amines can be prepared in three ways, but the method is seldom carried out with 3 mol of ammonia and 1 mol of carbonyl compound. Much more often they are prepared from primary or secondary amines.[179] The most common method for this purpose is the Eschweiler-Clarke procedure, that is, treatment of the primary or secondary amine with formaldehyde and formic acid. Amines of the form $RNMe_2$ and R_2NMe are prepared in this manner.[180] Another method for accomplishing the conversions $RNH_2 \rightarrow RNMe_2$ and $R_2NH \rightarrow R_2NMe$ is to treat the amine with aqueous formaldehyde and $NaBH_4$[181] or $NaBH_3CN$.[182]

Reductive alkylation has also been carried out on nitro, nitroso, azo, and other compounds that are reduced *in situ* to primary or secondary amines.

OS I, 347, 528, 531; II, 503; III, 328, 501, 717, 723; IV, 603; V, 552; VI, 499; VII, 27.

16-15 *The Mannich Reaction*

ACYL,AMINO-DE-OXO-BISUBSTITUTION, AND SO ON

$$\mathrm{H\text{-}\underset{\underset{\mathrm{O}}{\|}}{C}\text{-}H} + NH_4Cl + \mathrm{CH_3\text{-}\underset{\underset{\mathrm{O}}{\|}}{C}\text{-}R} \xrightarrow[OH^-]{H^+ \text{ or}} \mathrm{H_2N\text{-}CH_2\text{-}CH_2\text{-}\underset{\underset{\mathrm{O}}{\|}}{C}\text{-}R}$$

In the *Mannich reaction,* formaldehyde (or sometimes another aldehyde) is condensed with ammonia, in the form of its salt, and a compound containing an active hydrogen.[183] This can formally be considered as an addition of ammonia to give H_2NCH_2OH, followed by a nucleophilic substitution. Instead of ammonia, the reaction can be carried out with salts of primary or secondary amines,[184] or with amides,[185] in which cases the product is substituted on the nitrogen with R, R_2, and RCO, respectively. Arylamines do not normally give the reaction. The product is referred to as a *Mannich base.* The nucleophilic atoms of many active hydrogen compounds give the reaction, including ketones and aldehydes, esters, nitroalkanes, and nitriles as well as ortho carbons of phenols, the carbon of terminal alkynes, the oxygen of alcohols and the sulfur of thiols. The Mannich base can react further in three ways. If it is a primary or secondary amine, it may condense with one or two additional molecules of aldehyde and active compound, for example,

$$H_2NCH_2CH_2COR \xrightarrow[CH_3COR]{HCHO} HN(CH_2CH_2COR)_2 \xrightarrow[CH_3COR]{HCHO} N(CH_2CH_2COR)_3$$

If the active hydrogen compound has two or three active hydrogens, the Mannich base may condense with one or two additional molecules of aldehyde and ammonia or amine, for example,

$$H_2NCH_2CH_2COR \xrightarrow[NH_3]{HCHO} (H_2NCH_2)_2CHCOR \xrightarrow[NH_3]{HCHO} (H_2NCH_2)_3CHCOR$$

Another further reaction consists of condensation of the Mannich base with excess formaldehyde:

$$H_2NCH_2CH_2COR + HCHO \longrightarrow H_2C{=}NCH_2CH_2COR$$

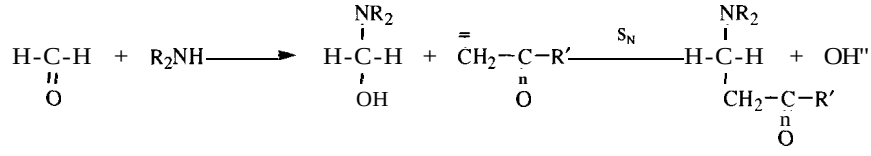
Sometimes it is possible to obtain these products of further condensation as the main products of the reaction. At other times they are side products.

When the Mannich base contains an amino group β to a carbonyl (and it usually does), ammonia is easily eliminated. This is a route to α,β-unsaturated aldehydes, ketones, esters, and so on:

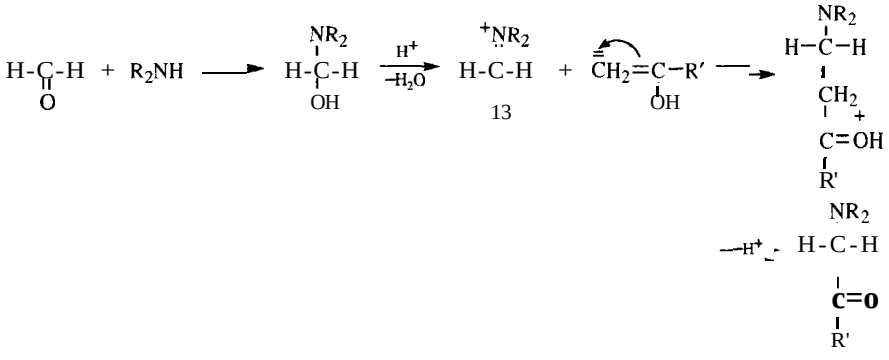
$$H_2NCH_2CH_2COR \xrightarrow{\Delta} H_2C{=}CHCOR$$

Studies of the reaction kinetics have led to the following proposals for the mechanism of the Mannich reaction.[186]

The base-catalyzed reaction



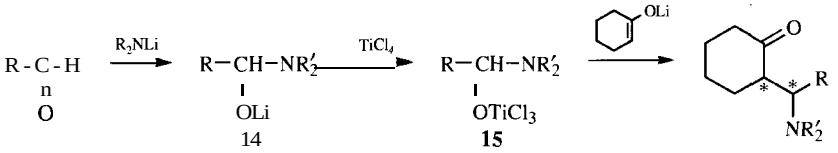
The acid-catalyzed reaction



According to this mechanism, it is the free amine, not the salt that reacts, even in acid solution; and the active-hydrogen compound (in the acid-catalyzed process) reacts as the enol when that is possible. This latter step is similar to what happens in 12-4. There is kinetic evidence for the intermediacy of the iminium ion (**13**).[187]

When an unsymmetrical ketone is used as the active-hydrogen component, two products are possible. Regioselectivity has been obtained by treatment of the ketone with preformed iminium ions:[188] the use of $Me_2N^+{=}CH_2\ CF_3COO^\ominus$ in CF_3COOH gives substitution at the more highly substituted position, while with $(i\text{-}Pr)_2N{=}CH_2^+ClO_4^-$ the reaction takes place at the less highly substituted position.[189] The

preformed iminium compound dimethyl(methylene)ammonium iodide ($CH_2{=}N^+Me_2$ I~), called *Eschenmoser's salt,*[190] has also been used in Mannich reactions.[191]



Another type of preformed reagent (15) has been used to carry out diastereoselective Mannich reactions. The lithium salts (14) are treated with $TiCl_4$ to give 15, which is then treated with the enolate of a ketone.[192] Silylenol ethers react with aldehydes and aniline in the presence of $InCl_3$ to give the P-amino ketone.[193] A similar reaction with imines on Montmorillonite K10 clay and microwave irradiation gives p-amino esters.[194] Enol ethers react similarly in the presence of $Yb(OTf)_3$.[195]

16-16 *The Addition of Amines to Isocyanates*

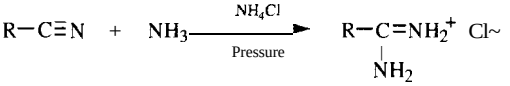
N-H YDRO- *C*-ALKYLAMINO-ADDITION

Ammonia and primary and secondary amines can be added to isocyanates[196] to give substituted ureas.[197] Isothiocyanates give thioureas. This is an excellent method for the preparation of ureas and thioureas, and these compounds are often used as derivatives for primary and secondary amines. Isocyanic acid (HNCO) also gives the reaction; usually its salts (e.g., NaNCO) are used. Wöhler's famous synthesis of urea involved the addition of ammonia to a salt of this acid.[198]

OS II, 79; III, 76, 617, 735; IV, 49, 180, 213, 515, 700; V, 555, 801, 802, 967; VI, 936, 951; VIII, 26.

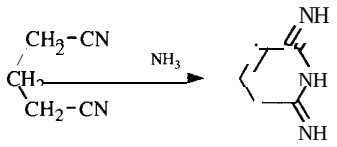
16-17 *The Addition of Ammonia or Amines to Nitrites*

N-H YDRO- *C*-AMINO-ADDITION



Unsubstituted amidines (in the form of their salts) can be prepared by addition of ammonia to nitriles.[199] Many amidines have been made in this way. Dinitriles of

suitable chain length can give imidines:[200]



Primary and secondary amines can be used instead of ammonia, to give substituted amidines, but only if the nitrile contains electron-withdrawing groups; for example, Cl_3CCN gives the reaction. Ordinary nitriles do not react, and, in fact, acetonitrile is often used as a solvent in this reaction.[201] However, ordinary nitriles can be converted to amidines by treatment with an alkylchloroaluminum amide, $MeAl(Cl)NR_2$ (R = H or Me).[202] The addition of ammonia to cyanamide NH_2CN gives guanidine $(NH_2)_2C{=}NH$.

If water is present, and a ruthenium complex catalyst is used, the addition of a primary or secondary amine to a nitrile gives an amide: RCN + R'NHR" + $H_2O \rightarrow$ $RCONR'R'' + NH_3$ (R" may be H).[203]

OS I, 302 (but also see OS V, 589); IV, 245, 247, 515, 566, 769. See also OS V, 39.

16-18 *The Addition of Amines to Carbon Disulfide and Carbon Dioxide*

S-METALLO-*C*-ALKYLAMINO-ADDITION

$$S = C{=}S + RNH_2 \xrightarrow{\text{base}} RNH\text{-}\underset{\underset{O}{\|}}{C}\text{-}S''$$

Salts of dithiocarbamic acid can be prepared by the addition of primary or secondary amines to carbon disulfide.[204] This reaction is similar to **16-9.** Hydrogen sulfide can be eliminated from the product, directly or indirectly, to give isothiocyanates (RNCS). Isothiocyanates can be obtained directly by the reaction of primary amines and CS_2 in pyridine in the presence of DCC.[205] In the presence of diphenyl phosphite and pyridine, primary amines add to CO_2 and to CS_2 to give, respectively, symmetrically substituted ureas and thioureas:[206]

$$RNH_2 + CO_2 \xrightarrow[HPO(OPh)_2]{\text{pyridine}} RNH\text{-}\underset{\underset{O}{\|}}{C}\text{-}NHR$$

OS I, 447; **III,** 360, 394, 599, 763; V, 223.

E. *Other Nitrogen Nucleophiles*

16-19 *The Addition of Hydrazine Derivatives to Carbonyl Compounds*

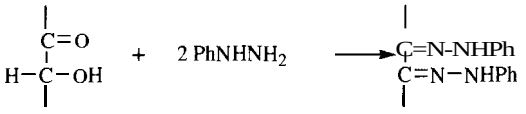
HYDRAZONO-DE-OXO-BISUBSTITUTION

$$\underset{\underset{O}{\|}}{-C-} \xrightarrow{RNHNH_2} \underset{\underset{N\text{-}NHR}{\|}}{-C-}$$

The product of condensation of a hydrazine and an aldehyde or ketone is called a *hydrazone.* Hydrazine itself gives hydrazones only with aryl ketones. With other aldehydes and ketones, either no useful product can be isolated, or the remaining NH_2 group condenses with a second mole of carbonyl compound to give an *azine.* This type of product is especially important for aromatic aldehydes:

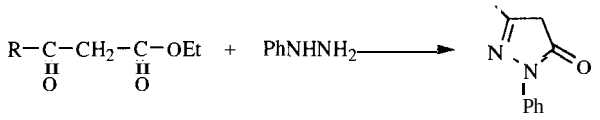
An azine

However, in some cases azines can be converted to hydrazones by treatment with excess hydrazine and NaOH.[207] Arylhydrazines, especially phenyl, *p*-nitrophenyl, and 2,4-dinitrophenyl,[208] are used much more often and give the corresponding hydrazones with most aldehydes and ketones.[209] Since these are usually solids, they make excellent derivatives and are commonly employed for this purpose. Cyclic hydrazones are also known,[210] as are conjugated hydrazones.[211] α-Hydroxy aldehydes and ketones and α-dicarbonyl compounds give *osazones,* in which two adjacent carbons have carbon–nitrogen double bonds:

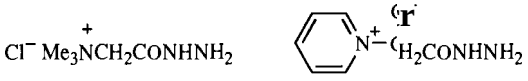


An osazone

Osazones are particularly important in carbohydrate chemistry. In contrast to this behavior, P-diketones and P-keto esters give *pyrazoles* and *pyrazolones*, respectively (illustrated for P-keto esters):



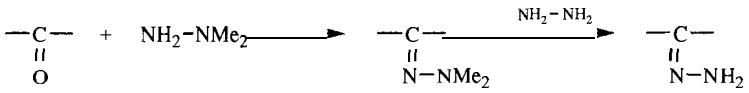
Other hydrazine derivatives frequently used to prepare the corresponding hydrazone are semicarbazide ($NH_2NHCONH_2$), in which case the hydrazone is called a semicarbazone, and *Girard's reagents T and P,* in which case the hydrazone



Girard's reagent T Girard's reagent P

is water soluble because of the ionic group. Girard's reagents are often used for purification of carbonyl compounds.[212]

Simple N-unsubstituted hydrazones can be obtained by an exchange reaction. The *N,N*-dimethylhydrazone is prepared first and then treated with hydrazine:[213]

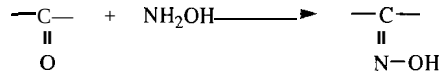


No azines are formed under these conditions.

OS II, 395; **III,** 96, 351; IV, 351, 377, 536, 884; V, 27, 258, 747, 929; VI, 10, 12, 62, 242, 293, 679, 791; **VII,** 77, 438. Also see OS **III,** 708; **VI,** 161; **VIII,** 597.

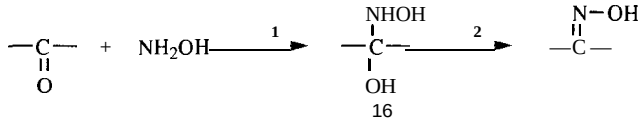
16-20 *The Formation of Oximes*

HYDROXYIMINO-DE-OXO-BISUBSTITUTION



In a reaction very much like **16-19,** oximes can be prepared by the addition of hydroxylamine to aldehydes or ketones. Derivatives of hydroxylamine, for example, H_2NOSO_3H and $HON(SO_3Na)_2$, have also been used. For hindered ketones, such as hexamethylacetone, high pressures (e.g., 10,000 atm) may be necessary.[214]

It has been shown[215] that the rate of formation of oximes is at a maximum at a pH that depends on the substrate but is usually ~4, and that the rate decreases as the pH is either raised or lowered from this point. We have previously seen (p. 425) that bell-shaped curves like this are often caused by changes in the rate-determining step. In this case, at low pH values step 2 is rapid (because it is acid catalyzed), and step 1



is slow (and rate determining), because under these acidic conditions most of the NH_2OH molecules have been converted to the conjugate NH_3OH^+ ions, which cannot attack the substrate. As the pH is slowly increased, the fraction of free NH_2OH molecules increases and consequently so does the reaction rate, until the maximum rate is reached at about pH = 4. As the rising pH has been causing an increase in the rate of step 1, it has also been causing a *decrease* in the rate of the acid-catalyzed step 2, although this latter process has not affected the overall rate since step 2 was still faster than step 1. However, when the pH goes above ~4, step 2 becomes rate determining, and although the rate of step 1 is still increasing (as it will until essentially all the NH_2OH is unprotonated), it is now step 2 that determines the rate, and this step is slowed by the decrease in acid concentration. Thus the overall rate decreases as the pH rises beyond ~4. It is likely that similar considerations apply to the reaction of aldehydes and ketones with amines, hydrazines, and other nitrogen nucleophiles.[216] There is evidence that when the nucleophile is 2-methylthiosemicarbazide, there is a second change in the rate-determining step: above pH about 10 *basic* catalysis of step 2 has increased the rate of this step to the point where step 1 is again rate determining.[217] Still a third change in the rate-determining step has been found at about pH = 1, showing that at least in some cases step 1 actually consists of two steps: formation of a zwitterion (e.g., $HOH_2\overset{+}{N}-\underset{|}{\overset{|}{C}}-O^-$) in the case shown above, and conversion of this to **16**.[218] The

intermediate **16** has been detected by NMR in the reaction between NH_2OH and acetaldehyde.[219]

In another type of process, oximes can be obtained by passing a mixture of ketone vapor, NH_3, and O_2 over a silica-gel catalyst.[220] Ketones can also be converted to oximes by treatment with other oximes, in a transoximation reaction.[221]

OS I, 318, 327; **II,** 70, 204, 313, 622; HI, 690, IV, 229; V, 139, 1031; **VII,** 149. See also OS VI, 670.

16-21 *The Conversion of Aldehydes to Nitrites*

NITRILO-DE-HYDRO,OXO-TERSUBSTITUTION

$$R\text{-}\underset{\underset{O}{\|}}{C}\text{-}H + NH_2OH\cdot HCl \xrightarrow{HCOOH} R{-}C{\equiv}N$$

Aldehydes can be converted to nitriles in one step by treatment with hydroxylamine hydrochloride and either formic acid,[222] SeO_2,[223] or pyridine-toluene.[224] The reaction is a combination of **16-20** and **17-30.** Direct nitrile formation has also been accomplished with certain derivatives of NH_2OH, notably, NH_2OSO_2OH.[225] Another method involves treatment with hydrazoic acid, though the Schmidt reaction **(18-16)** may compete.[226] Aromatic aldehydes have been converted to nitriles in good yield with NH_2OH/HCOOH on silica gel[227] or NH_2OH on Mexican bentonite[228] with microwave irradiation, dimethylhydrazine followed by dimethyl sulfoxide,[229] with trimethylsilyl azide,[230] and with hydroxylamine hydrochloride, $MgSO_4$, and TsOH.[231]

On treatment with two equivalents of dimethylaluminum amide (Me_2AlNH_2), carboxylic esters can be converted to nitriles: RCOOR' → RCN.[232] This is very likely a combination of **10-58** and **17-32.** See also **19-5.**

OS V, 656.

F. *Halogen Nucleophiles*

16-22 *The Formation of gem-Dihalides from Aldehydes and Ketones*

DIHALO-DE-OXO-BISUBSTITUTION

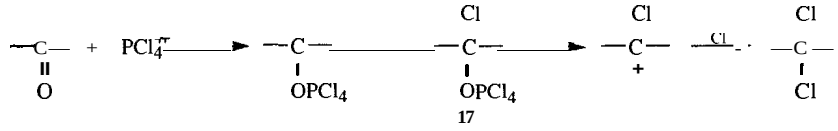
$$\underset{\underset{O}{\|}}{-C-} + PCl_5 \longrightarrow \underset{Cl}{\overset{Cl}{|}}{-C-}$$

Aliphatic aldehydes and ketones can be converted to *gem*-dichlorides[233] by treatment with PCl_5. The reaction fails for perhalo ketones.[234] If the aldehyde or ketone has an α hydrogen, elimination of HCl may follow and a vinylic chloride is a frequent side product:[235]

$$-\underset{Cl}{\overset{?}{C}}-\underset{H}{C}- \longrightarrow -C{=}\underset{Cl}{C}-$$

or even the main product.[236] Phosphorus pentabromide does not give good yields of *gem*-dibromides,[237] but these can be obtained from aldehydes, by the use of Br_2 and triphenyl phosphite.[238]

The mechanism of *gem*-dichloride formation involves initial attack of PCl_4^+, which is present in solid PCl_5, at the oxygen, followed by addition of Cl^- to the carbon:[239]

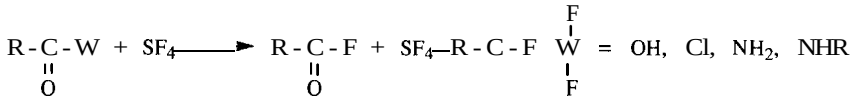


17

This chloride ion may come from PCl_6^-, (which is also present in solid PCl_5). There follows a two-step S_N1 process. Alternatively, 17 can be converted to the product without going through the chlorocarbocation, by an S_Ni process.

This reaction has sometimes been performed on carboxylic esters, though these compounds very seldom undergo any addition to the C=O bond. An example is the conversion of $F_3CCOOPh$ to F_3CCCl_2OPh.[240] However, formates commonly give the reaction.

Many aldehydes and ketones have been converted to *gem*-difluoro compounds with sulfur tetrafluoride (SF_4),[241] including quinones, which give 1,1,4,4-tetrafluorocyclohexadiene derivatives. With ketones, yields can be raised and the reaction temperature lowered, by the addition of anhydrous HF.[242] Carboxylic acids, acyl chlorides, and amides react with SF_4 to give 1,1,1-trifluorides. In these cases the first product is the acyl fluoride, which then undergoes the *gem*-difluorination reaction:



The acyl fluoride can be isolated. Carboxylic esters also give trifluorides, though more vigorous conditions are required, but in this case the carbonyl group of the ester is attacked first, and RCF_2OR' can be isolated from RCOOR',[243] and then converted to the trifluoride. Anhydrides can react in either manner, and both types of intermediate are isolable under the right conditions. Sulfer tetrafluoride even converts CO_2 to CF4. A disadvantage of reactions with SF4 is that they require a pressure vessel lined with stainless steel. Selenium tetrafluoride (SeF_4) gives similar reactions, but atmospheric pressure and ordinary glassware can be used.[244] Another reagent that is often used to convert aldehydes and ketones to *gem*-difluorides is the commercially available DAST (Et_2NSF_3) and CF_2Br_2 in the presence of zinc.[245]

The mechanism with SF_4 is probably similar in general nature, if not in specific detail, to that with PCl_5.

Treatment with hydrazine to give the hydrazone and then $CuBr_2$/*t*-BuOLi generated the *gem*-dibromide.[246] Oximes gives *gem*-dichlorides upon treatment with chlorine and $BF_3{\cdot}OEt_2$, and then HO.[247] Some dithianes can be converted to *gem*-

difluorides with a mixture of fluorine and iodine in acetonitrile.[248] Oximes give *gem*-difluorides with $NO^+BF_4^-$ and pyridinium polyhydrogen fluoride.[249]

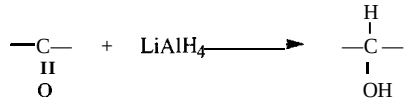
In a related process, a-halo ethers can be prepared by treatment of aldehydes and ketones with an alcohol and HX. The reaction is applicable to aliphatic aldehydes and ketones and to primary and secondary alcohols. The addition of HX to an aldehyde or ketone gives a-halo alcohols, which are usually unstable, though exceptions are known, especially with perfluoro and perchloro species.[250]

OS II, 549; V, 365, 396, 1082; VI, 505, 845; VIII, 247. Also see OS I, 506. For a-halo-ethers, see OS I, 377; IV, 101 (see, however, OS V, 218), 748; VI, 101.

G. *Attack by Hydrogen*

16-23 *Reduction of Aldehydes and Ketones to Alcohols*[251]

C,O-DIHYDRO- ADDITION



Aldehydes can be reduced to primary alcohols, and ketones to secondary alcohols, by a number of reducing agents,[252] of which $LiAlH_4$ and other metallic hydrides are the most commonly used.[253] These reagents have two main advantages over many other reducing agents: They do not reduce carbon-carbon double (or triple) bonds, and they generally contain a lot of hydrogen in a small amount of reagent—with $LiAlH_4$, all four hydrogens are usable for reduction. The reaction is broad and general. Lithium aluminum hydride easily reduces aliphatic, aromatic, alicyclic, and heterocyclic aldehydes, containing double or triple bonds and/or nonreducible groups such as NR_3, OH, OR, F, and so on. If the molecule contains a group reducible by $LiAlH_4$ (e.g., NO_2, CN, COOR), then it is also reduced. Lithium aluminum hydride reacts readily with water and alcohols, so these compounds must be excluded. Common solvents are ether and THF. Sodium borohydride has a similar scope but is more selective and so may be used with NO_2, Cl, COOR, CN, and so on in the molecule. Another advantage of $NaBH_4$ is that it can be used in water or alcoholic solvents and so reduces compounds such as sugars that are not soluble in ethers.[254] Sodium borohydride on alumina, under microwave irradiation, is also an effective reagent.[255] The scope of these reagents with ketones is similar to that with aldehydes. Lithium aluminum hydride reduces even sterically hindered ketones.

The double bonds that are generally not affected by metallic hydrides may be isolated or conjugated, but double bonds that are conjugated with the C=O group may or may not be reduced, depending on the substrate, reagent, and reaction conditions.[256] Some reagents that reduce only the C=O bonds of α,β-unsaturated aldehydes and ketones are AlH_3,[257] $NaBH_4$, or $LiAlH_4$ in the presence of lanthanide salts (e.g., $LaCl_3$, $CeBr_3$),[258] $NaBH_3(OAc)$,[259] $Zn(BH_4)_2$[260] on Y-zeolite,[261] and Et_3SiH.,[262] Also, both $LiAlH_4$[263] and $NaBH_4$[264] predominantly reduce only the

C=O bonds of C=C–C=O systems in most cases, though substantial amounts of fully saturated alcohols have been found in some cases[263] (p. 1007). For some reagents that reduce only the C=C bonds of conjugated aldehydes and ketones, see 15-11.

When a functional group is selectively attacked in the presence of a different functional group, the reaction is said to be *chemoselective*. A number of reagents have been found to reduce aldehydes much faster than ketones. Among these[265] are sodium triacetoxyborohydride,[266] $NaBH_4$–PhCOOH,[267] zinc borohydride in THF,[268,269] bis(isopropoxytitanium) borohydride,[270] a complex of $LiAlH_4$ and *N*-methyl-2-pyrrolidinone (of particular interest since it is stable in air and to heating),[271] and tributyltin hydride.[272] On the other hand, ketones can be chemoselectively reduced in the presence of aldehydes with $NaBH_4$ in aqueous EtOH at -15°C in the presence of cerium trichloride ($CeCl_3$).[273] The reagent lithium *n*-dihydropyridylaluminum hydride reduces diaryl ketones much better than dialkyl or alkyl aryl ketones.[274] Most other hydrides reduce diaryl ketones more slowly than other types of ketones. Saturated ketones can be reduced in the presence of α,β-unsaturated ketones with $NaBH_4$ 50% MeOH–CH_2Cl_2 at -78°C[275] and with zinc borohydride.[276] In general, $NaBH_4$ reduces carbonyl compounds in this order: aldehydes > α,β-unsaturated aldehydes > ketones > α,β-unsaturated ketones, and a carbonyl group of one type can be selectively reduced in the presence of a carbonyl group of a less reactive type.[277] A number of reagents will preferentially reduce the less sterically hindered of two carbonyl compounds, but by the use of DIBAL-H in the presence of the Lewis acid methylaluminum bis(2,16-di-*tert*-butyl-4-methylphenoxide), it was possible selectively to reduce the *more hindered* of a mixture of two ketones.[278] It is obvious that reagents can often be found to reduce one kind of carbonyl function in the presence of another.[279] For a discussion of selectivity in reduction reactions, see page 1544.

Quinones are reduced to hydroquinones by $LiAlH_4$, $SnCl_2$–HCl, or sodium hydrosulfite ($Na_2S_2O_4$), as well as by other reducing agents.

The reagent lithium tri-*sec*-butylborohydride $LiBH(s\text{-}Bu)_3$ reduces cyclic and bicyclic ketones in a highly stereoselective manner, giving the less stable isomer.[280] For example, 2-methylcyclohexanone gave *cis*-2-methylcyclohexanol with an isomeric purity >99%. The more usual reagents, (e.g., $LiAlH_4$, $NaBH_4$) reduce relatively unhindered cyclic ketones either with little or no stereoselectivity[281] or give predominant formation of the more stable isomer (axial attack).[282] Mixed reagents such as $LiBH_3[N(C_3H_7)_2]$ gives high selectivity for axial attack.[283] Reduction of cyclohexanone derivatives with the very hindered $LiAlH(CEt_2CMe_3)_3$ gave primarily the cis alcohol.[284] Cyclohexanones that have a large degree of steric hindrance near the carbonyl group usually give predominant formation of the less stable alcohol, even with $LiAlH_4$ and $NaBH_4$.

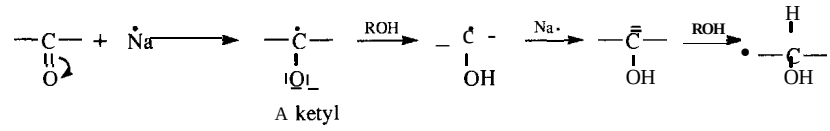
Among other reagents that reduce aldehydes and ketones to alcohols[285] are the following:

1. *Hydrogen and a Catalyst.*[286] The most common catalysts are platinum and ruthenium, but homogeneous catalysts have also been used.[287] Before the

discovery of the metal hydrides this was one of the most common ways of effecting this reduction, but it suffers from the fact that C=C, C≡C, C=N and C≡N bonds are more susceptible to attack than C=O bonds.[288] For aromatic aldehydes and ketones, reduction to the hydrocarbon (19-33) is a side reaction, stemming from hydrogenolysis of the alcohol initially produced (10-81).

2. *Sodium in Ethanol.*[289] This is called the *Bouveault–Blanc procedure* and was more popular for the reduction of carboxylic esters (19-38) than of aldehydes or ketones before the discovery of $LiAlH_4$.

For the reaction with sodium in ethanol the following mechanism[290] has been suggested:[291]

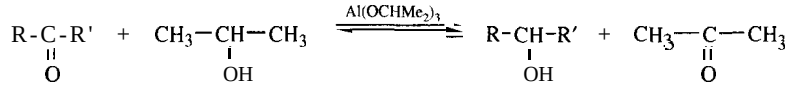


A ketyl

The ketyl intermediate can be isolated.[292]

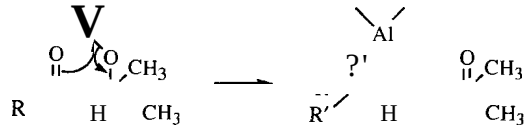
Other metals can be used, including $FeCl_3/Zn$ in aqueous DMF.[293]

3. *Isopropyl Alcohol and Aluminum Isopropoxide*. This is called the *Meerwein–Ponndorf–Verley reduction.*[294] It is reversible, and the reverse reaction is known as the *Oppenauer oxidation* (see 19-3):



The equilibrium is shifted by removal of the acetone by distillation. The reaction takes place under very mild conditions and is highly specific for aldehydes and ketones, so that C=C bonds (including those conjugated with the C=O bonds) and many other functional groups can be present without themselves being reduced.[295] This includes acetals, so that one of two carbonyl groups in a molecule can be specifically reduced if the other is first converted to an acetal. P-Keto esters, P-diketones, and other ketones and aldehydes with a relatively high enol content do not give this reaction. A SmI_3 assisted version of this reduction has been reported.[296]

The Meerwein-Ponndorf-Verley reaction usually[297] involves a cyclic transition state:



but in some cases 2 mol of aluminum alkoxide are involved one attacking the carbon and the other the oxygen, a conclusion that stems from the finding that in these cases the reaction was 1.5 order in alkoxide.[299] Although, for simpli-

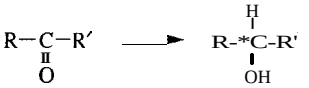
city, we have shown the alkoxide as a monomer, it actually exists as trimers and tetramers, and it is these that react.[300]

4. *Boranes.* Borane (BH_3) and substituted boranes reduce aldehydes and ketones in a manner similar to their addition to C=C bonds (**15-16**).[301] That is, the boron adds to the oxygen and the hydrogen to the carbon:[302]

The borate is then hydrolyzed to the alcohol. Both 9-BBN[303] (p. 1013) and BH_3–Me_2S[304] reduce only the C=O group of conjugated aldehydes and ketones.

5. *Metals in Water or Alcohol.* A single carbonyl group of an α-diketone can be reduced (to give an α-hydroxy ketone) by heating with zinc powder in aqueous DMF.[305] This has also been accomplished with aqueous VCl_2[306] and with Zn–$ZnCl_2$–EtOH.[307]
6. *Cannizzaro Reaction.* In the Cannizzaro reaction **(19-60)** aldehydes without an α hydrogen are reduced to alcohols.
7. *Silanes And Base.* In the presence of bases, certain silanes can selectively reduce carbonyls. Epoxy-ketones are reduced to epoxy-alcohols, for example with $(MeO)_3SiH$ and LiOMe.[308] Controlling temperature and solvent leads to different ratios of syn- and anti- products.[331] Silanes reduce ketones in the presence of $BF_3{\cdot}OEt_2$[309] and transition metal compounds catalyze this reduction.[310]

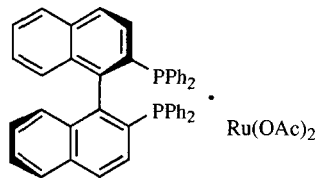
Unsymmetrical ketones are prochiral (p. 164); that is, reduction creates a new chiral center:



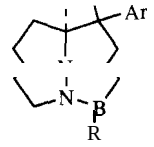
Much effort has been put into finding optically active reducing agents that will produce one enantiomer of the alcohol enantioselectively, and considerable success has been achieved,[311] both with biologically derived reducing agents[312] such as baker's yeast[313] or enzymes from other organisms,[314] and with synthetic reagents. Each reagent is more effective for certain types of ketones than for others.[315] Brown et al.[316] reduced various types of ketone with a number of reducing agents. These workers also determined the relative effectiveness of various reagents for reduction of eight other types of ketone, including heterocyclic, aralkyl, P-keto esters, P-keto acids,[317] and so on.[316] In most cases, ee values of >90% can be obtained with the proper reagent.[318] Substituents that are remote to the carbonyl group can play a role in facial selectivity of the reduction.[319]

Asymmetric reduction with very high ee values has also been achieved with achiral reducing agents and optically active catalysts.[320] The two most important

examples are (1) homogeneous catalytic hydrogenation with the catalyst 2,2'-bis(diphenylphosphino)-l,l'-binaphthyl-ruthenium acetate [BINAP–$Ru(OAc)_2$],[321]



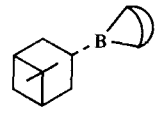
R (+)-BINAP



18

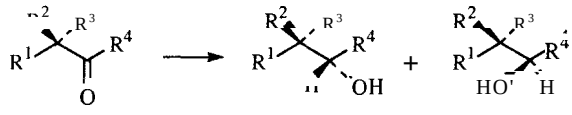
which reduces P-keto esters in >98% ee,[322] and (2) reduction with BH_3–THF or catecholborane, using an oxazaborolidine (18; R = H, Me, or n-Bu; Ar = Ph or β-naphthyl)[323] or related compounds[324] as a catalyst. Reduction with silanes and transition metal catalysts such as ruthenium compounds is also very effective.[325] This method gives high ee values with various types of ketone, especially α,β-unsaturated ketones. Other ruthenium catalysts[326] have also been used in catalytic hydrogenation.

Enantioselective reduction is not possible for aldehydes, since the products are primary alcohols in which the reduced carbon is not chiral, but deuterated aldehydes RCDO give a chiral product, and these have been reduced enantioselectively with B-(3-pinanyl)-9-borabicyclo[3.3.1]nonane (Alpine-Borane) with almost complete optical purity.[327]



Alpine-Borane

In the above cases, an optically active reducing agent or catalyst interacts with a prochiral substrate. Asymmetric reduction of ketones has also been achieved with an achiral reducing agent, if the ketone is complexed to an optically active transition metal Lewis acid.[328]

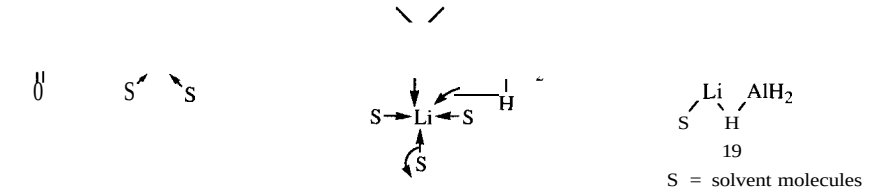


Diastereomers

There are other stereochemical aspects to the reduction of aldehydes and ketones. If there is a chiral center to the carbonyl group,[329] even an achiral reducing agent can give more of one diastereomer than of the other. Such diastereoselective reductions have been carried out with considerable success.[330] In most such cases Cram's rule (p. 147) is followed, but exceptions are known.[331]

With most reagents there is an initial attack on the carbon of the carbonyl group by H^- or some carrier of it, though with BH_3[332] the initial attack is on the oxygen.

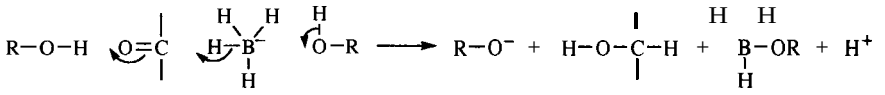
Detailed mechanisms are not known in most cases.[281] With AlH_4^- (or BH_4^-) compounds, the attacking species is the AlH_4^- (or BH_4^-) ion, which, in effect, transfers H^- to the carbon. The following mechanism has been proposed for $LiAlH_4$:[333]



19

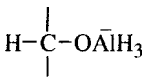
S = solvent molecules

Evidence that the cation plays an essential role, at least in some cases, is that when the Li^+ was effectively removed from $LiAlH_4$ (by the addition of a crown ether), the reaction did not take place.[334] The complex 19 must now be hydrolyzed to the alcohol. For $NaBH_4$ the Na^+ does not seem to participate in the transition state, but kinetic evidence shows that an OR group from the solvent does participate and remains attached to the boron:[335]



Free H~ cannot be the attacking entity in most reductions with boron or aluminum hydrides because the reactions are frequently sensitive to the size of the MH_4^- [or $MR_mH_n^-$ or $M(OR)_mH_n^-$, etc.].

There has been much controversy about whether the initial complex in the $LiAlH_4$ reduction (19), which can be written as



can reduce another carbonyl to give  , and so on. It has been shown[336] that this is probably not the case but that, more likely, 20 disproportionates to  and AlH_4^-, which is the only attacking species. Disproportionation has also been reported in the $NaBH_4$ reaction.[337]

Compound 20 is essentially $LiAlH_4$ with one of the hydrogens replaced by an alkoxy group (i.e., $LiAlH_3OR$). The fact that 20 and other alkoxy derivatives of $LiAlH_4$ are less reactive than $LiAlH_4$ itself has led to the use of such compounds as reducing agents that are less reactive and more selective than $LiAlH_4$.[338] We have already met some of these, for example, $LiAlH(O\text{-}t\text{-}Bu)_3$ (Reactions 10-89-10-91; see also Table 19.5). As an example of chemoselectivity in this reaction it may be

mentioned that $LiAlH(O\text{-}t\text{-}Bu)_3$ has been used to reduce only the keto group in a molecule containing both keto and carboxylic ester groups.[339] However, the use of such reagents is sometimes complicated by the disproportionation mentioned above, which may cause $LiAlH_4$ to be the active species, even if the reagent is an alkoxy derivative. Another highly selective reagent (reducing aldehydes and ketones, but not other functional groups), which does not disproportionate, is potassium triisopropoxyborohydride.[340]

The mechanism of catalytic hydrogenation of aldehydes and ketones is probably similar to that of Reaction **15-11,** though not much is known about it.[341]

For other reduction reactions of aldehydes and ketones, see **19-33,19-55,** and **19-60.**

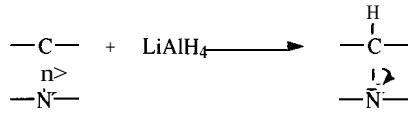
16-24 *Reduction of the Carbon–Nitrogen Double Bond*

C,N-DIHYDRO-ADDITION

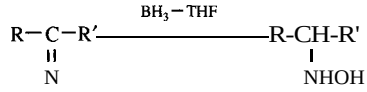
Imines and Schiff bases,[342] hydrazones,[343] and other C=N compounds can be reduced with $LiAlH_4$, $NaBH_4$, Na–EtOH, hydrogen and a catalyst, as well as with other reducing agents.[344] Reduction with Bu_2SnClH in HMPA has been shown to be chemoselective for imines.[345] Iminium salts are also reduced by $LiAlH_4$, though here there is no "addition" to the nitrogen:[346]



Reduction of imines has been carried out enantioselectively.[347]

Isocyanates have been catalytically hydrogenated to N-substituted formamides: RNCO → R–NH–CHO.[348] Isothiocyanates were reduced to thioformamides with SmI_2 in HMPA/*t*-BuOH.[349]

Oximes are generally reduced to amines (**19-44**),[350] but simple reduction to give hydroxylamines can be accomplished with borane[351] or sodium cyanoborohydride.[168]



OS III, 328, 827; **VI,** 905; **VIII,** 110, 568. Also see OS IV, 283.

16-25 *The Reduction of Nitrites to Amines*

CC,NN-TETRAHYDRO-BIADDITION

$$R\text{-}C{\equiv}N \;+\; LiAlH_4 \longrightarrow R{-}CH_2{-}NH_2$$

Nitriles can be reduced to primary amines with many reducing agents,[352] including $LiAlH_4$, and $BH_3{-}Me_2S$.[353] Sodium borohydride does not generally reduce nitriles but does so in alcoholic solvents when a $CoCl_2$ catalyst is added[354] or in the presence of Raney nickel.[355] The reaction is of wide scope and has been applied to many nitriles. When catalytic hydrogenation is used, secondary amines, $(RCH_2)_2NH$, are often side products.[356] These can be avoided by adding a compound such as acetic anhydride, which removes the primary amine as soon as it is formed,[357] or by the use of excess ammonia to drive the equilibria backward.[358]

It is not possible to stop with the addition of only 1 mol of hydrogen, that is., to convert the nitrile to an imine, except where the imine is subsequently hydrolyzed **(16-26).**

N-Alkylnitrilium ions are reduced to secondary amines by $NaBH_4$.[359]

$$RCN \xrightarrow{R'_3O^+\,BF_4^-} R{-}C{\equiv}\overset{+}{N}{-}R' \xrightarrow{NaBH_4} RCH_2{-}NH{-}R'$$

Since nitrilium salts can be prepared by treatment of nitriles with trialkyloxonium salts (see **16-8),** this is a method for the conversion of nitriles to secondary amines.

It is noted that the related compounds, the isonitriles ($R{-}{}^+N{\equiv}C^-$, also called isocyanides) have been reduced to N-methylamines with $LiAlH_4$ as well as with other reducing agents.

OS **III,** 229, 358, 720; VI, 223.

16-26 *The Reduction of Nitriles to Aldehydes*

HYDRO, OXY-DE-NITRILO-TERSUBSTITUTION

$$R{-}C{\equiv}N \xrightarrow[2.\ \text{hydrolysis}]{1.\ HCl,\ SnCl_2} RCH{=}O$$

There are two principal methods for the reduction of nitriles to aldehydes.[360] In one of these, known as the *Stephen reduction,* the nitrile is treated with HC1 to form

$$RCCl{=}\overset{+}{N}H_2\ \bar{C}l$$

21

This is reduced with anhydrous $SnCl_2$ to RCH=NH, which precipitates as a complex with $SnCl_4$ and is then hydrolyzed **(16-2)** to the aldehyde. The Stephen reduction is most successful when R is aromatic, but it can be done for aliphatic R up to about six carbons.[361] It is also possible to prepare **21** in a different way, by treating ArCONHPh with PCl_5, which can then be converted to the aldehyde. This is known as the *Sonn–Müller method.*

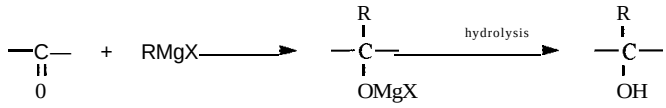
The other way of reducing nitriles to aldehydes involves using a metal hydride reducing agent to add 1 mol of hydrogen and hydrolysis, *in situ*, of the resulting imine (which is undoubtedly coordinated to the metal). This has been carried out with $LiAlH_4$, $LiAlH(OEt)_3$,[362] $LiAlH(NR_2)_3$,[363] and DIBAL-H.[364] The metal hydride method is useful for aliphatic and aromatic nitriles.

OS III, 626, 818; VI, 631.

H. *Carbon Attack by Organometallic Compounds*[365]

16-27 *The Addition of Grignard Reagents and Organolithium Reagents to Aldehydes and Ketones*

O-HYDRO-*C*-ALKYL-ADDITION



The addition of Grignard reagents to aldehydes and ketones is known as the *Grignard reaction*[366] Formaldehyde gives primary alcohols; other aldehydes give secondary alcohols; and ketones give tertiary alcohols. The reaction is of very broad scope, and R may be alkyl or aryl. Under certain conditions, the reaction can be done in water[367] although ether solvents are the usual choice. In many cases, the hydrolysis step is carried out with dilute HC1 or H_2SO_4, but this cannot be done for tertiary alcohols in which at least one R group is alkyl because such alcohols are easily dehydrated under acidic conditions (17-1). In such cases (and often for other alcohols as well) an aqueous solution of ammonium chloride is used instead of a strong acid.

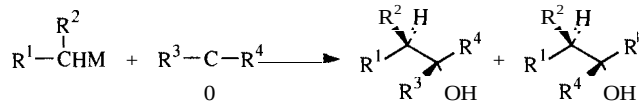
The reaction with alkyl- and aryllithium reagents has also been carried out without preliminary formation of RLi: A mixture of RX and the carbonyl compound was added to a suspension of lithium pieces in THF.[368] Yields were generally satisfactory. The magnesium analog of this process is called the *Barbier reaction*.[369] Lithium dimethylcuprate (Me_2CuLi) reacts with aldehydes[370] and with certain ketones[371] to give the expected alcohols. The similar reagents RCu(CN)ZnI also react with aldehydes, in the presence of BF_3–etherate, to give secondary alcohols. Carboxylic ester, nitrile, and imide groups in the R are not affected by the reaction conditions.[372]

α,β-Unsaturated aldehydes or ketones can give 1,4 addition as well as normal 1,2 addition (see **15-24**).[373] In general, alkyllithium reagents give less 1,4 addition than the corresponding Grignard reagents.[374] Quinones add Grignard reagents on one or both sides or give 1,4 addition. In a compound containing both an aldehyde and a ketone function it is possible to add RMgX chemoselectively to the aldehyde function without significantly disturbing the ketonic group (see also p. 1208).[375] In conjunction with $BeCl_2$, organolithium reagents add to conjugated ketones. In THF, 1,4 addition is observed, but in diethyl ether the 1,2-addition product is formed.[376] Organocerium reagents, generated from cerium chloride ($CeCl_3$ and a Grignard

reagent or an organolithium reagent) gives an organometallic reagent that can be chemoselective.[377]

As with the reduction of aldehydes and ketones **(16-23),** the addition of organometallic compounds to these substrates can be carried out enantioselectively and diastereoselectively.[378] Chiral secondary alcohols have been obtained with high ee values by addition to aromatic aldehydes of Grignard and organolithium compounds in the presence of optically active amino alcohols as ligands.[379]

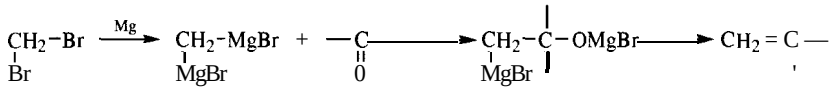
Diastereoselective addition[380] has been carried out with achiral reagents and chiral substrates,[381] similar to the reduction shown on page. 1201,[382] but because the attacking atom in this case is carbon, not hydrogen, it is also possible to get diastereoselective addition with an achiral substrate and an optically active reagent.[383] Use of suitable reactants creates, in the most general case, two new chiral centers, so the product can exist as two pairs of enantiomers:



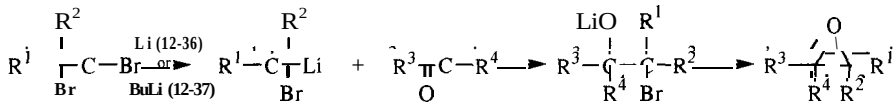
Diastereomers

Even if the organometallic compound is racemic, it still may be possible to get a diastereoselective reaction; that is, one pair of enantiomers is formed in greater amount than the other.[384]

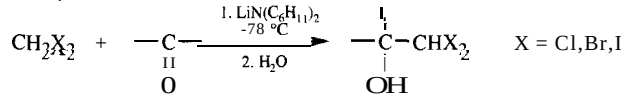
In some cases, the Grignard reaction can be performed intramolecularly.[385] For example, treatment of 5-bromo-2-pentanone with magnesium and a small amount of mercuric chloride in THF produced 1-methyl-1-cyclobutanol in 60% yield.[386] Other four- and five-membered ring compounds were also prepared by this procedure. Similar closing of five- and six-membered rings was achieved by treatment of a 5- or ε-halocarbonyl compound, not with a metal, but with a dianion derived from nickel tetraphenyporphine.[387]



The *gem*-disubstituted magnesium compounds formed from CH_2Br_2 or CH_2I_2 **(12-36)** react with aldehydes or ketones to give alkenes in moderate-to-good yields.[388] The reaction could not be extended to other *gem*-dihalides. Similar reactions with *gem*-dimetallic compounds prepared with metals other than magnesium have also produced alkenes.[389] The α,α-dimetallic derivatives of phenyl sulfones ($PhSO_2CM_2R$; M= Li or Mg) react with aldehydes or ketones R'COR" to give good yields of the α,β-unsaturated sulfones $PhSO_2CR{=}CR'R''$,[390] which can be reduced with aluminum amalgam (see **10-104)** or with $LiAlH_4$–$CuCl_2$ to give the alkenes $CHR{=}CR'R''$.[391] On the other hand, *gem*-dihalides treated with a carbonyl compound and Li or BuLi give epoxides (see also **16-61**).[392]

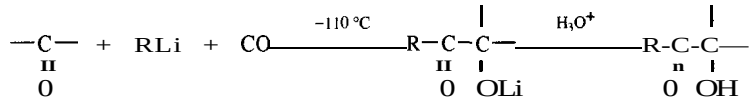


In other uses of *gem*-dihalo compounds, aldehydes and ketones add the CH_2I group, $R_2CO \rightarrow R_2C(OH)CH_2I$, when treated with CH_2I_2 in the presence of SmI_2[393] and the CHX_2 group when treated with methylene halides and lithium dicyclohexylamide at low temperatures.[394]



A hydroxymethyl group can be added to an aldehyde or ketone with the masked reagent $Me_2[(i\text{-}Pr)O]SiCH_2MgCl$, which with R_2CO gives $R_2C(OH)CH_2Si[O{-}(i\text{-}Pr)]Me_2$, which, with H_2O_2, give 1,2-diols, $R_2C(OH)CH_2OH$.[395]

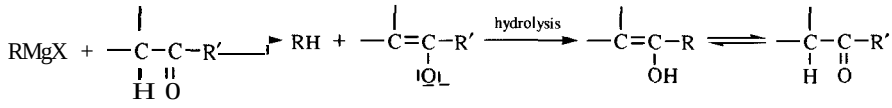
It is possible to add an acyl group to a ketone to give (after hydrolysis) an α-hydroxy ketone.[396] This can be done by adding RLi and CO to the ketone at −110°C:[397]



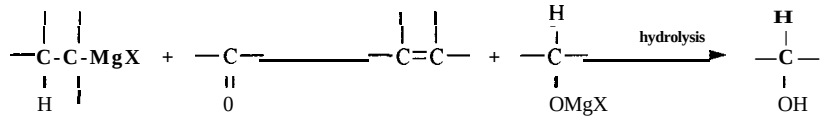
When the same reaction is carried out with carboxylic esters R′COOR″, α-diketones RCOCOR′ are obtained.[397]

Although most aldehydes and ketones react very nicely with most Grignard reagents, there are several potential side reactions[398] that occur mostly with hindered ketones and with bulky Grignard reagents. The two most important of these are *enolization* and *reduction.* The former requires that the aldehyde or ketone have an a hydrogen, and the latter requires that the Grignard reagent have a β hydrogen:

Enolization



Reduction



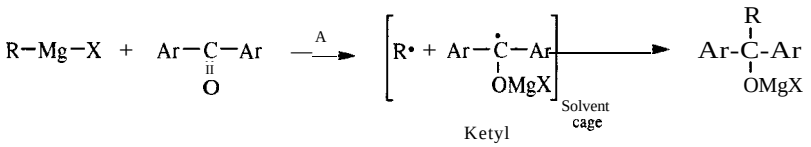
Enolization is an acid-base reaction **(12-23)** in which a proton is transferred from the a carbon to the Grignard reagent. The carbonyl compound is converted to its enolate ion form, which, on hydrolysis, gives the original ketone or aldehyde. Enolization is important not only for hindered ketones but also for those that have a relatively high percentage of enol form (e.g., β-keto esters). In reduction, the carbonyl compound is reduced to an alcohol **(16-23)** by the Grignard reagent, which itself undergoes elimination to give an alkene. Two other side reactions are condensation (between enolate ion and excess ketone) and Wurtz-type coupling **(10-101).** Such highly hindered tertiary alcohols as triisopropylcarbinol, tri-*Tert*-butylcarbinol, and diisopropylneopentylcarbinol cannot be prepared (or can be prepared only in extremely low yields) by the addition of Grignard reagents to ketones, because

reduction and/or enolization become prominent.[399] However, these carbinols can be prepared by the use of alkyllithium reagents at $-80°C$,[400] under which conditions enolization and reduction are much less important.[401] Other methods of increasing the degree of addition at the expense of reduction consist of complexing the Grignard reagent with $LiClO_4$ or $Bu_4N^+Br^-$,[402] or using benzene or toluene instead of ether as solvent.[403] Both reduction and enolization can be avoided by adding $CeCl_3$ to the Grignard reagent.[404]

Another way to avoid complications is to add $(RO)_3TiCl$, $TiCl_4$,[405] $(RO)_3ZrCl$, or $(R_2N)_3TiX$ to the Grignard or lithium reagent. This produces organotitanium or organozirconium compounds that are much more selective than Grignard or organolithium reagents.[406] An important advantage of these reagents is that they do not react with NO_2 or CN functions that may be present in the substrate, as Grignard and organolithium reagents do. Furthermore, organotitanium reagents can be made to add chemoselectively to aldehydes in the presence of ketones.[407] Organomanganese compounds are also chemoselective in this way.[408]

There has been much controversy regarding the mechanism of addition of Grignard reagents to aldehydes and ketones.[409] The reaction is difficult to study because of the variable nature of the species present in the Grignard solution (p. 234) and because the presence of small amounts of impurities in the magnesium seems to have a great effect on the kinetics of the reaction, making reproducible experiments difficult.[410] There seem to be two basic mechanisms, depending on the reactants and the reaction conditions. In one of these, the R group is transferred to the carbonyl carbon with its electron pair. A detailed mechanism of this type has been proposed by Ashby et al.,[411] based on the discovery that this reaction proceeds by two paths—one first order in MeMgBr and the other first order in Me_2Mg.[412] According to this proposal, both MeMgBr and Me_2Mg add to the carbonyl carbon, though the exact nature of the step by which MeMgBr or Me_2Mg reacts with the substrate is not certain. One possibility is a four-centered cyclic transition state:[413]

The other type of mechanism is a SET process[414] with a ketyl intermediate:[415]

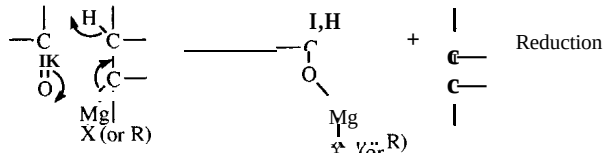


This mechanism, which has been mostly studied with diaryl ketones, is more likely for aromatic and other conjugated aldehydes and ketones than it is for strictly aliphatic ones. Among the evidence[416] for the SET mechanism are ESR spectra[417] and the fact that $Ar_2C(HO)-C(OH)Ar_2$ side products are obtained (from dimerization of the ketyl).[418] In the case of addition of RMgX to benzil (PhCOCOPh), ESR spectra of

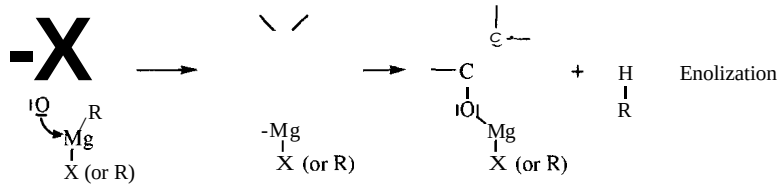
two different ketyl radicals were observed, both reported to be quite stable at room temperature.[419] Carbon isotope effect studies with $Ph^{14}COPh$ showed that the rate-determining step with most Grignard reagents is the carbon-carbon bond-forming step (marked A), though with allylmagnesium bromide it is the initial electron transfer step.[420]

Mechanisms for the addition of organolithium reagents have been investigated much less.[421] Addition of a cryptand that binds Li^+ inhibited the normal addition reaction, showing that the lithium is necessary for the reaction to take place.[422]

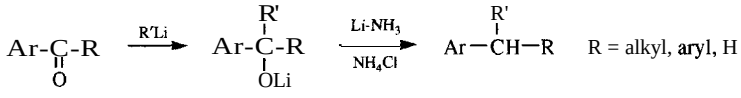
There is general agreement that the mechanism leading to reduction[423] is usually as follows:



There is evidence that the mechanism leading to enolization is also cyclic, but involves prior coordination with magnesium:[424]



Aromatic aldehydes and ketones can be alkylated and reduced in one reaction vessel by treatment with an alkyl- or aryllithium, followed by lithium and ammonia and then by ammonium chloride.[425]



A similar reaction has been carried out with N,N-disubstituted amides: $RCONR'_2 \rightarrow RR''CHNR'_2$.[426] When the reagent is $MeNbCl_4$, ketones R_2CO are converted to $R_2C(Cl)Me$.[427]

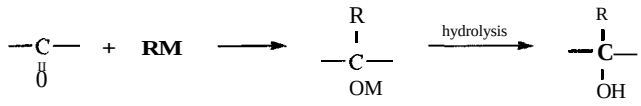
16-28 *Addition of Other Organometallics to Aldehydes and Ketones*

O-Hydro-*C*-alkyl-addition



Many organometallic compounds can be used[428] besides Grignard reagents and aryllithium reagents,[429] but in general only of active metals such as alkylzinc reagents[430] are useful (e.g., alkylmercurys do not react). For the addition of acetylenic groups, sodium may be the metal used: $RC{\equiv}CNa$ (16-41); while vinylic alanes (prepared as in 15-17) are the reagents of choice for the addition of vinylic groups.[431] The reagent $Me_3Al^-C{\equiv}CH\ Na^+$ also adds to aldehydes to give the ethynyl alcohol.[432]

Many methods have been reported for the addition of allylic groups,[433] including allyltrialkyltin compounds[434] (in the presence of BF_3–etherate),[435] as well as other allylic metal compounds.[436] Allylic alcohols and homo allylic alcohols add to aldehydes in the presence of $Sn(OTf)_2$.[437] For allylic halides, both activated manganese,[438] and $BiCl_3/NaBH_4$[439] can be used. In general, allyltin compounds readily add to aldehydes and ketones,[440] and asymmetric induction has been reported.[441] A variety of alkyl and allylic halides add to aldehydes or ketones in the presence of metals or metal compounds such as antimony,[442] barium,[443] lead,[444] $MgBiCl_3$,[445] zinc,[446] SmI_2,[447] and GeI_2[448] has been used. Allyl indium compounds[449] add to aldehydes or ketones in various solvents,[450] including water.[451] Many of these type of reactions are closely related to the *Barbier reaction* (see p. 1205), where the metal (originally magnesium), the ketone or aldehyde and an alkyl halide are mixed together to form the alkylated alcohol.

Although organoboranes do not generally add to aldehydes and ketones,[452] allylic boranes are exceptions.[453] When they add, an allylic rearrangement always takes place. Allylic rearrangements sometimes take place with the other reagents as well. In the presence of transition metal compounds, $RB(OH)_2$ and $ArB(OH)_2$ add to aldehydes to give the corresponding alcohol.[454]

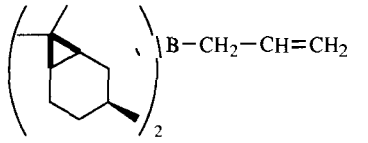
Certain functional groups (COOEt, $CONMe_2$, CN) can be present in the R group when organotin reagents $RSnEt_3$ are added to aldehydes.[455] Trimethylaluminum[456] and dimethyltitanium dichloride[457] exhaustively methylate ketones to give *gem*-dimethyl compounds (see also 10-99):[458]

The titanium reagent also dimethylates aromatic aldehydes.[459] Triethylaluminum reacts with aldehydes, however, to give the mono-ethyl alcohol, and in the presence of a chiral additive the reaction proceeds with good asymmetric induction.[460] A complex of $Me_3Ti{\cdot}MeLi$ has been shown to be selective for 1,2 addition with conjugated ketones, in the presence of nonconjugated ketones.[461]

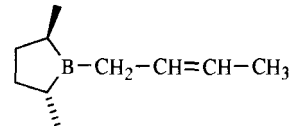
High ee values have also been obtained with organometallics,[462] including organotitanium compounds (methyl, aryl, allylic) in which an optically active ligand is coordinated to the titanium,[463] allylic boron compounds, and organozinc compounds.

A number of optically active allylic boron compounds have been used, including[464] B-allylbis(2-isocaranyl)borane (22),[465] (*E*)-and (*Z*)-crotyl-(*R*,*R*)-2,5-di-

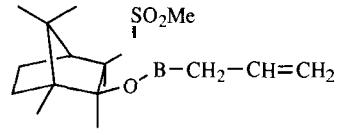
methylborolanes (23),[466] and the borneol derivative 24,[467] all of which add an



22



23



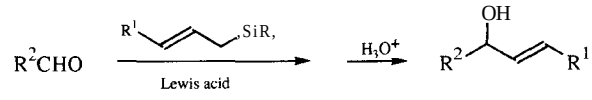
24

allyl group to aldehydes, with ee values of 90% or more. Where the substrate possesses an aryl group or a triple bond, enantioselectivity is enhanced by using a metal carbonyl complex of the substrate.[468]

As for the organozinc reagents, very high ee values (90-98%) were obtained from R_2Zn reagents (R = alkyl) and aromatic[469] aldehydes by the use of a small amount of various catalysts.[470] When benzaldehyde was treated with Et_2Zn in the presence of the optically active catalyst l-piperidino-3,3-dimethyl-2-butanol (31), a surprising result was obtained. Although the catalyst had only 10.7% excess of one enantiomer, the product PhCH(OH)Me had an ee of 82%.[471] When the catalyst ee was increased to 20.5%, the product ee rose to 88%. The question is, how could a catalyst produce a product with an ee much higher than itself? One possible explanation[472] is that (*R*) and *(S)* molecules of the catalyst form a complex with each other, and that only the uncomplexed molecules are actually involved in the reaction. Since initially the number of (*R*) and (*S*) molecules was not the same, the *(R:S)* ratio of the uncomplexed molecules must be considerably higher (or lower) than that of the initial mixture.

16-29 *Addition of Trialkylallylsilanes to Aldehydes and Ketones*

O-HYDRO-*C*-ALKYL-ADDITION

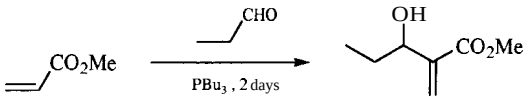


Allyltrialkylsilanes add to aldehydes in the presence of a Lewis acid.[473] The mechanism of this reaction has been examined.[474] When chiral titanium complexes are used in the reaction, allylic alcohols are produced with good asymmetric induction.[475] Other chiral additives have been used,[476] and chiral complexes of allyl silanes give good results.[477] Allyltrichlorosilanes have also been used in addition reactions with aldehydes.[478] Allylsilanes also add to aldehydes in the presence of Me_3SiOTf.[479]

16-30 *Addition of Conjugated Alkenes to Aldehydes: the Baylis–Hillman Reaction*

O-HYDRO-*C*-ALKENYL-ADDITION

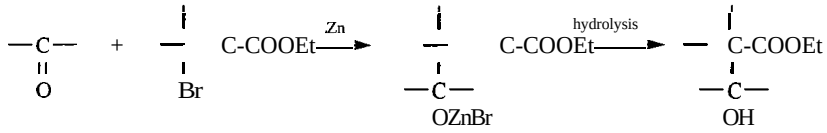
In the presence of a base such as 1,4-diazabicyclo[2.2.2]octane (DABCO) or trialkylphosphines, conjugated carbonyl compounds such as esters and amides add to aldehydes via the a-carbon to give α-alkenyl-β-hydroxy esters or amides. This sequence is called the *Baylis-Hillman reaction*,[480] and a simple example is [481]



Using a chiral auxiliary via the amide[482] or ester[483] leads to asymmetric induction.[484] Under certain conditions, rate enhancements have been observed.[485] Microwave irradiation has also been used to induce the reaction.[486]

16-31 *The Reformatsky Reaction*

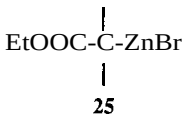
O-HYDRO-*C*-α-ETHOXYCARBONYLALKYL-ADDITION



The *Reformatsky reaction* is very similar to 16-27.[487] An aldehyde or ketone is treated with zinc and a halide; the halide is usually an a-halo ester or a vinylog of an a-halo ester (e.g., RCHBrCH=CHCOOEt), though a-halo nitriles,[488] a-halo ketones,[489] and a-halo N,N-disubstituted amides have also been used. Especially high reactivity can be achieved with activated zinc,[490] with zinc/silver-graphite,[491] and with zinc and ultrasound.[492] The reaction has also been carried out with other metals instead of zinc (e.g., In,[493] Mn,[494] low-valent Ti[495]) and with certain other compounds, including SmI_2[496] and $Sc(OTf)_3/PPh_3$.[497] The aldehyde or ketone can be aliphatic, aromatic, or heterocyclic or contain various functional groups. Solvents used are generally ethers, including Et_2O, THF, and 1,4-dioxane, although the reaction can be done in water[498] using dibenzoyl peroxide and $MgClO_4$.

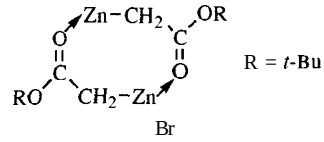
The use of additives such as germanium can lead to highly diastereoselective reactions.[499] Using chiral auxiliaries[500] or chiral additives,[501] good enantioselectivity[502] can be achieved.

Formally, the reaction can be regarded as if it were analogous to the Grignard reaction (16-27), with as an intermediate analogous to RMgX.[503] There *is* an



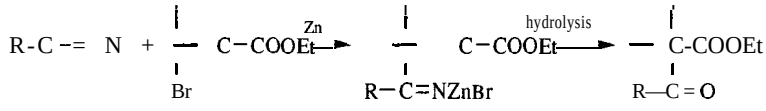
25

intermediate derived from zinc and the ester, the structure of which has been shown to be 26, by X-ray crystallography of the solid intermediate prepared from *t*-$BuOCOCH_2Br$ and Zn.[504] As can be seen, it has some of the characteristics of 25.

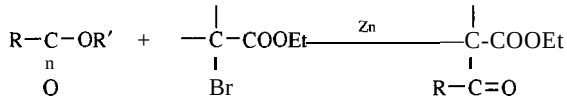


26

Usually, after hydrolysis, the alcohol is the product, but sometimes (especially with aryl aldehydes) elimination follows directly and the product is an alkene. By the use of Bu_3P along with Zn, the alkene can be made the main product,[505] making this an alternative to the Wittig reaction **(16-47).** Since Grignard reagents cannot be formed from α-halo esters, the method is quite useful, though there are competing reactions and yields are sometimes low. A similar reaction (called the *Blaise reaction)* has been carried out on nitriles:[506]



Carboxylic esters have also been used as substrates, but then, as might be expected (p. 1173), the result is substitution and not addition:



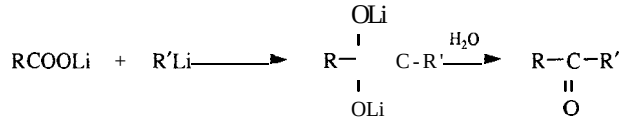
The product in this case is the same as with the corresponding nitrile, though the pathways are different.

For an alternative approach involving ester enolates, see **16-40.**

OS **III,** 408; **IV,** 120, 444; **IX,** 275.

16-32 *The Conversion of Carboxylic Acid Salts to Ketones With Organometallic Compounds*

ALKYL-DE-OXIDO-SUBSTITUTION



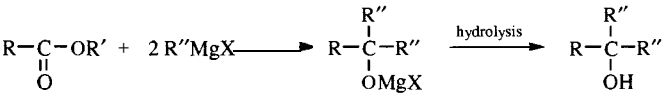
Good yields of ketones can often be obtained by treatment of the lithium salt of a carboxylic acid with an alkyllithium reagent, followed by hydrolysis.[507] The R' group may be aryl or primary, secondary, or tertiary alkyl. Both MeLi and PhLi have been employed most often. The R group may be alkyl or aryl, though lithium acetate generally gives low yields. Tertiary alcohols are side products.

A variation of this transformation reacts the acid with lithium naphthalenide in the presence of 1-chlorobutane. The product is the ketone.[508] A related reaction treats the lithium carboxylate with lithium metal and the alkyl halide, with sonication, to give the ketone.[509]

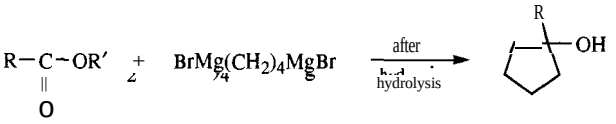
OS V, 775.

16-33 *The Addition of Grignard Reagents to Acid Derivatives*

DIALKYL,HYDROXY-DE-ALKOXY,OXO-TERSUBSTITUTION

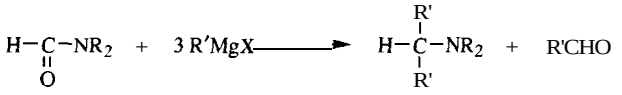


When carboxylic esters are treated with Grignard reagents, there is usually concomitant addition to the carbonyl **(16-27)** and substitution of R" for OR' (10-**114),** so that tertiary alcohols are formed in which two R groups are the same. In some cases, however, the ketone is the major product.[510] This generally occurs when there is steric hindrance to the carbonyl in the first-formed ketone. Formates give secondary alcohols and carbonates give tertiary alcohols in which all three R groups are the same: $(EtO)_2C{=}O + RMgX \rightarrow R_3COMgX$. Acyl halides and anhydrides behave similarly, though these substrates are employed less often.[511] There are many side reactions possible, especially when the acid derivative or the Grignard reagent is branched: enolizations, reductions (not for esters, but for halides), condensations, and cleavages, but the most important is simple substitution **(10-114),** which in some cases can be made to predominate. When 1,4-dimagnesium compounds are used, carboxylic esters are converted to cyclopentanols.[512] 1,5-Dimagnesium compounds give cyclohexanols, but in lower yields.[512]



Trimethylaluminum, which exhaustively methylates ketones **(16-27),** also exhaustively methylates carboxylic acids to give *tert*-butyl compounds (see also 10-99):[513]

Disubstituted formamides can give addition of 2 mol of Grignard reagent. The products of this reaction (called *Bouveault reaction)* are an aldehyde and a tertiary amine.[514] The use of an amide other than a formamide can give a ketone instead



of an aldehyde, but yields are generally low. The addition of two equivalents of phenyllithium to a carbamate gave good yields of the ketone, however.[515] Cerium reagents such as $MeCeCl_2$ also add two R groups to an amide.[516] More commonly, an organolithium reagent is treated with $CeCl_3$ to generate the organocerium reagent *in situ*.[517] It has proven possible to add two different R groups by sequential addition of two Grignard reagents.[518] Diketones have also been produced by using the bis-imidazole derivative of oxalic acid.[519] Alternatively, if R' contains an α hydrogen, the product may be an enamine, and enamines have been synthesized in goods yields by this method.[520]

OS **I,** 226; **II,** 179, 602; **III,** 237, 831, 839; **IV,** 601; **VI,** 240, 278; **VIII,** 474, 505.

16-34 *The Addition of Organometallic Compounds to CO_2 and CS_2*

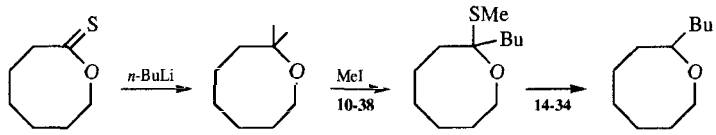
C-ALKYL-*O*-HALOMAGNESIO-ADDITION

$$O{=}C{=}O + RMgX \longrightarrow R{-}C{=}O \quad (OMgX)$$

Grignard reagents add to one C=O bond of CO_2 exactly as they do to an aldehyde or a ketone.[521] Here, of course, the product is the salt of a carboxylic acid. The reaction is usually performed by adding the Grignard reagent to dry ice. Many carboxylic acids have been prepared in this manner, and, along with the sequence **10-111-16-4** and Reaction **18-8,** this constitutes an important way of increasing a carbon chain by one unit. Since labeled CO_2 is commercially available, this is a good method for the preparation of carboxylic acids labeled in the carboxyl group. Other organometallic compounds have also been used (RLi,[522] RNa, RCaX, RBa,[523] etc.), but much less often. The formation of the salt of a carboxylic acid after the addition of CO_2 to a reaction mixture is regarded as a positive test for the presence of a carbanion or of a reactive organometallic intermediate in that reaction mixture (see also **16-43).**

When chiral additives such as (—)-sparteine has added to the initial reaction with the organolithium reagent, quenching with CO_2 produces carboxylic acids with good asymmetric induction.

In a closely related reaction, Grignard reagents add to CS_2 to give salts of dithiocarboxylic acids.[525] These salts can be trapped with amines to form thioamides.[526] Two other reactions are worthy of note. (1) Lithium dialkylcopper reagents react with dithiocarboxylic esters to give tertiary thiols (analogous to **16-33**).[527] (2) Thiono lactones can be converted to cyclic ethers,[528] for example:

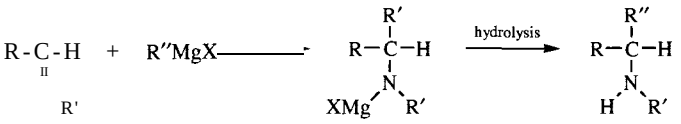


This is a valuable procedure because medium and large ring ethers are not easily made, while the corresponding thiono lactones can be prepared from the readily available lactones (see, e.g., **10-23)** by Reaction **16-10.**

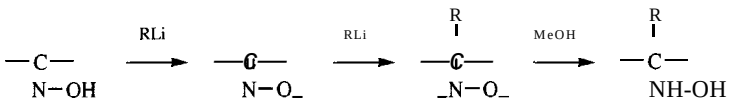
OS **I,** 361, 524; **II,** 425; **III,** 413, 553, 555; **V,** 890, 1043; VI, 845; IX, 317.

16-35 *The Addition of Organometallic Compounds to C=N Compounds*

N-HYDRO-*C*-ALKYL-ADDITION



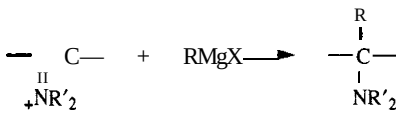
Aldimines can be converted to secondary amines by treatment with Grignard reagents.[529] Ketimines generally give reduction instead of addition. However, organolithium compounds give the normal addition product with both aldimines and ketimines.[530] When chiral additives are used in conjunction with the organolithium reagent, chiral amines are produced[531] with good asymmetric induction.[532,533] Chiral auxiliaries have been used in addition reactions to imines,[534] and to oxime derivatives.[535] Other organometallic compounds,[536] including allylic stannanes,[537] allylic samarium compounds,[538] and allylic indium compounds[539] add to aldimines in the same manner. Many other C=N systems (phenylhydrazones, oxime ethers, etc.) give normal addition when treated with Grignard reagents; others give reductions; others give miscellaneous reactions. Organocerium reagents add to hydrazones.[540] Oximes can be converted to hydroxylamines by treatment with 2 mol of an alkyllithium reagent, followed by methanol.[541]



The conjugate bases of nitro compounds (formed by treatment of the nitro compound with BuLi) react with Grignard reagents in the presence of C1CH=NMe_2^+ Cl^- to give oximes: RCH=N(O)OLi + R'MgX → RR′C=NOH.[542]

For the addition of an organometallic compound to an imine to give a primary amine, R' in RCH=NR' would have to be H, and such compounds are seldom stable. However, the conversion has been done, for R = aryl, by the use of the masked reagents $(ArCH{=}N)_2SO_2$ [prepared from an aldehyde RCHO and sulfamide $(NH_2)_2SO_2$]. Addition of R"MgX or R"Li to these compounds gives $ArCHR''NH_2$ after hydrolysis.[543]

Iminium salts[346] give tertiary amines directly, with just R adding:

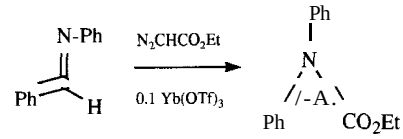


Chloroiminium salts $ClCH{=}NR_2'Cl^-$ (generated *in situ* from an amide $HCONR_2'$ and phosgene $COCl_2$) react with 2 mol of a Grignard reagent RMgX, one adding to the C=N and the other replacing the Cl, to give tertiary amines R_2CHNR_2'.[544]

OS IV, 605; VI, 64. Also see OS HI, 329.

16-36 *Addition of Carbenes and Diazoalkanes to C=N Compounds*

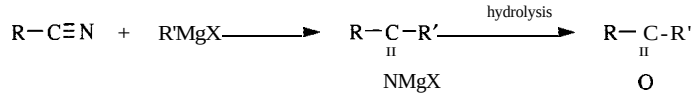
In the presence of metal catalysts such as $Yb(OTf)_3$, diazoalkanes add to imines to generate aziridines. An example is[545]



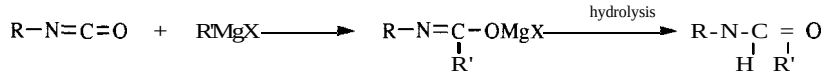
The reaction is somewhat selective for the cis diastereomer. The use of chiral additives in this reaction leads to aziridines enantioselectively.[546]

16-37 *The Addition of Grignard Reagents to Nitrites and Isocyanates*

ALKYL,OXO-DE-NITRILO-TERSUBSTITUTION (OVERALL TRANSFORMATION)



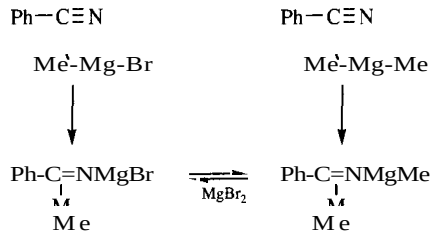
N-HYDRO-*C*-ALKYL-ADDITION



Ketones can be prepared by addition of Grignard reagents to nitriles and subsequent hydrolysis. Many ketones have been made in this manner, though when both R groups are alkyl, yields are not high.[547] Yields can be improved by the use of Cu(I) salts[548] or by using benzene containing one equivalent of ether as the solvent, rather than ether alone.[549] The ketimine salt does not in general react with Grignard reagents: Hence, tertiary alcohols or tertiary alkyl amines are not often side products.[550] By careful hydrolysis of the salt it is sometimes possible to isolate ketimines $R—\underset{\underset{NH}{\|}}{C}—R'$,[551] especially when R and R' = aryl. The addition of Grignard reagents to the C≡N group is normally slower than to the C=O group, and CN^- containing aldehydes add the Grignard reagent without disturbing the CN group.[552] Other metal compounds have been used, including Sm with allylic halides[553] and organocerium compounds such as $MeCeCl_2$.[554]

Addition of Grignard reagents[555] or organolithium reagents[556] to co-halo nitriles leads to 2-substituted cyclic imines.

The following mechanism has been proposed for the reaction of the methyl Grignard reagent with benzonitrile:[557]



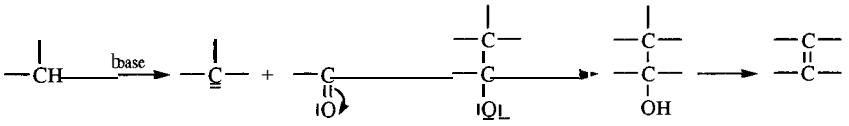
The addition of Grignard reagents to isocyanates gives, after hydrolysis, N-substituted amides.[558] This is a very good reaction and can be used to prepare derivatives of alkyl and aryl halides. The reaction has also been performed with alkyllithium compounds.[559] Isothiocyanates give N-substituted thioamides.

Other organometallic compounds add to isocyanates. Vinyltin reagents lead to conjugated amides.[560]

OS **III,** 26, 562; V, 520.

I. *Carbon Attack by Active Hydrogen Compounds*

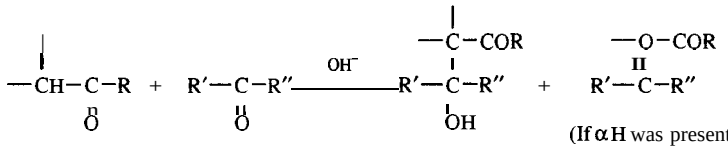
Reactions **16-38-16-49** are base-catalyzed condensations (though some of them are also catalyzed to acids).[561] **In 16-38-16-47,** a base removes a C—H proton to give a carbanion, which then adds to a C=O. The oxygen acquires a proton, and the resulting alcohol may or may not be dehydrated, depending on whether an α hydrogen is present and on whether the new double bond would be in conjugation with double bonds already present:



The reactions differ in the nature of the active hydrogen component and the carbonyl component. Table 16.1 illustrates the differences. Reaction **16-49** is an analogous reaction involving addition to C≡N.

16-38 *The Aldol Reaction*[562]

O-HYDRO-*C*-(α-ACYLALKYL)-ADDITION;
α-ACYLALKYLIDINE-DE-OXO-BISUBSTITUTION



In the *aldol reaction*[563] the a carbon of one aldehyde or ketone molecule adds to the carbonyl carbon of another.[564] Although acid catalyzed aldol reactions are known,[565] the most common form of the reaction uses a base. The base most often used is OH^-, though stronger bases such as alkoxides (RO~) are sometimes employed. Hydroxide ion is not a strong enough base to convert substantially all of an aldehyde or ketone molecule to the corresponding enolate ion, that is, the equilibrium lies

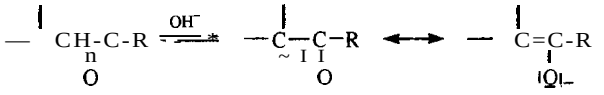


TABLE 16.1 Base Catalyzed Condensations Showing the Active-Hydrogen Components and the Carbonyl Compounds

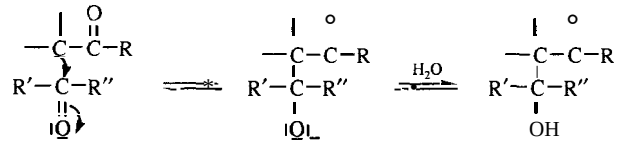
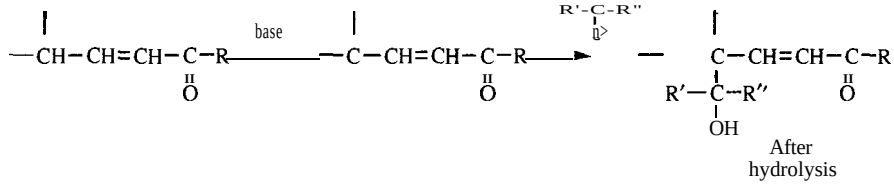
Reaction	Active-Hydrogen Component	Carbonyl Component	Subsequent Reaction
16-38 Aldol reaction	Aldehyde $-\overset{\vert}{C}H-CHO$ Ketone $-\overset{\vert}{C}H-COR$	Aldehyde, ketone	Dehydration may follow
16-40	Ester $-\overset{\vert}{C}H-CHOOR$	Aldehyde, ketone (usually without a-hydrogens)	Dehydration may follow
16-41 Knoevenagel reaction	$Z-CH_2-Z'$, Z-CHR-Z' and similar molecules	Aldehyde, ketone (usually without a-hydrogens)	Dehydration usually follows
16-42 Peterson reaction	$Me_3Si-\underline{\overset{\vert}{C}}H-$	Aldehyde, ketone may follow	Dehydration
16-43	$-\overset{\vert}{C}H-Z$ Z = COR, COOR, NO_2	CO_2, CS_2	
16-44 Perkin reaction	Anhydride -CH-COOCOR	Aromatic aldehyde usually follows	Dehydration
16-45 Darzen's reaction	α-Halo ester XCH-COOR	Aldehyde, ketone (S_N reaction) follows	Epoxidation
16-46 Tollens' reaction	Aldehyde $-\overset{\vert}{C}H-CHO$ Ketone -CH-COR	Formaldehyde reaction follows	Crossed Cannizzaro
16-47 Wittig reaction	Phosphorous ylid $Ph_3\overset{+}{P}-\underline{\overset{\vert}{C}}-$	Aldehyde, ketone always follows	"Dehydration"
16-49 Thorpe reaction	Nitrile $-\overset{\vert}{C}H-CN$	Nitrile	

well to the left, for both aldehydes and ketones. Nevertheless, enough enolate ion is present for the reaction to proceed:



The product is a (3-hydroxy aldehyde (called an *aldol*) or ketone, which in some cases is dehydrated during the course of the reaction. Even if the dehydration is not spontaneous, it can usually be done easily, since the new double bond is in conjugation with the C=O bond; so that this is a method of preparing α,β-unsaturated aldehydes and ketones as well as (3-hydroxy aldehydes and ketones. The entire reaction is an equilibrium (including the dehydration step), and α, (3-unsaturated and (3-hydroxy aldehydes and ketones can be cleaved by treatment with OH^- (the *retrograde aldol reaction).* There is evidence that an SET mechanism can intervene when the substrate is an aromatic ketone.[566]

Under the principle of vinylogy, the active hydrogen can be one in the *y* position of an α,β-unsaturated carbonyl compound:



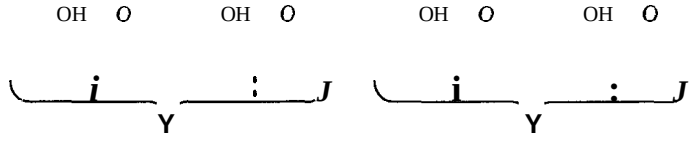
The scope of the aldol reaction may be discussed under five headings:

1. *Reaction between Two Molecules of the Same Aldehyde.* The equilibrium lies far to the right,[567] and the reaction is quite feasible. Many aldehydes have been converted to aldols and/or their dehydration products in this manner. The most effective catalysts are basic ion-exchange resins. Of course, the aldehyde must possess an α hydrogen.
2. *Reaction between Two Molecules of the Same Ketone.* In this case, the equilibrium lies well to the left[568] and the reaction is feasible only if the equilibrium can be shifted. This can often be done by allowing the reaction to proceed in a Soxhlet extractor (e.g., see OS I, 199). Two molecules of the same ketone can also be condensed without a Soxhlet extractor,[569] by treatment with basic Al_2O_3.[570] Unsymmetrical ketones condense on the side that has more hydrogens. (An exception is butanone, which reacts at the CH_2 group with acid catalysts, though with basic catalysts, it too reacts at the CH_3 group.)
3. *Reaction between Two Different Aldehydes.* In the most general case, this will produce a mixture of four products (eight, if the alkenes are counted). However, if one aldehyde does not have an a hydrogen, only two aldols are

possible, and in many cases the crossed product is the main one. The crossed aldol reaction is often called the *Claisen–Schmidtreaction.*[571]

4. *Reaction between Two Different Ketones.* This is seldom attempted (except with the use of preformed enolates, see below), but similar considerations apply.
5. *Reaction between an Aldehyde and a Ketone.* This is usually feasible, especially when the aldehyde has no a hydrogen, since there is no competition from ketone condensing with itself.[572] This is also called the *Claisen-Schmidt reaction.* Even when the aldehyde has an α hydrogen, it is the α carbon of the ketone that adds to the carbonyl of the aldehyde, not the other way around. The reaction can be made regioselective by preparing an enol derivative of the ketone separately[573] and then adding this to the aldehyde (or ketone), which assures that the coupling takes place on the desired side of an unsymmetrical ketone. Other types of preformed derivatives that react with aldehydes and ketones are enamines (with a Lewis acid catalyst),[574] and enol borinates ($R'CH{=}CR''{-}OBR_2$)[575], which can be synthesized by 15-25, or directly from an aldehyde or ketone.[576] Preformed metallic enolates are also used. For example lithium enolates (prepared by 12-21)[577] react with the substrate in the presence of $ZnCl_2$;[578] in this case, the aldol product is stabilized by chelation of its two oxygen atoms with the zinc ion.[579] Among other metallic enolates used for aldol reactions are those of Ti,[580] Zr,[581] Sn,[582] La,[583] Sm,[584] and Pd,[585] all of which give products regioselectively. α-Alkoxy ketones react with lithium enolates particularly rapidly.[586]

The reactions with preformed enol derivatives provide a way to control the stereoselectivity of the aldol reaction.[587] As with the Michael reaction (15-16), the aldol reaction creates two new chiral centers, and, in the most general case, there are four stereoisomers of the aldol product, which can be represented as



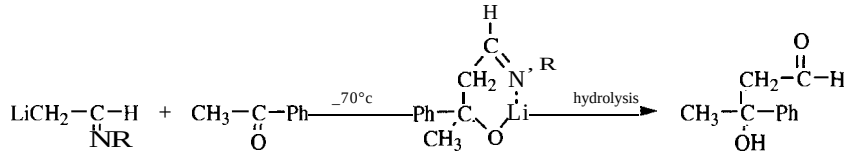
syn (or erythro) (±) Pair anti (or threo) (±) Pair

Among the preformed enol derivatives used in this way have been enolates of magnesium, lithium,[588] titanium,[589] zirconium,[522] and tin,[590] silyl enol ethers,[591] enol borinates,[592] and enol borates, $R'CH{=}CR''{-}OB(OR)_2$.[593] The nucleophilicity of silyl enol ethers has been examined.[594] In general, metallic Z enolates give the syn (or erythro) pair, and this reaction is highly useful for the diastereoselective synthesis of these products.[595] The *(E)* isomers generally react nonstereoselectively. However, anti (or threo) stereoselectivity has been achieved in a number of cases, with titanium enolates,[596] with magnesium enolates,[597] with certain enol borinates,[598] and with lithium enolates at -78°C.[599]

These reactions can also be made enantioselective[600] (in which case only one of the four isomers predominates)[601] by using[602] chiral enol derivatives,[603] chiral

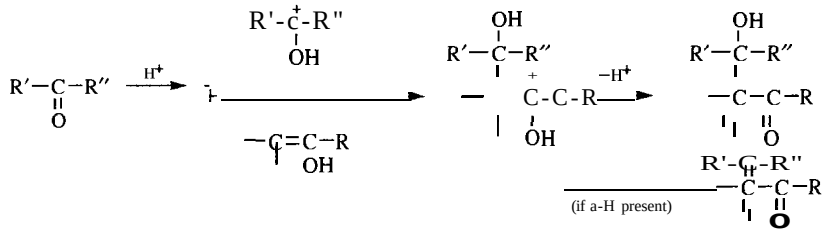
aldehydes or ketones,[604] or both.[605] Silyl enol ethers react with aldehydes in the presence of chiral boranes[606] or other additives[607] to give aldols with good asymmetric induction. Since both new chiral centers are formed enantioselectively, this kind of process is called *double asymmetric synthesis*.[608] A single one of the four stereoisomers has also been produced where both the enolate derivative and substrate were achiral, by carrying out the reaction in the presence of an optically active boron compound[609] or a diamine coordinated with a tin compound.[610]

It is possible to make the a carbon of the aldehyde add to the carbonyl carbon of the ketone, by using an imine instead of an aldehyde, and $LiN(i\text{-}Pr)_2$ as the base:[611]



This is known as the *directed aldol reaction.* Similar reactions have been performed with α-lithiated dimethylhydrazones of aldehydes or ketones[612] and with α-lithiated aldoximes.[613]

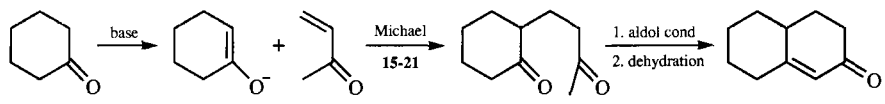
The aldol reaction can also be performed with acid catalysts, as mentioned above, in which case dehydration usually follows. Here there is initial protonation of the carbonyl group, which attacks the a carbon of the *enol* form of the other molecule:[614]



With respect to the enol, this mechanism is similar to that of halogenation (12-4).

A side reaction that is sometimes troublesome is further condensation, since the product of an aldol reaction is still an aldehyde or ketone.

Aldol reactions are often used to close five- and six-membered rings. Because of the favorable entropy (p. 280), such ring closures generally take place with ease,[615] even where a ketone condenses with a ketone. An important extension of this idea is the *Robinson annulation reaction*,[616] which has often been used in the synthesis of steroids and terpenes. In this reaction, a cyclic ketone is converted to another cyclic ketone, with one additional six-membered ring containing a double bond. The substrate is treated with methyl vinyl ketone (or a simple derivative of methyl vinyl ketone) and a base.[617] The enolate ion of the substrate adds to the methyl vinyl ketone in a Michael reaction (15-21) to give a diketone that undergoes or is made to undergo an internal aldol reaction and subsequent dehydration to give the product.[618]



Because methyl vinyl ketone has a tendency to polymerize, precursors are often used instead, that is, compounds that will give methyl vinyl ketone when treated with a base. One common example, $MeCOCH_2CH_2NEt_2Me^+ I^-$ (see **17-8),** is easily prepared by quaternization of $MeCOCH_2CH_2NEt_2$, which itself is prepared by a Mannich reaction **(16-15)** involving acetone, formaldehyde, and diethylamine. α-Silylated vinyl ketones, $RCOC(SiMe_3)=CH_2$, have also been used successfully in annulation reactions.[619] The $SiMe_3$ group is easily removed. 1,5-Diketones prepared in other ways are also frequently cyclized by internal aldol reactions. When the ring closure of a 1,5-diketone is catalyzed by the amino acid (*S*)-proline, the product is optically active with high enantiomeric excess.[620]

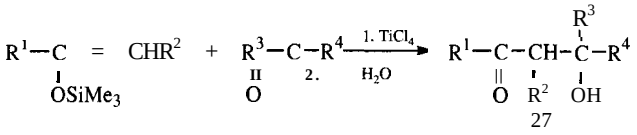
16-39 *Mukaiyama Aldol and Related Reactions*[621]

O-HYDRO-*C*-(α-ACYLALKYL)-ADDITION

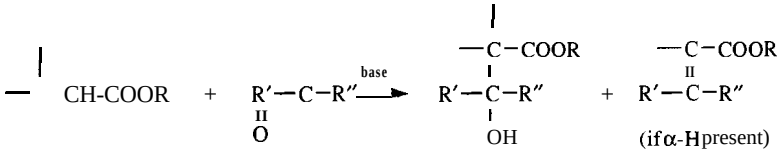
A reaction related to the aldol involves treatment of a ketone with a silyl ketene acetal $R_2C=C(OSiMe_3)OR'$[622] in the presence of $TiCl_4$ to give 27. The silyl ketene acetal can be considered a preformed enolate that give an aldol product, and when



combined with an aldehyde or ketone, with $TiCl_4$[623] (the *Mukaiyama reagent),* in aqueous solution, or with no catalyst at all.[624] The mechanism of this reaction has been explored.[625] Other catalysts have been used for this reaction as well, including $InCl_3$,[626] SmI_2,[627] $Sc(OTf)_3$,[628] HgI_2,[629] $Yb(OTf)_3$,[630] $Cu(OTf)_2$,[631] $[Cp_2Zr(Ot\text{-}Bu)$ THF] $^+[BPh4]^-$,[632] $LiClO_4$,[633] an iron catalyst,[634] and $Bi(OTf)_3$.[635] Asymmetric Mukaiyama aldol reactions have been reported, [636] usually using chiral additives[637] although chiral auxiliaries have also been used.[638] This reaction can also be run with the aldehyde or ketone in the form of its acetal $R^3R^4C(OR')_2$, in which case the product is the ether $R^1COCHR_2CR^3R^4OR'$ instead of 27.[639] Enol acetates and enol ethers also give this product when treated with acetals and $TiCl_4$ or a similar catalyst.[640] When the catalyst is dibutyltin bis(triflate), $Bu_2Sn(OTf)_2$, aldehydes react, but not their acetals, while acetals of ketones react, but not the ketones themselves.[641]

16-40 *Aldol-Type Reactions between Carboxylic Esters or Amides and Aldehydes or Ketones*

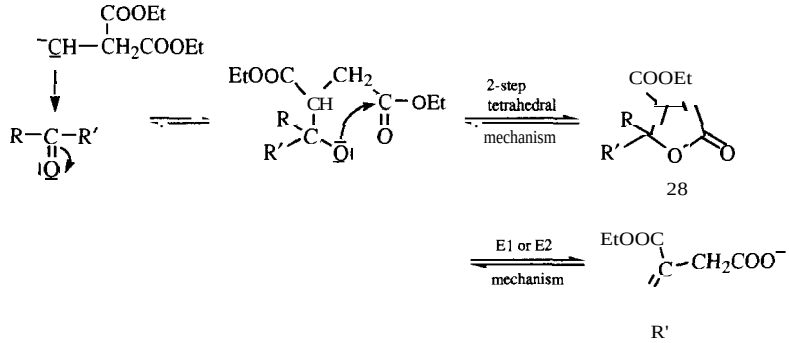
O-HYDRO-*C*-(α-ALKOXYCARBONYLALKYL)-ADDITION;
α-ALKOXYCARBONYLALKYLIDENE-DE-OXO-BISUBSTITUTION



In the presence of a strong base, the a carbon of a carboxylic ester can condense with the carbonyl carbon of an aldehyde or ketone to give a P-hydroxy ester,[642] which may or may not be dehydrated to the α,β-unsaturated ester. This reaction is sometimes called the *Claisen reaction*,[643] an unfortunate usage since that name is more firmly connected to **10-118.** In a modern example of how the reaction is used, addition of tert-butyl acetate to LDA in hexane at −78°C gives the lithium salt of *tert*-butyl acetate,[644] **(12-21)** an enolate anion. Subsequent reaction a ketone provides a simple rapid alternative to the Reformatsky reaction **(16-31)** as a means of preparing P-hydroxy tert-butyl esters. It is also possible for the α carbon of an aldehyde or ketone to add to the carbonyl carbon of a carboxylic ester, but this is a different reaction **(10-119)** involving nucleophilic substitution and not addition to a C=O bond. It can, however, be a side reaction if the aldehyde or ketone has an a hydrogen.

Besides ordinary esters (containing an α hydrogen), the reaction can also be carried out with lactones and, as in **16-38,** with the *y* position of α,β-unsaturated esters (vinylogy). There are also cases, where the enolate anion of an amide was condensed with an aldehyde.[645]

For most esters, a much stronger base is needed than for aldol reactions; *(i*-$Pr)_2NLi$ (see above), Ph_3CNa and $LiNH_2$ are among those employed. However, one type of ester reacts more easily, and such strong bases are not needed: diethyl succinate and its derivatives condense with aldehydes and ketones in the presence of bases such as NaOEt, NaH, or $KOCMe_3$. This reaction is called the *Stobbe condensation*.[646] One of the ester groups (sometimes both) is hydrolyzed in the course of the reaction. The following mechanism accounts for (1) the fact the succinic esters react so much better than others; (2) one ester group is always cleaved; and (3) the alcohol is not the product but the alkene. In addition, intermediate lactones (28) have been isolated from the mixture:[647]



The Stobbe condensation has been extended to di-*tert*-butyl esters of glutaric acid.[648]

The condensation of an ester enolate and a ketone[649] can be used as part of a Robinson annulation-like sequence (see **16-38).**

OS **I,** 252; **III,** 132; **V,** 80, 564; **70,** 256; **75,** 215. Also see OS IV, 278, 478; V, 251.

16-41 *The Knoevenagel Reaction*

BIS(ETHOXYCARBONYL)METHYLENE-DE-OXO-BISUBSTITUTION, AND SO ON

$$R-\underset{\underset{O}{\|}}{C}-R' + Z-CH_2-Z' \xrightarrow{\text{base}} R-\underset{\underset{Z-C-Z'}{|}}{\overset{}{C}}-R'$$

The condensation of aldehydes or ketones, usually not containing an a hydrogen, with compounds of the form $Z-CH_2-Z'$ or $Z-CHR-Z'$ is called the *Knoevenagel reaction.*[650] Both Z and Z' may be CHO, COR, COOH, COOR, CN, NO_2,[651] SOR, SO_2R, SO_2OR, or similar groups. When Z=COOH, decarboxylation of the product often takes place *in situ.*[652] If a strong enough base is used, the reaction can be performed on compounds possessing only a single Z, (e.g., CH_3Z or RCH_2Z). Other active hydrogen compounds can also be employed, among them $CHCl_3$, 2-methylpyridines, terminal acetylenes, cyclopentadienes, and so on.; in fact any compound that contains a C—H bond the hydrogen of which can be removed by a base. The following examples illustrate the wide scope of the reaction:

$$PhCHO + CH_3COCH_2COOEt \xrightarrow[0°C]{Et_2NH} Ph-CH=\underset{\underset{COCH_3}{|}}{C}-COOEt$$

$$PhCHO + CH_3NO_2 \xrightarrow{n\text{-}C_5H_{11}NH_2} Ph-CH=CH-NO_2$$

Ref. 651

$$PhCH_2CH_2CHO + [PhSO\bar{C}HCO\bar{C}H_2]^{2-}\,Li^+,Na^+ \xrightarrow[\text{hydrolysis}]{\text{(after}} PhCH_2CH_2\underset{\underset{OH}{|}}{C}HCH_2COCH_2SOPh$$

Ref. 653

$$PrCHO + HOOCCH_2COOH \xrightarrow[\text{piperidine}]{\text{pyridine}} PrCH=CHCOOH$$

We see from these examples that many of the carbon nucleophiles we encountered in Chapter 10 are also nucleophiles toward aldehydes and ketones (cf. Reactions 10-104-10-108 and 10-110). As we saw in Chapter 10, the initial products in many of these cases can be converted by relatively simple procedures (hydrolysis, reduction, decarboxylation, etc.) to various other products. In the reaction with terminal acetylenes,[654] sodium acetylides are the most common reagents (when they are used, the reaction is often called the *Nef reaction),* but lithium,[655] magnesium, and other metallic acetylides have also been used. A particularly convenient reagent is lithium acetylide–ethylenediamine complex,[656] a stable, free-flowing powder that is commercially available. Alternatively, the substrate may be treated with the alkyne itself in the presence of a base, so that the acetylide is generated *in situ.* This procedure is called the *Favorskii reaction,* not to be confused with the Favorskii rearrangement (18-7).[657]

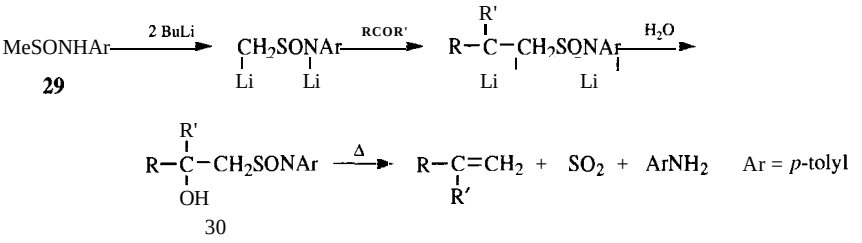
With most of these reagents the alcohol is not isolated (only the alkene) *if* the alcohol has a hydrogen in the proper position.[658] However, in some cases the alcohol is the major product. With suitable reactants, the Knoevenagel reaction, like the aldol (16-2), has been carried out diastereoselectively[659] and enantioselectively.[660]

When the reactant is of the form ZCH_2Z', aldehydes react much better than ketones and few successful reactions with ketones have been reported. However, it is possible to get good yields of alkene from the condensation of diethyl malonate, $CH_2(COOEt)_2$, with ketones, as well as with aldehydes, if the reaction is run with $TiCl_4$ and pyridine in THF.[661] In reactions with ZCH_2Z', the catalyst is most often a secondary amine (piperidine is the most common), though many other catalysts have been used. When the catalyst is pyridine (to which piperidine may or may not be added) the reaction is known as the *Doebner modification* of the Knoevenagel reaction. Alkoxides are also common catalysts.

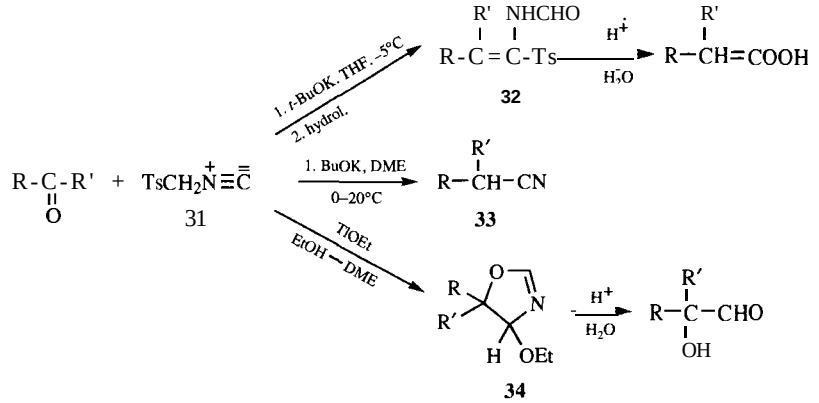
As with 16-38, these reactions have sometimes been performed with acid catalysts.[662] Ultrasound has been used to promote the reaction,[663] and it has also been done without solvent using microwave irradiation.[664] Another solid-state variation is done on moist LiBr.[665] Zeolites have been used to promote the reaction.[666] Transition metal compounds such as SmI_2 [667] or $BiCl_3$ [668] have been used to promote the Knoevenagel reaction.

A number of special applications of the Knoevenagel reaction follow:

1. The dilithio derivative of *N*-methanesulfinyl-*p*-toluidine[669] (29) adds to aldehydes and ketones to give, after hydrolysis, the hydroxysulfinamides (30), which, upon heating, undergo stereospecifically syn eliminations to give alkenes.[670] The reaction is thus a method for achieving the conversion $RR'CO \rightarrow RR'C{=}CH_2$ and represents an alternative to the Wittig reaction.[671]



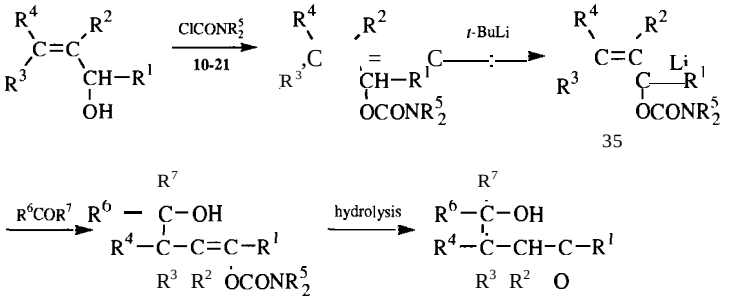
2. The reaction of ketones with tosylmethylisocyanide (31) gives different products,[672] depending on the reaction conditions.



When the reaction is run with potassium tert-butoxide in THF at -5°C, one obtains (after hydrolysis) the normal Knoevenagel product (32), except that the isocyano group has been hydrated (**16-65**).[673] With the same base but with DME as solvent the product is the nitrile (**33**).[674] When the ketone is treated with 31 and thallium(I) ethoxide in a 4:1 mixture of absolute ethanol and DME at room temperature, the product is a 4-ethoxy-2-oxazoline (**34**).[675] Since 33 can be hydrolyzed[676] to a carboxylic acid[673] and 34 to an α-hydroxy aldehyde,[675] this versatile reaction provides a means for achieving the conversion of RCOR' to RCHR'COOH, RCHR'CN, or RCR'(OH)CHO. The conversions to RCHR'COOH and to RCHR'CN[677] have also been carried out with certain aldehydes (R' = H).

3. Aldehydes and ketones RCOR' react with α-methoxyvinyllithium CH_2=C(Li)OMe to give hydroxy enol ethers $RR'C(OH)C(OMe)=CH_2$, which are easily hydrolyzed to acyloins, RR'C(OH)COMe.[678] In this reaction, the CH_2=C(Li)OMe is a synthon for the unavailable $H_3C-\overline{C}=O$.[679] The reagent also reacts with esters RCOOR' to give $RC(OH)(COMe=CH_2)_2$. A synthon for the Ph–C=O ion is $PhC(CN)OSiMe_3$, which adds to aldehydes and ketones RCOR' to give, after hydrolysis, the a-hydroxy ketones, RR'C(OH)-COPh.[680]

4. Lithiated allylic carbamates (35) (prepared as shown) react with aldehydes or ketones (R^6COR^7), in a reaction accompanied by an allylic rearrangement, to give (after hydrolysis) γ-hydroxy aldehydes or ketones.[681] The reaction is called *the homoaldol reaction,* since the product is a homolog of the product of **16-38**. The reaction has been performed enantioselectively.[682]



5. The lithium salt of an active hydrogen compound adds to the lithium salt of the tosylhydrazone of an aldehyde to give product 36. If X = CN, SPh, or SO_2R, 36 spontaneously loses N_2 and LiX to give the alkene 37. The entire process is done in one reaction vessel: The active hydrogen compound is mixed with the tosylhydrazone and the mixture is treated with $(i\text{-Pr})_2NLi$ to form both salts at once.[683] This process is another alternative to the Wittig reaction for forming double bonds.

Also see OS **III,** 395; V, 450.

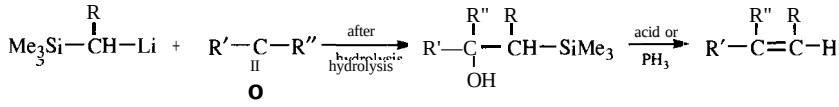
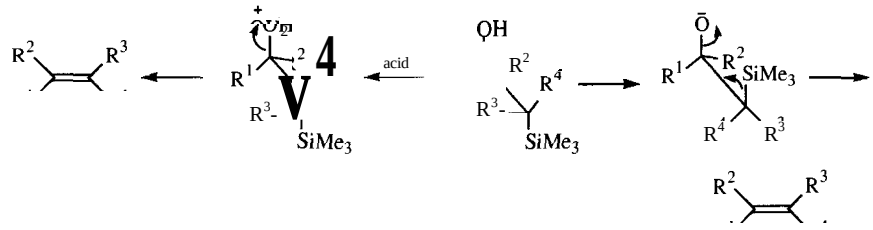
16-42 *The Peterson Alkenylation Reaction*

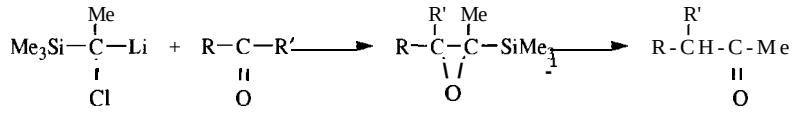
ALKYLIDENE-DE-OXO-BISUBSTITUTION



In the *Peterson Alkenylation reaction*,[684] the lithio (or sometimes magnesio) derivative of a trialkylsilane adds to an aldehyde or ketone to give a β-hydroxysilane, which spontaneously eliminates water, or can be made to do so by treatment with acid or base, to produce an alkene. This reaction is still another alternative to the Wittig reaction, and is sometimes called the *silyl–Wittig reaction*.[685] The R group can also be a COOR group, in which case the product is an α,β-unsaturated ester,[686] or an SO_2Ph group, in which case the product is a vinylic sulfone.[687] The stereochemistry of the product can often be controlled by whether an acid or a base is used to achieve elimination. The role of Si—O interactions has also been examined.[688] Use of a base generally gives syn elimination (E; mechanism, see p. 1323), while an acid usually results in anti elimination (E^2 mechanism, see p. 1300).[689]



When aldehydes or ketones are treated with reagents of the form 38, the product is an epoxy silane **(16-61),** which can be hydrolyzed to a methyl ketone.[690] For aldehydes, this is a method for converting RCHO to a methyl ketone (RCH_2COMe).



38

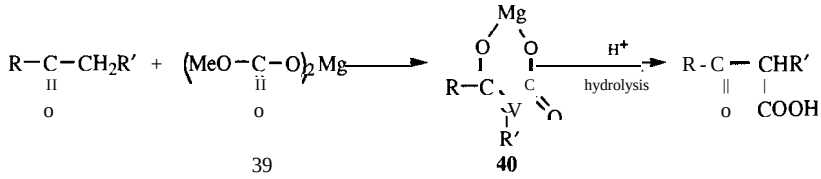
The reagents $Me_3SiCHRM$ (M = Li or Mg) are often prepared from Me_3SiCHR-Cl [691] (by **12-36** or **12-37),** but they have also been made by **12-20** and by other procedures.[692]

A new version of the reaction has been developed, reacting $Me_3SiCH_2CO_2Et$ with an aldehyde and a catalytic amount of CsF in DMSO.[693]

There are no references in *Organic Syntheses*, but see OS VIII, 602, for a related reaction.

16-43 *The Addition of Active Hydrogen Compounds to CO_2 and CS_2*

α-ACYLALKYL-DE-METHOXY-SUBSTITUTION (OVERALL REACTION)



39 **40**

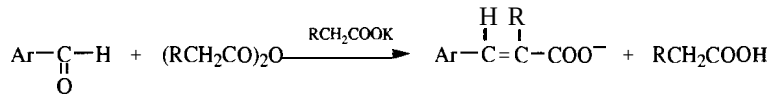
Ketones of the form $RCOCH_3$ and $RCOCH_2R'$ can be carboxylated indirectly by treatment with magnesium methyl carbonate (**39**).[694] Because formation of the chelate (40) provides the driving force of the reaction, carboxylation cannot be achieved at a disubstituted a position. The reaction has also been performed on CH_3NO_2 and compounds of the form RCH_2NO_2 [695] and on certain lactones.[696] Direct carboxylation has been reported in a number of instances. Ketones have been carboxylated in the α position to give P-keto acids.[697] The base here was lithium 4-methyl-2,16-di-*tert*-butylphenoxide.

Ketones ($RCOCH_2R'$), as well as other active hydrogen compounds, undergo base-catalyzed addition to CS_2 [698] to give a dianion intermediate $RCOCR'CSS^{2-}$, which can be dialkylated with a halide R"X to produce α-dithiomethylene ketones $RCOCR'{=}C(SR'')_2$.[699] Compounds of the form ZCH_2Z' also react with bases and CS_2 to give analogous dianions.[700]

OS VII, 476. See also OS VIII, 578.

16-44 *The Perkin Reaction*

α-CARBOXYALKYLIDNE-DE-OXO-BISUBSTITUTION

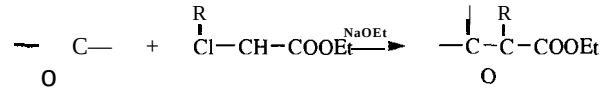


The condensation of aromatic aldehydes with anhydrides is called the *Perkin reaction*.[701] When the anhydride has two α hydrogens (as shown), dehydration always occurs; the P-hydroxy acid salt is never isolated. In some cases, anhydrides of the form $(R_2CHCO)_2O$ have been used, and then the hydroxy compound is the product since dehydration cannot take place. The base in the Perkin reaction is nearly always the salt of the acid corresponding to the anhydride. Although the Na and K salts have been most frequently used, higher yields and shorter reaction times have been reported for the Cs salt.[702] Besides aromatic aldehydes, their vinylogs ArCH=CHCHO also give the reaction. Otherwise, the reaction is not suitable for aliphatic aldehydes.[703]

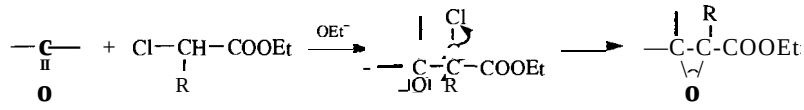
OS I, 398; II, 61, 229; III, 426.

16-45 *Darzens Glycidic Ester Condensation*

(2 + 1)*OC,CC-CYCLO*-α-ALKOXYCARBONYLMETHYLENE- ADDITION



Aldehydes and ketones condense with α-halo esters in the presence of bases to give α,β-epoxy esters, called *glycidic esters.* This is called *the Darzens condensation.*[704] The reaction consists of an initial Knoevenagel-type reaction (16-41), followed by an internal S_N2 reaction (10-13):[705]



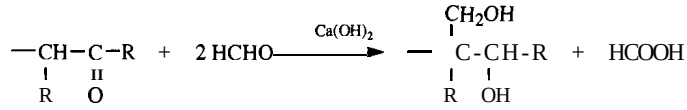
Although the intermediate halo alkoxide is generally not isolated,[706] it has been done, not only with α-fluoro esters (since fluorine is such a poor leaving group in nucleophilic substitutions) but also with α-chloro esters.[707] This is only one of several types of evidence that rule out a carbene intermediate.[708] Sodium ethoxide is often used as the base, though other bases, including sodium amide, are sometimes used. Aromatic aldehydes and ketones give good yields, but aliphatic aldehydes react poorly. However, the reaction can be made to give good yields (≈80%) with simple aliphatic aldehydes as well as with aromatic aldehydes and ketones by treatment of the a-halo ester with the base lithium bis(trimcthylsilyl)amide $LiN(SiMe_3)_2$ in THF at -78°C (to form the conjugate base of the ester) and addition of the aldehyde or ketone to this solution.[709] If a preformed dianion of an a-halo carboxylic acid $Cl-\bar{\bar{C}}R-COO^-$ is used instead, a,(3-epoxy acids are produced directly.[710] The Darzens reaction has also been carried out on a-halo ketones, a-halo nitriles,[711] a-halo sulfoxides[712] and sulfones,[713] a-halo N,N-disubstituted amides,[714] a-halo ketimines,[715] and even on allylic[716] and benzylic halides. Phase-transfer catalysis has been used.[717] The Darzens reaction has been performed enantioselectively, by coupling optically active a-bromo-P-hydroxy esters with aldehydes.[718,719]

Glycidic esters can easily be converted to aldehydes (12-38). The reaction has been extended to the formation of analogous aziridines by treatment of an imine with an a-halo ester or an a-halo N,N-disubstituted amide and *t*-BuOK in the solvent 1,2,-dimethoxyethane.[720] However, yields were not high. Acid-catalyzed Darzens reactions have also been reported.[721] See also 16-61.

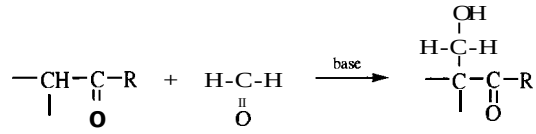
OS III, 727; IV, 459, 649.

16-46 *Tollens' Reaction*

O-HYDRO-*C*(β-HYDROXYALKYL)-ADDITION



In *Tollens' reaction,* an aldehyde or ketone containing an α hydrogen is treated with formaldehyde in the presence of $Ca(OH)_2$ or a similar base. The first step is a mixed aldol reaction **(16-38).**



The reaction can be stopped at this point, but more often a second mole of formaldehyde is permitted to reduce the newly formed aldol to a 1,3-diol, in a crossed Cannizzaro reaction **(19-60).** If the aldehyde or ketone has several α-hydrogens, they can all be replaced. An important use of the reaction is to prepare pentaerythritol from acetaldehyde:

$$CH_3CHO + 4\,HCHO \longrightarrow C(CH_2OH)_4 + HCOOH$$

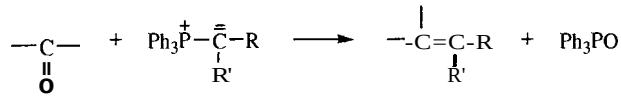
When aliphatic nitro compounds are used instead of aldehydes or ketones, no reduction occurs, and the reaction is essentially a Knoevenagel reaction, though it is usually also called a Tollens' reaction:

$$CH_3NO_2 + HCHO \xrightarrow{OH^-} HOCH_2CH_2NO_2$$

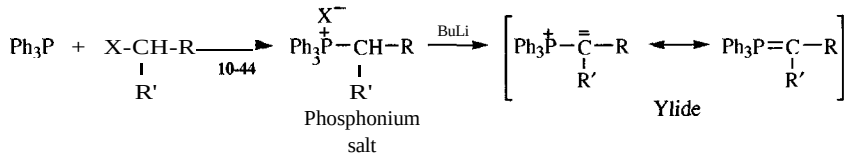
OS I, 425; IV, 907; V, 833.

16-47 *The Wittig Reaction*

ALKYLIDENE-DE-OXO-BISUBSTITUTION



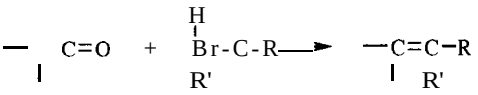
In the *Wittig reaction* an aldehyde or ketone is treated with a *phosphorus ylid* (also called a *phosphorane)* to give an alkene.[722] Phosphorus ylids are usually prepared by treatment of a phosphonium salt with a base,[723] and phosphonium salts are usually prepared from the phosphine and an alkyl halide **(10-44):**



The overall sequence of three steps may be called the Wittig reaction, or only the final step. Phosphonium salts are also prepared by addition of phosphines to Michael alkenes (like **15-8)** and in other ways. The phosphonium salts are most often converted to the ylids by treatment with a strong base such as butyllithium, sodium amide,[724] sodium hydride, or a sodium alkoxide, though weaker bases can be used if

the salt is acidic enough. For $(Ph_3P^+)_2CH_2$, sodium carbonate is a strong enough base.[725] When the base used does not contain lithium, the ylid is said to be prepared under "salt-free" conditions.[726]

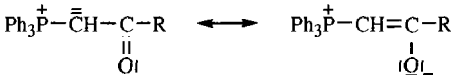
In the overall Wittig reaction, an alkene is formed from the aldehyde or ketone and an alkyl halide in which the halogen-bearing carbon contains at least one hydrogen:



This result is similar to that obtained in the Reformatsky reaction (16-31), but this is more general since no ester or other group is required to be a to the halogen. Another important advantage of the Wittig reaction is that the *position* of the new double bond is always certain, in contrast to the result in the Reformatsky reaction and in most of the base-catalyzed condensations (16-38-16-46). Examples of this are given below.

The reaction is very general. The aldehyde or ketone may be aliphatic, alicyclic, or aromatic (including diaryl ketones); it may contain double or triple bonds; it may contain various functional groups, such as OH, OR, NR_2, aromatic nitro or halo, acetal, amide,[727] or even ester groups.[728] Ylids have been shown to react with lactone, however, to form ω-alkenyl alcohols.[729] β-Lactams have also been converted to alkenyl-azetidine derivatives using phosphorus ylids.[730] Double or triple bonds *conjugated* with the carbonyl also do not interfere, the attack being at the C=O carbon. There is one variation where a benzylic alcohol is treated with a mixture of the ylid and $BaMnO_4$, producing the alkene in good yield.[731] In another variation, an allylic alcohol was treated with MnO_2 and the ylid.[732]

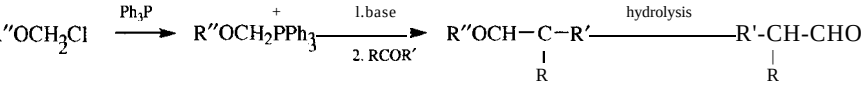
The phosphorus ylid may also contain double or triple bonds and certain functional groups. Simple ylids (R, R' = hydrogen or alkyl) are highly reactive, reacting with oxygen, water, hydrohalic acids, and alcohols, as well as carbonyl compounds and carboxylic esters, so the reaction must be run under conditions where these materials are absent. When an electron-withdrawing group (e.g., COR, CN, COOR, CHO) is present in the a position, the ylids are much more stable, because the charge on the carbon is spread by resonance:



These ylids react readily with aldehydes, but slowly or not at all with ketones.[733] In extreme cases (e.g., 41), the ylid does not react with ketones *or* aldehydes. Besides

41

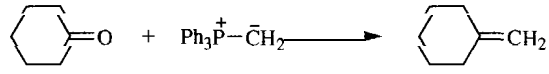
these groups, the ylid may contain one or two α halogens[734] or an α OR or OAr group. In the latter case the product is an enol ether, which can be hydrolyzed



(10-6) to an aldehyde,[735] so that this reaction is a means of achieving the conversion RCOR' → RR'CHCHO.[736] However, the ylid may not contain an α nitro group. If the phosphonium salt contains a potential leaving group, such as Br or OMe, in the β position, treatment with a base gives elimination, instead of the ylid:

However, a β COO^- group may be present, and the product is a β,γ-unsaturated acid:[737]

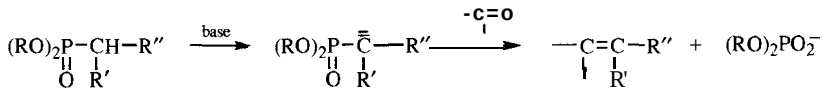
This is the only convenient way to make these compounds, since elimination by any other route gives the thermodynamically more stable α,β-unsaturated isomers. This is an illustration of the utility of the Wittig method for the specific location of a double bond. Another illustration is the conversion of cyclohexanones to alkenes containing exocyclic double bonds, for example,[738]



Still another example is the easy formation of anti-Bredt bicycloalkenones (see p. 188).[739] As indicated above, α,α'-dihalophosphoranes can be used to prepare 1,1-dihaloalkenes. Another way to prepare such compounds[740] is to treat the carbonyl compound with a mixture of CX_4 (X = Cl, Br, or I) and triphenylphosphine, either with or without the addition of zinc dust (which allows less Ph_3P to be used).[741]

The Wittig reaction has been carried out with polymer-supported ylids (see p. 509).[742] It has also been done on silica gel.[743]

Ylids are usually prepared from triphenylphosphine, but other triarylphosphines,[744] trialkylphosphines,[745] and triphenylarsine[746] have also been used. The Wittig reaction has also been carried out with other types of ylids, the most important being prepared from phosphonates:[747]



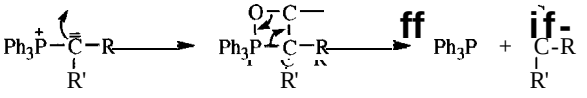
This method, sometimes called the *Horner–Emmons*, *Wadsworth–Emmons*, or *Wittig–Hornerreaction*,[748] has several advantages over the use of phosphoranes.[749] These ylids are more reactive than the corresponding phosphoranes, and when R' is

an electron-withdrawing group, these compounds often react with ketones that are inert to phosphoranes. In addition, the phosphorus product is a phosphate ester, and hence soluble in water, unlike Ph_3PO, which makes it easy to separate it from the alkene product. Phosphonates are also cheaper than phosphonium salts and can easily be prepared by the *Arbuzov reaction*:[750]

$$(EtO)_3P + RCH_2X \longrightarrow (EtO)_2\overset{\overset{O}{\|}}{P}-CH_2R$$

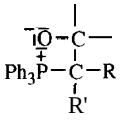
Stereoselective alkenylation reactions have been achieved using chiral additives[751] or auxiliaries.[752] Ylids formed from phosphinoxides $Ar_2\overset{\overset{O}{\|}}{P}-CHRR'$, phosphonic acid bisamides, $(R''_2N)_2POCHRR'$,[753] and alkyl phosphonothionates, $(MeO)_2PSCHRR'$,[754] share some of these advantages. Phosphonates $(Ph_2POCH_2NR'_2)$ react with aldehydes or ketones R_2COR^3 to give good yields of enamines $(R^2R^3C{=}CHNR)$.[755] (Z)-Selective reagents are also known.[756] An interesting variation in the reaction leads to alkynes. Intramolecular versions of the Horner-Emmons reaction are also known.[757] The reaction of a functionalized aldehyde (R–CHO) with $(MeO)_2POCHN_2$, leads to the alkyne (R–C≡CH).[758]

The mechanism[759] of the key step of the Wittig reaction is as follows:[760]



Oxaphosphetane

The energetics of ylid formation and their reaction is solution has been studied.[761] For many years it was assumed that a diionic compound, called a *betaine,* is an intermediate on the pathway from the starting compounds to the oxaphosphetane, and in fact it may be so, but there is little evidence for it.[762]

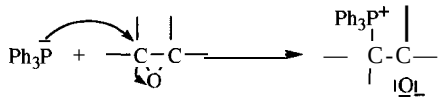


Betaine

"Betaine" precipitates have been isolated in certain Wittig reactions,[763] but these are betaine–lithium halide adducts, and might just as well have been formed from the oxaphosphetane as from a true betaine.[764] However, there is one report of an observed betaine lithium salt during the course of a Wittig reaction.[765] In contrast, there is much evidence for the presence of the oxaphosphetane intermediates, at least with unstable ylids. For example, ^{31}P NMR spectra taken of the reaction mixtures at low temperatures[766] are compatible with an oxaphosphetane structure that persists for some time but not with a tetra-coordinated phosphorus species. Since a betaine, an ylid, and a phosphine oxide all have tetra-coordinated phosphorus, these species

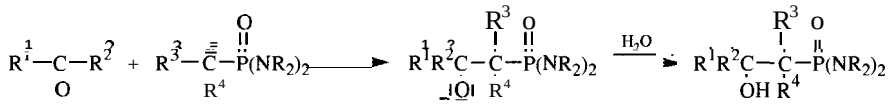
could not be causing the spectra, leading to the conclusion that an oxaphosphetane intermediate is present in the solution. In certain cases, oxaphosphetanes have been isolated.[767] It has even been possible to detect cis and trans isomers of the intermediate oxaphosphetanes by NMR spectroscopy.[768] According to this mechanism, an optically active phosphonium salt $RR'R''P^+CHR^2$ should retain its configuration all the way through the reaction, and it should be preserved in the phosphine oxide $RR'R''PO$. This has been shown to be the case.[769]

The proposed betaine intermediates can be formed, in a completely different manner, by nucleophilic substitution by a phosphine on an epoxide (10-50):



Betaines formed in this way can then be converted to the alkene, and this is one reason why betaine intermediates were long accepted in the Wittig reaction.

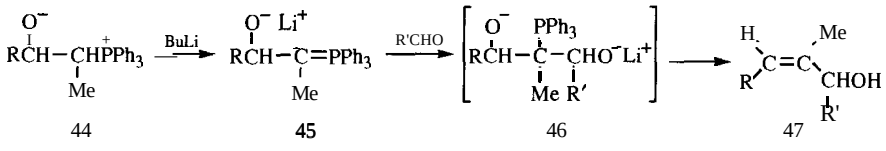
Some Wittig reactions give the (Z) alkene; some the (*E*), and others give mixtures, and the question of which factors determine the stereoselectivity has been much studied.[770] It is generally found that ylids containing stabilizing groups or formed from trialkylphosphines give (*E*) alkenes. However, ylids formed from triarylphosphines and not containing stabilizing groups often give (Z) or a mixture of (Z) and (*E*) alkenes.[771] One explanation for this[669] is that the reaction of the ylid with the carbonyl compound is a 2 + 2 cycloaddition, which in order to be concerted must adopt the $[\pi 2_s + \pi 2_a]$ pathway. As we have seen earlier (p. 1079), this pathway leads to the formation of the more sterically crowded product, in this case the (Z) alkene. If this explanation is correct, it is not easy to explain the predominant formation of (*E*) products from stable ylids, but (*E*) compounds are of course generally thermodynamically more stable than the (Z) isomers, and the stereochemistry seems to depend on many factors.



42 43

The (*E*/*Z*) ratio of the product can often be changed by a change in solvent or by the addition of salts.[772] Another way of controlling the stereochemistry of the product is by use of the aforementioned phosphonic acid bisamides. In this case the betaine (42) does form and when treated with water gives the (3-hydroxyphosphonic acid bisamides (43), which can be crystallized and then cleaved to $R^1R^2C{=}CR^3R^4$ by refluxing in benzene or toluene in the presence of silica gel.[753] Compounds 43 are generally formed as mixtures of diastereomers, and these mixtures can be separated by recrystallization. Cleavage of the two diastereomers gives the two isomeric alkenes. Optically active phosphonic acid bisamides have been used to give optically active alkenes.[773] Another method of controlling the stereochemistry of the alkene [to obtain either the (Z) or (*E*) isomer] starting with a phosphine oxide

(Ph_2POCH_2R), has been reported.[774]

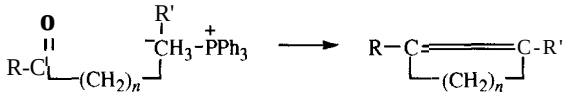


44 45 46 47

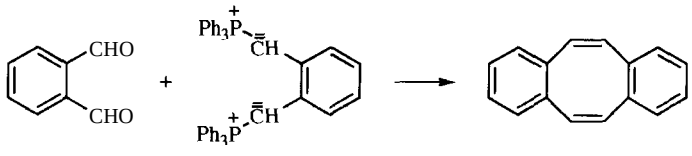
R = *n*-C_6H_{13}

In reactions where the betaine–lithium halide intermediate is present, it is possible to extend the chain further if a hydrogen is present α to the phosphorus. For example, reaction of ethylidnetriphenylphosphorane with heptanal at -78°C gave 44, which with butyllithium gave the ylid 45. Treatment of this with an aldehyde (R'CHO) gave the intermediate 46, which after workup gave 47.[775] This reaction gives the unsaturated alcohols 47 stereoselectively. Compound 45 also reacts with other electrophiles. For example, treatment of 45 with NCS or $PhICl_2$ gives the vinylic chloride RCH=CMeCl stereoselectively: NCS giving the cis and $PhICl_2$ the trans isomer.[776] The use of Br_2 and $FClO_3$ (see 12-4 for the explosive nature of this reagent) gives the corresponding bromides and fluorides, respectively.[777] Reactions of 45 with electrophiles have been called *scoopy* reactions (a substitution plus *c*arbonyl *alkeneylation* via β-*o*xido phosphorus *ylids*).[778]

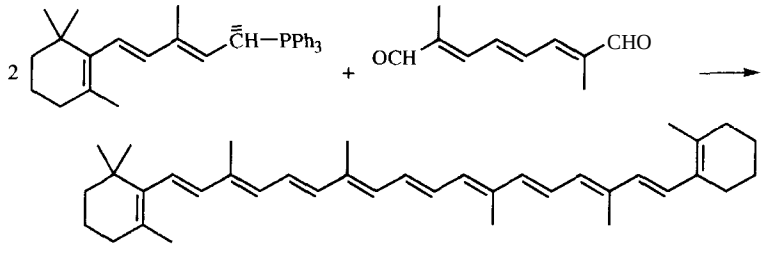
The Wittig reaction has been carried out intramolecularly, to prepare rings containing from 5 to 16 carbons,[779] both by single ring closure



and double ring closure.[780]

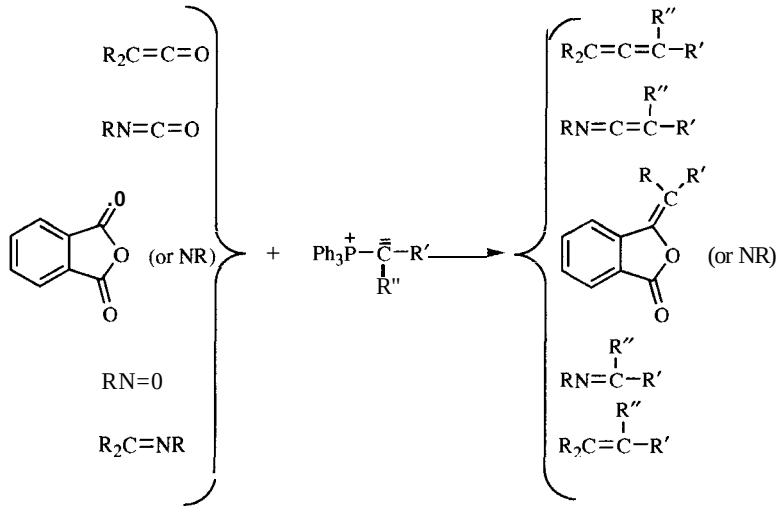


The Wittig reaction has proved very useful in the synthesis of natural products, some of which are quite difficult to prepare in other ways.[781] One example out of many is the synthesis of (i-carotene:[782]

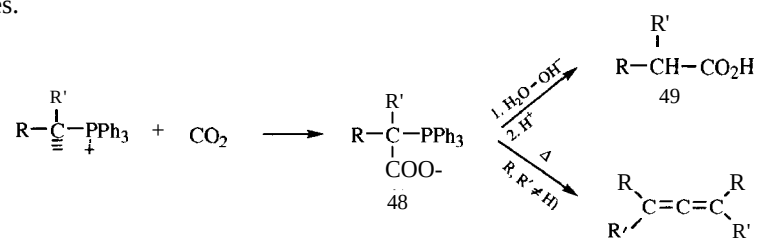


P-Carotene

Phosphorus ylids also react in a similar manner with the C=O bonds of ketenes,[783] isocyanates,[784] and certain anhydrides[785] and imides,[786] the N=O of nitroso groups, and the C=N of imines,[787] for example,



Phosphorus ylids react with carbon dioxide to give the isolable salts (**48**),[788] which can be hydrolyzed to the carboxylic acids (49) (thus achieving the conversion RR'CHX → RR'CHCOOH) or (if neither R nor R' is hydrogen) dimerized to allenes.



Although phosphorus ylids are most commonly used to alkenylation reactions, nitrogen ylids can occasionally be used. As an example, the reaction of *N*-benzyl-*N*-phenylpiperidinium bromide with base generated a *N*-ylid, which reacted with benzaldehyde to form styrene.[789]

16-48 *Tebbe, Petasis and Alternative Alkenylations*

METHYLENE-DE-OXO-BISUBSTITUTION

A useful alternative to phosphorus ylids are the titanium reagents such as **50** prepared from dicyclopentadienyltitanium dichloride and trimethylaluminum.[790] Treatment of a carbonyl compound with the titanium cyclopentadienide complex **50** *(Tebbe's reagent)* in toluene–THF containing a small amount of pyridine[791] leads to the alkene. Dimethyltitanocene (Me_2TiCp_2), called the *Petasis reagent,* has been used instead of 50.[792] Tebbe's reagent and the Petasis reagent give good results with ketones.[793] As we have seen, there are several methods for the conversion C=O to $C{=}CH_2$ when the substrate is an aldehyde or ketone (see **16-27, 16-31, 16-38-16-44, 16-47**), but very few ways to make the same conversion for a carboxylic ester. An important feature of these new reagents is that carboxylic esters and lactones can be converted in good yields to the corresponding enol ethers The enol ether can be hydrolyzed to a ketone (10-6), so this is also an indirect method for making the conversion RCOOR' → $RCOCH_3$ (see also **10-115).** Conjugated esters are converted to alkoxy-dienes with this reagent.[794] Besides stability and ease of preparation, another advantage of the Petasis reagent is that structural analogs can be prepared, including $Cp_2Ti(C_3H_5)_2$[795] (C_3H_5 = cyclopropyl), $CpTi(CH_2SiMe_3)_3$,[796] and Cp_2Ti-$Me(CH{=}CH_2)$.[797] In another variation, two equivalents of $Cp_2Ti[P(OEt)_3]_2$ reacted with a ketone in the presence of 1,1-diphenylthiocyclobutane to give the alkenylcyclobutane derivative.[798]

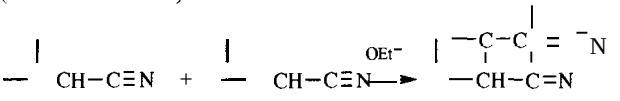
Carboxylic esters undergo the conversion C=O→ C=CHR (R = primary or secondary alkyl) when treated with $RCHBr_2$, Zn,[799] and $TiCl_4$ in the presence of *N,N,N′,N′*-tetramethylethylenediamine.[800] Metal carbene complexes[801] $R_2C{=}ML_n$ (L = ligand), where M is a transition metal such as Zr, W, or Ta, have also been used to convert the C=O of carboxylic esters and lactones to CR_2.[802] It is likely that the complex $Cp_2Ti{=}CH_2$ is an intermediate in the reaction with Tebbe's reagent.

There are a few other methods for converting ketones or aldehydes to alkenes. When a ketone is treated with $CH_3CHBr_2/Sm/SmI_2$, with a catalytic amount of $CrCl_3$, for example, the alkene is formed.[803] In another reaction, an aldehydes reacted with EtCHBr(OAc) in the presence of $Zn/CrCl_3$ to give the alkene.[804]

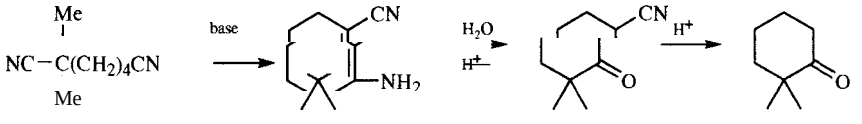
OS **VIII,** 512, OS **IX,** 404

16-49 *The Thorpe Reaction*

N-HYDRO-*C*-(α-CYANOALKYL)-ADDITION



In the *Thorpe reaction,* the α carbon of one nitrile molecule is added to the CN carbon of another, so this reaction is analogous to the aldol reaction **(16-38).** The C=NH bond is, of course, hydrolyzable (16-2), so β-keto nitriles can be prepared in this manner. The Thorpe reaction can be done intramolecularly, in which case it is



51

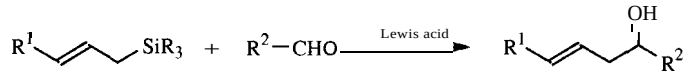
called the *Thorpe–Ziegler reaction.*[805] This is a useful method for closing large rings. Yields are high for 5- to 8-membered rings, fall off to about 0 for rings of 9–13 members, but are high again for 14-membered and larger rings, if high dilution techniques are employed. The product in the Thorpe–Ziegler reaction is not the imine, but the tautomeric enamine (e.g., 51); if desired this can be hydrolyzed to an α-cyano ketone (16-2), which can in turn be hydrolyzed and decarboxylated **(16-4, 12-38).** Other active-hydrogen compounds can also be added to nitriles.[806]

OS VI, 932.

J. *Other Carbon Nucleophiles*

16-50 *Addition of Silanes*

O-HYDRO-*C*-ALKYL-ADDITION



Allylic silanes react with aldehydes, in the presence of Lewis acids, to give an allyl-substituted alcohol.[807] In the case of benzylic silanes, this addition reaction has been induced with $Mg(ClO_4)_2$ under photochemical conditions.[808] The addition of chiral additives leads to the alcohol with good asymmetric induction.[809] In a related reaction, allylic silanes react with acyl halides to produce the corresponding carbonyl derivative. The reaction of phenyl chloroformate, trimethylallylsilane, and $AlCl_3$, for example, gave phenyl but-3-enoate.[810]

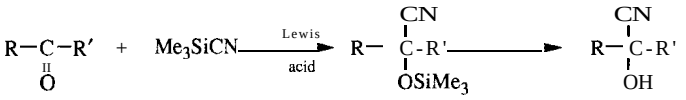
Allylic silanes also add to imines, in the presence of $TiCl_4$, to give amines.[811]

16-51 *The Formation of Cyanohydrins*

O-HYDRO-*C*-CYANO-ADDITION

The addition of HCN to aldehydes or ketones produces cyanohydrins.[812] This is an equilibrium reaction. For aldehydes and aliphatic ketones the equilibrium lies to the right; therefore the reaction is quite feasible, except with sterically hindered ketones such as diisopropyl ketone. However, ketones ArCOR give poor yields, and the reaction cannot be carried out with ArCOAr since the equilibrium lies too far to the left. With aromatic aldehydes the benzoin condensation **(16-54)** competes. With α,β-unsaturated aldehydes and ketones, 1,4 addition competes **(15-33).** Ketones of low reactivity, such as ArCOR, can be converted to cyanohydrins by treatment with diethylaluminum cyanide (Et_2AlCN; see OS VI, 307) or, indirectly, with cyanotrimethylsilane (Me_3SiCN)[813] in the presence of a Lewis acid or base,[813a] followed by hydrolysis of the resulting *O*-trimethylsilyl cyanohydrin (52). The use of chiral additives in this latter reaction leads to cyanohydrins with good asymmetric

induction.[814] When $TiCl_4$ is used, the reaction between Me_3SiCN and aromatic aldehydes or ketones gives α-chloro nitriles C—CRR′—CN.[815] Sulfoximine–titanium reagents have been used in enantioselective trimethylsilyl cyanations of aldehydes.[816]



52

Frequently, it is the bisulfite addition product that is treated with CN^-. This method is especially useful for aromatic aldehydes, since it avoids competition from the benzoin condensation. If desired, it is possible to hydrolyze the cyanohydrin *in situ* to the corresponding α-hydroxy acid. This reaction is important in the *Kiliani-Fischer* method of extending the carbon chain of a sugar.

The addition is nucleophilic and the actual nucleophile is CN^-, so the reaction rate is increased by the addition of base.[817] This was demonstrated by Lapworth in 1903, and consequently this was one of the first organic mechanisms to be known.[818]

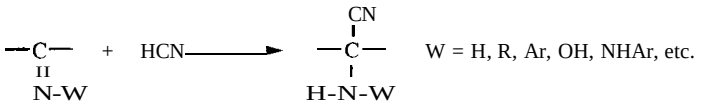
The reaction has been carried out enantioselectively: optically active cyanohydrins were prepared with the aid of optically active catalysts.[819]

A particularly useful variation of this reaction uses cyanide rather than HCN. α-Amino nitriles[820] can be prepared in one step by the treatment of an aldehyde or ketone with NaCN and NH_4Cl. This is called the *Strecker synthesis*;[821] and it is a special case of the Mannich reaction **(16-15).** Since the CN is easily hydrolyzed to the acid, this is a convenient method for the preparation of a-amino acids. The reaction has also been carried out with NH_3 + HCN and with NH_4CN. Salts of primary and secondary amines can be used instead of NH_4^+ to obtain N-substituted and N,N-disubstituted a-amino nitriles. Unlike **16-51,** the Strecker synthesis is useful for aromatic as well as aliphatic ketones. As in **16-51,** the Me_3SiCN method has been used; **64** is converted to the product with ammonia or an amine.[822]

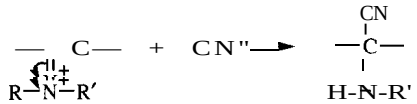
OS I, 336; **II,** 7, 29, 387; **III,** 436; IV, 58, 506; VI, 307; **VII,** 20, 381, 517, 521. For the reverse reaction, see OS **III,** 101. For the Strecker synthesis, see OS I, 21, 355; **III,** 66, 84, 88, 275; IV, 274; V, 437; VI, 334.

16-52 *The Addition of HCN to C=N and C≡N Bonds*

N-HYDRO-*C*-CYANO-ADDITION

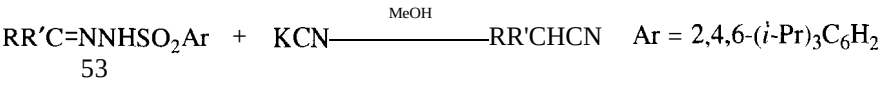


HCN adds to imines, Schiff bases, hydrazones, oximes, and similar compounds. The CN^- ion can be added to iminium ions:

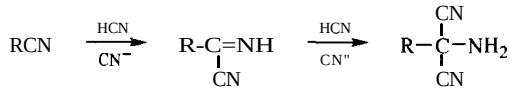


As in **16-49,** the addition to imines has been carried out enantioselectively.[823]

The addition of KCN to triisopropylbenzenesulfonyl hydrazones (53) provides an indirect method for achieving the conversion RR'CO → RR'CHCN.[824] The reaction is successful for hydrazones of aliphatic aldehydes and ketones.

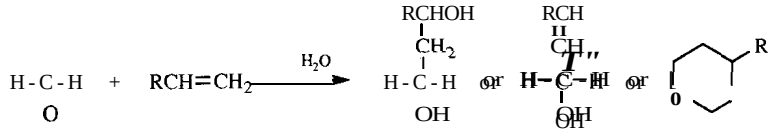


Hydrogen cyanide can also be added to the C≡N bond to give iminonitriles or α-aminomalononitriles.[825]

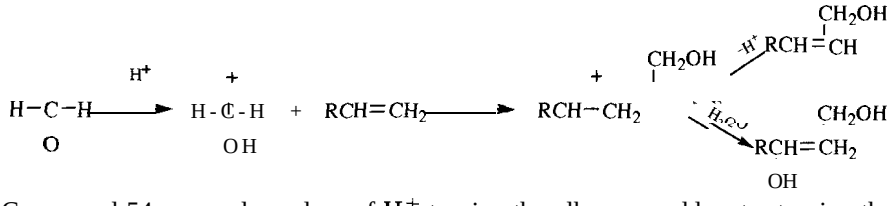


OS V, 344. See also OS V, 269.

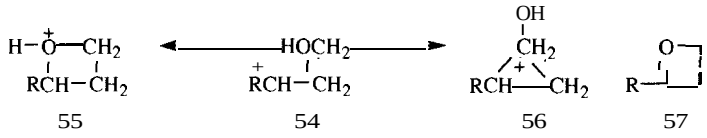
16-53 *The Prins Reaction*



The addition of an alkene to formaldehyde in the presence of an acid[826] catalyst is called the *Prins reaction*.[827] Three main products are possible; which one predominates depends on the alkene and the conditions. When the product is the 1,3-diol or the dioxane,[828] the reaction involves addition to the C=C as well as to the C=O. The mechanism is one of electrophilic attack on both double bonds. The acid first protonates the C=O, and the resulting carbocation attacks the C=C:



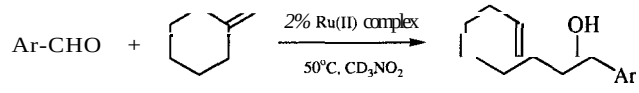
Compound 54 can undergo loss of H^+ to give the alkene or add water to give the diol.[829] It has been proposed that 54 is stabilized by neighboring-group attraction, with either the oxygen[830] or a carbon[831] stabilizing the charge (55 and 56,



respectively). This stabilization is postulated to explain the fact that with 2-butenes[832] and with cyclohexenes the addition is anti. A backside attack of H_2O on the three- or four-membered ring would account for it. Other products are obtained too, which can be explained on the basis of 55 or **56**.[830,831] Additional evidence for the intermediacy of 55 is the finding that oxetanes (57) subjected to the

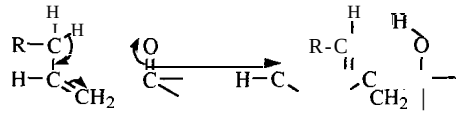
reaction conditions (which would protonate 57 to give **55)** give essentially the same product ratios as the corresponding alkenes.[833] An argument against the intermediacy of **55** and 56 is that not all alkenes show the anti stereoselectivity mentioned above. Indeed, the stereochemical results are often quite complex, with syn, anti, and nonstereoselective addition reported, depending on the nature of the reactants and the reaction conditions.[834] Since addition to the C=C bond is electrophilic, the reactivity of the alkene increases with alkyl substitution and Markovnikov's rule is followed. The dioxane product may arise from a reaction between the 1,3-diol and formaldehyde[835] **(16-5)** or between 54 and formaldehyde.

Lewis acids such as $SnCl_4$ also catalyze the reaction, in which case the species that adds to the alkenes is $H_2C^+—O—^-SnCl_4$.[836] Montmorillonite K10 clay containing zinc(IV) has been used to promote the reaction.[837] The reaction can also be catalyzed by peroxides, in which case the mechanism is probably a free-radical one. Other transition metal complexes can be used to form allylic alcohols. A typical example is.[838]

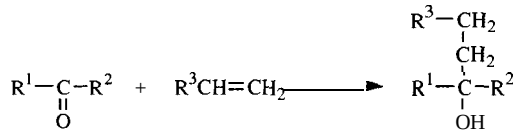


Samarium iodide promotes this addition reaction.[839] In a related reaction, simple alkene units add to esters in the presence of sodium and liquid ammonia to give an alcohol.[840]

A closely related reaction has been performed with other aldehydes and even with ketones; without a catalyst, but with heat.[841] The aldehydes and ketones here are active ones, such as chloral and acetoacetic ester. The product in these cases is a β-hydroxy alkene, and the mechanism is pericyclic:[842]



This reaction is reversible and suitable P-hydroxy alkenes can be cleaved by heat **(17-34).** There is evidence that the cleavage reaction occurs by a cyclic mechanism (p. 1351), and, by the principle of microscopic reversibility, the addition mechanism should be cyclic too.[843] Note that this reaction is an oxygen analog of the ene synthesis **(15-20).** This reaction can also be done with unactivated aldehydes[844] and ketones[845] if Lewis acid catalysts such as dimethylaluminum chloride (Me_2AlCl) or ethylaluminum dichloride ($EtAlCl_2$) are used.[846] Lewis acid catalysts also increase rates with activated aldehydes.[847] The use of optically active catalysts has given optically active products with high enantiomeric excesses.[848]



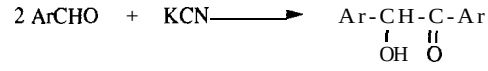
58

In a related reaction, alkenes can be added to aldehydes and ketones to give reduced alcohols 58. This has been accomplished by several methods,[849] including treatment with SmI_2[850] or Zn and Me_3SiCl,[851] and by electrochemical[852] and photochemical[853] methods. Most of these methods have been used for intramolecular addition and most or all involve free-radical intermediates.

OS IV, 786. See also OS VII, 102.

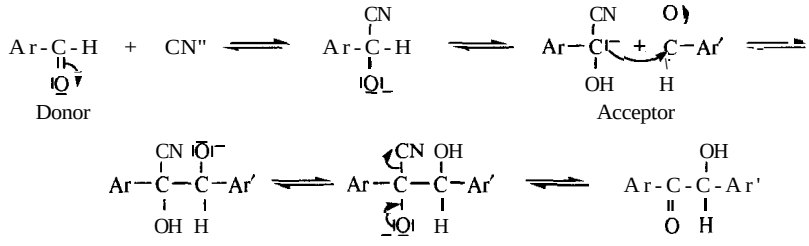
16-54 *The Benzoin Condensation*

BENZOIN ALDEHYDE CONDENSATION



When certain aldehydes are treated with cyanide ion, *benzoins* are produced in a reaction called the *benzoin condensation.* The condensation can be regarded as involving the addition of one molecule of aldehyde to the C=O group of another. The reaction can be accomplished only for aromatic aldehydes, though not for all of them,[854] and for glyoxals RCOCHO. The two molecules of aldehyde obviously perform different functions. The one that no longer has a C—H bond in the product is called the *donor,* because it has "donated"its hydrogen to the oxygen of the other molecule, the *acceptor.* Some aldehydes can perform only one of these functions and hence cannot be self-condensed, though they can often be condensed with a different aldehyde. For example, *p*-dimethylaminobenzaldehyde is not an acceptor but only a donor. Thus it cannot condense with itself, but it can condense with benzaldehyde, which can perform both functions, but is a better acceptor than it is a donor.

The following is the accepted mechanism,[855] which was originally proposed by Lapworth in 1903:[856]



The reaction is reversible. The key step, the loss of the aldehydic proton, can take place because the acidity of this C—H bond is increased by the electron-withdrawing power of the CN group. Thus, CN^- is a highly specific catalyst for this reaction, because, almost uniquely, it can perform three functions: (1) It acts as a nucleophile; (2) its electron-withdrawing ability permits loss of the aldehydic proton; and (3) having done this, it then acts as a leaving group. Certain thiazolium salts can also catalyze the reaction.[857] In this case aliphatic aldehydes can also be used[858] (the products are called *acyloins),* and mixtures of aliphatic and aromatic aldehydes give mixed α-hydroxy ketones.[859] The reaction has also been carried out without CN",

by using the benzoylated cyanohydrin as one of the components in a phase-transfer catalyzed process. By this means products can be obtained from aldehydes that normally fail to self-condense.[860]

OS I, 94; VII, 95.

16-55 *Addition of Radicals to C=O, C=S, C=N Compounds*

Radical cyclization is not limited to a radical attacking a C=C unit (see 15-35 and 15-36), and reactions with both C=N and C=O moieties are known. Reaction of $MeON{=}CH(CH_2)_3CHO$ with Bu_3SnH and AIBN, for example led to *trans*-2-(methoxyamino)cyclopentanol in good yield.[861] Addition of radical to the C=N unit of R–C=N–SPh [862] or R–C=N–OBz [863] led to cyclic imines. Radical addition to simple imines leads to aminocycloalkenes.[864] Radical also add to the carbonyl unit of phenylthio esters to give cyclic ketones.[865]

Reactions in Which Carbon Adds to the Hetero Atom

A. *Oxygen Adding to the Carbon*

16-56 *The Flitter Reaction*

N-HYDRO,*N*-ALKYL-*C*-OXO-BIADDITION

$$R{-}C{\equiv}N + R'OH \xrightarrow{H^+} R\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{H}{|}}{N}\text{-}R'$$

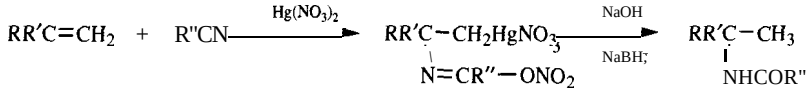
Alcohols can be added to nitriles in an entirely different manner from that of Reaction 16-8. In this reaction, the alcohol is converted by a strong acid to a carbocation, which adds to the negative nitrogen, water adding to the carbon:

$$R'OH \xrightarrow{H^+} R'^{+} + R{-}C{\equiv}N \longrightarrow R\text{-}\overset{+}{C}{=}N\text{-}R' \xrightarrow{H_2O} R\text{-}\underset{\underset{OH}{|}}{C}{=}N\text{-}R'$$

The immediate product tautomerizes to the N-alkyl amide. Only alcohols that give rise to fairly stable carbocations react (secondary, tertiary, benzylic, etc.); primary alcohols do not give the reaction. The carbocation need not be generated from an alcohol but may come from protonation of an alkene or from other sources. In any case, the reaction is called the *Ritter reaction*.[866] Hydrogen cyanide also gives the reaction, the product being a formamide. Trimethylsilyl cyanide has also been used.[867] Since the amides (especially the formamides) are easily hydrolyzable to amines, the Ritter reaction provides a method for achieving the conversions $R'OH \rightarrow R'NH_2$ (see 10-46) and alkene $\rightarrow R'NH_2$ (see 15-8) in those cases where R' can form a relatively stable carbocation. The reaction is especially useful for the preparation of tertiary alkyl amines because there are few alternate ways of preparing these compounds. The reaction can be extended to primary alcohols by

treatment with triflic anhydride[868] or Ph_2CCl^+ $SbCl_6^-$ or a similar salt[869] in the presence of the nitrile.

Alkenes of the form RCH=CHR' and $RR'C{=}CH_2$ add to nitriles in the presence of mercuric nitrate to give, after treatment with $NaBH_4$, the same amides that would be obtained by the Ritter reaction.[870] This method has the advantage of avoiding strong acids.

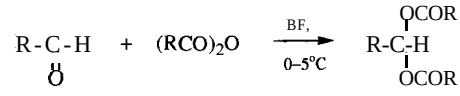


The Ritter reaction can be applied to cyanamides RNHCN to give ureas (RNHCONHR').[871]

OS V, 73, 471.

16-57 *Acylation of Aldehydes and Ketones*

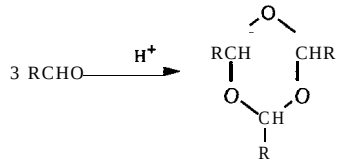
O-ACYL-*C*-ACYLOXY- ADDITION



Aldehydes can be converted to *acylals* by treatment with an anhydride in the presence of BF_3, other Lewis acids,[872] proton acids,[873] or PCl_3.[874] The reaction cannot normally be applied to ketones, though an exception has been reported when the reagent is trichloroacetic anhydride, which gives acylals with ketones without a catalyst.[875]

OS IV, 489.

16-58 *The Addition of Aldehydes to Aldehydes*



When catalyzed by acids, low molecular weight aldehydes add to each other to give cyclic acetals, the most common product being the trimer.[876] The cyclic trimer of formaldehyde is called *trioxane*,[877] and that of acetaldehyde is known as *paraldehyde*. Under certain conditions, it is possible to get tetramers[878] or dimers. Aldehydes can also polymerize to linear polymers, but here a small amount of water is required to form hemiacetal groups at the ends of the chains. The linear polymer formed from formaldehyde is called *paraformaldehyde*. Since trimers and polymers of aldehydes are acetals, they are stable to bases but can be hydrolyzed by acids. Because formaldehyde and acetaldehyde have low boiling points, it is often convenient to use them in the form of their trimers or polymers.

A slightly related reaction involves nitriles, which can be trimerized' with various acids, bases, or other catalysts to give triazines (see OS HI, 71).[879] HC1 is most often used. Most nitriles with an a hydrogen do not give the reaction.

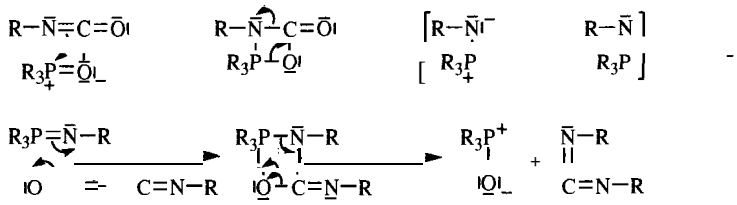
B. *Nitrogen Adding to the Carbon*

16-59 *The Addition of Isocyanates to Isocyanates (Formation of Carbodiimides)*

ALKYLIMINO-DE-OXO-BISUBSTITUTION

$$2R{-}N{=}C{=}O \xrightarrow{59} R\text{-}N{=}C{=}N\text{-}R$$

The treatment of isocyanates with 3-methyl-1-ethyl-3-phospholene-1-oxide (59) is a useful method for the synthesis of carbodiimides[880] in good yields.[881] The mechanism does not simply involve the addition of one molecule of isocyanate to another, since the kinetics are first order in isocyanate and first order in catalyst. The following mechanism has been proposed (the catalyst is here represented as $R_3P^+{-}O^\theta$):[882]



According to this mechanism, one molecule of isocyanate undergoes addition to C=O, and the other addition to C=N. Evidence is that ^{18}O labeling experiments have shown that each molecule of CO_2 produced contains one oxygen atom derived from the isocyanate and one from 71,[883] precisely what is predicted by this mechanism. Certain other catalysts are also effective.[884]

OS V, 501.

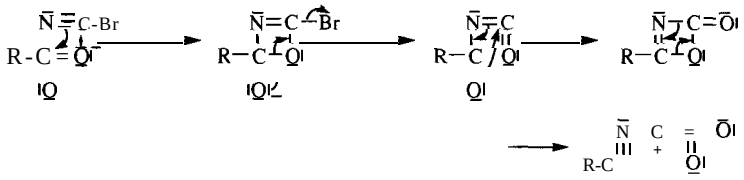
16-60 *The Conversion of Carboxylic Acid Salts to Nitriles*

NITRILO-DE-OXIDO, OXO-TERSUBSTITUTION

$$RCOO + BrCN \xrightarrow{250\text{–}300^\circ C} RCN + CO_2$$

Salts of aliphatic or aromatic carboxylic acids can be converted to the corresponding nitriles by heating with BrCN or C1CN. Despite appearances, this is not a substitution reaction. When $R^{14}COO^-$ was used, the label appeared in the nitrile, not in the CO_2,[885] and optical activity in R was retained.[886] The acyl isocyanate

RCON=C=O could be isolated from the reaction mixture; hence the following mechanism was proposed:[885]

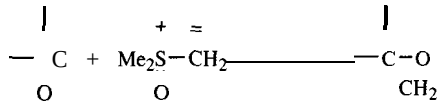


C. *Carbon Adding to the Carbon*

The reactions in this group (16-61-16-64) are cycloadditions.

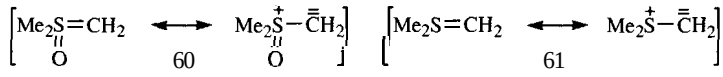
16-61 *The Formation of Epoxides from Aldehydes and Ketones*

(1 + 2)*OC,CC-cyclo*-METHYLENE-ADDITION

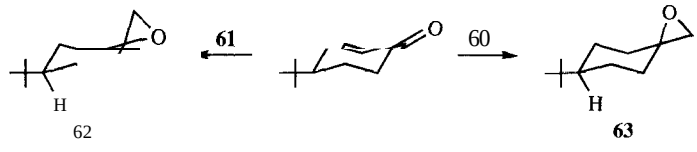


60

Aldehydes and ketones can be converted to epoxides[887] in good yields with the sulfur ylids dimethyloxosulfonium methylid (60) and dimethylsulfonium methylid (**61**).[888] For most purposes, 60 is the reagent of choice, because 61 is much less



stable and ordinarily must be used as soon as it is formed, while 60 can be stored several days at room temperature. When diastereomeric epoxides can be formed, 61 usually attacks from the more hindered and 60 from the less-hindered side. Thus, 4-tert-butylcyclohexanone, treated with 60 gave exclusively 63 while 61 gave mostly 62.[889] Another difference in behavior between the two reagents is that with α,β-

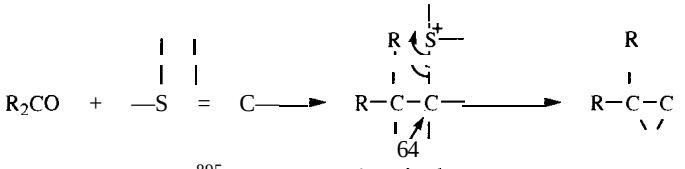


62 **63**

unsaturated ketones, 60 gives only cyclopropanes (Reaction 15-62), while 61 gives oxirane formation. Other sulfur ylids have been used in an analogous manner, to transfer CHR or CR_2.[890] High yields have been achieved by the use of sulfonium ylids anchored to insoluble polymers under phase-transfer conditions.[891] A solvent-free version of this reaction has been developed using powder K *tert*-butoxide and $Me_3S^+I^-$.[892] Chiral sulfur ylids have been prepared, giving the epoxide with good

asymmetric induction.[893] It is noted that treatment of epoxides with two equivalents of $Me_2S{=}CH_2$ leads to allylic alcohols.[894]

The generally accepted mechanism for the reaction between sulfur ylids and aldehydes or ketone is which is similar to that of the reaction of sulfur ylids with

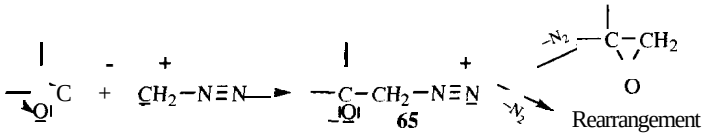


64

C=C double bonds (15-62).[895] The stereochemical difference in the behavior of 60 and 61 has been attributed to formation of the betaine 64 being reversible for 60 but not for the less stable 61, so that the more-hindered product is the result of kinetic control and the less hindered of thermodynamic control.[896]

Phosphorus ylids do not give this reaction, but give **16-47** instead.

Aldehydes and ketones can also be converted to epoxides by treatment with a diazoalkane,[897] most commonly diazomethane, but an important side reaction is the formation of an aldehyde or ketone with one more carbon than the starting compound (Reaction **18-9).** The reaction can be carried out with many aldehydes, ketones, and quinones. A mechanism that accounts for both products is



65 Rearrangement (18-9)

Compound **65** or nitrogen-containing derivatives of it have sometimes been isolated.

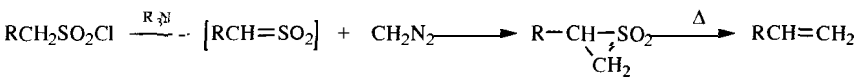
Dihalocarbenes and carbenoids, which readily add to C=C bonds **(15-62),** do not generally add to the C=O bonds of ordinary aldehydes and ketones.[898] See also 16-**56.**

OS V, 358, 755.

16-62 *The Formation of Episulfides and Episulfones*[899]

V

Epoxides can be converted directly to episulfides by treatment with NH4SCN and ceric ammonium nitrate.[900] Diazoalkanes, treated with sulfur, give episulfides.[901] It is likely that $R_2C{=}S$ is an intermediate, which is attacked by another molecule of diazoalkane, in a process similar to that shown in **16-61.** Thioketones *do* react with diazoalkanes to give episulfides.[902] Thioketones have also been converted to episulfides with sulfur ylids.[889]



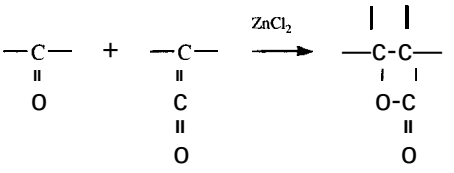
66 67

Alkanesulfonyl chlorides, when treated with diazomethane in the presence of a base (usually a tertiary amine), give episulfones (67).[903] The base removes HC1 from the sulfonyl halide to produce the highly reactive sulfene **(66) (17-13),** which then adds CH_2. The episulfone can then be heated to give off SO_2 **(17-20),** making the entire process a method for achieving the conversion $RCH_2SO_2Cl \rightarrow RCH{=}CH_2$.[904]

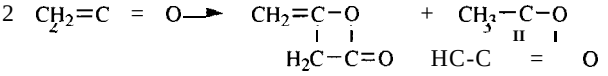
OS V, 231, 877.

16-63 *The Formation of β-Lactones and Oxetanes*

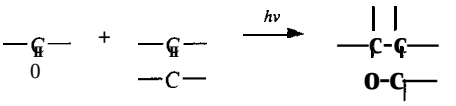
(2 + 2)*OC,CC-CYCLO*-[OXOETHYLENE]-1/2/ADDITION



Aldehydes, ketones, and quinones react with ketenes to give β-lactones, diphenylketene being used most often.[905] The reaction is catalyzed by Lewis acids, and without them most ketenes do not give adducts because the adducts decompose at the high temperatures necessary when no catalyst is used. When ketene was added to chloral (Cl_3CCHO) in the presence of the chiral catalyst (+)-quinidine, one enantiomer of the β-lactone was produced in 98% ee.[906] Other di- and trihalo aldehydes and ketones also give the reaction enantioselectively, with somewhat lower ee values.[907] Ketene adds to another molecule of itself:

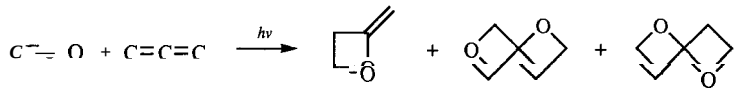


This dimerization is so rapid that ketene does not form [3-lactones with aldehydes or ketones, except at low temperatures. Other ketenes dimerize more slowly. In these cases the major dimerization product is not the [3-lactone, but a cyclobutanedione (see **15-61).** However, the proportion of ketene that dimerizes to [3-lactone can be increased by the addition of catalysts such as triethylamine or triethyl phosphite.[908] Ketene acetals $R_2C{=}C(OR')_2$ add to aldehydes and ketones in the presence of $ZnCl_2$ to give the corresponding oxetanes.[909]



Ordinary aldehydes and ketones can add to alkenes, under the influence of UV light, to give oxetanes. Quinones also react to give spirocyclic oxetanes.[910] This reaction, called the *Paterno–Büchi reaction*,[911] is similar to the photochemical dimerization of alkenes discussed at **15-61.** In general, the mechanism consists of the addition of an excited state of the carbonyl compound to the ground state of the alkene. Both singlet (S_1)[912] and *n,n** triplet[913] states have been shown to add to alkenes to give oxetanes. A diradical intermediate,[914]  , has been

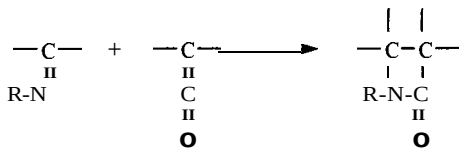
detected by spectroscopic methods.[915] Yields in the Patemo-Büchi reaction are variable, ranging from very low to fairly high (90%). The reaction can be highly diastereoselective.[916] There are several side reactions. When the reaction proceeds through a triplet state, it can in general be successful only when the alkene possesses a triplet energy comparable to, or higher than, the carbonyl compound; otherwise energy transfer from the excited carbonyl group to the ground-state alkene can take place (triplet-triplet photosensitization, see p. 316). In most cases quinones react normally with alkenes, giving oxetane products, but other α,β-unsaturated ketones usually give preferential cyclobutane formation **(15-61).** Aldehydes and ketones also add photochemically to allenes to give the corresponding alkylidneoxetanes and dioxaspiro compounds:[917]



OS **III**, 508; V, 456. For the reverse reaction, see OS V, 679.

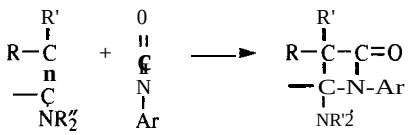
16-64 *The Formation of* (3-Lactams

(2 + 2)*NC,CC-CYCLO*-[OXOETHYLENE]-1/2/ADDITION



Ketenes add to imines to give β-lactams.[918] The reaction is generally carried out with ketenes of the form $R_2C{=}C{=}O$. It has not been successfully applied to $RCH{=}C{=}O$, except when these are generated *in situ* by decomposition of a diazo ketone (the Wolff rearrangement, **18-8)** in the presence of the imine. It has been done with ketene, but the more usual course with this reagent is an addition to the enamine tautomer of the substrate. Thioketenes[919] $R_2C{=}C{=}S$ give β-thiolactams.[920] Imines also form [3-lactams when treated with (1) zinc (or another metal) and an α-bromo ester (Reformatsky conditions—**16-31**),[921] or (2) the chromium carbene complexes $(CO)_5Cr{=}C(Me)OMe$.[922] The latter method has been used to prepare optically active (3-lactams.[923] Ketenes have also been added to certain hydrazones (e.g., $PhCH{=}NNMe_2$) to give N-amino (3-lactams.[924]

Like the similar cycloaddition of ketenes to alkenes **(15-61),** most of these reactions probably take place by the di-ionic mechanism *c* (p. 1078).[925] (3-Lactams have also been prepared in the opposite manner: by the addition of enamines to isocyanates:[926]



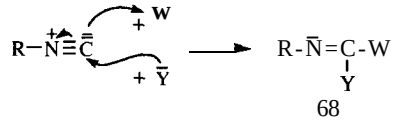
The reactive compound chlorosulfonyl isocyanate ($ClSO_2NCO$),[927] forms β-lactams even with unactivated alkenes,[928] as well as with imines,[929] allenes,[930] conjugated dienes,[931] and cyclopropenes.[932] With microwave irradiation, alkyl isocyanates also react.[933]

Allylic phosphonate esters react with imines, in the presence of a palladium catalyst, to give [3-lactams.[934] Alkynyl reagents such as $BuC{\equiv}CO^-Li^+$ react with imines to form [3-lactams.[935]

OS V, 673; VIII, 3, 216.

Addition to Isocyanides[936]

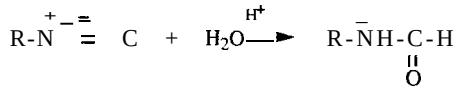
Addition to $R-{}^+N{\equiv}C^\theta$ is not a matter of a species with an electron pair adding to one atom and a species without a pair adding to the other, as is addition to the other types of double and triple bonds in this chapter and Chapter 15. In these additions, the electrophile and the nucleophile *both add to the carbon.* No species add to the nitrogen, which, however, loses its positive charge by obtaining as an unshared pair one of the triple-bond pairs of electrons:



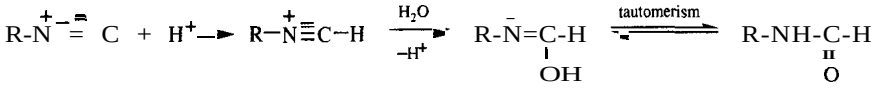
In most of the reactions considered below, 68 undergoes a further reaction, so the product is of the form R—NH—C—•

16-65 *The Addition of Water to Isocyanides*

1/*N*,2/*C*-Dihydro-2/*C*-oxo-biaddition



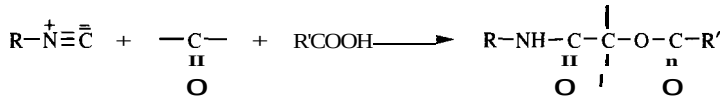
Formamides can be prepared by the acid-catalyzed addition of water to isocyanides. The mechanism is probably[937]



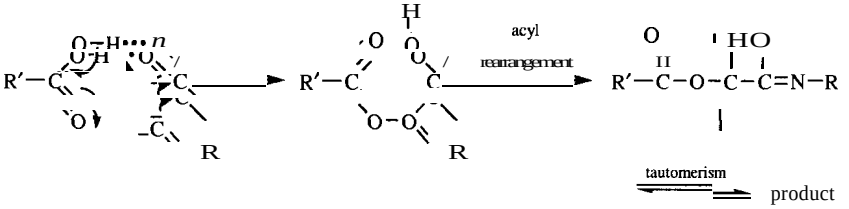
The reaction has also been carried out under alkaline conditions, with OH^- in aqueous dioxane.[938] The mechanism here involves nucleophilic attack by OH^- at the carbon atom.

16-66 *The Passerini and Ugi Reactions*[939]

1/*N*-Hydro-2/*C*-(α-acyloxyalkyl),2/*C*-oxo-biaddition



When an isocyanide is treated with a carboxylic acid and an aldehyde or ketone, an α-acyloxy amide is prepared. This is called the *Passerini reaction.* The following mechanism has been postulated:



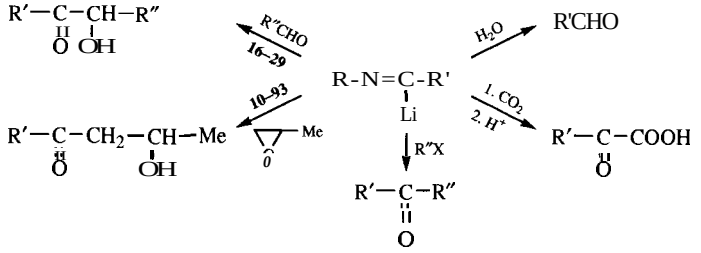
If ammonia or an amine is also added to the mixture (in which case the reaction is known as the *Ugi reaction,* or the *Ugi four-component condensation,* abbreviated 4 CC), the product is the corresponding bisamide $R'-\underset{\underset{O}{\|}}{C}-NH-\underset{\underset{O}{\|}}{\overset{|}{C}}-NH-R$ (from NH_3) or $R'-\underset{\underset{O}{\|}}{C}-NR''-\underset{\underset{O}{\|}}{\overset{|}{C}}-NH-R$ (from a primary amine $R''NH_2$). This product probably arises from a reaction between the carboxylic acid, the isocyanide, and the *imine* formed from the aldehyde or ketone and ammonia or the primary amine. The use of an N-protected amino acid or peptide as the carboxylic acid component and/or the use of an isocyanide containing a C-protected carboxyl group allows the reaction to be used for peptide synthesis.[940]

16-67 *The Formation of Metalated Aldimines*

1/1/LITHIO-ALKYL-ADDITION

$$R-\overset{+}{N}\equiv\overset{-}{C} + R'Li \longrightarrow R-N=\underset{\underset{Li}{|}}{C}-R'$$

Isocyanides that do not contain an α hydrogen react with alkyllithium compounds,[941] as well as with Grignard reagents, to give lithium (or magnesium) aldimines.[942] These metalated aldimines are versatile nucleophiles and react with various substrates as follows:



The reaction therefore constitutes a method for converting an organometallic compound R'M to aldehyde R'CHO (see also 12-30), an α-keto acid,[943] a ketone

R'COR (see also 12-30), an α-hydroxy ketone, or a β-hydroxy ketone. In each case, the C=N bond is hydrolyzed to a C=O bond (16-2).

In a related reaction, isocyanides can be converted to aromatic aldimines by treatment with an iron complex followed by irradiation in benzene solution: $RNC + C_6H_6 \rightarrow PhCH{=}NR$.[944]

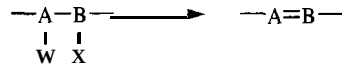
CHAPTER 17

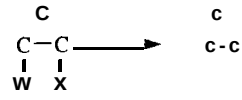
Eliminations

When two groups are lost from adjacent atoms so that a new double[1]



(or triple) bond is formed, the reaction is called β *elimination;* one atom is the a, the other is the β atom. In an a elimination, both groups are lost from the same atom to give a carbene (or a nitrene):

In a γ elimination, a three-membered ring is formed



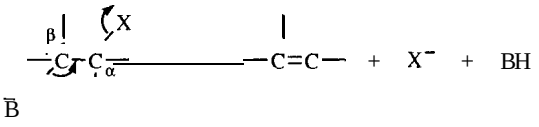
Some of these processes were discussed in Chapter 10. Another type of elimination involves the expulsion of a fragment from within a chain or ring (X—Y—Z → X—Z + Y). Such reactions are called *extrusion reactions.* This chapter discusses β elimination and (beginning on p. 1352) extrusion reactions; however, β elimination in which both X and W are hydrogens are oxidation reactions and are treated in Chapter 19.

MECHANISMS AND ORIENTATION

P Elimination reactions may be divided into two types: one type taking place largely in solution, the other (pyrolytic eliminations) mostly in the gas phase. In the reactions in solution, one group leaves with its electrons and the other without, the latter most often being hydrogen. In these cases, we refer to the former as the leaving group or nucleofuge. For pyrolytic eliminations there are two principal mechanisms, one pericyclic and the other a free-radical pathway. A few photochemical eliminations are also known (the most important is Norrish type II cleavage of ketones, p. 318), but these are not generally of synthetic importance[2] and will not be discussed further. In most β eliminations, the new bonds are C=C or C≡C; our discussion of mechanisms is largely confined to these cases.[3] Mechanisms in solution (E2, E1)[4] and E1cB are discussed first.

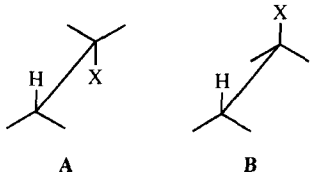
The E2 Mechanism

In the E2 mechanism (elimination, bimolecular), the two groups depart simultaneously, with the proton being pulled off by a base:



The mechanism thus takes place in one step and kinetically is second order: first order in substrate and first order in base. An *ab initio* study has produced a model for the E2 transition state geometry.[5] The IUPAC designation is $A_{xH}D_HD_N$, or more generally (to include cases where the electrofuge is not hydrogen), $A_nD_ED_N$. It is analogous to the S_N2 mechanism (p. 390) and often competes with it. With respect to the substrate, the difference between the two pathways is whether the species with the unshared pair attacks the carbon (and thus acts as a nucleophile) or the hydrogen (and thus acts as a base). As in the case of the S_N2 mechanism, the leaving group may be positive or neutral and the base may be negatively charged or neutral.

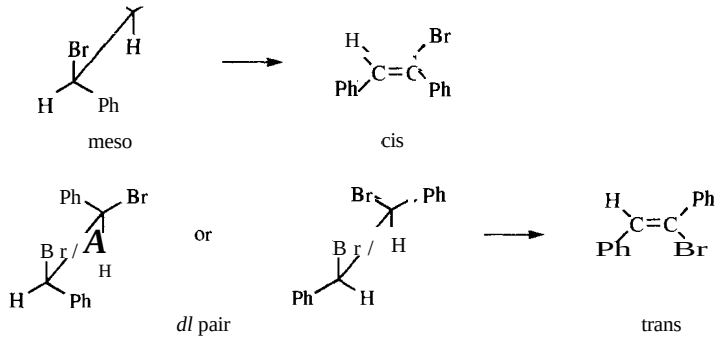
Among the evidence for the existence of the E2 mechanism are (1) the reaction displays the proper second-order kinetics; (2) when the hydrogen is replaced by deuterium in second-order eliminations, there is an isotope effect of from 3 to 8, consistent with breaking of this bond in the rate-determining step.[6] However, neither of these results alone could prove an E2 mechanism, since both are compatible with other mechanisms also (e.g., see E1cB p. 1308). The most compelling evidence for the E2 mechanism is found in stereochemical studies.[7] As will be illustrated in the examples below, the E2 mechanism is stereospecific: the five atoms involved (including the base) in the transition state must be in one plane. There are two ways for this to happen. The H and X may be trans to one another (A) with a dihedral angle



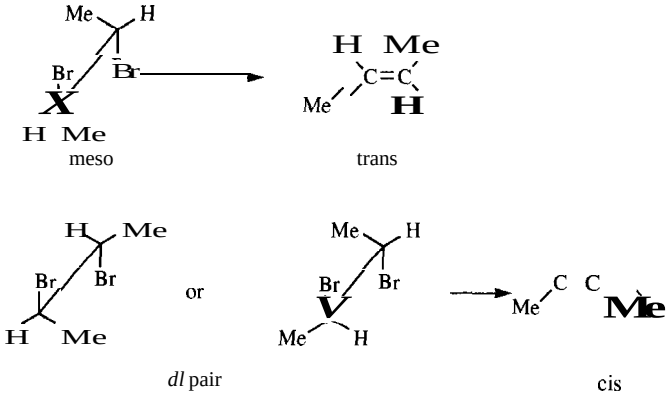
A **B**

of 180°, or they may be cis (B) with a dihedral angle of 0°.[8] Conformation A is called *anti-periplanar*, and this type of elimination, in which H and X depart in opposite directions, is called *anti elimination.* Conformation B is *syn-periplanar*, and this type of elimination, with H and X leaving in the same direction, is called *syn elimination.* Many examples of both kinds have been discovered. In the absence of special effects (discussed below) anti elimination is usually greatly favored over syn elimination, probably because A is a staggered conformation (p. 168) and the molecule requires less energy to reach this transition state than it does to reach the eclipsed transition state B. A few of the many known examples of predominant or exclusive anti elimination follow.

1. Elimination of HBr from *meso*-1,2-dibromo-1,2-diphenylethane gave *cis*-2-bromostilbene, while the (+) or (-) isomer gave the trans alkene. This stereospecific result, which was obtained in 1904,[9] demonstrates that in this

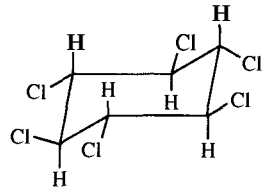


case elimination is anti. Many similar examples have been discovered since. Obviously, this type of experiment need not be restricted to compounds that have a meso form. Anti elimination requires that an erythro *dl* pair (or either isomer) give the cis alkene, and the threo *dl* pair (or either isomer) give the trans isomer, and this has been found many times. Anti elimination has also been demonstrated in cases where the electrofuge is not hydrogen. In the reaction of 2,3-dibromobutane with iodide ion, the two bromines are removed (17-22). In this case, the meso compound gave the trans alkene and the *dl* pair the cis:[10]



2. In open-chain compounds, the molecule can usually adopt that conformation in which H and X are anti periplanar. However, in cyclic systems this is not always the case. There are nine stereoisomers of 1,2,3,4,5,6-hexachlorocyclohexane: seven meso forms and a *dl* pair (see p. 161). Four of the meso compounds and the *dl* pair (all that were then known) were subjected to elimination of HC1. Only one of these (1) has no Cl trans to an H. Of the other isomers, the fastest elimination rate was about three times as fast as the

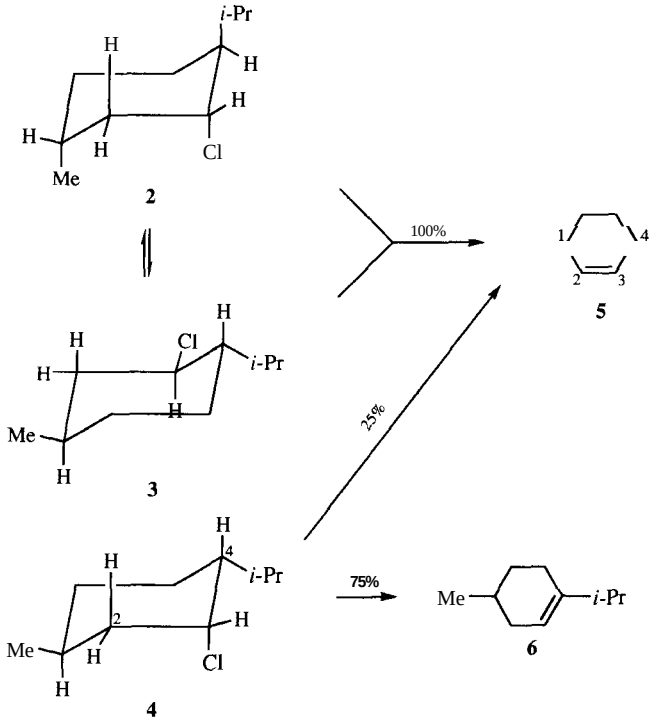
slowest, but the rate for 1 was 7000 times slower than that of the slowest of the other isomers.[11] This result demonstrates that with these compounds anti



1

elimination is greatly favored over syn elimination, though the latter must be taking place on 1, very slowly, to be sure.

3. The preceding result shows that elimination of HC1 in a six-membered ring proceeds best when the H and X are trans to each other. However, there is an additional restriction. Adjacent trans groups on a six-membered ring can be diaxial or diequatorial (p. 172) and the molecule is generally free to adopt either conformation, though one may have a higher energy than the other. Anti-periplanarity of the leaving groups requires that they be diaxial, even if this is the conformation of higher energy. The results with menthyl and neomenthyl chlorides are easily



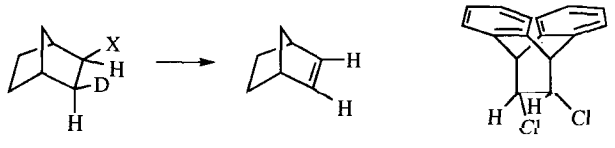
interpretable on this basis. Menthyl chloride has two chair conformations, 2 and 3. Compound 3, in which the three substituents are all equatorial, is the

more stable. The more stable chair conformation of neomenthyl chloride is 4, in which the chlorine is axial; there are axial hydrogens on both C-2 and C-4. The results are neomenthyl chloride gives rapid E2 elimination and the alkene produced is predominantly 6 (6/5 ratio is ~ 3:1) in accord with Zaitsev's rule (p. 1314). Since an axial hydrogen is available on both sides, this factor does not control the direction of elimination and Zaitsev's rule is free to operate. However, for menthyl chloride, elimination is much slower and the product is entirely the anti-Zaitsev 5. It is slow because the unfavorable conformation 2 has to be achieved before elimination can take place, and the product is 5 because only on this side is there an axial hydrogen.[12]

4. That anti elimination also occurs in the formation of triple bonds is shown by elimination from *cis*- and *trans*-HOOC–CH=CCl–COOH. In this case, the product in both cases is HOOCC≡CCOOH, but the trans isomer reacts about 50 times faster than the cis compound.[13]

Some examples of syn elimination have been found in molecules where H and X could not achieve an anti-periplanar conformation.

1. The deuterated norbornyl bromide (7, X = Br) gave 94% of the product containing no deuterium.[14] Similar results were obtained with other leaving groups and with bicyclo[2.2.2] compounds.[15] In these cases, the exo X group cannot achieve a dihedral angle of 180° with the endo β hydrogen because of the rigid structure of the molecule. The dihedral angle here is ~ 120°. These leaving groups prefer syn elimination with a dihedral angle of ~ 0° to anti elimination with an angle of ~ 120°.



7 8

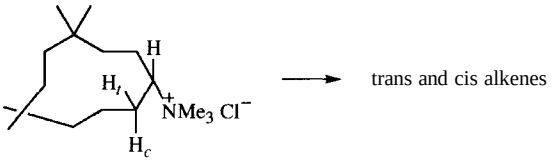
2. The molecule 8 is a particularly graphic example of the need for a planar transition state. In 8, each Cl has an adjacent hydrogen trans to it, and if planarity of leaving groups were not required, anti elimination could easily take place. However, the crowding of the rest of the molecule forces the dihedral angle to be ~ 120°, and elimination of HC1 from 8 is much slower than from corresponding nonbridged compounds.[16] (Note that syn elimination from 8 is even less likely than anti elimination.) Syn elimination can take place from the trans isomer of 8 (dihedral angle about 0°); this isomer reacted about eight times faster than **8**.[16]

The examples so far given illustrate two points. (1) Anti elimination *requires* a dihedral angle of 180°. When this angle cannot be achieved, anti elimination is greatly slowed or prevented entirely. (2) For the simple systems so far discussed syn

elimination is not found to any significant extent unless anti elimination is greatly diminished by failure to achieve the 180° angle.

As noted in Chapter 4 (p. 184), six-membered rings are the only ones among rings of 4-13 members in which strain-free anti-periplanar conformations can be achieved. It is not surprising, therefore, that syn elimination is least common in six-membered rings. Cooke and Coke subjected cycloalkyltrimethylammonium hydroxides to elimination (17-6) and found the following percentages of syn elimination with ring size: four-membered, 90%; five-membered, 46%; six-membered, 4% seven-membered, 31–37%.[17] It should be noted that the NMe_3^+ group has a greater tendency to syn elimination than do other common leaving groups such as OTs, Cl, and Br.

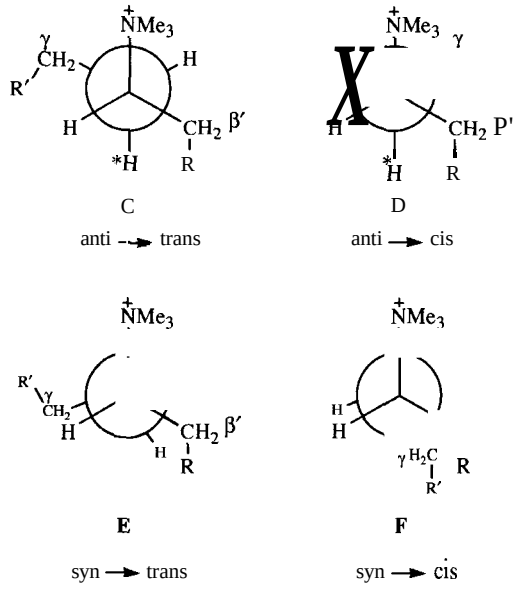
Other examples of syn elimination have been found in medium-ring compounds, where both cis and trans alkenes are possible (p. 158). As an illustration, we can look at experiments performed by Závada et al.[18] These workers subjected 1,1,4,4-tetramethyl-7-cyclodecyltrimethylammonium chloride (9) to elimination and



9

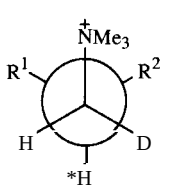
obtained mostly *trans*- but also some *cis*-tetramethylcyclodecenes as products. (Note that *trans*-cyclodecenes, though stable, are less stable than the cis isomers.) In order to determine the stereochemistry of the reaction, they repeated the elimination, this time using deuterated substrates. They found that when 9 was deuterated in the trans position (H_t = D), there was a substantial isotope effect in the formation of *both* cis and trans alkenes, but when 9 was deuterated in the cis position (H_c = D), there was *no* isotope effect in the formation of either alkene. Since an isotope effect is expected for an E2 mechanism,[19] these results indicated that *only* the trans hydrogen (H_t) was lost, whether the product was the cis or the trans isomer.[20] This in turn means that *the cis isomer must have been formed by anti elimination and the trans isomer by syn elimination.* (Anti elimination could take place from approximately the conformation shown, but for syn elimination the molecule must twist into a conformation in which the C–H_t and C–NMe_3^+ bonds are syn-periplanar.) This remarkable result, called the *syn-anti dichotomy*, has also been demonstrated by other types of evidence.[21] The fact that syn elimination in this case predominates over anti (as indicated by the formation of trans isomer in greater amounts than cis) has been explained by conformational factors.[22] The syn-anti dichotomy has also been found in other medium-ring systems (8- to 12-membered),[23] though the effect is greatest for 10-membered rings. With leaving groups,[24] the extent of this behavior decreases in the order NMe_3^+ > OTs > Br > Cl, which parallels steric requirements. When the leaving group is uncharged, syn elimination is favored by strong bases and by weakly ionizing solvents.[25]

Syn elimination and the syn-anti dichotomy have also been found in open-chain systems, though to a lesser extent than in medium-ring compounds. For example, in the conversion of 3-hexyl-4-*d*-trimethylammonium ion to 3-hexene with potassium *sec*-butoxide, ~67% of the reaction followed the syn-anti dichotomy.[26] In general syn elimination in open-chain systems is only important in cases where certain types of steric effect are present. One such type is compounds in which substituents are found on both the β' and the *y* carbons (the unprimed letter refers to the branch in which the elimination takes place). The factors that cause these results are not completely understood, but the following conformational effects have been proposed as a partial explanation.[27] The two anti- and two syn-periplanar conformations are, for a quaternary ammonium salt:

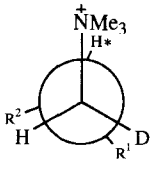


In order for an E2 mechanism to take place, a base must approach the proton marked *. In C, this proton is shielded on both sides by R and R'. In D, the shielding is on only one side. Therefore, when anti elimination does take place in such systems, it should give more cis product than trans. Also, when the normal anti elimination pathway is hindered sufficiently to allow the syn pathway to compete, the anti → trans route should be diminished more than the anti → cis route. When syn elimination begins to appear, it seems clear that E, which is less eclipsed than F, should be the favored pathway and syn elimination should generally give the trans isomer. In general, deviations from the syn-anti dichotomy are greater on the trans side than on the cis. Thus, trans alkenes are formed partly or mainly by syn elimination, but cis alkenes are formed entirely by anti elimination. Predominant syn elimination has also been found in compounds of the form $R^1R^2CHCHDNMe_3^+$, where R^1 and R^2 are both bulky.[28] In this case also, the conformation leading to syn elimination (H) is less strained than G, which gives anti elimination. Compound G

has three bulky groups (including NMe_3^+) in the *gauche* position to each other.

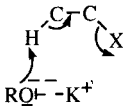


G



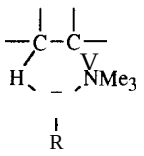
H

It was mentioned above that weakly ionizing solvents promote syn elimination when the leaving group is uncharged. This is probably caused by ion pairing, which is greatest in nonpolar solvents.[29] Ion pairing can



10

cause syn elimination with an uncharged leaving group by means of the transition state shown in 10. This effect was graphically illustrated by elimination from 1,1,4,4-tetramethyl-7-cyclodecyl bromide.[30] The ratio of syn to anti elimination when this compound was treated with *t*-BuOK in the nonpolar benzene was 55.0. But when the crown ether dicyclohexano-18-crown-6 was added (this compound selectively removes K^+ from the *t*-BuO^-K^+ ion pair and thus leaves *t*-BuO^- as a free ion), the syn/anti ratio decreased to 0.12. Large decreases in the syn/anti ratio on addition of the crown ether were also found with the corresponding tosylate and with other nonpolar solvents.[31] However, with positively charged leaving groups the effect is reversed. Here, ion pairing *increases* the amount of anti elimination.[32] In this case a relatively free base (e.g., PhO~) can be attracted to the leaving group, putting it in a favorable position for attack on the syn β hydrogen, while ion pairing would reduce this attraction.

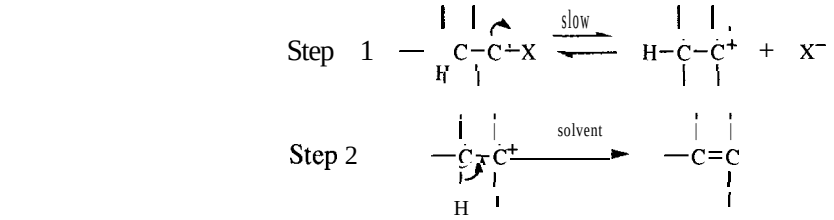


We can conclude that anti elimination is generally favored in the E2 mechanism, but that steric (inability to form the anti-periplanar transition state), conformational, ion pairing, and other factors cause syn elimination to intervene (and even predominate) in some cases.

The E1 Mechanism

The El mechanism is a two-step process in which the rate-determining step is ionization of the substrate to give a carbocation that rapidly loses a β proton to a base,

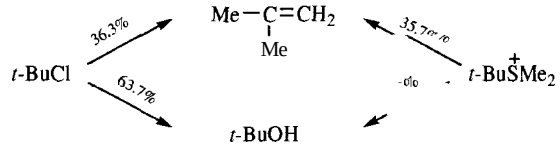
usually the solvent:



The IUPAC designation is D_N+D_E (or D_N+D_H). This mechanism normally operates without an *added* base. Just as the E2 mechanism is analogous to and competes with the S_N2, SO is the El mechanism related to the S_N1. In fact, the first step of the El is exactly the same as that of the S_N1 mechanism. The second step differs in that the solvent pulls a proton from the β carbon of the carbocation rather than attacking it at the positively charged carbon, as in the S_N1 process. In a pure El reaction (i.e., without ion pairs), the product should be completely nonstereospecific, since the carbocation is free to adopt its most stable conformation before giving up the proton.

Some of the evidence for the El mechanism is as follows:

1. The reaction exhibits first-order kinetics (in substrate) as expected. Of course the solvent is not expected to appear in the rate equation, even if it were involved in the rate-determining step (p. 291), but this point can be easily checked by adding a small amount of the conjugate base of the solvent. It is generally found that such an addition does not increase the rate of the reaction. If this more powerful base does not enter into the rate-determining step, it is unlikely that the solvent does. An example of an El mechanism with a rate-determining second step (proton transfer) has been reported.[33]
2. If the reaction is performed on two molecules that differ only in the leaving group (e.g., *t*-BuCl and *t*-BuSMe$_2^+$), the rates should obviously be different, since they depend on the ionizing ability of the molecule. However, once the carbocation is formed, if the solvent and the temperature are the same, it should suffer the same fate in both cases, since the nature of the leaving group does not affect the second step. This means that *the ratio of elimination to substitution should be the same.* The compounds mentioned in the example were solvolyzed at 65.3°C in 80% aqueous ethanol with the following results:[34]



Although the rates were greatly different (as expected with such different leaving groups), the product ratios were the same, within 1%. If this had taken place by a second-order mechanism, the nucleophile would not be expected to have the same ratio of preference for attack at the β hydrogen compared to

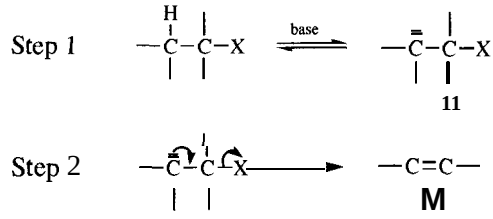
attack at a *neutral* chloride as for attack at the β hydrogen compared to attack at a *positive* SMe_2 group.

3. Many reactions carried out under first-order conditions on systems where E2 elimination is anti proceed quite readily to give alkenes where a cis hydrogen must be removed, often in preference to the removal of a trans hydrogen. For example, menthyl chloride (2, p. 1302), which by the E2 mechanism gave only 5, under El conditions gave 68% 6 and 32% 5, since the steric nature of the hydrogen is no longer a factor here, and the more stable alkene (Zaitsev's rule, p. 1314) is predominantly formed.
4. If carbocations are intermediates, we should expect rearrangements with suitable substrates. These have often been found in elimination reactions performed under El conditions.

The El reactions can involve ion pairs, just as is true for S_N1 reactions (p. 398).[35] This effect is naturally greatest for nondissociating solvents: it is least in water, greater in ethanol, and greater still in acetic acid. It has been proposed that the ion-pair mechanism (p. 400) extends to elimination reactions too, and that the S_N1, S_N2, El, and E2 mechanisms possess in common an ion-pair intermediate, at least occasionally.[36]

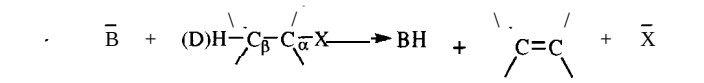
The E1cB Mechanism[37]

In the El mechanism, X leaves first, and then H. In the E2 mechanism, the two groups leave at the same time. There is a third possibility: the H leaves first, and then the X. This is a two-step process, called the *ElcB mechanism*, or the *carbanion mechanism*, since the intermediate is a carbanion:



The name ElcB comes from the fact that it is the conjugate base of the substrate that is giving up the leaving group (see the S_N1cB mechanism, p. 449). The IUPAC designation is $A_nD_E + D_N$ or $A_{xh}D_H + D_N$ (see p. 384). We can distinguish three limiting cases: (1) The carbanion returns to starting material faster than it forms product: step 1 is reversible; step 2 is slow. (2) Step 1 is the slow step, and formation of product is faster than return of the carbanion to starting material. In this case, step 1 is essentially irreversible. (3) Step 1 is rapid, and the carbanion goes slowly to product. This case occurs only with the most stable carbanions. Here, too, step 1 is essentially irreversible. These cases have been given the designations: (1) $(E1cB)_R$, (2) $(E1cB)_I$ (or $E1cB_{irr}$), and (3) $(E1)_{anion}$. Their characteristics are listed in Table 17.1.[38] Investigations of the reaction order are generally not very useful (except for

TABLE 17.1 Kinetic Predictions for Base-Induced β-Eliminations[38]



Mechanism	Kinetic[a] Order	β-Hydrogen Exchange Faster Than Elimination	General or Specific Base Catalysis	k_H/k_D	Electron Withdrawal at C_β[b]	Electron Release at C_α[b]	Leaving-Group Isotope Effect or Element Effect
$(E1)_{anion}$	1	Yes	General[c]	1.0	Rate decrease	Rate increase	Substantial
$(E1cB)_R$	2	Yes	Specific	1.0	Small rate increase	Small rate increase	Substantial
$(E1cB)_{ip}$	2	No	General[d]	1.0 → 1.2	Small rate increase	Small rate increase	Substantial
$(E1cB)_I$	2	No	General	2 → 8	Rate increase	Little effect	Small to negligible
E2[e]	2	No	General	2 → 8	Rate increase	Small rate increase	Small

[a] All mechanism exhibit first-order kinetics in substrate.
[b] Effect on rate assuming no change in mechanism is caused; steric factors upon substitution at C_α and rise to C_β have not been considered. The rate reductions are geared to substituent effects such as those giving rise to Hammett reaction constants on β- and α-aryl substitution.
[c] Specific base catalysis is predicted if the extent of substrate ionization is reduced from almost complete.
[d] Depends on whether an ion pair assists in removal of leaving group.
[e] Only transition states with considerable carbanion character are considered in this table.

case 3 which is first order), because cases 1 and 2 are second order and thus difficult or impossible to distinguish from the E2 mechanism by this procedure.[39] We would expect the greatest likelihood of finding the E1cB mechanism in substrates that have (a) a poor nucleofuge and (b) an acidic hydrogen, and most investigations have concerned such substrates. The following is some of the evidence in support of the E1cB mechanism:

1. The first step of the $(E1cB)_R$ mechanism involves a reversible exchange of protons between the substrate and the base. In that case, if deuterium is present in the base, recovered starting material should contain deuterium. This was found to be the case in the treatment of $Cl_2C{=}CHCl$ with NaOD to give $ClC{\equiv}CCl$. When the reaction was stopped before completion, there *was* deuterium in the recovered alkene.[40] A similar result was found for pentahaloethanes.[41] These substrates are relatively acidic. In both cases, the electron-withdrawing halogens increase the acidity of the hydrogen, and in the case of trichloroethylene there is the additional factor that a hydrogen on an sp^2 carbon is more acidic than one on an sp^3 carbon (p. 347). Thus, the E1cB mechanism is more likely to be found in eliminations yielding triple

bonds than in those giving double bonds. Another likely place for the E1cB mechanism should be in reaction of a substrate like $PhCH_2CH_2Br$, since the carbanion is stabilized by resonance with the phenyl group. Nevertheless, no deuterium exchange was found here.[42] If this type of evidence is a guide, then it may be inferred that the $(E1cB)_R$ mechanism is quite rare, at least for eliminations with common leaving groups such as Br, Cl, or OTs, which yield C=C double bonds.

2. When the reaction was carried out in water containing acetohydroxamate

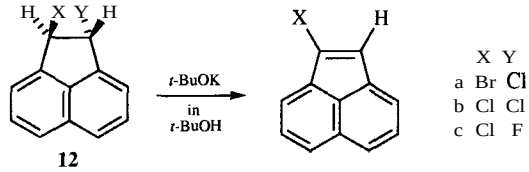
$$p\text{-}NO_2C_6H_4{-}CH_2{-}CH_2{-}\overset{+}{N}R_4 + B^- \longrightarrow p\text{-}NO_2C_6H_4{-}CH{=}CH_2 + BH + NR_3$$

buffers, a plot of the rate against the buffer concentration was curved and the rate leveled off at high buffer concentrations, indicating a change in rate-determining step.[43] This rules out an E2 mechanism, which has only one step. When D_2O was used instead of H_2O as solvent, there was an initial inverse solvent isotope effect of 7.7 (the highest inverse solvent isotope effect yet reported). That is, the reaction took place faster in D_2O than in H_2O. This is compatible only with an E1cB mechanism in which the proton-transfer step is not entirely rate determining. The isotope effect arises from a partitioning of the carbanion intermediate (11). This intermediate either can go to product or it can revert to starting compound, which requires taking a proton from the solvent. In D_2O, the latter process is slower (because the O—D bond of D_2O cleaves less easily than the O—H bond of H_2O), reducing the rate at which 11 returns to starting compound. With the return reaction competing less effectively, the rate of conversion of 11 to product is increased.

3. We have predicted that the E1cB mechanism would be most likely to be found with substrates containing acidic hydrogens and poor leaving groups. Compounds of the type ZCH_2CH_2OPh, where Z is an electron-withdrawing group (e.g., NO_2, SMe_2^+, $ArSO_2$, CN, and COOR), belong to this category, because OPh is a very poor leaving group (p. 446). There is much evidence to show that the mechanism here is indeed E1cB.[44] Isotope effects, measured for $MeSOCD_2CH_2OPh$ and $Me_2S^+CD_2CH_2OPh$ with NaOD in D_2O, are ~ 0.7. This is compatible with an (E1cB)R mechanism, but not with an E2 mechanism for which an isotope effect of perhaps 5 might be expected (of course, an E1 mechanism is precluded by the extremely poor nucleofugal ability of OPh). The fact that k_H/k_D is less than the expected value of 1 is attributable to solvent and secondary isotope effects. Among other evidence for an E1cB mechanism in these systems is that changes in the identity of Z had a dramatic effect on the relative rates: a span of 10^{11} between NO_2 and COO". Note that elimination from substrates of the type $RCOCH_2CH_2Y$ is the reverse of Michael-type addition to C=C bonds. We have seen (p. 975) that such addition involves initial attack by a nucleophile Y and subsequent attack by a proton. Thus the initial loss of a proton from substrates of this type (i.e., an E1cB mechanism) is in accord with the principle of microscopic reversibility.[45] It may also be recalled that benzyne formation (p. 855) can

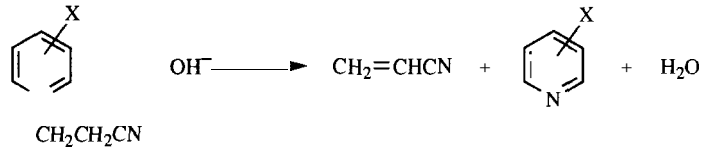
occur by such a process. It has been suggested that all base-initiated eliminations wherein the proton is activated by a strong electron-withdrawing group are E1cB reactions,[46] but there is evidence that this is not the case that when there is a good nucleofuge, the mechanism is E2 even when strong electron-withdrawing groups are present.[47] On the other hand, Cl^- has been found to be a leaving group in an E1cB reaction.[48]

Of the three cases of the E1cB mechanism, the one most difficult to distinguish from E2 is $(E1cB)_I$. One way to make this distinction is to study the effect of a change in leaving group. This was done in the case of the three acenaphthylenes (12), where it was found that (1) the three rates were fairly similar, the largest being only about four times that of the smallest, and (2) in



12

compound **12c** (X = Cl, Y = F), the only product contained Cl and no F, that is, only the poorer nucleofuge F departed while Cl remained.[49] Result (1) rules out all the E1cB mechanisms except $(E1cB)_I$, because the others should all have considerable leaving group effects (Table 17.1). An ordinary E2 mechanism should also have a large leaving group effect, but an E2 mechanism with substantial carbanionic character (see the next section) might not. However, no E2 mechanism can explain result (2), which can be explained by the fact that an a Cl is more effective than an a F in stabilizing the planar carbanion that remains when the proton is lost. Thus (as in the somewhat similar case of aromatic nucleophilic substitution, see p. 860), when X^- leaves in the second step, the one that leaves is not determined by which is the better nucleofuge, but by which has had its β hydrogen removed.[50] Additional evidence for the existence of the $(E1cB)_I$ mechanism was the observation of a change in the rate-determining step in the elimination reaction of *N-(2*-cyanoethyl)pyridinium ions (13), treated with base, when X was changed.[51]

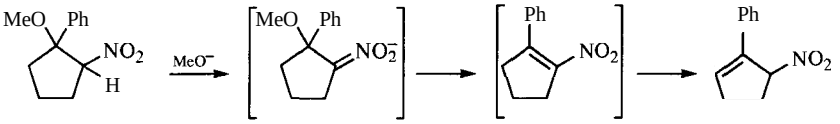


13

Once again, the demonstration that two steps are involved precludes the one-step E2 mechanism.

4. An example of an $(E1)_{anion}$ mechanism has been found with the substrate 14, which when treated with methoxide ion undergoes elimination to 16, which is

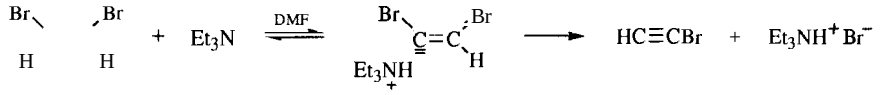
unstable under the reaction conditions and rearranges as shown.[52] Among the evidence for the proposed mechanism in this case were kinetic and isotope-effect results, as well as the spectral detection of 15.[53]



14 15 16

5. In many eliminations to form C=O and C≡N bonds the initial step is loss of a positive group (normally a proton) from the oxygen or nitrogen. These may also be regarded as E1cB processes.

There is evidence that some E1cB mechanisms can involve carbanion ion pairs, for example,[54]



This case is designated $(E1cB)_{ip}$; its characteristics are shown in Table 17.1.

The E1-E2-E1cB Spectrum

In the three mechanisms so far considered the similarities are greater than the differences. In each case, there is a leaving group that comes off with its pair of electrons and another group (usually hydrogen) that comes off without them. The only difference is in the order of the steps. It is now generally accepted that there is a spectrum of mechanisms ranging from one extreme, in which the leaving group departs well before the proton (pure E1), to the other extreme, in which the proton comes off first and then, after some time, the leaving group follows (pure E1cB). The *pure* E2 case would be somewhere in the middle, with both groups leaving simultaneously. However, most E2 reactions are not exactly in the middle, but somewhere to one side or the other. For example, the nucleofuge might depart just before the proton. This case may be described as an E2 reaction with a small amount of E1 character. The concept can be expressed by the question: In the transition state, which bond (C—H or C—X) has undergone more cleavage?[55]

One way to determine just where a given reaction stands on the E1–E2–E1cB spectrum is to study isotope effects, which ought to tell something about the behavior of bonds in the transition state.[56] For example, $CH_3CH_2NMe_3^+$ showed a nitrogen isotope effect (k^{14}/k^{15}) of 1.017, while $PhCH_2CH_2NMe_3^+$ gave a corresponding value of 1.009.[57] It would be expected that the phenyl group would move the reaction toward the E1cB side of the line, which means that for this compound the C-N bond is not as greatly broken in the transition state as it is for the unsubstituted one. The isotope effect bears this out, for it shows that in the phenyl compound, the mass of the nitrogen has less effect on the reaction rate than it does in

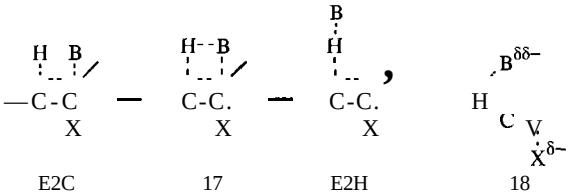
the unsubstituted compound. Similar results have been obtained with SR_2^+ leaving groups by the use of $^{32}S/^{34}S$ isotope effects[58] and with Cl ($^{35}Cl/^{37}Cl$).[59] The position of reactions along the spectrum has also been studied from the other side of the newly forming double bond by the use of H/D and H/T isotope effects,[60] though interpretation of these results is clouded by the fact that |3 hydrogen isotope effects are expected to change smoothly from small to large to small again as the degree of transfer of the |3 hydrogen from the β carbon to the base increases[61] [recall (p. 298) that isotope effects are greatest when the proton is half-transferred in the transition state], by the possibility of secondary isotope effects (e.g., the presence of a β deuterium or tritium may cause the leaving group to depart more slowly), and by the possibility of tunneling (see footnote 61 in Chapter 6).[62] Other isotope-effect studies have involved labeled a or |3 carbon, labeled a hydrogen, or labeled base.[56]

Another way to study the position of a given reaction on the spectrum involves the use of β aryl substitution. Since a positive Hammet p value is an indication of a negatively charged transition state, the p value for substituted |3 aryl groups should increase as a reaction moves from El-like to E1cB-like along the spectrum. This has been shown to be the case in a number of studies;[63] for example., p values of $ArCH_2CH_2X$ increase as the leaving-group ability of X decreases. A typical set of p values was X = I, 2.07; Br, 2.14; Cl, 2.61; SMe_2^+, 2.75; F, 3.12.[64] As we have seen, decreasing leaving-group ability correlates with increasing E1cB character.

Still another method measures volumes of activation.[65] These are negative for E2 and positive for E1cB mechanisms. Measurement of the activation volume therefore provides a continuous scale for deciding just where a reaction lies on the spectrum.

The E2C Mechanism[66]

Certain alkyl halides and tosylates undergo E2 eliminations faster when treated with such weak bases as Cl^- in polar aprotic solvents or PhS^- than with the usual E2 strong bases such as RO^- in ROH.[67] In order to explain these results Parker et al.[68] proposed that there is a spectrum[69] of E2 transition states in which the base can interact in the transition state with the α carbon as well as with the β hydrogen. At one end of this spectrum is a mechanism (called E2C) in which, in the transition



E2C 17 E2H 18

state, the base interacts mainly with the carbon. The E2C mechanism is characterized by strong nucleophiles that are weak bases. At the other extreme is the normal E2 mechanism, here called E2H to distinguish it from E2C, characterized by strong bases. Compound 17 represents a transition state between these extremes. Additional evidence[70] for the E2C mechanism is derived from Br0nsted equation

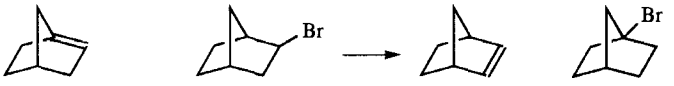
considerations (p. 337), from substrate effects, from isotope effects, and from the effects of solvents on rates.

However, the E2C mechanism has been criticized, and it has been contended that all the experimental results can be explained by the normal E2 mechanism.[71] McLennan suggested that the transition state is that shown as 18.[72] An ion-pair mechanism has also been proposed.[73] Although the actual mechanisms involved may be a matter of controversy, there is no doubt that a class of elimination reactions exists that is characterized by second-order attack by weak bases.[74] These reactions also have the following general characteristics:[75] (1) they are favored by good leaving groups; (2) they are favored by polar aprotic solvents; (3) the reactivity order is tertiary > secondary > primary, the opposite of the normal E2 order (p. 1319); (4) the elimination is always anti (syn elimination is not found), but in cyclohexyl systems, a diequatorial anti elimination is about as favorable as a diaxial anti elimination (unlike the normal E2 reaction, p. 1302); (5) they follow Zaitsev's rule (see below), where this does not conflict with the requirement for anti elimination.

Orientation of the Double Bond

With some substrates, a |3 hydrogen is present on only one carbon and (barring rearrangements) there is no doubt as to the identity of the product .For example, $PhCH_2CH_2Br$ can give only $PhCH{=}CH_2$. However, in many other cases two or three alkenyl products are possible. In the simplest such case, a sec-butyl compound can give either 1-butene or 2-butene. There are a number of rules that enable us to predict, in many instances, which product will predominantly form.[76]

1. No matter what the mechanism, a double bond does not go to a bridgehead carbon unless the ring sizes are large enough (Bredt's rule, see p. 188). This means, for example, not only that 19 gives only 20 and not 21 (indeed 21 is not a known compound), but also that 22 does not undergo elimination.



21 **19** **20** **22**

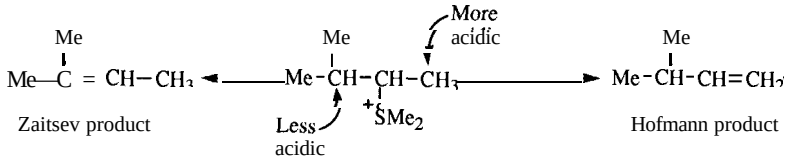
2. No matter what the mechanism, if there is a double bond *(C═C* or C=O) or an aromatic ring already in the molecule that can be in conjugation with the new double bond, the conjugated product usually predominates, sometimes even when the stereochemistry is unfavorable (for an exception, see p. 1317).
3. In the El mechanism, the leaving group is gone before the choice is made as to which direction the new double bond takes. Therefore the direction is determined almost entirely by the relative stabilities of the two (or three) possible alkenes. In such cases *Zaitsev's rule*[77] operates. This rule states that *the double bond goes mainly toward the most highly substituted carbon.* That

is, a *sec-butyl* compound gives more 2-butene than 1-butene, and 3-bromo-2,3-dimethylpentane gives more 2,3-dimethyl-2-pentene than either 3,4-dimethyl-2-pentene or 2-ethyl-3-methyl-l-butene. Thus Zaitsev's rule predicts that the alkene predominantly formed will be the one with the largest possible number of alkyl groups on the *C=C* carbons, and in most cases this is what is found. From heat of combustion data (see p. 24) it is known that alkene stability increases with alkyl substitution, though just why this should be is a matter of conjecture. The most common explanation is hyperconjugation. For El eliminations, Zaitsev's rule governs the orientation whether the leaving group is neutral or positive, since, as already mentioned, the leaving group is not present when the choice of direction is made. This statement does not hold for E2 eliminations, and it may be mentioned here, for contrast with later results, that El elimination of $Me_2CHCHMeSMe_2^+$ gave 91% of the Zaitsev product and 9% of the other.[78] However, there *are* cases in which the leaving group affects the direction of the double bond in El eliminations.[79] This may be attributed to ion pairs; that is, the leaving group is not completely gone when the hydrogen departs. Zaitsev's rule breaks down in cases where the non-Zaitsev product is more stable for steric reasons. For example, El or El like eliminations of l,2-diphenyl-2-X-propanes ($PhMeCXCH_2Ph$) were reported to give ~50% $CH_2{=}CPhCH_2Ph$, despite the fact that the double bond of the Zaitsev product ($PhMeC{=}CHPh$) is conjugated with two benzene rings.[80]

4. For the anti E2 mechanism a trans (3 proton is necessary; if this is available in only one direction, that is the way the double bond will form. Because of the free rotation in acyclic systems (except where steric hindrance is great), this is a factor only in cyclic systems. Where trans (3 hydrogens are available on two or three carbons, two types of behavior are found, depending on substrate structure and the nature of the leaving group. Some compounds follow Zaitsev's rule and give predominant formation of the most highly substituted alkene, but others follow *Hofmann's rule: The double bond goes mainly toward the least highly substituted carbon.* Though many exceptions are known, the following general statements can be made: In most cases, compounds containing uncharged nucleofuges (those that come off as negative ions) follow Zaitsev's rule, just as they do in El elimination, no matter what the structure of the substrate. However, elimination from compounds with charged nucleofuges (e.g., NR_3^+, SR_2^+) (those that come off as neutral molecules), follow Hofmann's rule if the substrate is acyclic,[81] but Zaitsev's rule if the leaving group is attached to a six-membered ring.[82]

Much work has been devoted to searching for the reasons for the differences in orientation. Since Zaitsev orientation almost always gives the thermodynamically more stable isomer, what needs to be explained is why in some cases the less stable Hofmann product predominates. Three explanations have been offered for the change in orientation in acyclic systems with a change from uncharged to charged nucleofuges. The first of these, by Hughes

and Ingold,[83] is that Hofmann orientation is caused by the fact that the acidity of the (3 hydrogen is decreased by the presence of the electron-donating alkyl groups. For example, under E2 conditions $Me_2CHCHMeSMe_2^+$ gives more of the Hofmann product; it is the more acidic hydrogen that is removed by the base.



Of course, the CH_3 hydrogens would still be more acidic than the Me_2CH hydrogen even if a neutral leaving group were present, but the explanation of Hughes and Ingold is that acidity matters with charged and not with neutral leaving groups, because the charged groups exert a strong electron-withdrawing effect, making differences in acidity greater than they are with the less electron-withdrawing neutral groups.83 The explanation of Bunnett[84] is similar. According to this, the change to a positive leaving group causes the mechanism to shift toward the E1 cB end of the spectrum, where there is more C—H bond breaking in the rate-determining step and where, consequently, acidity is more important. In this view, when there is a neutral leaving group, the mechanism is more El like, C—X bond breaking is more important, and alkene stability determines the direction of the new double bond. The third explanation, by Brown,[85,86] is completely different. In this picture, field effects are unimportant, and the difference in orientation is largely a steric effect caused by the fact that charged groups are usually larger than neutral ones. A CH_3 group is more open to attack than a CH_2R group and a CHR_2 group is still less easily attacked. Of course, these considerations also apply when the leaving group is neutral, but, according to Brown, they are much less important here because the neutral groups are smaller and do not block access to the hydrogens as much. Brown showed that Hofmann elimination increases with the size of the leaving group. Thus the percentage of 1-ene obtained from $CH_3CH_2CH_2CHXCH_3$ was as follows (X listed in order of increasing size): Br, 31%; I, 30%; OTs, 48%; SMe_2^+, 87%; SO_2Me, 89%; NMe_3^+, 98%.[85] Hofmann elimination was also shown to increase with increase in bulk of the substrate.[86] With large enough compounds, Hofmann orientation can be obtained even with halides (e.g., *tert*-amyl bromide gave 89% of the Hofmann product). Even those who believe in the acidity explanations concede that these steric factors operate in extreme cases.[87]

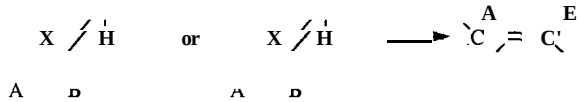
There is one series of results incompatible with the steric explanation—E2 elimination from the four 2-halopentanes gave the following percentages of 1-pentene: F, 83%; Cl, 37%; Br, 25%; I, 20%.[88] The same order was found for the four-2-halohexanes.[89] Although there is some doubt about the relative steric requirements of Br, Cl, and I, there is no doubt that F is the smallest of the halogens, and if the steric explanation were the only valid one, the

fluoroalkanes could not give predominant Hofmann orientation. Another result that argues against the steric explanation is the effect of changing the nature of the base. An experiment in which the effective size of the base was kept constant while its basicity was increased (by using as bases a series of $XC_6H_4O^-$ ions) showed that the percentage of Hofmann elimination increased with increasing base strength, though the size of the base did not change.[90] These results are in accord with the explanation of Bunnett, since an increase in base strength moves an E2 reaction closer to the E1cB end of the spectrum. In further experiments, a large series of bases of different kinds was shown to obey linear free energy relationships between basicity and percentage of Hofmann elimination,[91] though certain very large bases (e.g., 2,6-di-*tert*-butyl-phenoxide) did not obey the relationships, steric effects becoming important in these cases. How large the base must be before steric effects are observed depends on the pattern of alkyl substitution in the substrate, but not on the nucleofuge.[92] One further result may be noted. In the gas phase, elimination of H and BrH^+ or H and ClH^+ using Me_3N as the base predominantly followed Hofmann's rule,[93] although BrH^+ and ClH^+ are not very large.

5. Only a few investigations on the orientation of syn E2 eliminations have been carried out, but these show that Hofmann orientation is greatly favored over Zaitsev.[94]
6. In the E1cB mechanism the question of orientation seldom arises because the mechanism is generally found only where there is an electron-withdrawing group in the (3 position, and that is where the double bond goes.
7. As already mentioned, E2C reactions show a strong preference for Zaitsev orientation.[95] In some cases, this can be put to preparative use. For example, the compound $PhCH_2CHOTsCHMe_2$ gave ~98% $PhCH{=}CHCHMe_2$ under the usual E2 reaction conditions (f-BuOK in f-BuOH). In this case the double bond goes to the side with more hydrogens because on that side it will be able to conjugate with the benzene ring. However, with the weak base $Bu_4N^+ Br^-$ in acetone the Zaitsev product PhCH2CH=CMe2 was formed in 90% yield.[96]

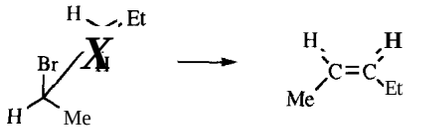
Steric Orientation of the Double Bond

When elimination takes place on a compound of the form $CH_3{-}CABX$ or CHAB–CGGX, the new alkene does not have cis-trans isomerism, but for compounds of the form CHEG-CABX (E and G *not* H) (23) and $CH_2E{-}CABX$ (24), cis and trans isomers arc possible. When the anti E2 mechanism is in operation,



23 24

23 gives the isomer arising from trans orientation of X and H and, as we have seen before (p. 1300), an erythro compound gives the cis alkene and a threo compound the trans. For 24, two conformations are possible for the transition state; these lead to different isomers and often both are obtained. However, the one that predominates is often determined by an eclipsing effect.[97] For example, Zaitsev elimination from 2-bromopentane can occur as follows:

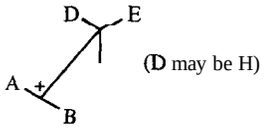


I 18%

J 51%

In conformation I the ethyl group is between Br and Me, while in J it is between Br and H. This means that J is more stable, and most of the elimination should occur from this conformation. This is indeed what happens, and 51% of the trans isomer is formed (with KOEt) compared to 18% of the cis (the rest is the Hofmann product).[98] These effects become larger with increasing size of A, B, and E.

However, eclipsing effects are not the only factors that affect the cis/trans ratio in anti E2 eliminations. Other factors are the nature of the leaving group, the base, the solvent, and the substrate. Not all these effects are completely understood.[99]



(D may be H)

25

For E1 eliminations, if there is a free carbocation (25), it is free to rotate, and no matter what the geometry of the original compound, the more stable situation is the one where the larger of the D-E pair is opposite the smaller of the A-B pair and the corresponding alkene should form. If the carbocation is not completely free, then to that extent, E2 type products are formed. Similar considerations apply in E1cB eliminations.[100]

REACTIVITY

In this section, we examine the effects of changes in the substrate, base, leaving group, and medium on (1) overall reactivity, (2) E1 versus E2 versus E1cB,[101] and (3) elimination versus substitution.

Effect of Substrate Structure

1. *Effect on Reactivity.* We refer to the carbon containing the nucleofuge (X) as the a carbon and to the carbon that loses the positive species as the (3 carbon. Groups attached to the α or (3 carbons can exert at least four kinds of influence:
   a. They can stabilize or destabilize the incipient double bond (both α and (3 groups).
   b. They can stabilize or destabilize an incipient negative charge, affecting the acidity of the proton ((3 groups only).
   c. They can stabilize or destabilize an incipient positive charge (a groups only).
   d. They can exert steric effects (e.g., eclipsing effects) (both oc and (3 groups).

   Effects (a) and (d) can apply in all three mechanisms, though steric effects are greatest for the E2 mechanism. Effect (b) does not apply in the El mechanism, and effect (c) does not apply in the E1cB mechanism. Groups such as Ar and C=C increase the rate by any mechanism, except perhaps when formation of the C=C bond is not the rate-determining step, whether they are α or (3 (effect a). Electron-withdrawing groups increase the acidity when in the β position, but have little effect in the a position unless they also conjugate with the double bond. Thus Br, Cl, CN, Ts, NO_2, CN, and SR in the (3 position all increase the rate of E2 eliminations.
2. *Effect on El versus E2 versus E1cB.* The oc alkyl and oc aryl groups stabilize the carbocation character of the transition state, shifting the spectrum toward the El end. The (3 alkyl groups also shift the mechanism toward E1, since they *decrease* the acidity of the hydrogen. However, (3 aryl groups shift the mechanism the other way (toward E1cB) by stabilizing the carbanion. Indeed, as we have seen (p. 1310), all electron-withdrawing groups in the (3 position shift the mechanism toward E1cB.[102] α alkyl groups also increase the extent of elimination with weak bases (E2C reactions).
3. *Effect on Elimination versus Substitution.* Under second-order conditions a branching increases elimination, to the point where tertiary substrates undergo few S_N2 reactions, as we saw in Chapter 10. For example, Table 17.2 shows results on some simple alkyl bromides. Similar results were obtained with SMe_2^+ as the leaving group.[103] Two reasons can be presented for this trend. One is statistical: as oc branching increases, there are usually more hydrogens for the base to attack. The other is that oc branching presents steric hindrance to attack of the base at the carbon. Under first-order conditions, increased a branching also increases the amount of elimination (El vs. S_N1), though not so much, and usually the substitution product predominates. For example, solvolysis of *tert*-butylbromide gave only 19% elimination (cf. with Table 17.2).[104] The β branching also increases the amount of E2 elimination with respect to S_N2 substitution (Table 17.2), not because elimination is faster but because the S_N2 mechanism is so greatly slowed (p. 431). Under first-

TABLE 17.2 The Effect of a **and β Branching** on the **Rate of E2 Elimination and the** Amount **of Alkene Formed**[a]

Substrate	Temperature (°C)	Alkene (%)	Rate x 10^5 of E2 Reaction	Reference
CH_3CH_2Br	55	0.9	1.6	106
$(CH_3)_2CHBr$	24	80.3	0.237	107
$(CH_3)_3CBr$	25	97	4.17	105
$CH_3CH_2CH_2Br$	55	8.9	5.3	103
$(CH_3)_2CHCH_2Br$	55	59.5	8.5	103

[a]The reactions were between the alkyl bromide and OEt^-. The rate for isopropyl bromide was actually greater than that for ethyl bromide, if the temperature difference is considered. Neopentyl bromide, the next compound in the P-branching series, cannot be compared because it has no (3-hydrogen and cannot give an elimination product without rearrangement.

order conditions too, |3 branching favors elimination over substitution, probably for steric reasons.[105] However, E2 eliminations from compounds with charged leaving groups are slowed by |3 branching. This is related to Hofmann's rule (p. 1315). Electron-withdrawing groups in the |3 position not only increase the rate of E2 eliminations and shift the mechanisms toward the E1cB end of the spectrum but also increase the extent of elimination as opposed to substitution.

Effect of the Attacking Base

1. *Effect on El versus E2 versus ElcB.* In the El mechanism, an external base is generally not required: The solvent acts as the base. Hence, when external bases are added, the mechanism is shifted toward E2. Stronger bases and higher base concentrations cause the mechanism to move toward the ElcB end of the El-E2-ElcB spectrum.[108] However, weak bases in polar aprotic solvents can also be effective in elimination reactions with certain substrates (the E2C reaction). Normal E2 elimination has been accomplished with the following bases:[109] H_2O, NR_3, OH", OAc", OR", OAr^-, NH_2^-, CO_3^{2-}, $LiAlH_4$, I", CN^-, and organic bases. However, the only bases of preparative importance in the normal E2 reaction are OH", OR", and NH_2^-, usually in the conjugate acid as solvent, and certain amines. Weak bases effective in the E2C reaction are Cl~, Br^-, F^-, OAc", and RS^-. These bases are often used in the form of their R_4N^+ salts.
