Red cell metabolism produces 2,3-BPG from glycolysis. 2,3-BPG accumulates because it is sequestered by binding to deoxyhaemoglobin. The binding of 2,3-BPG stabilizes the T conformation and reduces its affinity for oxygen. The P_{50} is the partial pressure of oxygen at which the haemoglobin is 50% saturated with oxygen. P_{50} increases with 2,3-BPG concentrations, which increase when oxygen availability is reduced in conditions such as hypoxia or anaemia. P_{50} also rises with increasing body temperature, which may be beneficial during prolonged exercise. Haemoglobin regulates oxygen transport as shown in the oxyhaemoglobin dissociation curve. When the primary limitation to oxygen transport is in the periphery, e.g. heavy exercise, anaemia, the P_{50} is increased to enhance oxygen unloading. When the primary limitation is in the lungs, e.g. lung disease, high altitude exposure, the P_{50} is reduced to enhance oxygen loading.

A summary of normal red cell production and destruction is given in Figure 8.5.

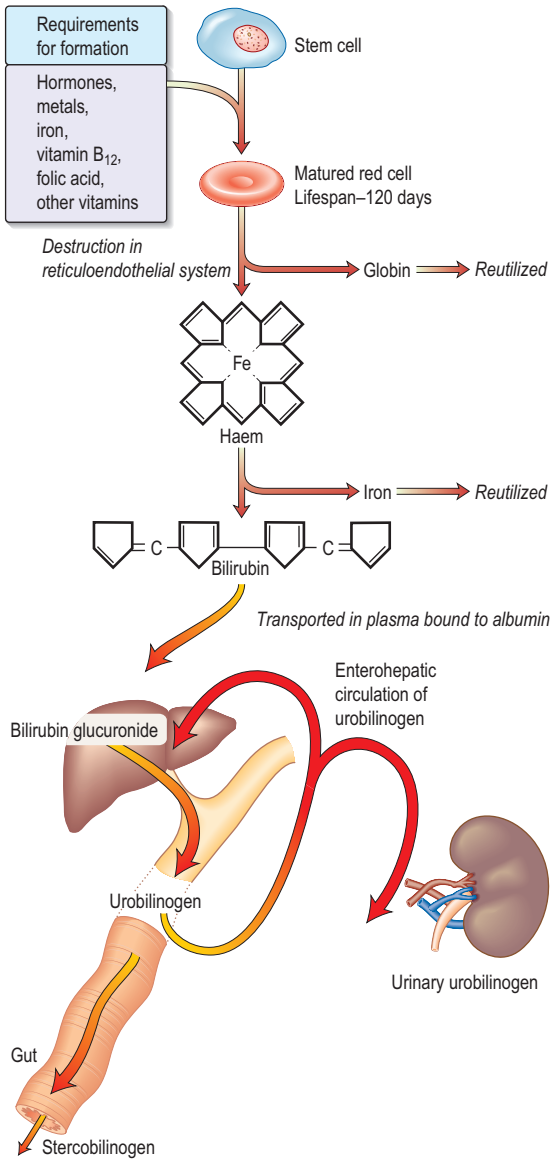

Fig. 8.5 **Red cell production and breakdown** (see p. 322).

ANAEMIA

Anaemia is present when there is a decrease in the level of haemoglobin in the blood below the reference level for the age and sex of the individual (Table 8.1). Alterations in the level of Hb may occur as a result of changes in the plasma volume, as shown in Figure 8.6. A reduction in the plasma volume will lead to a spuriously high Hb – this is seen with dehydration and in the clinical condition of apparent polycythaemia (see p. 421). A raised plasma volume produces a spurious anaemia, even when combined with a small increase in red cell volume as occurs in pregnancy.

The various types of anaemia, classified by MCV, are shown in Figure 8.7. There are three major types:

- hypochromic microcytic with a low MCV
- normochromic normocytic with a normal MCV
- macrocytic with a high MCV.

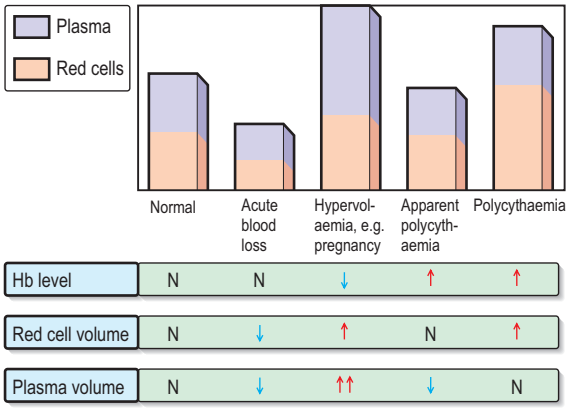

Fig. 8.6 **Alterations of haemoglobin in relation to plasma.**

Clinical features

Patients with anaemia may be asymptomatic. A slowly falling level of Hb allows for haemodynamic compensation and enhancement of the oxygen-carrying capacity of the blood. A rise in 2,3-BPG causes a shift of the oxygen dissociation curve to the right, so that oxygen is more readily given up to the tissues. Where blood loss is rapid, more severe symptoms will occur, particularly in elderly people.

Symptoms (all non-specific)

- Fatigue, headaches and faintness are all very common in the general population
- Breathlessness
- Angina
- Intermittent claudication
- Palpitations.

A common problem is that anaemia exacerbates cardiorespiratory problems especially in the elderly. For example, angina or intermittent claudication may be precipitated by anaemia. A good way to assess the effects of anaemia is to ask about breathlessness in relation to different levels of exercise (e.g. walking on the flat or climbing one flight of stairs).

Signs

- Pallor
- Tachycardia
- Systolic flow murmur
- Cardiac failure.

Specific signs seen in the different types of anaemia will be discussed in the appropriate sections. Examples include:

- koilonychia – spoon-shaped nails seen in iron deficiency anaemia
- jaundice – found in haemolytic anaemia
- bone deformities – found in thalassaemia major

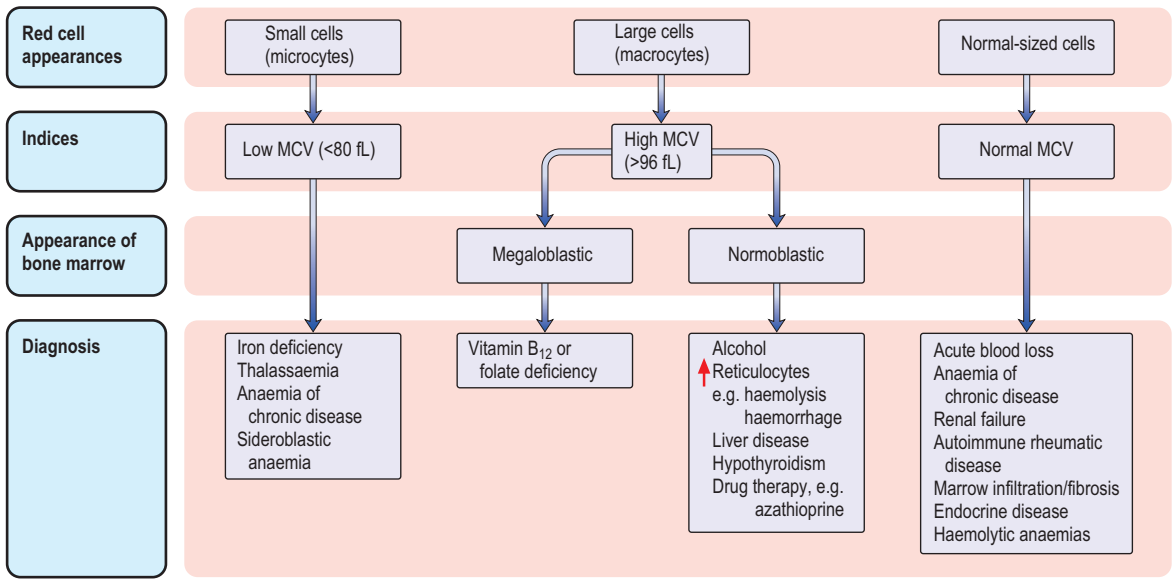

Fig. 8.7 **Classification of anaemia.** MCV, mean corpuscular volume.

- leg ulcers – occur in association with sickle cell disease.

It must be emphasized that anaemia is not a diagnosis, and a cause must be found.

Investigations

Peripheral blood

A low haemoglobin should always be considered in relation to:

- the white blood cell (WBC) count
- the platelet count
- the reticulocyte count (as this indicates marrow activity)
- the blood film, as abnormal red cell morphology (Fig. 8.9) may indicate the diagnosis. Where two populations of red cells are seen, the blood film is said to be dimorphic. This may, for example, be seen in patients with 'double deficiencies' (e.g. combined iron and folate deficiency in coeliac disease, or following treatment of anaemic patients with the appropriate haematinic).

Bone marrow

Examination of the bone marrow is performed to further investigate abnormalities found in the peripheral blood (Practical Box 8.1). Aspiration provides a film which can be examined by microscopy for the morphology of the developing haemopoietic cells. The trephine provides a core of bone which is processed as a histological specimen and allows an overall view of the bone marrow architecture, cellularity and presence/absence of abnormal infiltrates.

The following are assessed:

- cellularity of the marrow
- type of erythropoiesis (e.g. normoblastic or megaloblastic)
- cellularity of the various cell lines
- infiltration of the marrow
- iron stores.

Special tests may be performed for further diagnosis: cytogenetic, immunological, cytochemical markers, biochemical analyses (e.g. deoxyuridine suppression test), microbiological culture.

Practical Box 8.1 Techniques for obtaining bone marrow

The technique should be explained to the patient and consent obtained

Aspiration

Site – usually iliac crest
Give local anaesthetic injection
Use special bone marrow needle (e.g. Salah)
Aspirate marrow
Make smear with glass slide
Stain with:
  Romanowsky technique
  Perls' reaction (acid ferrocyanide) for iron

Trephine

Indications include:
  'Dry tap' obtained with aspiration
  Better assessment of cellularity, e.g. aplastic anaemia
  Better assessment of presence of infiltration or fibrosis

Technique

Site – usually posterior iliac crest
Give local anaesthetic injection
Use special needle (e.g. Jamshidi – longer and wider than for aspiration)
Obtain core of bone
Fix in formalin; decalcify – this takes a few days
Stain with:
  Haematoxylin and eosin
  Reticulin stain

MICROCYTIC ANAEMIA

Iron deficiency is the most common cause of anaemia in the world, affecting 30% of the world's population equivalent to 500 million people. This is because of the body's limited ability to absorb iron and the frequent loss of iron owing to haemorrhage. Although iron is abundant, most is in the insoluble ferric (Fe^{3+}) form, which has poor bioavailability. Ferrous (Fe^{2+}) is more readily absorbed. Free iron is toxic, and it is bound to various proteins for transport and storage.

The other causes of a microcytic hypochromic anaemia are anaemia of chronic disease, sideroblastic anaemia and thalassaemia. In thalassaemia (see p. 407) there is a defect in globin synthesis, in contrast to the other three causes of microcytic anaemia where the defect is in the synthesis of haem.

Iron

Dietary intake

The average daily diet in the UK contains 15–20 mg of iron, although normally only 10% of this is absorbed. Absorption may be increased to 20–30% in iron deficiency and pregnancy.

Non-haem iron is mainly derived from cereals, which are commonly fortified with iron; it forms the main part of dietary iron. Haem iron is derived from haemoglobin and myoglobin in red or organ meats. Haem iron is better absorbed than non-haem iron, whose availability is more affected by other dietary constituents.

Absorption (Fig. 8.8a,b)

Factors influencing iron and haem iron absorption are shown in Table 8.2

Dietary haem iron is more rapidly absorbed than non-haem iron derived from vegetables and grain. Most haem is absorbed in the proximal intestine, with absorptive capacity decreasing distally. The intestinal haem transporter HCP1 (haem carrier protein 1) has been identified and found to be highly expressed in the duodenum. It is upregulated by hypoxia and iron deficiency. Some haem iron may be reabsorbed intact into circulation via the cell by two exporter proteins – BCRP (breast cancer resistant protein) and FLVCR (feline leukaemia virus subgroup C).

Non-haem iron absorption occurs primarily in the duodenum. Non-haem iron is dissolved in the low pH of the stomach and reduced from the ferric to the ferrous form by a brush border ferrireductase. Cells in duodenal crypts are able to sense the body's iron requirements and retain this

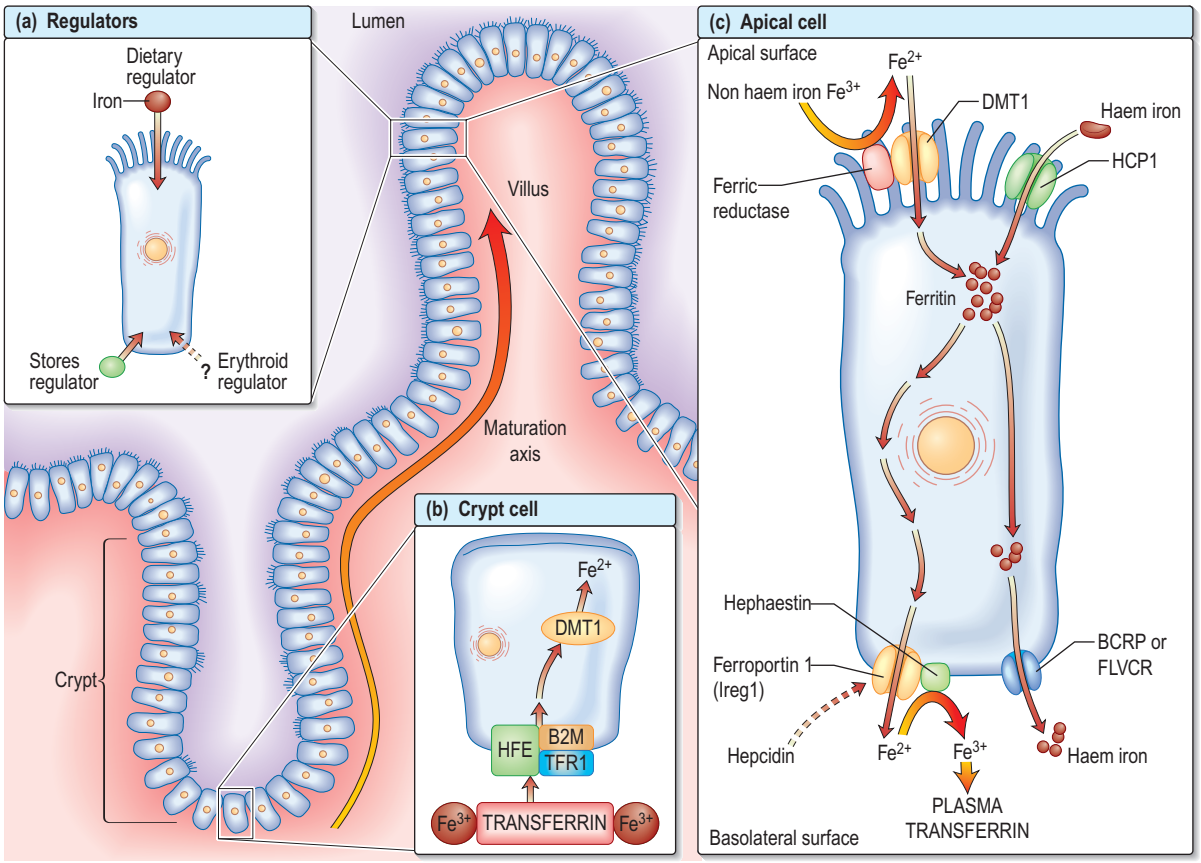

Fig. 8.8 **(a) Regulation of the absorption of intestinal iron.** The iron-absorbing cells of the duodenal epithelium originate in the intestinal crypts and migrate toward the tip of the villus as they differentiate (maturation axis). Absorption of intestinal iron is regulated by at least three independent mechanisms. First, iron absorption is influenced by recent dietary iron intake (dietary regulator). After a large dietary bolus, absorptive cells are resistant to iron uptake for several days. Second, iron absorption can be modulated considerably in response to body iron stores (stores regulator). Third, a signal communicates the state of bone marrow erythropoiesis to the intestine (erythroid regulator).
(b) Duodenal crypt cells sense body iron status through the binding of transferrin to the HFE/B_2M/TFR1 complex. Cytosolic enzymes change the oxidative state of iron from ferric (Fe^{3+}) to ferrous (Fe^{2+}). A decrease in crypt cell iron concentration upregulates the divalent metal transporter (DMT1). This increases as crypt cells migrate up the villus and become mature absorptive cells.
(c) Apical cell. Dietary iron is reduced from the ferric to the ferrous state by the brush border ferrireductase. DMT1 facilitates iron absorption from the intestinal lumen. The export proteins, e.g. ferroportin 1 (Ireg1) and hephaestin, transfer iron from the enterocyte into the circulation. BCRP, breast cancer resistant protein; B2M, β_2-microglobulin; FLVCR, feline leukaemia virus subgroup C; HCP-1, Haem carrier protein-1; HFE, hereditary haemochromatosis gene.

Table 8.2 Factors influencing iron absorption

Haem iron is absorbed better than non-haem iron
Ferrous iron is absorbed better than ferric iron
Gastric acidity helps to keep iron in the ferrous state and soluble in the upper gut
Formation of insoluble complexes with phytate or phosphate decreases iron absorption
Iron absorption is increased with low iron stores and increased erythropoietic activity, e.g. bleeding, haemolysis, high altitude
There is a decreased absorption in iron overload, except in hereditary haemochromatosis, where it is increased

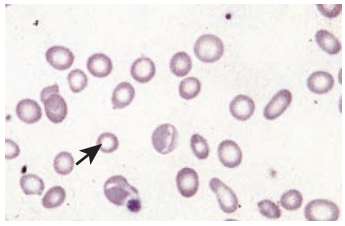

Fig. 8.9 **Hypochromic microcytic cells (arrow) on a blood film.** Poikilocytosis and anisocytosis are seen.

information as they mature into cells capable of absorbing iron at the tips of the villi. A protein, divalent metal transporter 1 (DMT1) or natural resistance-associated macrophage protein (NRAMP2), transports iron (and other metals) across the apical (luminal) surface of the mucosal cells in the small intestine. Haem iron is absorbed in a separate less-well-characterized process.

Once inside the mucosal cell, iron may be transferred across the cell to reach the plasma, or be stored as ferritin; the body's iron status at the time the absorptive cell developed from the crypt cell is probably the crucial

deciding factor. Iron stored as ferritin will be lost into the gut lumen when the mucosal cells are shed; this regulates iron balance. The mechanism of transport of iron across the basolateral surface of mucosal cells involves a transporter protein, ferroportin 1 (Ireg1). This transporter protein requires an accessory, multicopper protein, hephaestin (Fig. 8.8c).

The body iron content is closely regulated by the control of iron absorption but there is no physiological mechanism for eliminating excess iron from the body. The key molecule regulating iron absorption is hepcidin, a 25 amino acid peptide synthesized in the liver. Hepcidin acts by regulating the activity of the iron exporting protein ferroportin by binding to ferroportin causing its internalization and degradation, thereby decreasing iron efflux from iron exporting tissues into plasma. Therefore, high levels of hepcidin will destroy ferroportin and limit iron absorption, and vice versa low levels of hepcidin will encourage iron absorption. However, the importance of hepcidin goes further than its role in physiologic iron absorption. For example, most forms of haemochromatosis result from dysregulation of hepcidin or defects of hepcidin or ferroportin themselves.

A longstanding mystery is why anaemias characterized by ineffective erythropoiesis such as thalassaemia are associated with excessive and inappropriate iron absorption. Preliminary evidence again suggests that the increased iron absorption in beta-thalassaemia is mediated by downregulation of hepcidin and upregulation of ferroportin.

Transport in the blood

The normal serum iron level is about 13–32 μmol/L; there is a diurnal rhythm with higher levels in the morning. Iron is transported in the plasma bound to transferrin, a β-globulin that is synthesized in the liver. Each transferrin molecule binds two atoms of ferric iron and is normally one-third saturated. Most of the iron bound to transferrin comes from macrophages in the reticuloendothelial system and not from iron absorbed by the intestine. Transferrin-bound iron becomes attached by specific receptors to erythroblasts and reticulocytes in the marrow and the iron is removed (Fig. 8.2).

In an average adult male, 20 mg of iron, chiefly obtained from red cell breakdown in the macrophages of the reticuloendothelial system, is incorporated into Hb every day.

Iron stores

About two-thirds of the total body iron is in the circulation as haemoglobin (2.5–3 g in a normal adult man). Iron is stored in reticuloendothelial cells, hepatocytes and skeletal muscle cells (500–1500 mg). About two-thirds of this is stored as ferritin and one-third as haemosiderin in normal individuals. Small amounts of iron are also found in plasma (about 4 mg bound to transferrin), with some in myoglobin and enzymes.

Ferritin is a water-soluble complex of iron and protein. It is more easily mobilized than haemosiderin for Hb formation. It is present in small amounts in plasma.

Haemosiderin is an insoluble iron–protein complex found in macrophages in the bone marrow, liver and spleen. Unlike ferritin, it is visible by light microscopy in tissue sections and bone marrow films after staining by Perls' reaction.

Requirements

Each day 0.5–1.0 mg of iron is lost in the faeces, urine and sweat. Menstruating women lose 30–40 mL of blood per month, an average of about 0.5–0.7 mg of iron per day. Blood loss through menstruation in excess of 100 mL will usually result in iron deficiency as increased iron absorption from the gut cannot compensate for such losses of iron. The demand for iron also increases during growth (about 0.6 mg per day) and pregnancy (1–2 mg per day). In the normal adult the iron content of the body remains relatively fixed. Increases in the body iron content (haemochromatosis) are classified into:

- Hereditary haemochromatosis (see p. 356), where a mutation in the HFE gene causes increased iron absorption.
- Secondary haemochromatosis (transfusion siderosis; see p. 408). This is due to iron overload in conditions where repeated transfusion is the only therapy.

Iron deficiency

Iron deficiency anaemia develops when there is inadequate iron for haemoglobin synthesis. A normal level of Hb is maintained for as long as possible after the iron stores are depleted; latent iron deficiency is said to be present during this period.

- blood loss
- increased demands such as growth and pregnancy
- decreased absorption (e.g. postgastrectomy)
- poor intake.

Most iron deficiency is due to blood loss, usually from the uterus or gastrointestinal tract. Premenopausal women are in a state of precarious iron balance owing to menstruation. Iron deficiency affects more than a quarter of the world's population, but isolated nutritional iron deficiency is rare in developed countries. The most common cause of iron deficiency world-wide is blood loss from the gastrointestinal tract resulting from hookworm infestation. The poor quality of the diet, predominantly containing vegetables, also contributes to the high prevalence of iron deficiency in developing countries. Even in developed countries, iron deficiency is not uncommon in infancy where iron intake is insufficient for the demands of growth. It is more prevalent in infants born prematurely or where the introduction of mixed feeding is delayed.

Clinical features

The symptoms of anaemia are described on page 392. Other clinical features occur as a result of tissue iron deficiency. These are mainly epithelial changes induced by the effect of inadequate iron in the cells:

- brittle nails
- spoon-shaped nails (koilonychia)
- atrophy of the papillae of the tongue
- angular stomatitis
- brittle hair
- a syndrome of dysphagia and glossitis (Plummer–Vinson or Paterson–Brown–Kelly syndrome; see p. 255).

The diagnosis of iron deficiency anaemia relies on a clinical history with questions about dietary intake, regular self-

medication with non-steroidal anti-inflammatory drugs (which may give rise to gastrointestinal bleeding), and the presence of blood in the faeces (which may be a sign of haemorrhoids or carcinoma of the lower bowel). In women, a careful enquiry about the duration of periods, the occurrence of clots and the number of sanitary towels or tampons (normal 3–5/day) used should be made.

Investigations

- ***Blood count and film***. A characteristic blood film is shown in Figure 8.9. The red cells are microcytic (MCV < 80 fL) and hypochromic (MCH (mean corpuscular haemoglobin) < 27 pg). There is poikilocytosis (variation in shape) and anisocytosis (variation in size). Target cells are seen.
- ***Serum iron and iron-binding capacity***. The serum iron falls and the total iron-binding capacity (TIBC) rises in iron deficiency compared with normal. Iron deficiency is regularly present when the transferrin saturation (i.e. serum iron divided by TIBC) falls below 19% (Table 8.3).
- ***Serum ferritin***. The level of serum ferritin reflects the amount of stored iron. The normal values for serum ferritin are 30–300 μg/L (11.6–144 nmol/L) in males and 15–200 μg/L (5.8–96 nmol/L) in females. In simple iron deficiency, a low serum ferritin confirms the diagnosis. However, ferritin is an acute-phase reactant, and levels increase in the presence of inflammatory or malignant diseases. In these cases, measurement of serum iron/TIBC, serum ferritin and soluble transferrin receptors is used.
- ***Serum soluble transferrin receptors***. The number of transferrin receptors increases in iron deficiency. The results of this immunoassay compare well with results from bone marrow aspiration at estimating iron stores. This assay can help to distinguish between iron deficiency and anaemia of chronic disease (Table 8.3), and may avoid the need for bone marrow examination even in complex cases.
- ***Bone marrow***. Erythroid hyperplasia with ragged normoblasts is seen in the marrow in iron deficiency. Staining using Perls' reaction (acid ferrocyanide) does not show the characteristic Prussian-blue granules of stainable iron in the bone marrow fragments or in the erythroblasts. Examination of the bone marrow is not essential for the diagnosis of iron deficiency but it may be helpful in the investigation of complicated cases of anaemia, e.g. to determine if iron deficiency is present in a patient with anaemia of chronic disease.
- ***Other investigations***. These will be indicated by the clinical history and examination. Investigations of the gastrointestinal tract are often required to determine the cause of the iron deficiency (see p. 270).

Differential diagnosis

The presence of anaemia with microcytosis and hypochromia does not necessarily indicate iron deficiency. The most common other causes are thalassaemia, sideroblastic anaemia and anaemia of chronic disease, and in these disorders the iron stores are normal or increased. The differential diagnosis of microcytic anaemia is shown in Table 8.3.

Treatment

Iron deficiency is not a diagnosis per se. The correct management of iron deficiency is to find and treat the underlying cause, and to give iron to correct the anaemia and replace iron stores. The response to iron therapy can be monitored using the reticulocyte count and Hb level, with an expected rise in haemoglobin of 1 g/dL per week.

Oral iron is all that is required in most cases. The best preparation is ferrous sulphate (200 mg three times daily, a total of 180 mg ferrous iron), which is absorbed best when the patient is fasting. If the patient has side-effects such as nausea, diarrhoea or constipation, taking the tablets with food or reducing the dose using a preparation with less iron such as ferrous gluconate (300 mg twice daily, only 70 mg ferrous iron) is all that is usually required to reduce the symptoms. The use of expensive iron compounds, particularly the slow-release ones, which release iron beyond its main sites of absorption, is unnecessary.

In developing countries, distribution of iron tablets and fortification of food are the main approaches for the alleviation of iron deficiency. However, iron supplementation programmes have been ineffective, probably mainly because of poor compliance.

Oral iron should be given for long enough to correct the Hb level and to replenish the iron stores. This can take 6 months. The commonest causes of failure of response to oral iron are:

- lack of compliance
- continuing haemorrhage
- incorrect diagnosis, e.g. thalassaemia trait.

Table 8.3 Microcytic anaemia: the differential diagnosis

	Iron deficiency	Anaemia of chronic disease	Thalassaemia trait (α or β)	Sideroblastic anaemia
MCV	Reduced	Low normal or normal	Very low for degree of anaemia	Low in inherited type but often raised in acquired type
Serum iron	Reduced	Reduced	Normal	Raised
Serum TIBC	Raised	Reduced	Normal	Normal
Serum ferritin	Reduced	Normal or raised	Normal	Raised
Serum soluble transfer receptors	Increased	Normal	Normal or raised	Normal or raised
Iron in marrow	Absent	Present	Present	Present
Iron in erythroblasts	Absent	Absent or reduced	Present	Ring forms

TIBC, total iron binding capacity.

These possibilities should be considered before parenteral iron is used. However, parenteral iron is required by occasional patients, e.g. intolerant to oral preparation, severe malabsorption, chronic disease (e.g. inflammatory bowel disease). Iron stores are replaced much faster with parenteral iron than with oral iron, but the haematological response is no quicker. Parenteral iron can be given as repeated deep intramuscular injections of iron–sorbitol (1.5 mg of iron per kg bodyweight) or by intravenous infusion of low molecular weight iron dextran (test dose required) or iron sucrose.

Anaemia of chronic disease

One of the most common types of anaemia, particularly in hospital patients, is the anaemia of chronic disease, occurring in patients with chronic infections such as tuberculosis or chronic inflammatory disease such as Crohn's disease, rheumatoid arthritis, systemic lupus erythematosus (SLE), polymyalgia rheumatica and malignant disease. There is decreased release of iron from the bone marrow to developing erythroblasts, an inadequate erythropoietin response to the anaemia, and decreased red cell survival.

The exact mechanisms responsible for these effects are not clear but it now seems likely that high levels of hepcidin expression play a key role (see iron absorption).

The serum iron and the TIBC are low, and the serum ferritin is normal or raised because of the inflammatory process. The serum soluble transferrin receptor level is normal (Table 8.3). Stainable iron is present in the bone marrow, but iron is not seen in the developing erythroblasts. Patients do not respond to iron therapy, and treatment is, in general, that of the underlying disorder. Recombinant erythropoietin therapy is used in the anaemia of renal disease (see p. 633), and occasionally in inflammatory disease (rheumatoid arthritis, inflammatory bowel disease).

Sideroblastic anaemia

Sideroblastic anaemias are inherited or acquired disorders characterized by a refractory anaemia, a variable number of hypochromic cells in the peripheral blood, and excess iron and ring sideroblasts in the bone marrow. The presence of ring sideroblasts is the diagnostic feature of sideroblastic anaemia. There is accumulation of iron in the mitochondria of erythroblasts owing to disordered haem synthesis forming a ring of iron granules around the nucleus that can be seen with Perls' reaction. The blood film is often dimorphic; ineffective haem synthesis is responsible for the microcytic hypochromic cells. Sideroblastic anaemias are classified as shown in Table 8.4. A structural defect in δ-aminolaevulinic acid (ALA) synthase, the pyridoxine-dependent enzyme responsible for the first step in haem synthesis (Fig. 8.2), has been identified in one form of inherited sideroblastic anaemia. Primary acquired sideroblastic anaemia is one of the myelodysplastic syndromes (see p. 422). Lead toxicity is described on page 944.

Table 8.4 Classification of sideroblastic anaemia

Inherited
X-linked disease – transmitted by females
Acquired
Myelodysplasia
Myeloproliferative disorders
Myeloid leukaemia
Drugs, e.g. isoniazid
Alcohol abuse
Lead toxicity
Other disorders, e.g. rheumatoid arthritis, carcinoma, megaloblastic and haemolytic anaemias

Treatment

Some patients respond when drugs or alcohol are withdrawn, if these are the causative agents. In occasional cases, there is a response to pyridoxine. Treatment with folic acid may be required to treat accompanying folate deficiency.

NORMOCYTIC ANAEMIA

Normocytic, normochromic anaemia is seen in anaemia of chronic disease, in some endocrine disorders (e.g. hypopituitarism, hypothyroidism and hypoadrenalism) and in some haematological disorders (e.g. aplastic anaemia and some haemolytic anaemias) (Fig. 8.7). In addition, this type of anaemia is seen acutely following blood loss.

MACROCYTIC ANAEMIAS

These can be divided into megaloblastic and non-megaloblastic types, depending on bone marrow findings.

MEGALOBLASTIC ANAEMIA

Megaloblastic anaemia is characterized by the presence in the bone marrow of erythroblasts with delayed nuclear maturation because of defective DNA synthesis (megaloblasts). Megaloblasts are large and have large immature nuclei. The nuclear chromatin is more finely dispersed than normal and has an open stippled appearance (Fig. 8.10). In addition, giant metamyelocytes are frequently seen in megaloblastic anaemia. These cells are about twice the size of normal cells and often have twisted nuclei. Megaloblastic changes occur in:

- vitamin B_{12} deficiency or abnormal vitamin B_{12} metabolism
- folic acid deficiency or abnormal folate metabolism
- other defects of DNA synthesis, such as congenital enzyme deficiencies in DNA synthesis (e.g. orotic aciduria), or resulting from therapy with drugs interfering with DNA synthesis (e.g. hydroxycarbamide (hydroxyurea), azathioprine, zidovudine – AZT)
- myelodysplasia due to dyserythropoiesis.

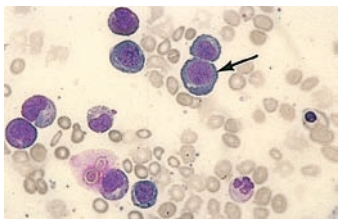

Fig. 8.10 **Megaloblasts (arrowed) in the bone marrow.**

Haematological findings

- Anaemia may be present. The MCV is characteristically >96 fL unless there is a coexisting cause of microcytosis when there may be a dimorphic picture with a normal/low average MCV.
- The peripheral blood film shows oval macrocytes with hypersegmented polymorphs with six or more lobes in the nucleus (Fig. 8.11).
- If severe, there may be leucopenia and thrombocytopenia.

Biochemical basis of megaloblastic anaemia

The key biochemical problem common to both vitamin B_{12} and folate deficiency is a block in DNA synthesis owing to an inability to methylate deoxyuridine monophosphate to deoxythymidine monophosphate, which is then used to build DNA (Fig. 8.12). The methyl group is supplied by the folate coenzyme, methylene tetrahydrofolate.

Deficiency of folate reduces the supply of this coenzyme; deficiency of vitamin B_{12} also reduces its supply by slowing the demethylation of methyltetrahydrofolate (methyl THF) and preventing cells receiving tetrahydrofolate for synthesis of methylene tetrahydrofolate polyglutamate.

Other congenital and acquired forms of megaloblastic anaemia are due to interference with purine or pyrimidine synthesis causing an inhibition in DNA synthesis.

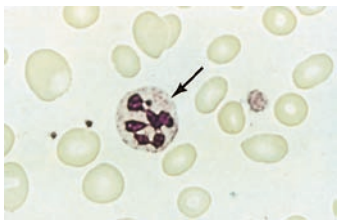

Fig. 8.11 **Macrocytes and a hypersegmented neutrophil (arrowed) on a peripheral blood film.**

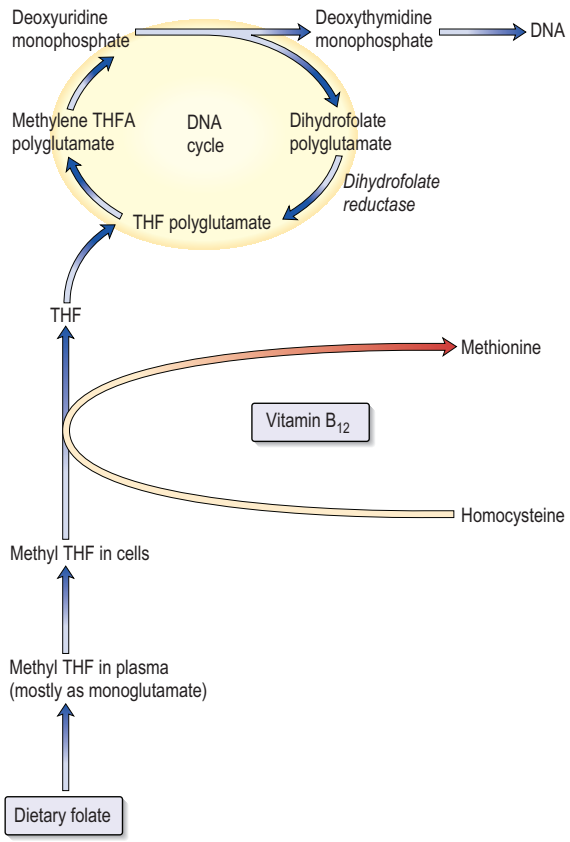

Fig. 8.12 **Biochemical basis of megaloblastic anaemia.** The metabolic relationship between vitamin B_{12} and folate and their role in DNA synthesis. THF, tetrahydrofolate.

Deoxyuridine suppression test

This is a useful method for rapidly determining the nature and severity of the vitamin B_{12} or folate deficiency in severe or complex cases of megaloblastic anaemia.

Tritiated thymidine is added to the patient's bone marrow in vitro. In a normoblastic marrow, the thymidine requirement is supplied by the methylation of deoxyuridine and this 'suppresses' the requirement for preformed tritiated thymidine to less than 5%. In a megaloblastic marrow, however, much more tritiated thymidine is used (5–50%). If the addition of B_{12} corrects the abnormality, it suggests that B_{12} is the cause of the deficiency. The addition of folate corrects the abnormality in both vitamin B_{12} and folate deficiency.

Vitamin B_{12}

Vitamin B_{12} is synthesized by certain microorganisms, and humans are ultimately dependent on animal sources. It is found in meat, fish, eggs and milk, but not in plants. Vitamin B_{12} is not usually destroyed by cooking. The average daily diet contains 5–30 µg of vitamin B_{12}, of which 2–3 µg is absorbed. The average adult stores some 2–3 mg, mainly in the liver, and it may take 2 years or more after absorptive failure before B_{12} deficiency develops, as the daily losses are small (1–2 µg).

Structure and function

Cobalamins consist of a planar group with a central cobalt atom (corrin ring) and a nucleotide set at right-angles (Fig. 8.13). Vitamin B_{12} was first crystallized as cyanocobalamin, but the main natural cobalamins have deoxyadenosyl-, methyl- and hydroxocobalamin groups attached to the cobalt atom.

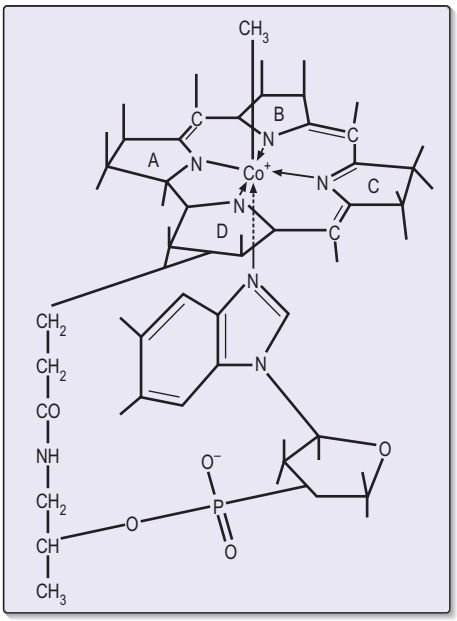

Fig. 8.13 **Methylcobalamin structure.** This is the main form of vitamin B_{12} in the plasma.

The main function of B_{12} is the methylation of homocysteine to methionine with the demethylation of methyl THF polyglutamate to THF. THF is a substrate for folate polyglutamate synthesis.

Deoxyadenosylcobalamin is a coenzyme for the conversion of methylmalonyl CoA to succinyl CoA. Measurement of methylmalonic acid in urine was used as a test for vitamin B_{12} deficiency but it is no longer carried out routinely.

Absorption and transport

Vitamin B_{12} is liberated from protein complexes in food by gastric enzymes and then binds to a vitamin B_{12}-binding protein ('R' binder) which is related to *plasma transcobalamin I* (TCI) and is derived from saliva. Vitamin B_{12} is released from the 'R' binder by pancreatic enzymes and then becomes bound to intrinsic factor.

Intrinsic factor is a glycoprotein with a molecular weight of 45 000. It is secreted by gastric parietal cells along with H^+ ions. It combines with vitamin B_{12} and carries it to specific receptors on the surface of the mucosa of the ileum. Vitamin B_{12} enters the ileal cells and intrinsic factor remains in the lumen and is excreted. Vitamin B_{12} is transported from the enterocytes to the bone marrow and other tissues by the *glycoprotein transcobalamin II* (TCII). Although TCII is the essential carrier protein for vitamin B_{12}, the amount of B_{12} on TCII is low. However, it has a rapid clearance and is able to deliver cobalamin to all cells of the body. Vitamin B_{12} in plasma is mainly bound to TCI (70–90%), but the functional role of this protein is unknown. About 1% of an oral dose of B_{12} is absorbed 'passively' without the need for intrinsic factor.

Vitamin B_{12} deficiency

There are a number of causes of B_{12} deficiency and abnormal B_{12} metabolism (Table 8.5). The most common cause of vitamin B_{12} deficiency in adults is pernicious anaemia. Malabsorption of vitamin B_{12} because of pancreatitis, coeliac disease or treatment with metformin is mild and does not usually result in significant vitamin B_{12} deficiency.

Pernicious anaemia

Pernicious anaemia (PA) is an autoimmune disorder in which there is atrophic gastritis with loss of parietal cells in the gastric mucosa with consequent failure of intrinsic factor production and vitamin B_{12} malabsorption.

Table 8.5 Vitamin B_{12} deficiency and abnormal B_{12} utilization: further causes (see text)

Low dietary intake	Abnormal utilization
Vegans	Congenital transcobalamin II deficiency
	Nitrous oxide (inactivates B_{12})
Impaired absorption	
Stomach	
Pernicious anaemia	
Gastrectomy	
Congenital deficiency of intrinsic factor	
Small bowel	
Ileal disease or resection	
Bacterial overgrowth	
Tropical sprue	
Fish tapeworm (*Diphyllobothrium latum*)	

Pathogenesis of pernicious anaemia

This disease is common in the elderly, with 1 in 8000 of the population aged over 60 years being affected in the UK. It can be seen in all races, but occurs more frequently in fair-haired and blue-eyed individuals, and those who have the blood group A. It is more common in females than males.

There is an association with other autoimmune diseases, particularly thyroid disease, Addison's disease and vitiligo. Approximately one-half of all patients with PA have thyroid antibodies. There is a higher incidence of gastric carcinoma with PA (1–3%) than in the general population.

Parietal cell antibodies are present in the serum in 90% of patients with PA – and also in many older patients with gastric atrophy. Conversely, intrinsic factor antibodies, although found in only 50% of patients with PA, are specific for this diagnosis. Two types of intrinsic factor antibodies are found: a blocking antibody, which inhibits binding of intrinsic factor to B_{12}, and a precipitating antibody, which inhibits the binding of the B_{12}–intrinsic factor complex to its receptor site in the ileum.

B_{12} deficiency may rarely occur in children from a congenital deficiency or abnormality of intrinsic factor, or as a result of early onset of the adult autoimmune type.

Pathology

Autoimmune gastritis (see p. 263) affecting the fundus is present with plasma cell and lymphoid infiltration. The parietal and chief cells are replaced by mucin-secreting cells. There is achlorhydria and absent secretion of intrinsic factor. The histological abnormality can be improved by corticosteroid therapy, which supports an autoimmune basis for the disease.

Clinical features

The onset of PA is insidious, with progressively increasing symptoms of anaemia. Patients are sometimes said to have a lemon-yellow colour owing to a combination of pallor and mild jaundice caused by excess breakdown of haemoglobin. A red sore tongue (glossitis) and angular stomatitis are sometimes present.

The neurological changes, if left untreated for a long time, can be irreversible. These neurological abnormalities occur only with very low levels of serum B_{12} (less than 60 ng/L or 50 pmol/L) and occasionally occur in patients who are not clinically anaemic. The classical neurological features are those of a polyneuropathy progressively involving the peripheral nerves and the posterior and eventually the lateral columns of the spinal cord (subacute combined degeneration; see p. 1175). Patients present with symmetrical paraesthesiae in the fingers and toes, early loss of vibration sense and proprioception, and progressive weakness and ataxia. Paraplegia may result. Dementia, psychiatric problems, hallucinations, delusions, and optic atrophy may occur from vitamin B_{12} deficiency.

Investigations

- **Haematological findings** show the features of a megaloblastic anaemia as described on page 398.
- **Bone marrow** shows the typical features of megaloblastic erythropoiesis (Fig. 8.10), although

it is frequently not performed in cases of straightforward macrocytic anaemia and a low serum vitamin B_{12}.

- **Serum bilirubin** may be raised as a result of ineffective erythropoiesis. Normally a minor fraction of serum bilirubin results from premature breakdown of newly formed red cells in the bone marrow. In many megaloblastic anaemias, where the destruction of developing red cells is much increased, the serum bilirubin can be increased. LDH can also be raised due to haemolysis.
- **Serum methylmalonic acid (MMA) and homocysteine (HC)** are raised in B_{12} deficiency. They are only useful in cases where the B_{12} and folate levels are not conclusive with only HC raised in folate deficiency.
- **Serum vitamin B_{12}** is usually well below 160 ng/L, which is the lower end of the normal range. Serum vitamin B_{12} can be assayed using radioisotope dilution or immunological assays.
- **Serum folate level** is normal or high, and the red cell folate is normal or reduced owing to inhibition of normal folate synthesis.

Absorption tests

Vitamin B_{12} absorption tests are performed only occasionally when the underlying cause of the B_{12} deficiency is not obvious. They cannot be performed in the UK as radioactive B_{12} is not available. However, the principle of the absorption test is useful.

Schilling test. Radioactive B_{12} is given orally followed by an i.m. injection of non-radioactive B_{12} to saturate B_{12} binding proteins and to flush out ^{58}Co-B_{12}. The urine is collected for 24 hours and >10% of the oral dose would be excreted in a normal person. If this is abnormal, the test is repeated with the addition of oral intrinsic factor capsules. If the excretion is now normal, the diagnosis is pernicious anaemia or gastrectomy. If the excretion is still abnormal, the lesion must be in the terminal ileum or there may be bacterial overgrowth. The latter could be confirmed by repeating the test after a course of antibiotics.

Gastrointestinal investigations

In PA there is achlorhydria. Intubation studies can be performed to confirm this but are rarely carried out in routine practice. Endoscopy or barium meal examination of the stomach is performed only if gastric symptoms are present.

Differential diagnosis

Vitamin B_{12} deficiency must be differentiated from other causes of megaloblastic anaemia, principally folate deficiency, but usually this is quite clear from the blood level of these two vitamins.

Pernicious anaemia should be distinguished from other causes of vitamin B_{12} deficiency (Table 8.5). Any disease involving the terminal ileum or bacterial overgrowth in the small bowel can produce vitamin B_{12} deficiency (see p. 280). Gastrectomy can lead, in the long term, to vitamin B_{12} deficiency. Vegans are strict vegetarians and eat no meat or animal products and prophylactic B_{12} should be given.

Treatment

See page 401.

Folic acid

Folic acid monoglutamate is not itself present in nature but occurs as polyglutamates (extra glutamic acid residues). Folates are present in food as polyglutamates in the reduced dihydrofolate or tetrahydrofolate (THF) forms (Fig. 8.14), with methyl (CH_3), formyl (CHO) or methylene (CH_2) groups attached to the pteridine part of the molecule. Polyglutamates are broken down to monoglutamates in the upper gastrointestinal tract, and during the absorptive process these are converted to methyl THF monoglutamate, which is the main form in the serum. The methylation of homocysteine to methionine requires both methylcobalamin and methyl THF as coenzymes. This reaction is the first step in which methyl THF entering cells from the plasma is converted into folate polyglutamates. Intracellular polyglutamates are the active forms of folate and act as coenzymes in the transfer of single carbon units in amino acid metabolism and DNA synthesis (Fig. 8.12).

Dietary intake

Folate is found in green vegetables such as spinach and broccoli, and offal, such as liver and kidney. Cooking causes a loss of 60–90% of the folate. The minimal daily requirement is about 100 μg.

Folate deficiency

The causes of folate deficiency are shown in Table 8.6. The main cause is poor intake, which may occur alone or in combination with excessive utilization or malabsorption. The

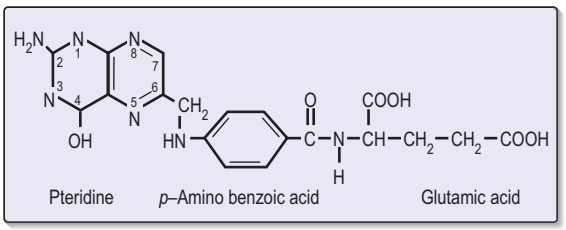

Fig. 8.14 **Folic acid structure.** This is formed from three building blocks as shown. Tetrahydrofolate has additional hydrogen atoms at positions 5, 6, 7 and 8.

Table 8.6 Causes of folate deficiency

Nutritional (major cause)

Poor intake
Old age
Poor social conditions
Starvation
Alcohol excess (also causes impaired utilization)

Poor intake due to anorexia
Gastrointestinal disease, e.g. partial gastrectomy, coeliac disease, Crohn's disease
Cancer

Antifolate drugs
Anticonvulsants:
Phenytoin
Primidone
Methotrexate
Pyrimethamine
Trimethoprim

Excess utilization

Physiological
Pregnancy
Lactation
Prematurity

Pathological
Haematological disease with excess red cell production, e.g. haemolysis
Malignant disease with increased cell turnover
Inflammatory disease
Metabolic disease, e.g. homocystinuria
Haemodialysis or peritoneal dialysis

Malabsorption
Occurs in small bowel disease, but the effect is minor compared with that of anorexia

body's reserves of folate, unlike vitamin B_{12}, are low (about 10 mg). On a deficient diet, folate deficiency develops over the course of about 4 months, but folate deficiency may develop rapidly in patients who have both a poor intake and excess utilization of folate (e.g. patients in intensive care units).

There is no simple relationship between maternal folate status and fetal abnormalities but folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce the incidence of neural tube defects. Despite worldwide public health campaigns recommending periconceptional daily supplementation of synthetic folic acid to reduce the risk of neural tube defects, many women are not following these recommendations. In the USA and Canada mandatory fortification of grain products, e.g. bread, flour and rice, has substantially improved folate status and has been associated with a significant fall in neural tube defects.

Clinical features

Patients with folate deficiency may be asymptomatic or present with symptoms of anaemia or of the underlying cause. Glossitis can occur. Unlike with B_{12} deficiency, neuropathy does not occur.

Investigations

The haematological findings are those of a megaloblastic anaemia as discussed on page 398.

Blood measurements

Serum and red cell folate are assayed by radioisotope dilution or immunological methods. Normal levels of serum folate are 4–18 μg/L (5–63 nmol/L). The amount of folate in the red cells is a better measure of tissue folate; the normal range is 160–640 μg/mL.

Further investigations

In many cases of folate deficiency the cause is not obvious from the clinical picture or dietary history. Occult gastrointestinal disease should then be suspected and appropriate investigations, such as small bowel biopsy, should be performed.

Treatment and prevention of megaloblastic anaemia

Treatment depends on the type of deficiency. Blood transfusion is not indicated in chronic anaemia; indeed, it is dangerous to transfuse elderly patients, as heart failure may be precipitated. Folic acid may produce a haematological response in vitamin B_{12} deficiency but may aggravate the neuropathy. Large doses of folic acid alone should not be used to treat megaloblastic anaemia unless the serum vitamin B_{12} level is known to be normal. In severely ill patients, it may be necessary to treat with both folic acid and vitamin B_{12} while awaiting serum levels.

Treatment of vitamin B_{12} deficiency

Hydroxocobalamin 1000 μg can be given intramuscularly to a total of 5–6 mg over the course of 3 weeks; 1000 μg is then necessary every 3 months for the rest of the patient's life. Alternatively, it is now recommended that oral B_{12} 2 mg per day is given, as 1–2% of an oral dose is absorbed by diffusion and therefore does not require intrinsic factor.

Compliance with an oral daily regimen may be a problem, particularly in elderly patients. The use of sublingual nuggets of B_{12} (2×1000 μg daily) has been suggested to be an effective and more convenient option.

Clinical improvement may occur within 48 hours and a reticulocytosis can be seen some 2–3 days after starting therapy, peaking at 5–7 days. Improvement of the polyneuropathy may occur over 6–12 months, but longstanding spinal cord damage is irreversible. Hypokalaemia can occur and, if severe, supplements should be given. Iron deficiency often develops in the first few weeks of therapy. Hyperuricaemia also occurs but clinical gout is uncommon. In patients who have had a total gastrectomy or an ileal resection, vitamin B_{12} should be monitored; if low levels occur, prophylactic vitamin B_{12} should be given.

Treatment of folate deficiency

Folate deficiency can be corrected by giving 5 mg of folic acid daily; the same haematological response occurs as seen after treatment of vitamin B_{12} deficiency. Treatment should be given for about 4 months to replace body stores. Any underlying cause, e.g. coeliac disease, should be treated.

Prophylactic folic acid (400 μg daily) is recommended for all women planning a pregnancy to reduce neural tube defects. Many authorities also recommend prophylactic administration of folate throughout pregnancy. Whether this can be achieved by increased consumption of foods with a high folate content or whether women should take folate supplements is under debate.

Women who have had a child with a neural tube defect should take 5 mg folic acid daily before and during a subsequent pregnancy.

Prophylactic folic acid is also given in chronic haematological disorders where there is rapid cell turnover. A dose of 5 mg each week is probably sufficient.

MACROCYTOSIS WITHOUT MEGALOBLASTIC CHANGES

A raised MCV with macrocytosis on the peripheral blood film can occur with a normoblastic rather than a megaloblastic bone marrow.

A common *physiological* cause of macrocytosis is pregnancy. Macrocytosis may also occur in the newborn.

Common *pathological* causes are:

- alcohol excess
- liver disease
- reticulocytosis
- hypothyroidism
- some haematological disorders (e.g. aplastic anaemia, sideroblastic anaemia, pure red cell aplasia)
- drugs (e.g. cytotoxics – azathioprine)
- spurious (agglutinated red cells measured on red cell counters)
- cold agglutinins due to autoagglutination of red cells (see p. 416) (the MCV decreases to normal with warming of the sample to 37°C).

In all these conditions, normal serum levels of vitamin B_{12} and folate will be found. The exact mechanisms in each case are uncertain, but in some there is increased lipid deposition in the red cell membrane.

An increased number of reticulocytes leads to a raised MCV because they are large cells.

Alcohol is a frequent cause of a raised MCV in an otherwise normal individual. A megaloblastic anaemia can also occur in people who abuse alcohol; this is due to a toxic effect of alcohol on erythropoiesis or to dietary folate deficiency.

ANAEMIA DUE TO MARROW FAILURE (APLASTIC ANAEMIA)

Aplastic anaemia is defined as pancytopenia with hypocellularity (aplasia) of the bone marrow; there are no leukaemic, cancerous or other abnormal cells in the peripheral blood or bone marrow. It is an uncommon but serious condition that may be inherited but is more commonly acquired.

Aplastic anaemia is due to a reduction in the number of pluripotential stem cells (Fig. 8.1) together with a fault in those remaining or an immune reaction against them so that they are unable to repopulate the bone marrow. Failure of only one cell line may also occur, resulting in isolated deficiencies such as the absence of red cell precursors in pure red cell aplasia. Evolution to myelodysplasia, paroxysmal nocturnal haemoglobinuria (PNH) or acute myeloblastic leukaemia occurs in some cases, probably owing to the emergence of an abnormal clone of haemopoietic cells.

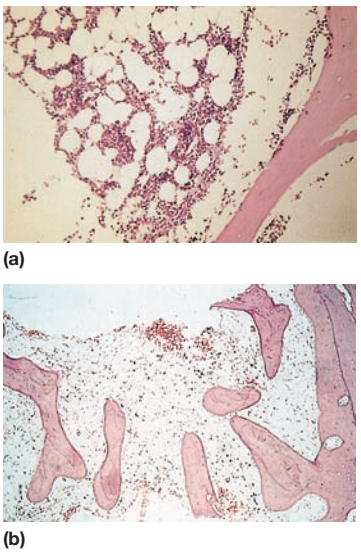
Causes

A list of causes of aplasia is given in Table 8.7. Immune mechanisms are probably responsible for most cases of idiopathic acquired aplastic anaemia and play a part in at least the persistence of many secondary cases. Activated cytotoxic T cells in blood and bone marrow are responsible for the bone marrow failure.

Many drugs may cause marrow aplasia, including cytotoxic drugs such as busulfan and doxorubicin, which are expected to cause transient aplasia as a consequence of their therapeutic use. However, some individuals develop aplasia due to sensitivity to non-cytotoxic drugs such as chloramphenicol, gold, carbimazole, chlorpromazine, phenytoin, ribovirin, tolbutamide, non-steroidal anti-inflammatory agents, and many others which have been reported to cause occasional cases of aplasia.

Congenital aplastic anaemias are rare. Gene mutations are being identified, e.g. the telomerase RNA component, and have been seen in one-third of aplastic anaemias. Fanconi's anaemia is inherited as an autosomal recessive and is associated with skeletal, renal and central nervous system abnormalities. It usually presents between the ages of 5 and 10 years.

Clinical features



The clinical manifestations of marrow failure from any cause are anaemia, bleeding and infection. Bleeding is often the predominant initial presentation of aplastic anaemia with bruising with minimal trauma or blood blisters in the mouth. Physical findings include ecchymoses, bleeding gums and epistaxis. Mouth infections are common. Lymphadenopathy and hepatosplenomegaly are rare in aplastic anaemia.

Investigations

- Pancytopenia
- The virtual absence of reticulocytes
- A hypocellular or aplastic bone marrow with increased fat spaces (Fig. 8.15).

Differential diagnosis

This is from other causes of pancytopenia (Table 8.8). A bone marrow trephine is essential for assessment of the bone marrow cellularity.

(a)

(b)

Fig. 8.15 **Bone marrow trephine biopsies in low-power view. (a)** Normal cellularity. **(b)** Hypocellularity in aplastic anaemia.

Table 8.7 Causes of aplastic anaemia

Primary
Congenital, e.g. Fanconi's anaemia
Idiopathic acquired (67% of cases)

Secondary
Chemicals, e.g. benzene, toluene, glue sniffing
Drugs:
- e.g. chemotherapeutic (idiosyncratic reactions)
- Antibiotics, e.g. chloramphenicol, gold, penicillamine, phenytoin, carbamazepine, carbimazole

Insecticides
Ionizing radiation
Infections:
- Viral, e.g. hepatitis, EBV, HIV,erythrovirus
- Other, e.g. tuberculosis

Paroxysmal nocturnal haemoglobinuria
Miscellaneous, e.g. pregnancy

Table 8.8 Causes of pancytopenia

Aplastic anaemia (see Table 8.7)
Drugs
Megaloblastic anaemia
Bone marrow infiltration or replacement:
- Hodgkin's and non-Hodgkin's lymphoma
- Acute leukaemia
- Myeloma
- Secondary carcinoma:
  - Myelofibrosis

Hypersplenism
Systemic lupus erythematosus
Disseminated tuberculosis
Paroxysmal nocturnal haemoglobinuria
Overwhelming sepsis

Treatment and prognosis

The treatment of aplastic anaemia depends on providing supportive care while awaiting bone marrow recovery and specific treatment to accelerate marrow recovery.

The main danger is infection and stringent measures should be undertaken to avoid this (see also p. 461). Any suspicion of infection in a severely neutropenic patient should lead to immediate institution of broad-spectrum parenteral antibiotics. Supportive care including transfusions of red cells and platelets should be given as necessary. The cause of the aplastic anaemia must be eliminated if possible.

The course of aplastic anaemia can be variable, ranging from a rapid spontaneous remission to a persistent increasingly severe pancytopenia, which may lead to death through haemorrhage or infection. The most reliable determinants for the prognosis are the number of neutrophils, reticulocytes, platelets, and the cellularity of the bone marrow.

A bad prognosis (i.e. severe aplastic anaemia) is associated with the presence of two of the following three features:

- neutrophil count of $<0.5 \times 10^9$/L
- platelet count of $<20 \times 10^9$/L
- reticulocyte count of $<40 \times 10^9$/L.

In severe aplastic anaemia, there is a very poor outcome without treatment.

Bone marrow transplantation is the treatment of choice for some patients. For the patients *under the age of 40* who fail to respond to immunosuppression, bone marrow transplantation using unrelated donors is an option, but the results are poor (5-year survival of only 30%) owing to a high incidence of graft rejection, graft-versus-host disease and viral infections. For those with an HLA-identical sibling donor, it gives a 75–90% chance of long-term survival and restoring the blood count to normal. Patients *over the age of 40* are not eligible for bone marrow transplantation whether an HLA-identical donor is available or not, because of the high risk of graft-versus-host disease as a complication of bone marrow transplantation. Immunosuppressive therapy is used for patients without HLA-matched siblings and those over the age of 40 years; antilymphocyte globulin (ALG) and ciclosporin in combination give a response rate of 60–80%.

Levels of haemopoietic growth factors (Fig. 8.1) are normal or increased in most patients with aplastic anaemia, and are ineffective as primary treatment.

Androgens (e.g. oxymetholone) are sometimes useful in patients not responding to immunosuppression and in patients with moderately severe aplastic anaemia.

Steroids have little activity in severe aplastic anaemia but are used for serum sickness due to ALG. They are also used to treat children with congenital pure red cell aplasia (Diamond–Blackfan syndrome). Adult pure red cell aplasia is associated with a thymoma in 30% of cases and thymectomy may induce a remission. It may also be associated with autoimmune disease or may be idiopathic. Steroids and ciclosporin are effective treatment in some cases.

HAEMOLYTIC ANAEMIAS: AN INTRODUCTION

Haemolytic anaemias are caused by increased destruction of red cells. The red cell normally survives about 120 days, but in haemolytic anaemias the red cell survival times are considerably shortened.

Breakdown of normal red cells occurs in the macrophages of the bone marrow, liver and spleen (Fig. 8.5).

Consequences of haemolysis (Fig. 8.16)

Shortening of red cell survival does not always cause anaemia as there is a compensatory increase in red cell production by the bone marrow. If the red cell loss can be contained within the marrow's capacity for increased output, then a haemolytic state can exist without anaemia (*compensated haemolytic disease*). The bone marrow can increase its output by six to eight times by increasing the proportion of cells committed to erythropoiesis (*erythroid hyperplasia*) and by expanding the volume of active marrow. In addition, immature red cells (*reticulocytes*) are released prematurely. These cells are larger than mature cells and stain with a light blue tinge on a peripheral blood film (the description of this appearance on the blood film is *polychromasia*). Reticulocytes may be counted accurately as a percentage of all red cells on a blood film using a supravital stain for residual RNA (e.g. new methylene blue).

Sites of haemolysis

Extravascular haemolysis

In most haemolytic conditions red cell destruction is extravascular. The red cells are removed from the circulation by macrophages in the reticuloendothelial system, particularly the spleen.

Intravascular haemolysis

When red cells are rapidly destroyed within the circulation, haemoglobin is liberated (Fig. 8.17). This is initially bound to plasma haptoglobins but these soon become saturated.

Excess free plasma Hb is filtered by the renal glomerulus and enters the urine, although small amounts are reabsorbed by the renal tubules. In the renal tubular cell, Hb is broken down and becomes deposited in the cells as *haemosiderin*. This can be detected in the spun sediment of urine using Perls' reaction. Some of the free plasma Hb is oxidized to *methaemoglobin*, which dissociates into *ferrihaem* and globin. *Plasma haemopexin* binds ferrihaem; but if its binding capacity is exceeded, ferrihaem becomes attached to albumin, forming *methaemalbumin*. On spectrophotometry of the plasma, methaemalbumin forms a characteristic band; this is the basis of *Schumm's test*.

The *liver* plays a major role in removing Hb bound to haptoglobin and haemopexin and any remaining free Hb.

Evidence for haemolysis

Increased red cell breakdown is accompanied by increased red cell production. This is shown in Figure 8.16.

Demonstration of shortened red cell lifespan

Red cell survival can be estimated from ^{51}Cr-labelled red cells given intravenously but is rarely performed.

Intravascular haemolysis

This is suggested by raised levels of plasma Hb, haemosiderinuria, very low or absent haptoglobins, and the presence of methaemalbumin (positive Schumm's test).

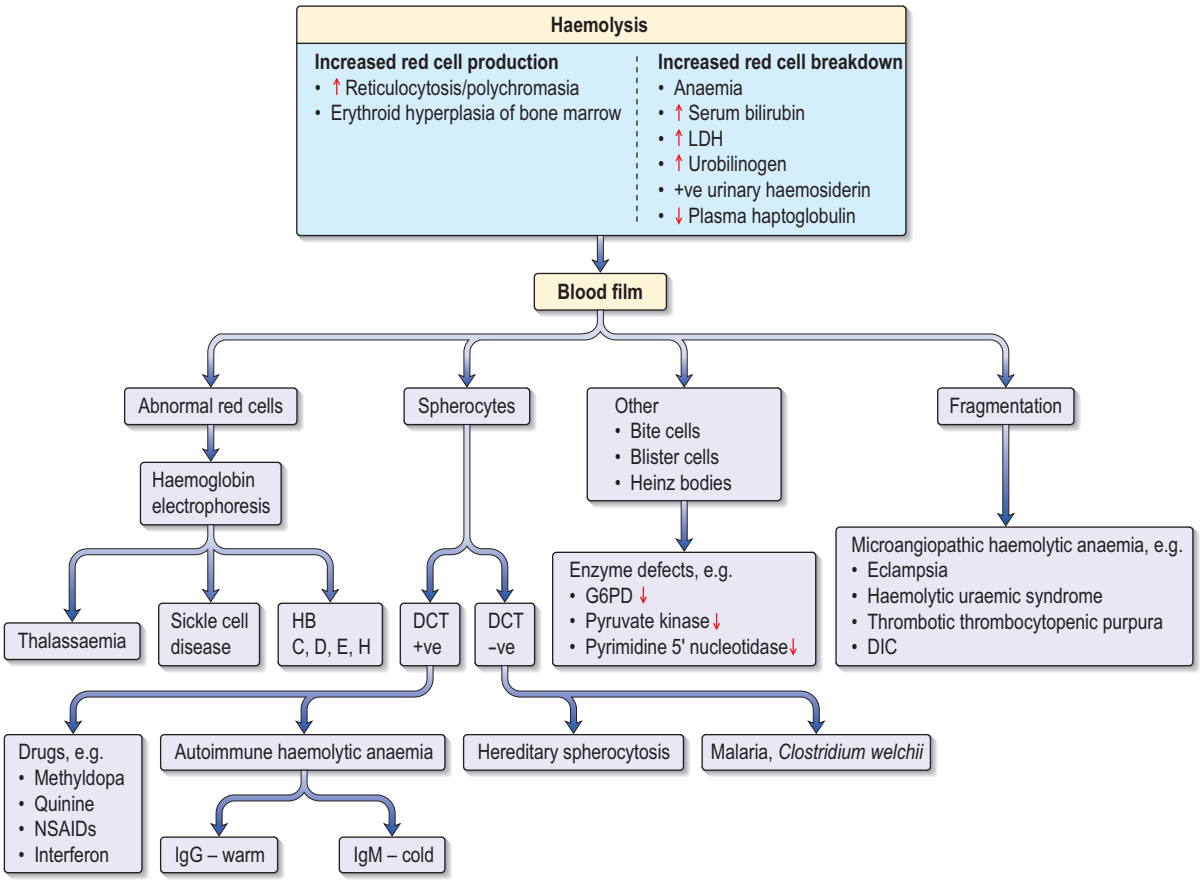

Fig. 8.16 **Haemolysis.** DCT, direct Coombs' test; G6PD, glucose-6-phosphate dehydrogenase; LDH, lactate dehydrogenase.

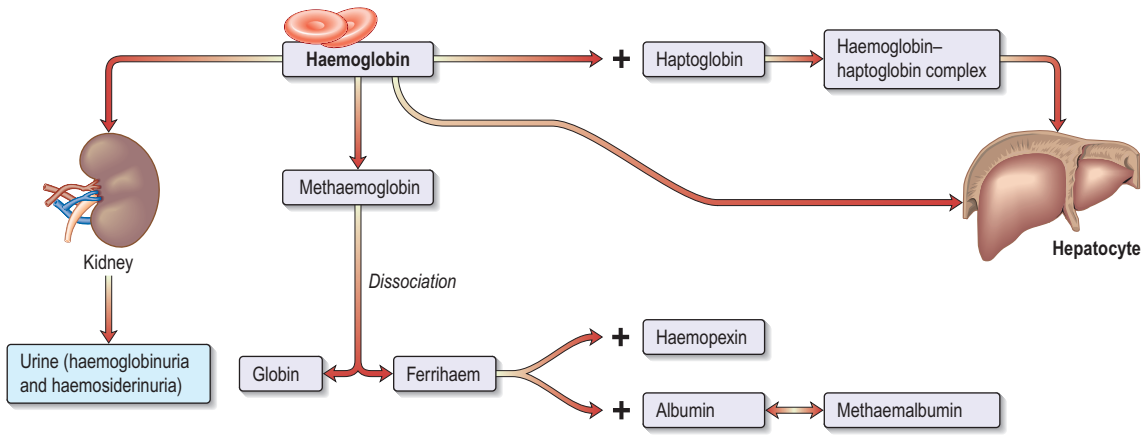

Fig. 8.17 **The fate of haemoglobin in the plasma following haemolysis.**

Various laboratory studies will be necessary to determine the exact type of haemolytic anaemia present. The causes of haemolytic anaemias are shown in Table 8.9.

INHERITED HAEMOLYTIC ANAEMIA

RED CELL MEMBRANE DEFECTS

The normal red cell membrane consists of a lipid bilayer crossed by integral proteins with an underlying lattice of proteins (or cytoskeleton), including spectrin, actin, ankyrin and protein 4.1, attached to the integral proteins (Fig. 8.18).

Hereditary spherocytosis (HS)

HS is the most common inherited haemolytic anaemia in northern Europeans, affecting 1 in 5000. It is inherited in an autosomal dominant manner, but in 25% of patients neither parent is affected and it is presumed that HS has occurred by spontaneous mutation. HS is due to defects in the red cell membrane, resulting in the cells losing part of the cell membrane as they pass through the spleen, possibly because the lipid bilayer is inadequately supported by the membrane

skeleton. The best-characterized defect is a deficiency in the structural protein spectrin, but quantitative defects in other membrane proteins have been identified (Fig. 8.18), with ankyrin defects being the most common. The abnormal red cell membrane in HS is associated functionally with an increased permeability to sodium, and this requires an increased rate of active transport of sodium out of the cells which is dependent on ATP produced by glycolysis. The surface-to-volume ratio decreases, and the cells become spherocytic. Spherocytes are more rigid and less deformable than normal red cells. They are unable to pass through the splenic microcirculation so they have a shortened lifespan.

Clinical features

The condition may present with jaundice at birth. However, the onset of jaundice can be delayed for many years and some patients may go through life with no symptoms and are detected only during family studies. The patient may eventually develop anaemia, splenomegaly and ulcers on the leg. As in many haemolytic anaemias, the course of the disease may be interrupted by aplastic, haemolytic and megaloblastic crises. Aplastic anaemia usually occurs after infections, particularly with erythro(parvo)virus, whereas megaloblastic anaemia is the result of folate depletion owing to the hyperactivity of the bone marrow. Chronic haemolysis leads to the formation of pigment gallstones (see p. 367).

Table 8.9 Causes of haemolytic anaemia

Inherited

Red cell membrane defect
Hereditary spherocytosis
Hereditary elliptocytosis

Haemoglobin abnormalities
Thalassaemia
Sickle cell disease

Metabolic defects
Glucose-6-phosphate dehydrogenase deficiency
Pyruvate kinase deficiency
Pyrimidine kinase deficiency

Miscellaneous
Infections, e.g. malaria, mycoplasma
Clostridium welchii, generalized sepsis
Drugs and chemicals causing damage to the red cell membrane or oxidative haemolysis
Hypersplenism
Burns

Acquired

Immune
Autoimmune (see Table 8.15)
- Warm
- Cold

Alloimmune
- Haemolytic transfusion reactions
- Haemolytic disease of the newborn
- After allogeneic bone marrow or organ transplantation

Drug-induced

Non-immune
Acquired membrane defects
- Paroxysmal nocturnal haemoglobinuria

Mechanical
- Microangiopathic haemolytic anaemia
- Valve prosthesis
- March haemoglobinuria

Secondary to systemic disease
- Renal and liver failure

Investigations

- **Anaemia**. This is usually mild, but occasionally can be severe.
- **Blood film**. This shows spherocytes (Fig. 8.19) and reticulocytes.
- **Haemolysis** is evident (e.g. the serum bilirubin and urinary urobilinogen will be raised).
- **Osmotic fragility**. When red cells are placed in solutions of increasing hypotonicity, they take in water, swell, and eventually lyse. Spherocytes tolerate hypotonic solutions less well than do normal biconcave red cells. Osmotic fragility tests are infrequently carried out in routine practice, but may be useful to confirm a suspicion of spherocytosis on a blood film.
- **Direct antiglobulin (Coombs') test** is negative in hereditary spherocytosis, virtually ruling out autoimmune haemolytic anaemia where spherocytes are also commonly present.

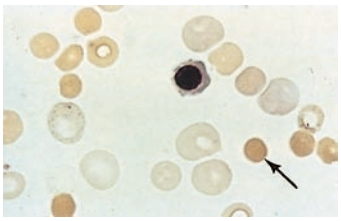

Fig. 8.19 **Spherocytes (arrowed). This blood film also shows reticulocytes, polychromasia and a nucleated erythroblast.**

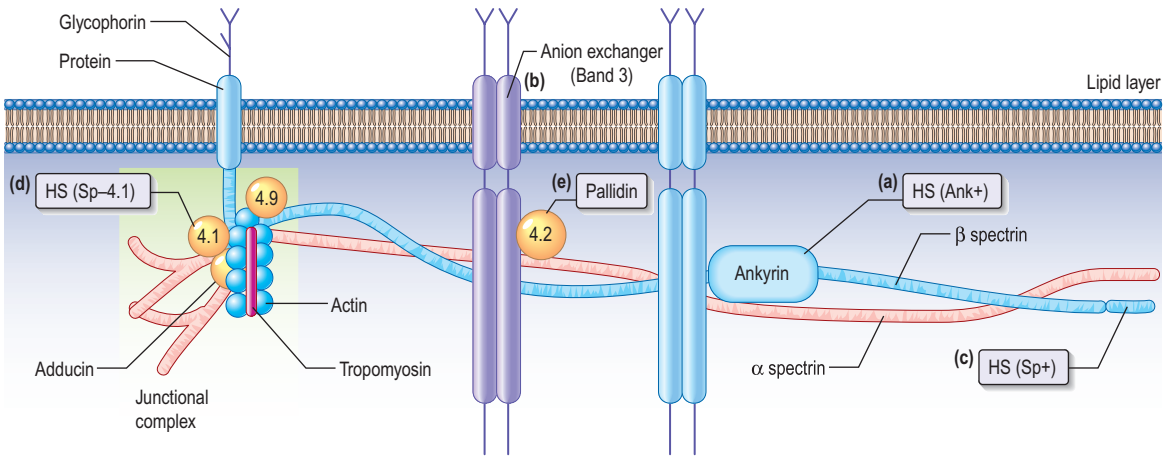

Fig. 8.18 **Hereditary spherocytosis (HS) and hereditary elliptocytosis (HE): red cell membrane showing the sites (purple) of the principal defects.** Vertical interactions producing HS: **(a)** ankyrin mutation, HS (Ank+) producing deficiency (45% of cases); **(b)** HS band 3 deficiency (20%); **(c)** β spectrin deficiency, HS (Sp+) (<20%); **(d)** abnormal spectrin/protein 4.1 binding, HS (Sp–4.1); **(e)** protein 4.2 (pallidin) deficiency (Japanese). These produce various autosomal dominant and recessive forms of the disease. Horizontal interactions producing HE: α spectrin (80%), protein 4.1 (15%), β spectrin (5%).

Treatment

The spleen, which is the site of cell destruction, should be removed in all but the mildest cases. The decision about splenectomy in symptomless patients is difficult, but a raised bilirubin and especially the presence of gallstones should encourage splenectomy.

It is best to postpone splenectomy until after childhood, as sudden overwhelming fatal infections, usually due to encapsulated organisms such as pneumococci, may occur (see p. 423). Splenectomy should be preceded by appropriate immunization and followed by lifelong penicillin prophylaxis (see Box 8.3).

Following splenectomy, the spherocytes persist but the Hb level usually returns to normal as the red cells are no longer destroyed.

Folate deficiency often occurs in chronic haemolysis with rapid cell turnover. Folate levels should be monitored, or folic acid can be given prophylactically.

Hereditary elliptocytosis

This disorder of the red cell membrane is inherited in an autosomal dominant manner and has a prevalence of 1 in 2500 in Caucasians. The red cells are elliptical due to deficiencies of protein 4.1 or the spectrin/actin/4.1 complex which leads to weakness of the horizontal protein interaction and to the membrane defect (Fig. 8.18). Clinically it is a similar condition to HS but milder. Only a minority of patients have anaemia and only occasional patients require splenectomy.

Rarely, hereditary spherocytosis or elliptocytosis may be inherited in a homozygous fashion giving rise to a severe haemolytic anaemia sometimes necessitating splenectomy in early childhood.

Hereditary stomatocytosis

Stomatocytes are red cells in which the pale central area appears slit-like. Their presence in large numbers may occur in a hereditary haemolytic anaemia associated with a membrane defect, but excess alcohol intake is also a common cause. Although these hereditary conditions are very rare, a correct diagnosis is required since splenectomy is surprisingly contraindicated as it may result in fatal thromboembolic events.

HAEMOGLOBIN ABNORMALITIES

In early embryonic life, haemoglobins Gower 1, Gower 2 and Portland predominate (Fig. 8.20). Later, fetal haemoglobin (Hb F), which has two α and two γ chains, is produced. There is increasing synthesis of β chains from 13 weeks of gestation and at term there is 80% Hb F and 20% Hb A. The switch from Hb F to Hb A occurs after birth when the genes for γ chain production are further suppressed and there is rapid increase in the synthesis of β chains. The exact mechanism responsible for the switch remains unknown. There is little Hb F produced (normally less than 1%) from 6 months after birth. The δ chain is synthesized just before birth and Hb A_2 ($\alpha_2\beta_2$) remains at a level of about 2% throughout adult life (Table 8.10).

Globin chains are synthesized in the same way as any protein (see p. 31). Four globin chain genes are required to control α-chain production (Fig. 8.20). Two are present on each haploid genome (genes derived from one parent). These are situated close together on chromosome 16. The genes controlling the production of ε, γ, δ and β chains are close together on chromosome 11. The globin genes are arranged on chromosomes 16 and 11 in the order in which they are expressed and combine to give different haemoglobins. Normal haemoglobin synthesis is discussed on page 390.

Abnormal haemoglobins

Abnormalities occur in:

- globin chain production (e.g. thalassaemia)
- structure of the globin chain (e.g. sickle cell disease)
- combined defects of globin chain production and structure, e.g. sickle cell β-thalassaemia.

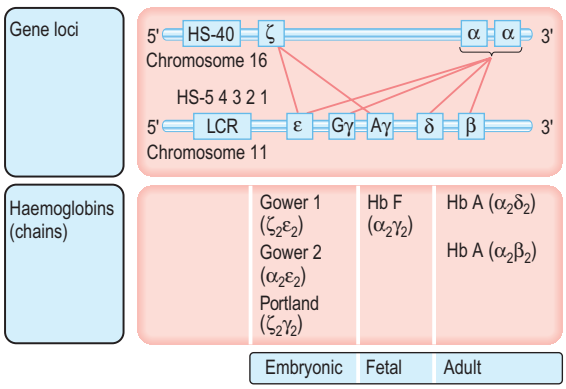

Fig. 8.20 **Loci of genes on chromosomes 16 and 11 and the combination of various chains to produce different haemoglobins.** HS-40 (for α genes) and locus control region (LCR) HS1–5 (for β genes) are regulatory control elements.

Table 8.10 Some types of haemoglobin

	Haemoglobin	Structure	Comment
Normal	A	$\alpha_2\beta_2$	Comprises 97% of adult haemoglobin
	A_2	$\alpha_2\delta_2$	Comprises 2% of adult haemoglobin Elevated in β-thalassaemia
	F	$\alpha_2\gamma_2$	Normal haemoglobin in fetus from 3rd to 9th month Increased in β-thalassaemia Comprises < 1% of haemoglobin in adult
Abnormal chain production	H	β_4	Found in α-thalassaemia Biologically useless
	Barts	γ_4	Comprises 100% of haemoglobin in homozygous α-thalassaemia Biologically useless
Abnormal chain structure	S	$\alpha_2\beta_2^S$	Substitution of valine for glutamine acid in position 6 of β chain

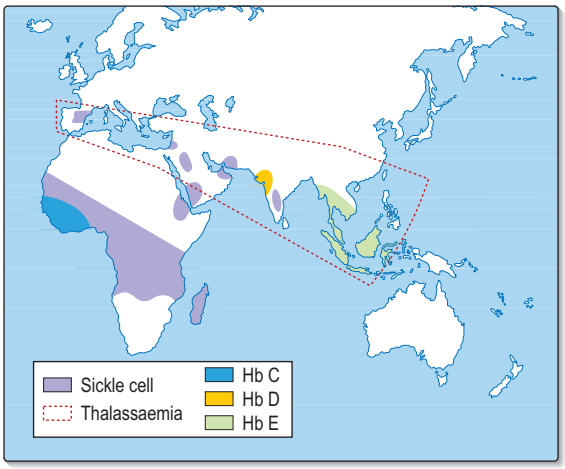

Fig. 8.21 **Major haemoglobin abnormalities: geographical distribution.**

Genetic defects in haemoglobin are the most common of all genetic disorders.

THE THALASSAEMIAS

The thalassaemias affect people throughout the world (Fig. 8.21). Normally there is balanced (1 : 1) production of α and β chains. The defective synthesis of globin chains in thalassaemia leads to 'imbalanced' globin chain production, leading to precipitation of globin chains within the red cell precursors and resulting in ineffective erythropoiesis. Precipitation of globin chains in mature red cells leads to haemolysis.

β-Thalassaemia

In *homozygous* β-thalassaemia, either no normal β chains are produced (β^0), or β-chain production is very reduced (β+). There is an excess of α chains, which precipitate in erythroblasts and red cells causing ineffective erythropoiesis and haemolysis. The excess α chains combine with whatever β, δ and γ chains are produced, resulting in increased quantities of Hb A_2 and Hb F and, at best, small amounts of Hb A. In heterozygous β-thalassaemia there is usually symptomless microcytosis with or without mild anaemia. Table 8.11 shows the findings in the homozygote and heterozygote for the common types of β-thalassaemia.

Molecular genetics

The molecular errors accounting for over 200 genetic defects leading to β-thalassaemia have been characterized. Unlike in α-thalassaemia, the defects are mainly point mutations rather than gene deletions. The mutations result in defects in transcription, RNA splicing and modification, translation via frame shifts and nonsense codons producing highly unstable β-globin which cannot be utilized.

Clinical syndromes

Clinically, β-thalassaemia can be divided into the following:

- thalassaemia minor (or trait), the symptomless heterozygous carrier state
- thalassaemia intermedia, with moderate anaemia, rarely requiring transfusions
- thalassaemia major, with severe anaemia requiring regular transfusions.

Table 8.11 β-Thalassaemia: common findings

Type of thalassaemia	Findings in homozygote	Findings in heterozygote
β^+	Thalassaemia major Hb A + F + A_2	Thalassaemia minor Hb A_2 raised
β^0	Thalassaemia major Hb F + A_2	Thalassaemia minor Hb A_2 raised
δβ	Thalassaemia intermedia Hb F only	Thalassaemia minor Hb F 5–15% Hb A_2 normal
$\delta\beta^+$ (Lepore)	Thalassaemia major or intermedia Hb F and Lepore	Thalassaemia minor Hb Lepore 5–15% Hb A_2 normal

Hb Lepore is a cross fusion product of δ and β globin genes.

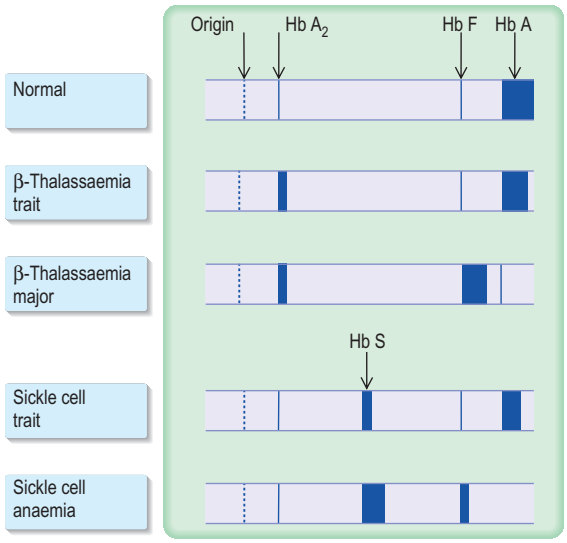

Fig. 8.22 **Patterns of haemoglobin electrophoresis.**

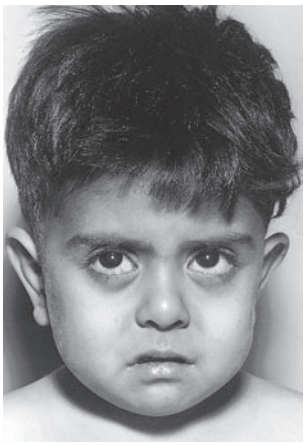
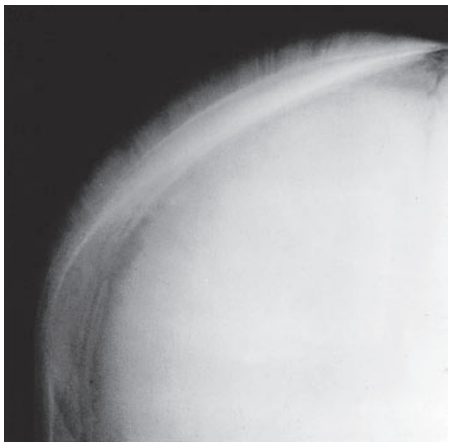


Thalassaemia minor (trait)

This common carrier state (heterozygous β-thalassaemia) is asymptomatic. Anaemia is mild or absent. The red cells are hypochromic and microcytic with a low MCV and MCH, and it may be confused with iron deficiency. However, the two are easily distinguished, as in thalassaemia trait the serum ferritin and the iron stores are normal (Table 8.3). The RDW is usually normal (see p. 389). Hb electrophoresis usually shows a raised Hb A_2 and often a raised Hb F (Fig. 8.22). Iron should not be given to these patients unless they have proven coincidental iron deficiency.



Thalassaemia intermedia

Thalassaemia intermedia includes patients who are symptomatic with moderate anaemia (Hb 7–10 g/dL) and who do not require regular transfusions.

Thalassaemia intermedia may be due to a combination of homozygous mild β+- and α-thalassaemia, where there is reduced α-chain precipitation and less ineffective erythropoi-

(C)

Fig. 8.23 **Thalassaemia. (a)** A child with thalassaemia, showing the typical facial features. **(b)** Skull X-ray of a child with β-thalassaemia, showing the 'hair on end' appearance. **(c)** X-ray of hand, showing expansion of the marrow and a thinned cortex.

esis and haemolysis. The inheritance of hereditary persistence of Hb F with homozygous β-thalassaemia also results in a milder clinical picture than unmodified β-thalassaemia major because the excess α chains are partially removed by the increased production of γ chains.

Patients may have splenomegaly and bone deformities. Recurrent leg ulcers, gallstones and infections are also seen. It should be noted that these patients may be iron overloaded despite a lack of regular blood transfusions. This is caused by excessive iron absorption which results from the underlying dyserythropoiesis (see iron absorption, p. 393).

Thalassaemia major (Cooley's anaemia)

Most children affected by homozygous β-thalassaemia present during the first year of life with:

- failure to thrive and recurrent bacterial infections
- severe anaemia from 3 to 6 months when the switch from γ- to β-chain production should normally occur
- extramedullary haemopoiesis that soon leads to hepatosplenomegaly and bone expansion, giving rise to the classical thalassaemic facies (Fig. 8.23a).

Skull X-rays in these children show the characteristic 'hair on end' appearance of bony trabeculation as a result of expansion of the bone marrow into cortical bone (Fig. 8.23b). The expansion of the bone marrow is also shown in an X-ray of the hand (Fig. 8.23c).

The classic features of untreated thalassaemia major are generally only observed in patients from countries without good blood transfusion support.

Management

The aims of treatment are to suppress ineffective erythropoiesis, prevent bony deformities and allow normal activity and development.

- *Long-term folic acid* supplements are required.
- *Regular transfusions* should be given to keep the Hb above 10 g/dL. Blood transfusions may be required every 4–6 weeks.
- If *transfusion requirements* increase, splenectomy may help, although this is usually delayed until after the age of 6 years because of the risk of infection. Prophylaxis against infection is required for patients undergoing splenectomy (see p. 423).
- *Iron overload* caused by repeated transfusions (transfusion haemosiderosis) may lead to damage to the endocrine glands, liver, pancreas and the myocardium by the time patients reach adolescence. Magnetic resonance imaging (myocardial T2- relaxation time) is useful for monitoring iron overload in thalassaemia, both the heart and the liver can be monitored. The standard iron-chelating agent remains desferrioxamine, although it has to be administered parenterally. Desferrioxamine is given as an overnight subcutaneous infusion on 5–7 nights each week. Ascorbic acid 200 mg daily is given, as it increases the urinary excretion of iron in response to desferrioxamine. Often young children have a very high standard of chelation as it is organized by their parents. However, when the children become adults and take on this role themselves they often rebel and chelation with desferrioxamine may become problematic. Preliminary results on a new once-daily oral iron chelator, deferasirox, indicate that it is safe, similar in effectiveness to desferrioxamine and well tolerated. Deferiprone, an oral iron chelator, is also now available.
- Intensive treatment with desferrioxamine has been reported to reverse damage to the heart in patients with severe iron overload, but excessive doses of desferrioxamine may cause cataracts, retinal damage and nerve deafness. Infection with *Yersinia enterocolitica* occurs in iron-loaded patients treated with desferrioxamine. Iron overload should be periodically assessed by measuring the serum ferritin and by assessment of hepatic iron stores by MRI.
- *Bone marrow transplantation* has been used in young patients with HLA-matched siblings. It has been successful in patients in good clinical condition with a 3-year mortality of less than 5%, but there is a high

mortality (>50%) in patients in poor condition with iron overload and liver dysfunction.

- *Prenatal diagnosis and gene therapy* are discussed on page 45.
- *Patients' partners should be tested.* If both partners have β-thalassaemia trait, there is a 1 in 4 chance of such pregnancy resulting in a child having β-thalassaemia major. Therefore, couples in this situation must be offered prenatal diagnosis.

α-Thalassaemia

Molecular genetics

In contrast to β-thalassaemia, α-thalassaemia is often caused by gene deletions, although mutations of the alpha globin genes may also occur. The gene for α globin chains is duplicated on both chromosomes 16, i.e. a normal person has a total of four alpha globin genes. Deletion of one α-chain gene (α+) or both α-chain genes (α0) on each chromosome 16 may occur (Table 8.12). The former is the most common of these abnormalities.

- **Four-gene deletion** (deletion of both genes on both chromosomes); there is no α-chain synthesis and only Hb Barts (γ4) is present. Hb Barts cannot carry oxygen and is incompatible with life (Tables 8.10 and 8.12). Infants are either stillborn at 28–40 weeks or die very shortly after birth. They are pale, oedematous and have enormous livers and spleens – a condition called hydrops fetalis.
- **Three-gene deletion**; there is moderate anaemia (Hb 7–10 g/dL) and splenomegaly (Hb H disease). The patients are not usually transfusion-dependent. Hb A, Hb Barts and Hb H (β4) are present. Hb A_2 is normal or reduced.
- **Two-gene deletion** (α-thalassaemia trait); there is microcytosis with or without mild anaemia. Hb H bodies may be seen on staining a blood film with brilliant cresyl blue.
- **One-gene deletion**; the blood picture is usually normal.

Globin chain synthesis studies for the detection of a reduced ratio of α to β chains may be necessary for the definitive diagnosis of α-thalassaemia trait.

Less commonly, α-thalassaemia may result from genetic defects other than deletions, for example mutations in the stop codon producing an α chain with many extra amino acids (Hb Constant Spring).

Table 8.12 The α-thalassaemias

Gene deletion		Haemoglobin type	Clinical picture
4 genes	α^0––/––	Hb Barts (γ4)	Hydrops fetalis
3 genes	α^0––/–α	Hb H (β4) Splenomegaly	Moderate anaemia
2 genes	α^0––/αα	Some Hb H bodies	Mild anaemia
	Or		
	–α/–α	Hb A	α-Thalassaemia trait
1 gene	α^+–α/αα	'Normal'	α-Thalassaemia trait

SICKLE SYNDROMES

Sickle cell haemoglobin (Hb S) results from a single-base mutation of adenine to thymine which produces a substitution of valine for glutamic acid at the sixth codon of the β-globin chain ($\alpha_2\beta_2^{6glu\rightarrow val}$). In the homozygous state (*sickle cell anaemia*) both genes are abnormal (Hb SS), whereas in the heterozygous state (sickle cell trait, Hb AS) only one chromosome carries the gene. As the synthesis of Hb F is normal, the disease usually does not manifest itself until the Hb F decreases to adult levels at about 6 months of age.

The sickle gene is commonest in Africans (up to 25% gene frequency in some populations) but is also found in India, the Middle East and Southern Europe.

Pathogenesis

Deoxygenated Hb S molecules are insoluble and polymerize. The flexibility of the cells is decreased and they become rigid and take up their characteristic sickle appearance (Fig. 8.24). This process is initially reversible but, with repeated sickling, the cells eventually lose their membrane flexibility and become irreversibly sickled. This is due to dehydration, partly caused by potassium leaving the red cells via calcium activated potassium channels called the Gados channel. These irreversibly sickled cells are dehydrated and dense and will not return to normal when oxygenated. Sickling can produce:

- a shortened red cell survival
- impaired passage of cells through the microcirculation, leading to obstruction of small vessels and tissue infarction.

Sickling is precipitated by infection, dehydration, cold, acidosis or hypoxia. In many cases the cause is unknown, but adhesion proteins on activated endothelial cells (VCAM-1) may play a causal role, particularly in vaso-occlusion when rigid cells are trapped, facilitating polymerization. Hb S releases its oxygen to the tissues more easily than does normal Hb, and patients therefore feel well despite being anaemic (except of course during crises or complications).

Depending on the type of haemoglobin chain combinations, three clinical syndromes occur:

- homozygous Hb SS have the most severe disease
- combined heterozygosity (Hb SC) for Hb S and C (see below) who suffer intermediate symptoms
- heterozygous Hb AS (sickle cell trait) have no symptoms (see p. 411).

Sickle cell anaemia

Clinical features

Vaso-occlusive crises

The earliest presentation in the first few years of life is acute pain in the hands and feet (dactylitis) owing to vaso-

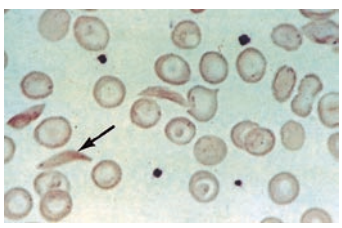

Fig. 8.24 **Sickle cells (arrowed) and target cells.**

occlusion of the small vessels. Severe pain in other bones, e.g. femur, humerus, vertebrae, ribs, pelvis, occurs in older children/adults. These attacks vary in frequency from daily to perhaps only once a year. Fever often accompanies the pain.

Anaemia

Chronic haemolysis produces a stable haemoglobin level, usually in the 6–8 g/dL range but an acute fall in the haemoglobin level can occur owing to:

- splenic sequestration
- bone marrow aplasia
- further haemolysis.

Splenic sequestration

Vaso-occlusion produces an acute painful enlargement of the spleen. There is splenic pooling of red cells and hypovolaemia, leading in some to circulatory collapse and death. The condition occurs in childhood before multiple infarctions have occurred. The latter eventually leads to a fibrotic non-functioning spleen. Liver sequestration can also occur.

Bone marrow aplasia

This most commonly occurs following infection with erythrovirus B19, which invades proliferating erythroid progenitors. There is a rapid fall in haemoglobin with no reticulocytes in the peripheral blood, because of the failure of erythropoiesis in the marrow.

Haemolysis due to drugs, acute infection or associated G6PD deficiency also occurs. Anaemia can also result from folate deficiency.

Long-term problems

In adults, nearly every organ is involved eventually, as patients survive longer with better treatment.

Growth and development. Young children are short but regain their height by adulthood. However, they remain below the normal weight. There is often delayed sexual maturation which may require hormone therapy.

Bones are a common site for vaso-occlusive episodes, leading to chronic infarcts. Avascular necrosis of hips, shoulders, compression of vertebrae and shortening of bones in the hands and feet occur. These episodes are the common cause for the painful crisis. Osteomyelitis is commoner in sickle cell disease and is caused by *Staphylococcus aureus*, *Staph. pneumoniae* and salmonella (see p. 541). Occasionally hip joint replacement may be required.

Infections are common in tissues susceptible to vaso-occlusion, e.g. bones, lungs, kidneys.

Respiratory. The acute chest syndrome occurs in up to 30%, and pulmonary hypertension and chronic lung disease are the commonest cause of death in adults with sickle cell disease. The acute chest syndrome is caused by infection, fat embolism from necrotic bone marrow or pulmonary infarction due to sequestration of sickle cells. It comprises shortness of breath, chest pain, hypoxia, and new chest X-ray changes due to consolidation. The presentation may be gradual or very rapid, leading to death in a few hours. Initial management is with pain relief, inspired oxygen, antibiotics and exchange transfusion to reduce the amount of Hb S to <20%; occasionally ventilation may be necessary. Infections can be due to chlamydia and mycoplasma, as well as *Streptococcus pneumoniae*.

Leg ulcers occur spontaneously (vaso-occlusive episodes) or following trauma and are usually over the medial or lateral malleoli. They often become infected and are quite resistant to treatment, sometimes blood transfusion may facilitate ulcer healing.

Cardiac problems occur, with cardiomegaly, arrhythmias and iron overload cardiomyopathy. Myocardial infarctions occur due to thrombotic episodes which are not secondary to atheroma.

Neurological complications occur in 25% of patients, with transient ischaemic attacks, fits, cerebral infarction, cerebral haemorrhage and coma. Strokes occur in about 11% of patients under 20 years of age. The most common finding is obstruction of a distal intracranial internal carotid artery or a proximal middle cerebral artery. 10% of children without neurological signs or symptoms have abnormal blood-flow velocity indicative of clinically significant arterial stenosis; such patients have very high risk of stroke. It has now been demonstrated that if children with stenotic cranial artery lesions, as demonstrated on transcranial Doppler ultrasonography, are maintained on a regular programme of transfusion that is designed to suppress erythropoiesis so that no more than 30% of the circulating red cells are their own, about 90% of strokes in such children could be prevented.

Cholelithiasis. Pigment stones occur as a result of chronic haemolysis.

Liver. Chronic hepatomegaly and liver dysfunction are caused by trapping of sickle cells.

Renal. Chronic tubulo-interstitial nephritis occurs (see p. 605).

Priapism. An unwanted painful erection occurs from vaso-occlusion and can be recurrent. This may result in impotence. Treatment is with an α-adrenergic blocking drug, analgesia and hydration.

Eye. Background retinopathy, proliferative retinopathy, vitreous haemorrhages and retinal detachments all occur. Regular yearly eye checks are required.

Pregnancy. Impaired placental blood flow causes spontaneous abortion, intrauterine growth retardation, pre-eclampsia and fetal death. Painful episodes, infections and severe anaemia occur in the mother. Prophylactic transfusion does not improve fetal outcome. Oral contraceptives with low-dose oestrogens are safe.

Investigations

- **Blood count**. The level of Hb is in the range 6–8 g/dL with a high reticulocyte count (10–20%).
- **Blood films** can show features of hyposplenism (see Fig. 8.29) and sickling (Fig. 8.24).
- **Sickle solubility test**. A mixture of Hb S in a reducing solution such as sodium dithionite gives a turbid appearance because of precipitation of Hb S, whereas normal Hb gives a clear solution. A number of commercial kits such as Sickledex are available for rapid screening for the presence of Hb S, for example before surgery in appropriate ethnic groups and in the A&E department.
- **Hb electrophoresis** (Fig. 8.22) is always needed to confirm the diagnosis. There is no Hb A, 80–95% Hb SS and 2–20% Hb F.
- **The parents** of the affected child will show features of sickle cell trait.

Table 8.13 Complications requiring inpatient management

Pain – uncontrolled by non-opiate analgesia
Swollen painful joints
Acute sickle chest syndrome or pneumonia
Mesenteric sickling and bowel ischaemia
Splenic or hepatic sequestration
Central nervous system deficit
Cholecystitis (pigment stones)
Cardiac arrhythmias
Renal papillary necrosis resulting in colic or severe haematuria
Hyphema and retinal detachment
Priapism

Management

Precipitating factors (see above) should be avoided or treated quickly. The complications requiring inpatient management are shown in Table 8.13.

Acute painful attacks require supportive therapy with intravenous fluids, and adequate analgesia. Oxygen and antibiotics are only given if specifically indicated. Crises can be extremely painful and require strong, usually narcotic, analgesia. Morphine is the drug of choice. Milder pain can sometimes be relieved by codeine, paracetamol and NSAIDs (Box 8.1).

Prophylaxis is with penicillin 500 mg daily and vaccination with polyvalent pneumococcal and *Haemophilus influenzae* type B vaccine (see p. 423). Folic acid is given to all patients with haemolysis.

Anaemia

Blood transfusions should only be given for clear indications. Patients with steady state anaemia, those having minor surgery or having painful episodes without complications should not be transfused. Transfusions should be given for heart failure, TIAs, strokes, acute chest syndrome, acute splenic sequestration and aplastic crises. Before elective operations and during pregnancy, repeated transfusions may be used to reduce the proportion of circulating Hb S to less than 20% to prevent sickling. Exchange transfusions may be necessary in patients with severe or recurrent crises, or before emergency surgery. Transfusion and splenectomy may be life-saving for young children with splenic sequestration. A full blood crossmatching compatibility screen should always be performed.

Hydroxycarbamide (hydroxyurea) is the first drug which has been widely used as therapy for sickle cell anaemia. It acts, at least in part, by increasing Hb F concentrations. Hydroxycarbamide has been shown in trials to reduce the episodes of pain, the acute chest syndrome, and the need for blood transfusions.

Inhaled nitric oxide inhibits platelet function, reduces vascular adhesion of red cells and is also a vasodilator. It has been shown to reduce opiate requirements in acute painful episodes.

Bone marrow transplantation has been used to treat sickle cell anaemia although in fewer numbers than for thalassaemia. Children and adolescents younger than 16 years of age who have severe complications (strokes, recurrent chest syndrome or refractory pain) and have an HLA-matched donor are the best candidates for transplantation.

Box 8.1 Management of acute painful crisis in opioid naïve adults with sickle cell disease. Higher doses may be required for patients who have previously received opioids.

Morphine/diamorphine

- 0.1 mg/kg i.v./s.c. every 20 min until pain controlled, then
- 0.05–0.1 mg/kg i.v./s.c. (or oral morphine) every 2–4 hours
- Patient controlled analgesia (PCA) when pain controlled

Patient controlled analgesia (PCA) (example for adults >50 kg)

Diamorphine

- Continuous infusion: 0–10 mg/h
- PCA bolus dose: 2–10 mg
- Dose duration: 1 min
- Lockout time: 20–30 min

Adjuvant oral analgesia

- Paracetamol 1 g 6 hourly
- +/– Ibuprofen* 400 mg 8 hourly
- Or diclofenac* 50 mg 8 hourly

Laxatives (all patients)

For example:

- Lactulose 10 ml × 2 daily
- Senna 2–4 tablets daily
- Sodium docusate 100 mg × 2 daily
- Macrogol 1 sachet daily
- Lubiprostone

Other adjuvants

Anti-pruritics

- Hydroxyzine 25 mg × 2 as required

Antiemetics

- Prochlorperazine 5–10 mg × 3 as required
- Cyclizine 50 mg × 3 as required

Anxiolytic

- Haloperidol 1–3 mg oral/i.m. × 2 as required

*Caution advised with NSAIDs in renal impairment.
Adapted from Rees DC, Olujohungbe AD, Parker NE et al. Guidelines for the management of the acute painful crisis in sickle cell disease. *British Journal of Haematology* 2003; **120**(5): 744–752.

Counselling

A multidisciplinary team should be involved, with regular clinic appointments to build up relationships. Adolescents require careful counselling over psychosocial issues, drug and birth control.

Prognosis

Some patients with Hb SS die in the first few years of life from either infection or episodes of sequestration. However, there is marked individual variation in the severity of the disease and some patients have a relatively normal lifespan with few complications.

Sickle cell trait

These individuals have no symptoms unless extreme circumstances cause anoxia, such as flying in non-pressurized aircraft. Sickle cell trait gives some protection against *Plasmodium falciparum* malaria (see p. 154), and consequently the sickle gene has been seen as an example of a

balanced polymorphism (where the advantage of the malaria protection in the heterozygote is balanced by the mortality of the homozygous condition). Typically there is 60% Hb A and 40% Hb S. It should be emphasized that unlike thalassaemia trait, the blood count and film of a person with sickle cell trait are normal. The diagnosis is made by a positive sickle test or by Hb electrophoresis (Fig. 8.22).

Other structural globin chain defects

There are many Hb variants (e.g. Hb C, D), many of which are not associated with clinical manifestations.

Hb C ($\alpha_2\beta_2^{6glu\rightarrow lys}$) disease may be associated with Hb S (Hb SC disease). The clinical course is similar to that with Hb SS, but there is an increased likelihood of thrombosis, which may lead to life-threatening episodes of thrombosis in pregnancy, and retinopathy.

Combined defects of globin chain production and structure

Abnormalities of Hb structure (e.g. Hb S, C) can occur in combination with thalassaemia. The combination of β-thalassaemia trait and sickle cell trait (sickle cell β-thalassaemia) resembles sickle cell anaemia (Hb SS) clinically.

Hb E ($\alpha_2\beta_2^{26glu\rightarrow lys}$) is the most common Hb variant in South East Asia, and the second most prevalent haemoglobin variant world-wide. Hb E heterozygotes are asymptomatic; the haemoglobin level is normal, but red cells are microcytic. Homozygous Hb E causes a mild microcytic anaemia, but the combination of heterozygosity for Hb E and β-thalassaemia produces a variable anaemia, which can be as severe as β-thalassaemia major.

Prenatal screening and diagnosis of severe haemoglobin abnormalities

Of the offspring of parents who both have either β-thalassaemia or sickle cell trait, 25% will have β-thalassaemia major or sickle cell anaemia, respectively. Recognition of these heterozygous states in parents and family counselling provide a basis for antenatal screening and diagnosis.

Prognosis

Pregnant women with either sickle cell trait or thalassaemia trait must be identified at antenatal booking either by selective screening of high-risk groups on the basis of ethnic origin or by universal screening of all pregnant women. β-Thalassaemia trait can always be detected by a low MCV and MCH and confirmed by haemoglobin electrophoresis. However, sickle cell trait is undetectable from a blood count and the laboratory need a specific request to screen for sickle cell trait.

If a pregnant woman is found to have a haemoglobin defect, her partner should be tested. Antenatal diagnosis is offered if both are affected as there is a risk of a severe fetal Hb defect, particularly β-thalassaemia major. Fetal DNA analysis can be carried out using amniotic fluid, chorionic villus or fetal blood samples. Abortion is offered if the fetus is found to be severely affected. Chorionic villus biopsy has the advantage that it can be carried out in the first trimester, thus avoiding the need for second trimester abortions.

Gene therapy would be the ultimate corrective therapy for severe Hb abnormalities. Normal Hb genes could be inserted into the patient's haemopoietic cells in vitro and these cells could be transplanted back into the patient after ablative bone marrow treatment.

METABOLIC DISORDERS OF THE RED CELL

Red cell metabolism

The mature red cell has no nucleus, mitochondria or ribosomes and is therefore unable to synthesize proteins. Red cells have only limited enzyme systems but they maintain the viability and function of the cells. In particular, energy is required in the form of ATP for the maintenance of the flexibility of the membrane and the biconcave shape of the cells to allow passage through small vessels, and for regulation of the sodium and potassium pumps to ensure osmotic equilibrium. In addition, it is essential that Hb be maintained in the reduced state.

The enzyme systems responsible for producing energy and reducing power are (Fig. 8.25):

- the glycolytic (Embden–Meyerhof) pathway, in which glucose is metabolized to pyruvate and lactic acid with production of ATP
- the hexose monophosphate (pentosephosphate) pathway, which provides reducing power for the red cell in the form of NADPH.

About 90% of glucose is metabolized by the former and 10% by the latter. The hexose monophosphate shunt maintains glutathione (GSH) in a reduced state. Glutathione is necessary to combat oxidative stress to the red cell, and failure of this mechanism may result in:

- rigidity due to cross-linking of spectrin, which decreases membrane flexibility (see Fig. 8.18) and causes 'leakiness' of the red cell membrane
- oxidation of the Hb molecule, producing methaemoglobin and precipitation of globin chains as Heinz bodies localized on the inside of the membrane; these bodies are removed from circulating red cells by the spleen.

2,3-BPG is formed from a side-arm of the glycolytic pathway (Fig. 8.25). It binds to the central part of the Hb tetramer, fixing it in the low-affinity state (Fig. 8.4). A decreased affinity with a shift in the oxygen dissociation curve to the right enables more oxygen to be delivered to the tissues.

In addition to the G6PD, pyruvate kinase and pyrimidine 5′ nucleotidase deficiencies described below, there are a number of rare enzyme deficiencies that need specialist investigation.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency

The enzyme G6PD holds a vital position in the hexose monophosphate shunt (Fig. 8.25), oxidizing glucose-6-phosphate to 6-phosphoglycerate with the reduction of NADP to NADPH. The reaction is necessary in red cells where it is the only source of NADPH, which is used via glutathione to protect the red cell from oxidative damage. G6PD deficiency is a common condition that presents with a haemolytic anaemia and affects millions of people throughout the world, particu-

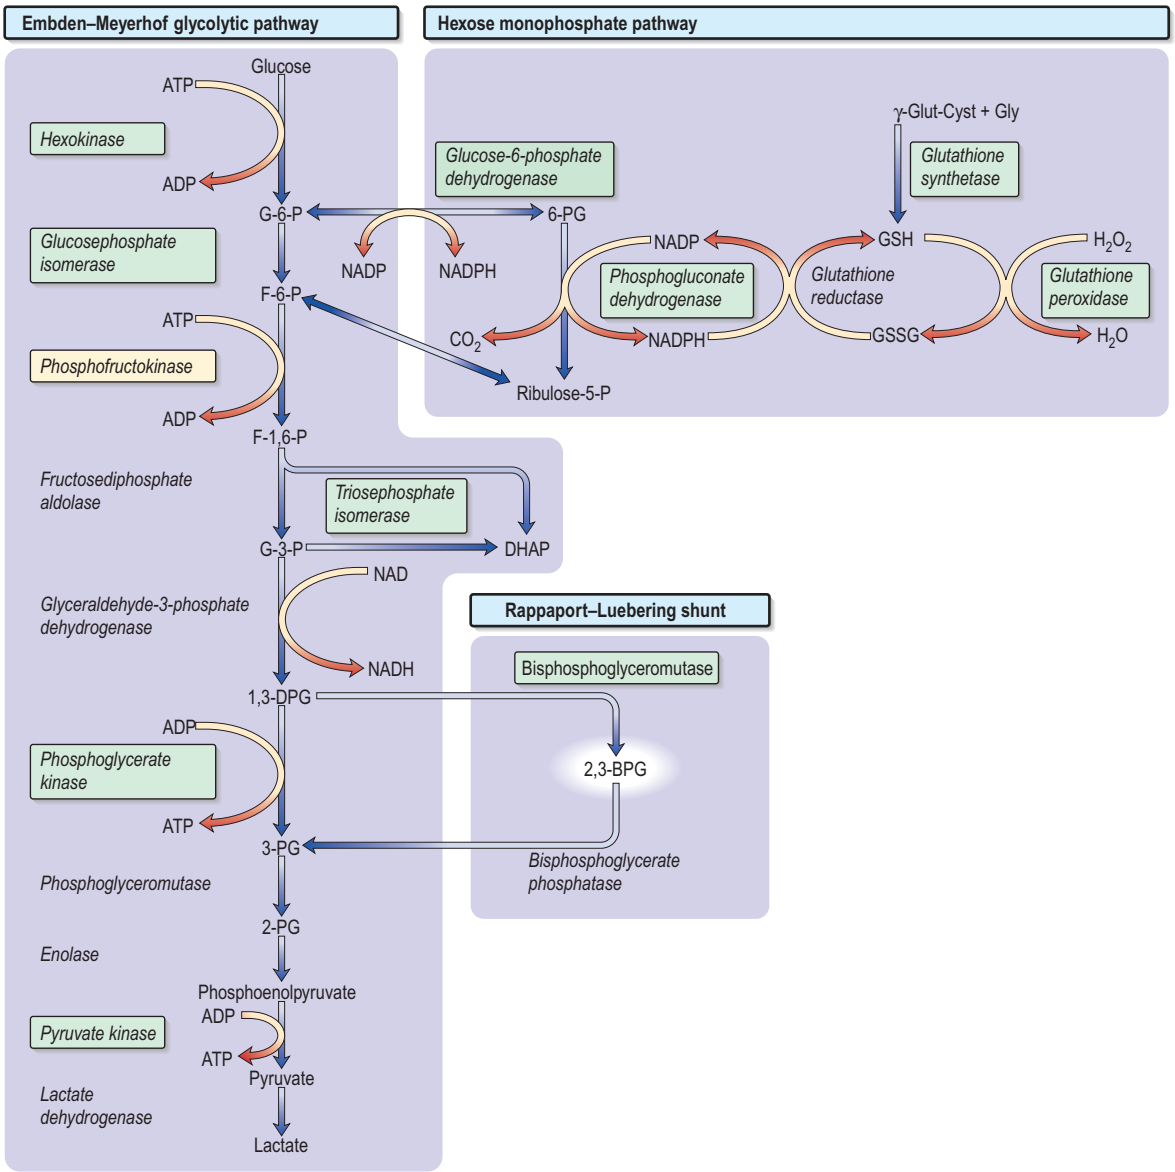

Fig. 8.25 **Glucose metabolism pathways in red cells.** The enzymes in green boxes indicate documented hereditary deficiency diseases. BPG, bisphosphoglycerate; DHAP, dihydroxyacetone phosphate; F, fructose; G, glucose; GSSG, oxidized glutathione; GSH, reduced glutathione; P, phosphate; PG, phosphoglycerate.

larly in Africa, around the Mediterranean, the Middle East (around 20%) and southeast Asia (up to 40% in some regions).

The gene for G6PD is localized to chromosome Xq28 near the factor VIII gene. The deficiency is more common in males than in females. However, female heterozygotes can also have clinical problems due to lyonization, whereby because of random X-chromosome inactivation female heterozygotes have two populations of red cells – a normal one and a G6PD-deficient one.

There are over 400 structural types of G6PD, and mutations are mostly single amino acid substitutions (missense point mutations). WHO has classified variants by the degree of enzyme deficiency and severity of haemolysis. The most common types with normal activity are called type B^+, which is present in almost all Caucasians and about 70% of black Africans, and type A^+, which is present in about 20% of black Africans. There are many variants with reduced activity but only two are common. In the African, or A^- type, the degree of deficiency is mild and more marked in older cells. Haemolysis is self-limiting as the young red cells newly produced by the bone marrow have nearly normal enzyme activity. However, in the Mediterranean type, both young and old red cells have very low enzyme activity. After an oxidant shock the Hb level may fall precipitously; death may follow unless the condition is recognized and the patient is transfused urgently.

Clinical syndromes

- Acute drug-induced haemolysis (Table 8.14) – usually dose related
- Favism (ingestion of fava beans)
- Chronic haemolytic anaemia
- Neonatal jaundice
- Infections and acute illnesses will also precipitate haemolysis in patients with G6PD deficiency.

Table 8.14	Drugs causing haemolysis in glucose-6-phosphate deficiency

Analgesics, such as:
Aspirin
Phenacetin (withdrawn in the UK)

Antimalarials, such as:
Primaquine
Pyrimethamine
Quinine
Chloroquine
Pamaquin

Antibacterials, such as:
Most sulphonamides
Dapsone
Nitrofurantoin
Chloramphenicol
Quinolones

Miscellaneous drugs, such as:
Vitamin K
Probenecid
Quinidine
Dimercaprol
Phenylhydrazine

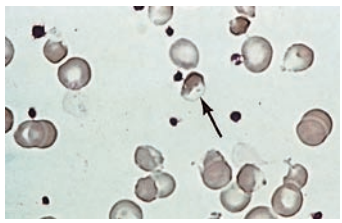

Fig. 8.26 **'Blister' cells (arrowed) in G6PD deficiency.**

Mothballs containing naphthalene can also cause haemolysis.

The clinical features are due to rapid intravascular haemolysis with symptoms of anaemia, jaundice and haemoglobinuria.

Investigations

- **Blood count** is normal between attacks.
- **During an attack** the blood film may show irregularly contracted cells, bite cells (cells with an indentation of the membrane), blister cells (cells in which the Hb appears to have become partially detached from the cell membrane; Fig. 8.26), Heinz bodies (best seen on films stained with methyl violet) and reticulocytosis.
- **Haemolysis** is evident (see p. 403).
- **G6PD deficiency** can be detected using several screening tests, such as demonstration of the decreased ability of G6PD-deficient cells to reduce dyes. The level of the enzyme may also be directly assayed. There are two diagnostic problems. Immediately after an attack the screening tests may be normal (because the oldest red cells with least 6GPD activity are destroyed selectively). The diagnosis of heterozygous females may be difficult because the enzyme level may range from very low to normal depending on lyonization. However, the risk of clinically significant haemolysis is minimal in patients with borderline G6PD activity.

Treatment

- Any offending drugs should be stopped.
- Underlying infection should be treated.
- Blood transfusion may be life-saving.
- Splenectomy is not usually helpful.

Pyruvate kinase deficiency

This is the most common defect of red cell metabolism after G6PD deficiency, affecting thousands rather than millions of people. The site of the defect is shown in Figure 8.25. There is reduced production of ATP, causing rigid red cells. Homozygotes have haemolytic anaemia and splenomegaly. It is inherited as an autosomal recessive.

Investigations

- **Anaemia** of variable severity is present (Hb 5–10 g/dL). The oxygen dissociation curve is shifted to the right as a result of the rise in intracellular 2,3-BPG, and this reduces the severity of symptoms due to anaemia.
- **Blood film** shows distorted ('prickle') cells and a reticulocytosis.
- **Pyruvate kinase activity** is low (affected homozygotes have levels of 5–20%).

Treatment

Blood transfusions may be necessary during infections and pregnancy. Splenectomy may improve the clinical condition and is usually advised for patients requiring frequent transfusions.

Pyrimidine 5′ nucleotidase deficiency

This autosomal disorder produces a haemolytic anaemia with basophilic stippling of the red cells. The enzyme degrades pyrimidine nucleotides to cytidine and uridine (pentose phosphate shunt), which in turn lead to the degradation of RNA in the reticulocytes. Lack of the enzyme results in accumulation of partially degraded RNA, which shows as basophilic stippling in mature red cells. The enzyme is also inhibited by lead (see p. 945) and thus basophilic stippling is seen in lead poisoning. The hereditary form can be diagnosed by measuring the enzyme in erythrocytes. A screening test using the ultraviolet absorption spectrum of red cells is available.

ACQUIRED HAEMOLYTIC ANAEMIA

These anaemias may be divided into those due to immune, non-immune, or other causes (Table 8.9)

Causes of immune destruction of red cells

- Autoantibodies
- Drug-induced antibodies
- Alloantibodies.

Causes of non-immune destruction of red cells

- Acquired membrane defects (e.g. paroxysmal nocturnal haemoglobinuria; see p. 418).
- Mechanical factors (e.g. prosthetic heart valves, or microangiopathic haemolytic anaemia; see p. 419)
- Secondary to systemic disease (e.g. renal and liver disease).

Table 8.15 Causes and major features of autoimmune haemolytic anaemias

	Warm	Cold
Temperature at which antibody attaches best to red cells	37°C	Lower than 37°C
Type of antibody	IgG	IgM
Direct Coombs' test	Strongly positive	Positive
Causes of primary conditions	Idiopathic	Idiopathic
Causes of secondary condition	Autoimmune disorders, e.g. systemic lupus erythematosus Chronic lymphocytic leukaemia Lymphomas Hodgkin's lymphoma Carcinomas Drugs, many including methyldopa, penicillins, cephalosporins, NSAIDs, quinine, interferon	Infections, e.g. infectious mononucleosis, *Mycoplasma pneumoniae*, other viral infections (rare) Lymphomas Paroxysmal cold haemoglobinuria (IgG)

Miscellaneous causes

- Various toxic substances can disrupt the red cell membrane and cause haemolysis (e.g. arsenic, and products of *Clostridium welchii*).
- Malaria frequently causes anaemia owing to a combination of a reduction in red cell survival and reduced production of red cells.
- Hypersplenism (see p. 423) results in a reduced red cell survival, which may also contribute to the anaemia seen in malaria.
- Extensive burns result in denaturation of red cell membrane proteins and reduced red cell survival.
- Some drugs (e.g. dapsone, sulfasalazine) cause oxidative haemolysis with Heinz bodies.
- Some ingested chemicals (e.g. weedkillers such as sodium chlorate) can cause severe oxidative haemolysis leading to acute renal failure.

AUTOIMMUNE HAEMOLYTIC ANAEMIAS

Autoimmune haemolytic anaemias (AIHA) are acquired disorders resulting from increased red cell destruction due to red cell autoantibodies. These anaemias are characterized by the presence of a positive direct antiglobulin (Coombs') test, which detects the autoantibody on the surface of the patient's red cells (Fig. 8.27).

AIHA is divided into 'warm' and 'cold' types, depending on whether the antibody attaches better to the red cells at body temperature (37°C) or at lower temperatures. The major features and the causes of these two forms of AIHA are shown in Table 8.15. In warm AIHA, IgG antibodies predominate and the direct antiglobulin test is positive with IgG alone, IgG and complement, or complement only. In cold AIHA, the antibodies are usually IgM. They easily elute off red cells, leaving complement which is detected as C3d.

Immune destruction of red cells

IgM or IgG red cell antibodies which fully activate the complement cascade cause lysis of red cells in the circulation (intravascular haemolysis).

IgG antibodies frequently do not activate complement and the coated red cells undergo extravascular haemolysis (Fig. 8.28). They are either completely phagocytosed in the spleen through an interaction with Fc receptors on

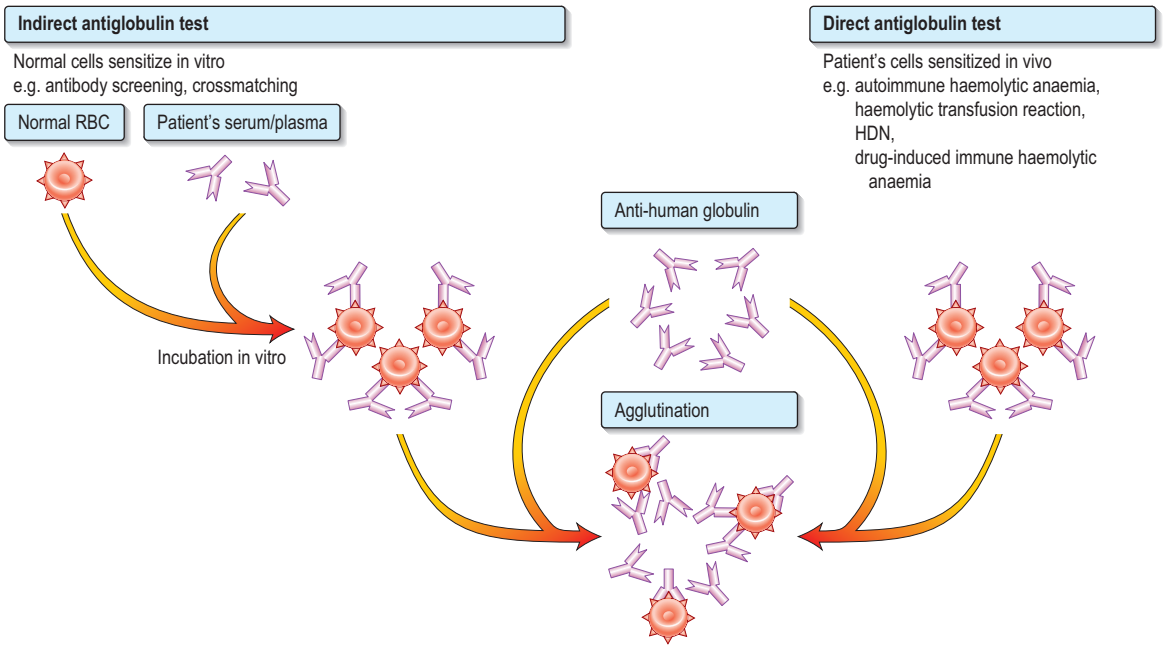

Fig. 8.27 **Antiglobulin (Coombs') tests.** The anti-human globulin forms bridges between the sensitized cells causing visible agglutination. The direct test detects patients' cells sensitized in vivo. The indirect test detects normal cells sensitized in vitro. HDN, haemolytic disease of newborn.

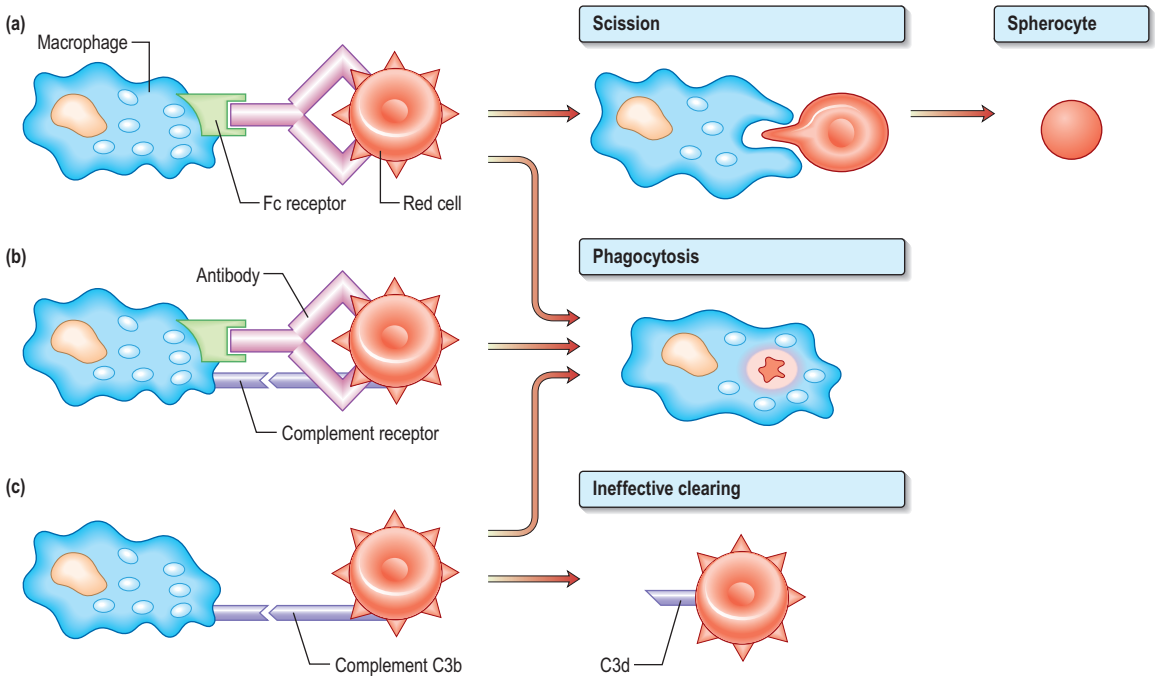

Fig. 8.28 **Extravascular haemolysis is due to interaction of antibody-coated cells with cells in the reticuloendothelial system, predominantly in the spleen. (a)** Spherocytosis results from partial phagocytosis. **(b)** Complete phagocytosis may occur and this is enhanced if there is complement as well as antibody on the cell surface. **(c)** Cells coated with complement only are ineffectively removed and circulate with C3d or C3b on their surface.

macrophages, or they lose part of the cell membrane through partial phagocytosis and circulate as spherocytes until they become sequestered in the spleen. Some IgG antibodies partially activate complement, leading to deposition of C3b on the red cell surface, and this may enhance phagocytosis as macrophages also have receptors for C3b.

Non-complement-binding IgM antibodies are rare and have little or no effect on red cell survival. IgM antibodies which partially rather than fully activate complement cause adherence of red cells to C3b receptors on macrophages, particularly in the liver, although this is an ineffective mechanism of haemolysis. Most of the red cells are released from the macrophages when C3b is cleaved to C3d and then circulate with C3d on their surface.

'Warm' autoimmune haemolytic anaemias

Clinical features

These anaemias may occur at all ages and in both sexes, although they are most frequent in middle-aged females. They can present as a short episode of anaemia and jaundice but they often remit and relapse and may progress to an intermittent chronic pattern. The spleen is often palpable. Infections or folate deficiency may provoke a profound fall in the haemoglobin level.

In more than 30% of cases, the cause remains unknown. These anaemias may be associated with lymphoid malignancies or diseases such as rheumatoid arthritis and SLE or drugs (Table 8.15).

Investigations

- **Haemolytic anaemia** is evident (see p. 403).
- **Spherocytosis** is present as a result of red cell damage.
- **Direct antiglobulin test** is positive, with either IgG alone (67%), IgG and complement (20%), or complement alone (13%) being found on the surface of the red cells.
- **Autoantibodies** may have specificity for the Rh blood group system (e.g. for the e antigen).
- **Autoimmune thrombocytopenia** and/or neutropenia may also be present (Evans' syndrome).

Treatment and prognosis

Corticosteroids (e.g. prednisolone in doses of 1 mg/kg daily) are effective in inducing a remission in about 80% of patients. Steroids reduce both production of the red cell autoantibody and destruction of antibody-coated cells. Splenectomy may be necessary if there is no response to steroids or if the remission is not maintained when the dose of prednisolone is reduced. Other immunosuppressive drugs, such as azathioprine and rituximab, may be effective in patients who fail to respond to steroids and splenectomy. Blood transfusion may be necessary if there is severe anaemia; compatibility testing is complicated by the presence of red cell autoantibodies.

'Cold' autoimmune haemolytic anaemias

Normally, low titres of IgM cold agglutinins reacting at 4°C are present in plasma and are harmless. At low temperatures these antibodies can attach to red cells and cause their agglutination in the cold peripheries of the body. In addition, activation of complement may cause intravascular haemolysis when the cells return to the higher temperatures in the core of the body.

After certain infections (such as *Mycoplasma*, cytomegalovirus, Epstein–Barr virus (EBV)) there is increased synthesis

of polyclonal cold agglutinins producing a mild to moderate transient haemolysis.

Chronic cold haemagglutinin disease (CHAD)

This usually occurs in the elderly with a gradual onset of haemolytic anaemia owing to the production of monoclonal IgM cold agglutinins. After exposure to cold, the patient develops an acrocyanosis similar to Raynaud's as a result of red cell autoagglutination.

Investigations

- **Red cells** agglutinate in the cold or at room temperature. Agglutination is sometimes seen in the sample tube after cooling but is more easily seen on the peripheral blood film made at room temperature. The agglutination is reversible after warming the sample. The agglutination may cause a spurious increase in the MCV (see p. 392).
- **Direct antiglobulin test** is positive with complement (C3d) alone.
- **Monoclonal IgM antibodies** with specificity for the Ii blood group system, usually for the I antigen but occasionally for the i antigen.

Treatment

The underlying cause should be treated, if possible. Patients should avoid exposure to cold. Steroids, alkylating agents and splenectomy are usually ineffective. Treatment with anti-CD20 (rituximab) has been successful in some cases. Blood transfusion may be necessary, and if so, the patient should be in a warm environment; compatibility testing may be difficult due to the cold agglutinin.

Paroxysmal cold haemoglobinuria (PCH)

This is a rare condition associated with common childhood infections, such as measles, mumps and chickenpox. Intravascular haemolysis is associated with polyclonal IgG complement-fixing antibodies. These antibodies are biphasic, reacting with red cells in the cold in the peripheral circulation, with lysis occurring due to complement activation when the cells return to the central circulation. The antibodies have specificity for the P red cell antigen. The lytic reaction is demonstrated in vitro by incubating the patient's red cells and serum at 4°C and then warming the mixture to 37°C (Donath–Landsteiner test). Haemolysis is self-limiting but red cell transfusions may be necessary.

DRUG-INDUCED IMMUNE HAEMOLYTIC ANAEMIA

Drug-induced haemolytic anaemias are rare, although over 100 drugs have been reported to cause immune haemolytic anaemia. The interaction between a drug and red cell membrane may produce three types of antibodies:

- *Antibodies to the drug* only, e.g. quinidine, rifampicin. Immune complexes attach to red cells, and may cause acute and severe intravascular haemolysis, sometimes associated with renal failure. The haemolysis usually resolves quickly once the drug is withdrawn.
- *Antibodies to the cell membrane* only, e.g. methyldopa, fludarabine. There is extravascular haemolysis and the clinical course tends to be more protracted.
- *Antibodies to part-drug, part-cell membrane*, e.g. penicillin. This develops only in patients receiving large doses of penicillin. The haemolysis typically develops over 7–10 days, and recovery is gradual after drug withdrawal.

Confirmation of the diagnosis requires a temporal association between administration of a drug and haemolytic anaemia, and recovery after withdrawal of the drug. In addition, the direct antiglobulin test should be positive, and drug-dependent red cell antibodies are detectable in the first and third mechanisms described above. In the second, the antibodies are not drug-dependent and are indistinguishable from autoantibodies.

ALLOIMMUNE HAEMOLYTIC ANAEMIA

Antibodies produced in one individual react with the red cells of another. This situation occurs in haemolytic disease of the newborn, haemolytic transfusion reactions (see p. 427) and after allogeneic bone marrow, renal, liver or cardiac transplantation when donor lymphocytes transferred in the allograft ('passenger lymphocytes') may produce red cell antibodies against the recipient and cause haemolytic anaemia.

Haemolytic disease of the newborn (HDN)

HDN is due to fetomaternal incompatibility for red cell antigens. Maternal alloantibodies against fetal red cell antigens pass from the maternal circulation via the placenta into the fetus, where they destroy the fetal red cells. Only IgG antibodies are capable of transplacental passage from mother to fetus.

The most common type of HDN is that due to ABO incompatibility, where the mother is usually group O and the fetus group A.

HDN due to ABO incompatibility is usually mild and exchange transfusion is rarely needed. HDN due to RhD incompatibility has become much less common in developed countries following the introduction of anti-D prophylaxis (see below). HDN may be caused by antibodies against antigens in many blood group systems (e.g. other Rh antigens such as c and E, and Kell, Duffy and Kidd; see p. 424).

Sensitization occurs as a result of passage of fetal red cells into the maternal circulation (which most readily occurs at the time of delivery), so that first pregnancies are rarely affected. However, sensitization may occur at other times, for example after a miscarriage, ectopic pregnancy or blood transfusion, or due to episodes during pregnancy which cause transplacental bleeding such as amniocentesis, chorionic villus sampling and threatened miscarriage.

Clinical features

These vary from a mild haemolytic anaemia of the newborn to intrauterine death from 18 weeks' gestation with the characteristic appearance of hydrops fetalis (hepatosplenomegaly, oedema and cardiac failure).

Kernicterus occurs owing to severe jaundice in the neonatal period, where the unconjugated (lipid-soluble) bilirubin

exceeds 250 µmol/L and bile pigment deposition occurs in the basal ganglia. This can result in permanent brain damage, choreoathetosis and spasticity. In mild cases it may present as deafness.

Investigations

Routine antenatal serology

All mothers should have their ABO and RhD groups determined and tested for atypical antibodies after attending the antenatal booking clinic. These tests should be repeated at 28 weeks' gestation.

If an antibody is detected, its blood group specificity should be determined and the mother should be retested at least monthly. A rising antibody titre of IgG antibodies or a history of HDN in a previous pregnancy is an indication for referral to a fetal medicine unit.

Antenatal assessment and treatment

If a clinically significant antibody capable of causing HDN, e.g. ant-D, anti-c or anti-K, is detected, the father's phenotype provides useful information to predict the likelihood of the fetus carrying the relevant red cell antigen. If the father is heterozygous, the genotype of the fetus can be determined from fetal DNA obtained by amniocentesis, chorionic villous sampling or fetal blood sampling. Soluble fetal DNA in maternal plasma can also be used for RhD typing, avoiding an invasive procedure.

The severity of anaemia is assessed by Doppler flow velocity of the fetal middle cerebral artery; measurement of bile pigments in the amniotic fluid is no longer routinely used. If the infant appears to have severe anaemia by non-invasive monitoring, ultrasound-guided fetal blood sampling is used to confirm this directly, and if necessary, an intravascular fetal transfusion of red cells is given.

At the birth of an affected infant

A sample of cord blood is obtained. This shows:

- anaemia with a high reticulocyte count
- a positive direct antiglobulin test
- a raised serum bilirubin.

Postnatal management

In mild cases, phototherapy may be used to convert bilirubin to water-soluble biliverdin. Biliverdin can be excreted by the kidneys and this therefore reduces the chance of kernicterus.

In more severely affected cases, exchange transfusion may be necessary to replace the infant's red cells and to remove bilirubin. Indications for exchange transfusion include:

- a cord Hb of <12 g/dL (normal cord Hb is 13.6–19.6 g/dL)
- a cord bilirubin of >60 µmol/L
- a later serum bilirubin of >300 µmol/L
- a rapidly rising serum bilirubin level.

Further exchange transfusions may be necessary to remove the unconjugated bilirubin.

The blood used for exchange transfusions should be ABO-compatible with the mother and infant, lack the antigen against which the maternal antibody is directed, be fresh (no more than 5 days from the day of collection) and be CMV-seronegative to prevent transmission of cytomegalovirus.

Prevention of RhD immunization in the mother

Anti-D should be given after delivery when all of the following are present:

- the mother is RhD negative
- the fetus is RhD positive
- there is no maternal anti-D detectable in the mother's serum; i.e. the mother is not already immunized.

The dose is 500 i.u. of IgG anti-D intramuscularly within 72 hours of delivery. The Kleihauer test is used to assess the number of fetal cells in the maternal circulation. A blood film prepared from maternal blood is treated with acid, which elutes Hb A. Hb F is resistant to this treatment and can be seen when the film is stained with eosin. If large numbers of fetal red cells are present in the maternal circulation, a higher or additional dose of anti-D will be necessary.

It may be necessary to give prophylaxis to RhD-negative women at other times when sensitization may occur, for example after an ectopic pregnancy, threatened miscarriage or termination of pregnancy. The dose of anti-D is 250 i.u. before 20 weeks' gestation and 500 i.u. after 20 weeks. A Kleihauer test should be carried out after 20 weeks to determine if more anti-D is required.

Of previously non-immunized RhD-negative women carrying RhD-positive fetuses, 1–2% became immunized by the time of delivery. Antenatal prophylaxis with administration of 500 i.u. anti-D to RhD-negative women at both 28 and 34 weeks' gestation has been shown to reduce the incidence of immunization, and its routine use is being implemented in the UK. Monoclonal anti-D could in principle replace polyclonal anti-D, which is collected from RhD-negative women immunized in pregnancy and deliberately immunized RhD-negative males, but it is likely to be some years before trials have been completed to confirm its safety and effectiveness.

FURTHER READING

Schwartz RS. Paroxysmal nocturnal hemoglobinuria. *New England Journal of Medicine* 2004; **350:** 537–538.

NON-IMMUNE HAEMOLYTIC ANAEMIA

Paroxysmal nocturnal haemoglobinuria (PNH)

Paroxysmal nocturnal haemogloblinuria is a rare form of haemolytic anaemia which results from the clonal expression of haematopoietic stems cells that have mutations in the X-linked gene *PIG-A*. These mutations result in an impaired synthesis of glycosylphosphatidylinositol (GPI), which anchors many proteins to the cell surface such as decay accelerating factor (DAF; CD55) and membrane inhibitor of reactive lysis (MIRL; CD59) to cell membranes. CD55 and CD59 and other proteins are involved in complement degradation (at the C3 and C5 levels), and in their absence the haemolytic action of complement continues.

Clinical features

The major clinical signs are intravascular haemolysis, venous thrombosis and haemoglobinuria. Haemolysis may be precipitated by infection, iron therapy or surgery. Characteristically only the urine voided at night and in the morning on waking is dark in colour, although the reason for this phenomenon is not clear. In severe cases all urine samples are dark. Urinary iron loss may be sufficient to cause iron deficiency.

Some patients present insidiously with signs of anaemia and recurrent abdominal pains.

Venous thrombotic episodes are very common in unusual places and severe thromboses may occur, for example in hepatic (Budd–Chiari syndrome), mesenteric or cerebral veins. The cause of the increased predisposition to thrombosis is not known, but may be due to complement-mediated activation of platelets deficient in CD55 and CD59. Another suggestion is that intravascular haemolysis, which releases haemoglobin in the plasma, lowers plasma nitric oxide, which causes the symptoms and venous thrombosis.

Investigations

- **Intravascular haemolysis** is evident (see p. 403).
- **Flow cytometric analysis** of red cells with anti-CD55 and anti-CD59 has replaced the Ham's test.
- **Bone marrow** is sometimes hypoplastic (or even aplastic) despite haemolysis.

Treatment and prognosis

PNH is a chronic disorder requiring supportive measures such as blood transfusions, which are necessary for patients with severe anaemia. Leucocyte-depleted blood should be used in order to prevent transfusion reactions resulting in complement activation and acceleration of the haemolysis. Treatment is with eculizumab, a recombinant humanized monoclonal antibody that prevents the cleavage of C5 (and therefore the formation of the membrane attack complex). It reduces intravascular haemolysis, haemoglobinuria, the need for transfusion and gives an improved quality of life.

Long-term anticoagulation may be necessary for patients with recurrent thrombotic episodes. In patients with bone marrow failure, treatment options include immunosuppression with antilymphocyte globulin, ciclosporin or bone marrow transplantation. Bone marrow transplantation has been successfully carried out using either HLA-matched sibling donors in patients under the age of 50 or matched unrelated donors in patients under the age of 25.

The course of PNH is variable. PNH may transform into aplastic anaemia or acute leukaemia, but it may remain stable for many years and the PNH clone may even disappear, which must be taken into account if considering potentially dangerous treatments such as bone marrow transplantation. The median survival is 10–15 years.

Gene therapy will perhaps be possible in the future.

MECHANICAL HAEMOLYTIC ANAEMIA

Red cells may be injured by physical trauma in the circulation. Direct injury may cause immediate cell lysis or be followed by resealing of the cell membrane with the formation of distorted red cells or 'fragments'. These cells may circulate for a short period before being destroyed prematurely in the reticuloendothelial system.

The causes of mechanical haemolytic anaemia include:

- damaged artificial heart valves
- march haemoglobinuria, where there is damage to red cells in the feet associated with prolonged marching or running
- microangiopathic haemolytic anaemia (MAHA), where fragmentation of red cells occurs in an abnormal microcirculation caused by malignant hypertension, eclampsia, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, vasculitis or disseminated intravascular coagulation.

MYELOPROLIFERATIVE DISORDERS

In these disorders there is uncontrolled clonal proliferation of one or more of the cell lines in the bone marrow, namely erythroid, myeloid and megakaryocyte lines. Myeloproliferative disorders include polycythaemia vera (PV), essential thrombocythaemia (ET), myelofibrosis (all of which have a JAK-2 molecular lesion) and chronic myeloid leukaemia (CML) (a genetic BCR-ABL lesion). These disorders are grouped together as there can be transition from one disease to another; for example PV can lead to myelofibrosis. They may also transform to acute myeloblastic leukaemia. The non-leukaemic myeloproliferative disorders (PV, ET and myelofibrosis) will be discussed in this section. Chronic myeloid leukaemia is described on page 472.

POLYCYTHAEMIA

Polycythaemia (or erythrocytosis) is defined as an increase in haemoglobin, PCV and red cell count. PCV is a more reliable indicator of polycythaemia than is Hb, which may be disproportionately low in iron deficiency. Polycythaemia can be divided into absolute erythrocytosis where there is a true increase in red cell volume, or relative erythrocytosis where the red cell volume is normal but there is a decrease in the plasma volume (Fig. 8.6).

Absolute erythrocytosis is due to primary polycythaemia (PV) or secondary polycythaemia. Secondary polycythaemia is due to either an appropriate increase in red cells in response to anoxia, or an inappropriate increase associated with tumours, such as a renal carcinoma. The causes of polycythaemia are given in Table 8.16.

Primary polycythaemia: polycythaemia vera (PV)

PV is a clonal stem cell disorder in which there is an alteration in the pluripotent progenitor cell leading to excessive prolif-

Table 8.16 Causes of polycythaemia

Primary
Polycythaemia vera
Mutations in erythropoietin receptor
High-oxygen-affinity haemoglobins

Secondary

Due to an appropriate increase in erythropoietin:
High altitude
Lung disease
Cardiovascular disease (right-to-left shunt)
Heavy smoking
Increased affinity of haemoglobin, e.g. familial polycythaemia

Due to an inappropriate increase in erythropoietin:
Renal disease–renal cell carcinoma, Wilms' tumour
Hepatocellular carcinoma
Adrenal tumours
Cerebellar haemangioblastoma
Massive uterine fibroma

Relative:
Stress or spurious polycythaemia
Dehydration
Burns

eration of erythroid, myeloid and megakaryocytic progenitor cells. Over 95% of patients with PV have acquired mutations of the gene Janus Kinase 2 (JAK2). There is a V617F mutation which causes the substitution of phenylalanine for valine at position 617. JAK2 is a cytoplasmic tyrosine kinase that transduces signals, especially those triggered by haematopoietic growth factors such as erythropoietin, in normal and neoplastic cells. The significance of the discovery is twofold: first of immediate significance is the clinical utility of the detection of JAK2 mutations for the diagnosis of PV and second is the prospect of the development of new treatments for the myeloproliferative disorders based on targeting JAK2 activity.

Clinical features

The onset is insidious. It usually presents in patients aged over 60 years with tiredness, depression, vertigo, tinnitus and visual disturbance. It should be noted that these symptoms are also common in the normal population over the age of 60 and consequently PV is easily missed. These features, together with hypertension, angina, intermittent claudication and a tendency to bleed, are suggestive of PV.

Severe itching after a hot bath or when the patient is warm is common. Gout due to increased cell turnover may be a feature, and peptic ulceration occurs in a minority of patients. Thrombosis and haemorrhage are the major complications of PV.

The patient is usually plethoric and has a deep dusky cyanosis. Injection of the conjunctivae is commonly seen. The spleen is palpable in 70% and is useful in distinguishing PV from secondary polycythaemia. The liver is enlarged in 50% of patients.

Diagnosis

Box 8.2 shows the revised WHO criteria for diagnosis in adults. The measurement of red cell and plasma volume are not necessary. There may be a raised serum uric acid, leucocyte alkaline phosphatase and a raised serum vitamin B_{12} and vitamin B_{12} binding protein (transcobalamin 1).

Course and management

Treatment is designed to maintain a normal blood count and to prevent the complications of the disease, particularly thromboses and haemorrhage. Treatment is aimed at keeping the PCV below 0.45 L/L and the platelet count below 400×10^9/L. There are three types of specific treatment:

- **Venesection**. The removal of 400–500 mL weekly will successfully relieve many of the symptoms of PV. Iron deficiency limits erythropoiesis. Venesection is often used as the sole treatment and other therapy is reserved to control the thrombocytosis. The aim is to maintain a packed cell volume (PVC) of <0.45 L/L.
- **Chemotherapy**. Continuous or intermittent treatment with hydroxycarbamide (hydroxyurea) is used frequently because of the ease of controlling thrombocytosis and general safety in comparison to the alkylating agents such as busulfan, which carry an increased risk of acute leukaemia. Low-dose intermittent busulfan may be more convenient for elderly people, and this must be weighed against the potential risk of long-term complications.
- **Low dose aspirin** 100 mg daily with the above treatments is used for patients with recurrent thrombotic episodes.

Box 8.2 Modified from proposed revised WHO criteria for polycythaemia vera (PV)

Major criteria

Haemoglobin > 18.5 g/dL in men, 16.5 g/dL in women or other evidence of increased red cell volume

Presence of JAK2 tyrosine kinase V617F or other functionally similar mutation such as JAK2 exon 12 mutation

Minor criteria

Bone marrow biopsy, showing hypercellularity for age with trilineage growth (panmyelosis) with prominent erythroid, granulocytic and megakaryocytic proliferation

Serum erythropoietin level below the reference range for normal

Endogenous erythroid colony (EEC) formation in vitro*

Diagnosis requires the presence of both major criteria and one minor criterion or the presence of the first major criterion together with two minor criteria

*EEC. This is not routinely available but colony formation in the absence of exogenous erythropoietin in vitro is 100% specific and sensitive in patients without previous treatment.

This research was originally published in *Blood*. Tefferi A, Thiele J, Orazi A et al. Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. *Blood* 2007; **110:** 1092–1097. © American Society of Hematology.

- **Anagrelide** inhibits megakaryocyte differentiation and is useful for thrombolysis.

General treatment

Radioactive ^{32}P is only given to patients over 70 years because of the increased risk of transformation to acute leukaemia. *Allopurinol* is given to block uric acid production. The pruritus is lessened by avoiding very hot baths. *H1-receptor antagonists* have largely proved unsuccessful in relieving distressing pruritus, but *H2-receptor antagonists* such as cimetidine are occasionally effective.

Surgery. Polycythaemia should be controlled before surgery. Patients with uncontrolled PV have a high operative risk; 75% of patients have severe haemorrhage following surgery and 30% of these patients die. In an emergency, reduction of the haematocrit by venesection and appropriate fluid replacement must be carried out.

Prognosis

PV develops into myelofibrosis in 30% of cases and into acute myeloblastic leukaemia in 5% as part of the natural history of the disease.

Secondary polycythaemias

Many high-oxygen affinity haemoglobin mutants (HOAHM) have been described which lead to increased oxygen affinity but decreased oxygen delivery to the tissues, resulting in compensatory polycythaemia. A congenital autosomal recessive disorder (Chuvasch polycythaemia) is due to a defect in the oxygen-sensing erythropoietin production pathway caused by a mutation of the von Hippel–Lindau (VHL) gene, resulting in an increased production of erythropoietin.

The causes of secondary polycythaemias are shown in Table 8.16.

Serum erythropoietin (EPO) levels are normal or raised in secondary polycythaemia. Rarely the discovery of a high EPO level may be the clue to the presence of an EPO secreting tumour.

The *treatment* is that of the precipitating factor; for example, renal or posterior fossa tumours need to be resected. The commonest cause is heavy smoking, which can produce as much as 10% carboxyhaemoglobin and this can produce polycythaemia because of a reduction in the oxygen-carrying capacity of the blood. Heavy smokers also often have respiratory disease.

Complications of secondary polycythaemia are similar to those seen in PV, including thrombosis, haemorrhage and cardiac failure, but the complications due to myeloproliferative disease such as progression to myelofibrosis or acute leukaemia do not develop. Venesection may be symptomatically helpful in the hypoxic patient, particularly if the PCV is above 0.55 L/L.

'Relative' or 'apparent' polycythaemia (Gaisböck's syndrome)

This condition was originally thought to be stress-induced. The red cell volume is normal, but as the result of a decreased plasma volume, there is a relative polycythaemia. 'Relative' polycythaemia is more common than PV and occurs in middle-aged men, particularly in smokers who are obese and hypertensive. The condition may present with cardiovascular problems such as myocardial or cerebral ischaemia. For this reason, it may be justifiable to venesect the patient. Smoking should be stopped.

Essential thrombocythaemia (ET)

Essential thrombocythaemia (ET) is a myeloproliferative disorder closely related to PV. Patients have normal Hb levels and WBC but elevated platelet counts. At diagnosis the platelet count will usually be $>600 \times 10^9$/L, and may be as high as 2000×10^9/L or rarely even higher. ET presents either symptomatically with thromboembolic or less commonly bleeding problems or incidentally (e.g. at a routine medical check).

The diagnosis of ET is not straightforward as there is no global gold standard test. The JAK2 mutation tests (see PV) are useful in that the gene is mutated in about half of all cases of ET, confirming a myeloproliferative disorder. For the remaining 50% of patient with a normal JAK2 gene, clinical assessment and observation over a period of time are required. As a generalization a person with a very high platelet count ($>1000 \times 10^9$/L) who is clinically normal with good health will most likely prove to have ET. In a patient with a lower platelet count, e.g. 600×10^9/L, and in poor health the diagnosis can be more difficult. Other disorders which may give rise to reactive high platelet counts include autoimmune rheumatic disorders and malignancy. Individuals who have been splenectomized (for any reason, including trauma) sometimes have high platelet counts.

Treatment

Treatment is with hydroxycarbamide (hydroxyurea), anagrelide or busulfan to control the platelet count to less than 400×10^9/L.

α-Interferon is also effective; it is administered by subcutaneous injection. ET may eventually transform into PV, myelofibrosis or acute leukaemia, but the disease may not progress for many years.

MYELOFIBROSIS (MYELOSCLEROSIS)

The terms myelosclerosis and myelofibrosis are interchangeable. There is clonal proliferation of stem cells and myeloid metaplasia in the liver, spleen and other organs. Increased fibrosis in the bone marrow is caused by hyperplasia of abnormal megakaryocytes which release fibroblast-stimulating factors such as platelet-derived growth factor. In about 25% of cases there is a preceding history of PV and 50% have the JAK2 mutation seen in PV.

Clinical features

The disease presents insidiously with lethargy, weakness and weight loss. Patients often complain of a 'fullness' in the upper abdomen due to splenomegaly. Severe pain related to respiration may indicate perisplenitis secondary to splenic infarction, and bone pain and attacks of gout can complicate the illness. Bruising and bleeding occur because of thrombocytopenia or abnormal platelet function. Other physical signs include anaemia, fever and massive splenomegaly (for other causes, see p. 423).

Investigations

- **Anaemia** with leucoerythroblastic features is present (see p. 430). Poikilocytes and red cells with characteristic tear-drop forms are seen. The WBC count may be over 100×10^9/L, and the differential WBC count may be very similar to that seen in chronic myeloid leukaemia (CML); later leucopenia may develop.
- **The platelet count** may be very high, but in later stages, thrombocytopenia occurs.
- **Bone marrow aspiration** is often unsuccessful and this gives a clue to the presence of the condition. A bone marrow trephine is necessary to show the markedly increased fibrosis. Increased numbers of megakaryocytes may be seen.
- **The Philadelphia chromosome** is absent; this helps to distinguish myelofibrosis from most cases of CML.
- **The leucocyte alkaline phosphatase (LAP)** score is normal or high.
- **A high serum urate** is present.
- **Low serum folate** levels may occur owing to the increased haemopoietic activity.

Differential diagnosis

The major diagnostic difficulty is the differentiation of myelofibrosis from CML as in both conditions there may be marked splenomegaly and a raised WBC count with many granulocyte precursors seen in the peripheral blood. The main distinguishing features are the appearance of the bone marrow and the absence of the Philadelphia chromosome in myelofibrosis.

Fibrosis of the marrow, often with a leucoerythroblastic anaemia, can also occur secondarily to leukaemia or lymphoma, tuberculosis or malignant infiltration with metastatic carcinoma, or to irradiation.

Treatment

This consists of general supportive measures such as blood transfusion, folic acid, analgesics and allopurinol. Drugs such as hydroxycarbamide (hydroxyurea) and busulfan are used to reduce metabolic activity and high WBC count and platelet levels. Chemotherapy and radiotherapy are used to reduce splenic size. If the spleen becomes very large and painful,

Ask the authors
www.studentconsult.com

and transfusion requirements are high, it may be advisable to perform splenectomy. Splenectomy may also result in relief of severe thrombocytopenia.

Prognosis

Patients may survive for 10 years or more; median survival is 3 years. Death may occur in 10–20% of cases from transformation to acute myeloblastic leukaemia. The most common causes of death are cardiovascular disease, infection and gastrointestinal bleeding.

MYELODYSPLASIA (MDS)

Myelodysplasia (MDS) describes a group of acquired bone marrow disorders that are due to a defect in stem cells. They are characterized by increasing bone marrow failure with quantitative and qualitative abnormalities of all three myeloid cell lines (red cells, granulocyte/monocytes and platelets). The natural history of MDS is variable, but there is a high morbidity and mortality owing to bone marrow failure, and transformation into acute myeloblastic leukaemia occurs in about 30% of cases. A classification of the myelodysplastic syndrome is shown in Table 8.17.

Clinical and laboratory features

MDS occurs mainly in the elderly, and presents with symptoms of anaemia, infection or bleeding due to pancytopenia. Serial blood counts show evidence of increasing bone marrow failure with anaemia, neutropenia, monocytosis and thrombocytopenia, either alone or in combination. By contrast, in chronic myelomonocytic leukaemias (CMML), monocytes are $>1 \times 10^9$/L and the WBC count may be $>100 \times 10^9$/L.

The bone marrow usually shows increased cellularity despite the pancytopenia. Dyserythropoiesis is present, and granulocyte precursors and megakaryocytes also have abnormal morphology. Ring sideroblasts are present in all types. In refractory anaemia with excess blasts (RAEB) and refractory anaemia with excess blasts in transformation (RAEB-t), the number of blasts in the bone marrow is increased, and the prognosis is worse than in those types with a low number of blast cells (<5%).

Table 8.17 Classification of myelodysplasia (based on WHO and FAB)

	Category	Peripheral blasts (%)	Bone marrow (%)	Median prognosis (months)
1a	Refractory anaemia (RA)	< 1	Blasts < 5 RS < 15	≈ 50
2a	RA and ring sideroblasts (RARS)	< 1	Blasts < 5 RS > 15	≈ 50
3a	RA with excess blasts (RAEB) I	1–4	Blasts 5–10	10
3b	RAEB-t II	5–19	Blasts 11–19	5

In all categories, monocytes in the peripheral blood < 1.0×10^9/L.
RS, ring sideroblasts; RAEB-t (in transformation) also includes the 5q syndrome (deletion of 5q–) – usually elderly females but with good prognosis.

Management

Patients with <5% blasts in the bone marrow are usually managed conservatively with red cell and platelet transfusions and antibiotics for infections, as they are needed. Haemopoietic growth factors (e.g. erythropoietin, G-CSF) may be useful in some patients.

Patients with >5% blasts have a less favourable prognosis, and a number of treatment options are available:

- **Supportive care** only is suitable for elderly patients with other medical problems.
- **'Gentle' chemotherapy** (low-dose or single-agent, e.g. azacytidine) may be useful in patients with high WBC counts.
- **Intensive chemotherapy** schedules used for acute myeloblastic leukaemia (see p. 469) may be tried in patients under the age of 60, but the remission rate is less, and prolonged pancytopenia may occur owing to poor haemopoietic regeneration because of the defect in stem cells.
- **Lenalidomide** (a thalidomide analogue) has been proven to be remarkably successful in the treatment of early stage myelodysplasia with a chromosome 5q deletion (the 5q– syndrome). Avoid use in women of child-bearing age.
- **Bone marrow transplantation** offers the hope of cure in the small proportion of MDS patients who are under the age of 50 and who have an HLA-identical sibling or an unrelated HLA-matched donor.

THE SPLEEN

The spleen is the largest lymphoid organ in the body and is situated in the left hypochondrium. There are two anatomical components:

- the red pulp, consisting of sinuses lined by endothelial macrophages and cords (spaces)
- the white pulp, which has a structure similar to lymphoid follicles.

Blood enters via the splenic artery and is delivered to the red and white pulp. During the flow the blood is 'skimmed', with leucocytes and plasma preferentially passing to white pulp. Some red cells pass rapidly through into the venous system while others are held up in the red pulp.

Functions

Sequestration and phagocytosis. Normal red cells, which are flexible, pass through the red pulp into the venous system without difficulty. Old or abnormal cells are damaged by the hypoxia, low glucose and low pH found in the sinuses of the red pulp and are therefore removed by phagocytosis along with other circulating foreign matter. Howell–Jolly and Heinz bodies and sideroblastic granules have their particles removed by 'pitting' and are then returned to the circulation. IgG-coated red cells are removed through their Fc receptors by macrophages.

Extramedullary haemopoiesis. Pluripotential stem cells are present in the spleen and proliferate during severe haematological stress, such as in haemolytic anaemia or thalassaemia major.

Immunological function. About 25% of the body's T lymphocytes and 15% of B lymphocytes are present in the spleen. The spleen shares the function of production of antibodies with other lymphoid tissues.

Blood pooling. Up to one-third of the platelets are sequestrated in the spleen and can be rapidly mobilized. Enlarged spleens pool a significant percentage (up to 40%) of the red cell mass.

SPLENOMEGALY

Causes

A clinically palpable spleen can have many causes.

- Infection:
  (a) acute, e.g. septic shock, infective endocarditis, typhoid, infectious mononucleosis
  (b) chronic, e.g. tuberculosis and brucellosis
  (c) parasitic, e.g. malaria, kala-azar and schistosomiasis.
- Inflammation: rheumatoid arthritis, sarcoidosis, SLE.
- Haematological: haemolytic anaemia, haemoglobinopathies and the leukaemias, lymphomas and myeloproliferative disorders.
- Portal hypertension: liver disease.
- Miscellaneous: storage diseases, amyloid, primary and secondary neoplasias, tropical splenomegaly.

Massive splenomegaly. This is seen in myelofibrosis, chronic myeloid leukaemia, chronic malaria, kala-azar or, rarely, Gaucher's disease.

Hypersplenism

This can result from splenomegaly due to any cause. It is commonly seen with splenomegaly due to haematological disorders, portal hypertension, rheumatoid arthritis (Felty's syndrome) and lymphoma. Hypersplenism produces:

- pancytopenia
- haemolysis due to sequestration and destruction of red cells in the spleen
- increased plasma volume.

Treatment. This is often dependent on the underlying cause, but splenectomy is sometimes required for severe anaemia or thrombocytopenia.

Splenectomy

Splenectomy is performed mainly for:

- trauma
- immune thrombocytopenic purpura (see p. 436)
- haemolytic anaemias (see p. 408)
- hypersplenism.

Problems after splenectomy

An immediate problem is an increased platelet count (usually 600–1000 $\times$ 10^9/L) for 2–3 weeks. Thrombo-embolic phenomena may occur. In the longer term there is an increased risk of overwhelming infections, particularly pneumococcal infections.

Box 8.3 Prophylaxis against infection after splenectomy or splenic dysfunction

Vaccinate 2–3 weeks before elective splenectomy.

- A 23-valent unconjugated pneumococcal polysaccharide vaccine repeated every 5 years
- Meningococcal group C conjugate vaccine
- Annual influenza vaccine
- *Haemophilus influenzae* type b (Hib) vaccine
- Long-term penicillin V 500 mg 12-hourly (if sensitive, use erythromycin)
- Meningococcal polysaccharide vaccine (ACWY) for travellers to Africa/Saudi Arabia, e.g. during Hajj and Umrah pilgrimages

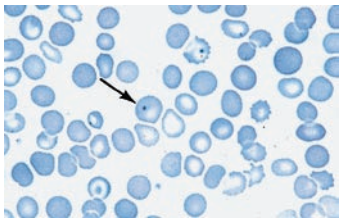

Fig. 8.29 **Postsplenectomy film with Howell–Jolly bodies (arrowed), target cells and irregularly contracted cells.**

Prophylaxis against infection after splenectomy or splenic dysfunction (Box 8.3)

All patients should be educated about the risk of infection and the importance of its early recognition and treatment. They should be given an information leaflet and should carry a card or bracelet to alert health professionals to their risk of overwhelming infection.

Postsplenectomy haematological features

- *Thrombocytosis* persists in about 30% of cases.
- *The WBC count* is usually normal but there may be a mild lymphocytosis and monocytosis.
- *Abnormalities in red cell morphology* are the most prominent changes and include Howell–Jolly bodies (contain basophilic nuclear remnants), Pappenheimer bodies (contain sideroblastic granules), target cells and irregular contracted red cells (Fig. 8.29). Pitted red cells can be counted.

Splenic atrophy

This is seen in sickle cell disease due to infarction. It is also seen in coeliac disease, in dermatitis herpetiformis, and occasionally in ulcerative colitis and essential thrombocythaemia. Postsplenectomy haematological features are seen.

BLOOD TRANSFUSION

The cells and proteins in the blood express antigens which are controlled by polymorphic genes; that is, a specific antigen may be present in some individuals but not in others. A blood transfusion may immunize the recipient against donor antigens that the recipient lacks (alloimmunization), and repeated transfusions increase the risk of the occurrence

FURTHER READING

Davies JM, Barnes R, Milligan D. Update of guidelines for the prevention and treatment of infection in patients with an absent or dysfunctional spleen. *Clinical Medicine* 2003; **2:** 440–443.

of alloimmunization. Similarly, the transplacental passage of fetal blood cells during pregnancy may alloimmunize the mother against fetal antigens inherited from the father. Antibodies stimulated by blood transfusion or pregnancy, such as Rh antibodies, are termed immune antibodies and are usually IgG, in contrast to naturally occurring antibodies, such as ABO antibodies, which are made in response to environmental antigens present in food and bacteria and which are usually IgM.

BLOOD GROUPS

The blood groups are determined by antigens on the surface of red cells; more than 280 blood groups are recognized. The ABO and Rh systems are the two major blood groups, but incompatibilities involving many other blood groups (e.g. Kell, Duffy, Kidd) may cause haemolytic transfusion reactions and/or haemolytic disease of the newborn (HDN).

ABO system

This blood group system involves naturally occurring IgM anti-A and anti-B antibodies which are capable of producing rapid and severe intravascular haemolysis of incompatible red cells.

The ABO system is under the control of a pair of allelic genes, *H* and *h*, and also three allelic genes, *A, B* and *O*, producing the genotypes and phenotypes shown in Table 8.18. The A, B and H antigens are very similar in structure; differences in the terminal sugars determine their specificity. The H gene codes for enzyme H, which attaches fucose to the basic glycoprotein backbone to form H substance, which is the precursor for A and B antigens (Fig. 8.30).

Table 8.18 The ABO system: antigens and antibodies

Phenotype	Genotype	Antigens	Antibodies	Frequency UK (%)
O	OO	None	Anti-A and anti-B	43
A	AA or AO	A	Anti-B	45
B	BB or BO	B	Anti-A	9
AB	AB	A and B	None	3

The *A* and *B* genes control specific enzymes responsible for the addition to H substance of *N*-acetylgalactosamine for Group A and d-galactose for Group B. The O gene is amorphic and does not transform H substance and therefore O is not antigenic. The A, B and H antigens are present on most body cells. These antigens are also found in soluble form in tissue fluids such as saliva and gastric juice in the 80% of the population who possess secretor genes.

Rh system

There is a high frequency of development of IgG RhD antibodies in RhD-negative individuals after exposure to RhD-positive red cells. The antibodies formed cause HDN and haemolytic transfusion reactions.

This system is coded by allelic genes, *C* and *c*, *E* and *e*, *D* and no *D*, which is signified as *d*; they are inherited as triplets on each chromosome 1, one from each pair of genes (i.e. *CDE/cde*). RhD-negative individuals have no D protein in the red cell membrane which explains why it is so immunogenic. In Caucasians, the RhD-negative phenotype almost always results from a complete deletion of the RhD gene; in black Africans, it can also result from an inactive gene containing stop codons in the reading frame.

PROCEDURE FOR BLOOD TRANSFUSION

The safety of blood transfusion depends on meticulous attention to detail at each stage leading to and during the transfusion. Avoidance of simple errors involving patient and blood sample identification at the time of collection of the sample for compatibility testing and at the time of transfusion would avoid most serious haemolytic transfusion reactions, almost all of which involve the ABO system.

Pretransfusion compatibility testing

Blood grouping

The ABO and RhD groups of the patient are determined.

Antibody screening

The patient's serum or plasma is screened for atypical antibodies that may cause a significant reduction in the survival of the transfused red cells. The patient's serum or plasma is

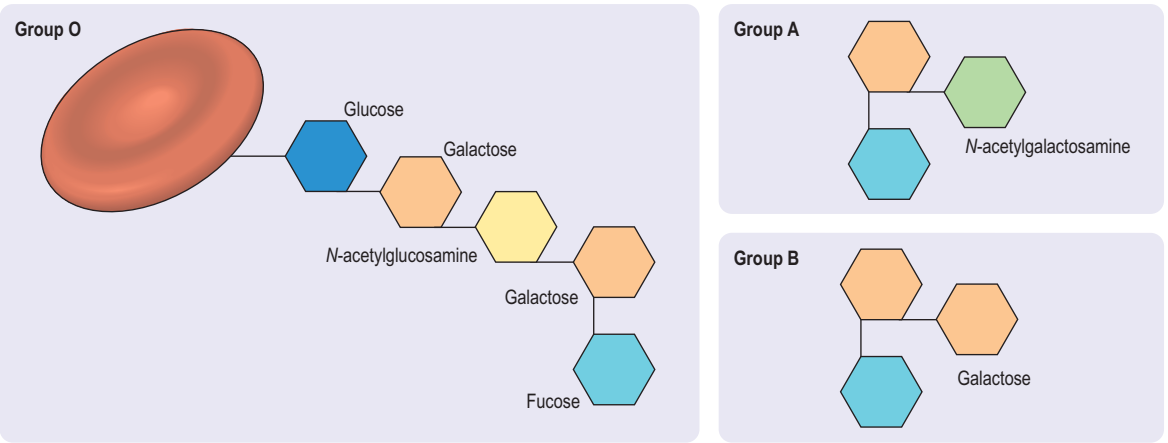

Fig. 8.30 **Sugar chains in the ABO blood group system.** Reproduced from Fricker J. Conversion of red blood cells to group O. *Lancet* 1996; **347**: 680, with permission from Elsevier.

tested against red cells from at least two group O donors, expressing a wide range of red cell antigens, for detection of IgM red cell alloantibodies (using a direct agglutination test of cells suspended in saline) and IgG antibodies (using an indirect antiglobulin test, see p. 415). About 10% of patients have a positive antibody screening result; in which case, further testing is carried out using a comprehensive panel of typed red cells to determine the blood group specificity of the antibody (clinically significant red cell antibodies are detected in about 20% of patients with positive antibody screens).

Selection of donor blood and crossmatching

Donor blood of the same ABO and RhD group as the patient is selected. Matching for additional blood groups is carried out for patients with clinically significant red cell antibodies (see below), for patients who are likely to be multitransfused and at high risk of developing antibodies, e.g. sickle cell disease, and many centres routinely provide c-negative and Kell-negative blood for women of child-bearing age to minimize the risk of alloimmunization and subsequent HDN.

Crossmatching procedures

Patients without atypical red cell antibodies. The full crossmatch involves testing the patient's serum or plasma against the donor red cells suspended in saline in a direct agglutination test, and also using an indirect antiglobulin test. In many hospitals this serological crossmatch has been omitted as the negative antibody screen makes it highly unlikely that there will be any incompatibility with the donor units. A greater risk is that of a transfusion error involving the collection of the patient sample or a mix-up of samples in the laboratory. Laboratories can use their information system to check the records of the patient and authorize the release of the donor units if a number of criteria are met (*computer or electronic crossmatching*), including:

- The system is automated for ABO and RhD grouping and antibody screening including positive sample identification and electronic transfer of results.
- The antibody screening procedure conforms to national recommendations.
- The patient's serum or plasma does not contain clinically significant red cell antibodies.
- The release of ABO incompatible blood must be prevented by conformation of laboratory computer software to the following requirements:
  (a) the issue of blood is not allowed if the patient has only been grouped once
  (b) the issue of blood is not allowed if the current group does not match the historical record
  (c) the system must not allow the reservation and release of units which are ABO incompatible with the patient.
- The laboratory must assure the validity of the ABO and RhD group of the donor blood either by written verification from the Blood Service supplying the donor units or confirmatory testing in the laboratory; the UK Blood Transfusion Services guarantee that the blood group information is correct.

Alternatively, the crossmatch can be shortened to an *'immediate spin crossmatch'* where the patient's serum or plasma is briefly incubated with the donor red cells, followed by centrifugation and examination for agglutination; this rapid crossmatch is an acceptable method of excluding ABO incompatibility in patients known to have a negative antibody screen.

Patients with atypical red cell antibodies. Donor blood should be selected that lacks the relevant red cell antigen(s), as well as being the same ABO and RhD group as the patient. A full crossmatch should always be carried out.

Several other systems for blood grouping, antibody screening and crossmatching are available to hospital transfusion laboratories. They do not depend on agglutination of red cells in suspension, but rather on the differential passage of agglutinated and unagglutinated red cells through a column of dextran gel matrix (e.g. DiaMed and Ortho Biovue systems), or on the capture of antibodies by red cells immobilized on the surface of a microplate well (e.g. Capture-R solid phase system).

Blood ordering

Elective surgery

Many hospitals have guidelines for the ordering of blood for elective surgery (maximum surgical blood ordering schedules). These are aimed at reducing unnecessary crossmatching and the amount of blood that eventually becomes outdated. Many operations in which blood is required only occasionally for unexpectedly high blood loss can be classified as 'group and save'; this means that, where the antibody screen is negative, blood is not reserved in advance but can be made available quickly if necessary, i.e. in a few minutes, using the immediate spin or electronic crossmatch procedures. If a patient has atypical antibodies, compatible blood should always be reserved in advance; this may take several days if the patient has multiple or unusual antibodies.

Emergencies

There may be insufficient time for full pretransfusion testing. The options include:

- Blood required immediately – use of 2 units of O RhD negative blood ('emergency stock'), to allow additional time for the laboratory to group the patient.
- Blood required in 10–15 minutes – use of blood of the same ABO and RhD groups as the patient (*'group compatible blood'*).
- Blood required in 45 minutes – most laboratories will be able to provide fully crossmatched blood within this time.

COMPLICATIONS OF BLOOD TRANSFUSION (Table 8.19)

In the USA, it has been mandatory to report transfusion-associated deaths to the Food and Drug Administration since 1975; such reports have provided useful data which have contributed to efforts to improve the safety of blood transfusion. Similar reporting schemes under the term '*haemovigilance'* have been set up in other countries, including the Serious Hazards of Transfusion (SHOT) scheme which produced its first report in the UK in 1997. Figure 8.31 shows the reports to SHOT up to 2005, indicating that '*incorrect blood component transfused'* is the most frequent type of

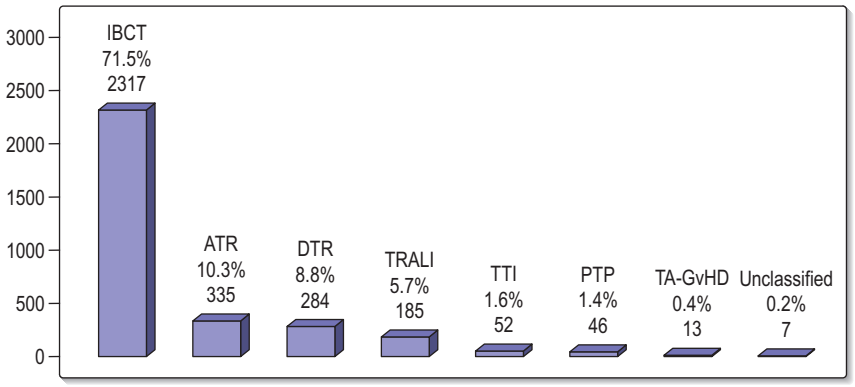

Fig. 8.31 **Overview of 3239 cases reported to the Serious Hazards of Transfusion (SHOT) scheme between 1996 and 2005.** ATR, acute transfusion reaction; DTR, delayed transfusion reaction; IBCT, incorrect blood component transfused; PTP, post-transfusion purpura; TA-GvHD, transfusion-associated graft-vs-host disease; TRALI, transfusion-related acute lung injury; TTI, transfusion-transmitted infection.

Table 8.19 Complications of blood transfusion

Immunological	Non-immunological
Alloimmunization and incompatibility	***Transmission of infection***
Red cells	Viruses
Immediate haemolytic transfusion reactions	– HAV, HBV, HCV
Delayed haemolytic transfusion reactions	– HIV, HHV8
Leucocytes and platelets	– CMV, EBV, HTLV-1, WNV
Non-haemolytic (febrile) transfusion reactions	Parasites
Post-transfusion purpura	– malaria, trypanosomiasis, toxoplasmosis
Poor survival of transfused platelets and granulocytes	Bacteria
Graft-versus-host disease	Prion – CJD
Lung injury (TRALI)	***Circulatory failure*** due to volume overload
Plasma proteins	***Iron overload*** due to multiple transfusions (see p. 408)
Urticarial and anaphylactic reactions	***Massive transfusion*** of stored blood may cause bleeding reactions and electrolyte changes
	Physical damage due to freezing or heating
	Thrombophlebitis
	Air embolism

serious incident. Errors at the time of collection of blood from the fridge and/or the administration of blood (53%) were the commonest source of error in 2005, followed by laboratory errors (43%) and mistakes in the collection of blood samples for compatibility testing (5%). Death or serious morbidity can also be attributed to other complications of blood transfusion including transfusion-associated lung injury (TRALI), transfusion-associated graft-versus-host disease (TA-GvHD) and bacterial infection of blood components.

Prevention

The serious consequences of such failures emphasize the need for meticulous checks at all stages in the procedure of blood transfusion. Written procedures and good training of staff is essential. Regular audit to ensure compliance with these procedures is also required. New approaches are also being used including the use of barcode patient identification and new technology at the bedside. Handheld devices can be used to prompt staff through the key steps and check that the barcode on the patient's wristband matches the barcode on the unit of blood (Fig. 8.32).

Fig. 8.32 The traditional method of pre-transfusion bedside checking requires two nurses and checks of multiple items of written documentation. With barcode technology, a handheld computer reads a barcode on the patient wristband containing full patient details. The handheld computer checks that the patient details on the wristband barcode match those on the barcode (in the red box) on the compatibility label attached to the unit after pre-transfusion testing. This barcode also contains the unique number of the unit, and is matched with the barcode number of the unit (top left of the bag) to ensure that the blood bank has attached the right compatibility label. This figure was originally published as the front cover of the September 2003 issue of *Transfusion* **43**. Reproduced with permission from Wiley–Blackwell.

Immunological complications

Alloimmunization

Blood transfusion carries a risk of alloimmunization to the many 'foreign' antigens present on red cells, leucocytes, platelets and plasma proteins. Alloimmunization also occurs during pregnancy – to fetal antigens inherited from the father and not shared by the mother (see p. 417).

Alloimmunization does not usually cause clinical problems with the first transfusion but these may occur with

subsequent transfusions. There may also be delayed consequences of alloimmunization, such as HDN and rejection of tissue transplants.

Incompatibility

This may result in poor survival of transfused cells, such as red cells and platelets, and also in the harmful effects of antigen–antibody reaction.

1. Red cells

Haemolytic transfusion reactions

Immediate reaction. This is the most serious complication of blood transfusion and is usually due to ABO incompatibility. There is complement activation by the antigen–antibody reaction, usually caused by IgM antibodies, leading to rigors, lumbar pain, dyspnoea, hypotension, haemoglobinuria and renal failure. The initial symptoms may occur a few minutes after starting the transfusion. Activation of coagulation also occurs and bleeding due to disseminated intravascular coagulation (DIC) is a bad prognostic sign. Emergency treatment for shock (p. 904) is needed to maintain the blood pressure and renal function.

Diagnosis

This is confirmed by finding evidence of haemolysis (e.g. haemoglobinuria), and incompatibility between donor and recipient. All documentation should be checked to detect errors such as:

- failure to check the identity of the patient when taking the sample for compatibility testing (i.e. sample from the wrong patient)
- mislabelling the blood sample with the wrong patient's name
- simple labelling or handling errors in the laboratory
- errors in the collection of blood, leading to delivery of the wrong blood to the ward/theatre
- failure to perform proper identity checks before the blood is transfused (i.e. blood transfused to the wrong patient).

Investigations

To confirm where the error occurred, blood grouping should be carried out on:

- the patient's original sample (used for the compatibility testing)
- a new sample taken from the patient after the reaction
- the donor units.

At the first suspicion of any serious transfusion reaction, the transfusion should always be stopped and the donor units returned to the blood transfusion laboratory with a new blood sample from the patient to exclude a haemolytic transfusion reaction.

Delayed reaction. This occurs in patients alloimmunized by previous transfusions or pregnancies. The antibody level is too low to be detected by pretransfusion compatibility testing, but a secondary immune response occurs after transfusion, resulting in destruction of the transfused cells, usually by IgG antibodies.

Haemolysis is usually extravascular as the antibodies are IgG, and the patient may develop anaemia and jaundice about a week after the transfusion, although most of these episodes are clinically silent. The blood film shows spherocytosis and reticulocytosis. The direct antiglobulin test is positive and detection of the antibody is usually straightforward.

2. Leucocytes and platelets

Non-haemolytic (febrile) transfusion reactions

Febrile reactions are a common complication of blood transfusion in patients who have previously been transfused or pregnant. The usual causes are the presence of leucocyte antibodies in an alloimmunized recipient acting against donor leucocytes in red cell concentrates leading to release of pyrogens, or the release of cytokines from donor leucocytes in platelet concentrates. Typical signs are flushing and tachycardia, fever (>38°C), chills and rigors. Aspirin may be used to reduce the fever, although it should not be used in patients with thrombocytopenia. The introduction of leucocyte-depleted blood in the UK, to minimize the risk of transmission of variant Creutzfeldt–Jakob disease (vCJD) by blood transfusion (see below), has reduced the incidence of febrile reactions.

Potent leucocyte antibodies in the plasma of donors, who are usually multiparous women, may cause severe pulmonary reactions (called transfusion-related acute lung injury or TRALI) characterized by dyspnoea, fever, cough, and shadowing in the perihilar and lower lung fields on the chest X-ray. Prompt respiratory support is essential; mechanical ventilation is frequently necessary. It usually resolves within 48–96 hours, but the mortality is approximately 20% in the 185 cases of TRALI reported to SHOT up to 2005.

Platelets

Post-transfusion purpura. See page 437.

3. Plasma proteins

Urticaria and anaphylaxis

Urticarial reactions are often attributed to plasma protein incompatibility, but in most cases, they are unexplained. They are common but rarely severe; stopping or slowing the transfusion and administration of chlorphenamine 10 mg i.v. are usually sufficient treatment.

Anaphylactic reactions (see p. 73) occasionally occur; severe reactions are seen in patients lacking IgA who produce anti-IgA that reacts with IgA in the transfused blood. The transfusion should be stopped and *epinephrine (adrenaline)* 0.5 mg i.m. and *chlorphenamine* 10 mg i.v. should be given immediately; endotracheal intubation may be required. Patients who have had severe urticarial or anaphylactic reactions should receive washed red cells, autologous blood or blood from IgA-deficient donors for patients with IgA deficiency.

Immunosuppression

Transfusions are known to have a favourable effect on the survival of subsequent renal allografts, due to transfusion-induced immunomodulation. Although the mechanism is unclear, the transfusion-induced immunosuppression is assumed to be due to allogeneic leucocytes Other clinical effects caused by transfusion-induced immunosuppression, such as postoperative infection and tumour recurrence, have been debated, but their clinical significance, if any, appears to be minor.

Non-immunological complications

Transmission of infection

Viral contamination: donor blood in the UK is currently tested for HBV, HCV, HIV-1 and HTLV-1. CMV-seronegative tested blood is given to immunosuppressed patients who are susceptible to acquiring CMV. Blood Services continue a vigilant search for new infectious agents such as HHV-8 which may be transmitted by blood transfusion, and for methods to prevent their transmission including donor screening, testing and pathogen inactivation. Donor questionnaires record recent travel to exclude possible risks of West Nile virus (WNV) and severe acute respiratory syndrome (SARS). WNV is the causal agent of meningoencephalitis and has been transmitted by transfusion and transplantation in the USA.

The incidence of transmission of HBV is about 1 in 400 000 units transfused, and it is less than 1 in 30 million units transfused for HCV since the introduction of testing minipools of donor plasma (48 donations per pool) for viral DNA.

In the UK the incidence of transmission of HIV by blood transfusion is extremely low – under 1 in 5 million units transfused. Prevention is based on self-exclusion of donors in 'high-risk' groups and testing each donation for anti-HIV.

There is still a potential risk of viral transmission from coagulation factor concentrates prepared from large pools of plasma. Measures for inactivating viruses such as treatment with solvents and detergents are undertaken. Viral transmission via blood transfusion is still a major issue in the developing world.

Bacterial contamination of blood components is rare but it is one of the most frequent causes of death associated with transfusion. Some organisms such as *Yersinia enterocolitica* can proliferate in red cell concentrates stored at 4°C, but platelet concentrates stored at 22°C are a more frequent cause of this problem. Systems to avoid bacterial contamination include automated culture systems and bacterial antigen detection systems, but these are not currently in routine use.

Transfusion-transmitted syphilis is very rare in the UK. Spirochaetes do not survive for more than 72 hours in blood stored at 4°C, and each donation is tested using the *Treponema pallidum haemagglutination assay* (TPHA).

There continues to be concern about the risk of transmitting the prion protein causing vCJD (see p. 121) by transfusion: four transmissions of vCJD have occurred following a blood transfusion in the UK. A number of measures have been taken in the UK, including universal leucocyte depletion of blood components (in 1999) because the prion protein is thought to be primarily associated with lymphocytes. Blood donors are excluded if they have had a blood transfusion since 1980. UK donor plasma is not used for the manufacture of blood products; imported plasma from the USA is used instead. For children under the age of 16 years, fresh frozen plasma (FFP) is sourced from plasma (from unremunerated donors) imported from the USA, on the basis that exposure to bovine spongiform encephalitis (BSE) from food was eliminated by 1 January 1996. FFP for this group is treated with methylthioninium chloride (methylene blue) to inactivate viruses.

While stringent measures are being taken to minimize the risk of transfusion-transmitted infection, it may never be possible to guarantee that donor blood is absolutely 'safe'. The current approach to the safety of blood components and plasma in the UK is extremely cautious, but it is not an absolute guarantee of safety. Clinicians should always carefully consider the patient's requirement for transfusion, and only transfuse if clinically appropriate (see below).

Circulatory failure due to volume overload – see management of acute heart failure, page 742.

Iron overload – see page 408.

Strategies for the avoidance of unnecessary transfusion

These include:

- strict criteria for the use of blood components and blood products
- stopping drug therapy (anticoagulants and antiplatelet drugs) that may potentiate bleeding in surgical patients
- the identification and treatment of anaemia prior to surgery
- the use of anti-fibrinolytic drugs, e.g. aprotinin and tranexamic acid in major surgery
- *recombinant factor VIIa* is being increasingly used for people with haemophilia with inhibitors and to treat patients with severe bleeding, e.g. postoperative, trauma, intracerebral haemorrhage. However, there is little evidence of its safety and effectiveness for this latter indication.

Artificial haemoglobin solutions and other blood substitutes continue to be evaluated. They have a short intravascular half-life and a recent meta-analysis found a significant risk of mortality as well as myocardial infarction.

Autologous transfusion

An alternative to using blood from volunteer donors is to use the patient's own blood. There are three types of autologous transfusion:

- *Predeposit*. The patient donates 2–5 units of blood at approximately weekly intervals before elective surgery.
- *Preoperative haemodilution*. 1 or 2 units of blood are removed from the patient immediately before surgery and retransfused to replace operative losses.
- *Blood salvage*. Blood lost during or after surgery may be collected and retransfused. Several techniques of varying levels of sophistication are available. The operative site must be free of bacteria, bowel contents and tumour cells.

Predeposit autologous transfusion has been abandoned in the UK except for patients where it is not possible to identify compatible blood because of multiple antibodies. There is little evidence that this approach reduces blood requirements, and because blood is perceived as being 'safe'. Blood salvage is increasingly being used as a way of avoiding the use of donor blood. In developing countries, autologous blood and blood from relatives are commonly used because of a lack of donor blood.

BLOOD, BLOOD COMPONENTS AND BLOOD PRODUCTS

Most blood collected from donors is processed as follows:

- **Blood components**, such as red cell and platelet concentrates, fresh frozen plasma (FFP) and

cryoprecipitate, are prepared from a single donation of blood by simple separation methods such as centrifugation and are transfused without further processing.
- **Blood products**, such as coagulation factor concentrates, albumin and immunoglobulin solutions, are prepared by complex processes using the plasma from many donors as the starting material (UK donor plasma is not used, see above).

In most circumstances it is preferable to transfuse only the blood component or product required by the patient ('*component therapy*') rather than use whole blood. This is the most effective way of using donor blood, which is a scarce resource, and reduces the risk of complications from transfusion of unnecessary components of the blood.

Whole blood
The average volume of blood withdrawn is 470 mL taken into 63 mL of anticoagulant. Blood stored at 4°C has a 'shelf-life' of 5 weeks when at least 70% of the transfused red cells should survive normally. Whole blood is now rarely used for transfusion; donated blood is processed into red cell concentrates and other blood components.

Red cell concentrates
Virtually all the plasma is removed and is replaced by about 100 mL of an optimal additive solution, such as SAG-M, which contains sodium chloride, adenine, glucose and mannitol. The mean volume is about 330 mL. The PCV is about 0.57 L/L, but the viscosity is low as there are no plasma proteins in the additive solution, and this allows fast administration if necessary. All blood components (red cell and platelet concentrates, and plasma) are leucocyte-depleted in the UK by filtration within 48 hours of collection of the donor blood.

Washed red cell concentrates
These are preparations of red cells suspended in saline, produced by cell separators to remove all but traces of plasma proteins. They are used in patients who have had severe recurrent urticarial or anaphylactic reactions.

Platelet concentrates
These are prepared either from whole blood by centrifugation or by plateletpheresis of single donors using cell separators. They may be stored for up to 5 days at 22°C with agitation. They are used to treat bleeding in patients with severe thrombocytopenia, and prophylactically to prevent bleeding in patients with bone marrow failure.

Granulocyte concentrates
These are prepared from single donors using cell separators and are used for patients with severe neutropenia with definite evidence of bacterial infection. The numbers of granulocytes are increased by treating donors with G-CSF and steroids.

Fresh frozen plasma
FFP is prepared by freezing the plasma from 1 unit of blood at 30°C within 6 hours of donation. The volume is approximately 200 mL. FFP contains all the coagulation factors present in fresh plasma and is used mostly for replacement of coagulation factors in acquired coagulation factor deficiencies. It may be further treated by a pathogen-inactivation process, e.g. methylene blue or solvent detergent, to minimize the risk of disease transmission. For children, see page 428.

Cryoprecipitate
This is obtained by allowing the frozen plasma from a single donation to thaw at 4–8°C and removing the supernatant. The volume is about 20 mL and it is stored at –30°C. It contains factor VIII:C, von Willebrand factor (VWF) and fibrinogen, and may be useful in DIC and other conditions where the fibrinogen level is very low. It is no longer used for the treatment of haemophilia A and von Willebrand disease because of the greater risk of virus transmission compared with virus-inactivated coagulation factor concentrates.

Factor VIII and IX concentrates
These are freeze-dried preparations of specific coagulation factors prepared from large pools of plasma. They are used for treating patients with haemophilia and von Willebrand disease, where recombinant coagulation factor concentrates are unavailable. Recombinant coagulation factor concentrates, where they are available, are the treatment of choice for patients with inherited coagulation factor deficiencies (see p. 438).

Albumin
There are two preparations:

- *Human albumin solution 4.5%,* previously called plasma protein fraction (PPF), contains 45 g/L albumin and 160 mmol/L sodium. It is available in 50, 100, 250 and 500 mL bottles.
- *Human albumin solution 20%,* previously called 'salt-poor' albumin, contains approximately 200 g/L albumin and 130 mmol/L sodium and is available in 50 and 100 mL bottles.

Human albumin solutions are generally considered to be inappropriate fluids for acute volume replacement or for the treatment of shock because they are no more effective in these situations than synthetic colloid solutions such as polygelatins (Gelofusine) or hydroxyethyl starch (Haemaccel). However, albumin solutions are indicated for treatment of acute severe hypoalbuminaemia and as the replacement fluid for plasma exchange. The 20% albumin solution is particularly useful for patients with nephrotic syndrome or liver disease who are fluid overloaded and resistant to diuretics. Albumin solutions should not be used to treat patients with malnutrition or chronic renal or liver disease with low serum albumin.

Normal immunoglobulin
This is prepared from normal plasma. It is used in patients with hypogammaglobulinaemia, to prevent infections, and in patients with, for example, immune thrombocytopenic purpura (see p. 436).

Specific immunoglobulins
These are obtained from donors with high titres of antibodies. Many preparations are available, such as anti-D, anti-hepatitis B and anti-varicella zoster.

THE WHITE CELL (see also Ch. 3)

The five types of leucocytes found in peripheral blood are neutrophils, eosinophils and basophils (which are all called granulocytes) and lymphocytes and monocytes. The development of these cells is shown in Figure 8.1.

NEUTROPHILS

The earliest morphologically identifiable precursors of neutrophils in the bone marrow are myeloblasts, which are large cells constituting up to 3.5% of the nucleated cells in the marrow. The nucleus is large and contains 2–5 nucleoli. The cytoplasm is scanty and contains no granules. Promyelocytes are similar to myeloblasts but have some primary cytoplasmic granules, containing enzymes such as myeloperoxidase. Myelocytes are smaller cells without nucleoli but with more abundant cytoplasm and both primary and secondary granules. Indentation of the nucleus marks the change from myelocyte to metamyelocyte. The mature neutrophil is a smaller cell with a nucleus with 2–5 lobes, with predominantly secondary granules in the cytoplasm which contain lysozyme, collagenase and lactoferrin.

Peripheral blood neutrophils are equally distributed into a circulating pool and a marginating pool lying along the endothelium of blood vessels. In contrast to the prolonged maturation time of about 10 days for neutrophils in the bone marrow, their half-life in the peripheral blood is extremely short, only 6–8 hours. In response to stimuli (e.g. infection, corticosteroid therapy), neutrophils are released into the circulating pool from both the marginating pool and the marrow. Immature white cells are released from the marrow when a rapid response (within hours) occurs in acute infection (described as a 'shift to the left' on a blood film).

Function

The prime function of neutrophils is to ingest and kill bacteria, fungi and damaged cells. Neutrophils are attracted to sites of infection or inflammation by chemotaxins. Recognition of foreign or dead material is aided by coating of particles with immunoglobulin and complement (opsonization) as neutrophils have Fc and C3b receptors (see p. 56). The material is ingested into vacuoles where it is subjected to enzymic destruction, which is either oxygen-dependent with the generation of hydrogen peroxide (myeloperoxidase) or oxygen-independent (lysosomal enzymes and lactoferrin). Leucocyte alkaline phosphatase (LAP) is an enzyme found in leucocytes. It is raised when there is a neutrophilia due to an acute illness. It is also raised in polycythaemia and myelofibrosis and reduced in CML.

Neutrophil leucocytosis

A rise in the number of circulating neutrophils to $>10 \times 10^9$/L occurs in bacterial infections or as a result of tissue damage. This may also be seen in pregnancy, during exercise and after corticosteroid administration (Table 8.20). With any tissue necrosis there is a release of various soluble factors, causing a leucocytosis. Interleukin 1 is also released in tissue necrosis and causes a pyrexia. The pyrexia and leucocytosis accompanying a myocardial infarction are a good example of this and may be wrongly attributed to infection.

A leukaemoid reaction (an overproduction of white cells, with many immature cells) may occur in severe infections, tuberculosis, malignant infiltration of the bone marrow and occasionally after haemorrhage or haemolysis.

In leucoerythroblastic anaemia, nucleated red cells and white cell precursors are found in the peripheral blood. Causes include marrow infiltration with metastatic carcinoma, myelofibrosis, osteopetrosis, myeloma, lymphoma, and occasionally severe haemolytic or megaloblastic anaemia.

Neutropenia and agranulocytosis

Neutropenia is defined as a circulatory neutrophil count below 1.5×10^9/L. A virtual absence of neutrophils is called agranulocytosis. The causes are given in Table 8.21. It should

Table 8.20 Neutrophil leucocytosis

Bacterial infections
Tissue necrosis, e.g. myocardial infarction, trauma
Inflammation, e.g. gout, rheumatoid arthritis
Drugs, e.g. corticosteroids, lithium
Haematological:
Myeloproliferative disease
Leukaemoid reaction
Leucoerythroblastic anaemia
Physiological, e.g. pregnancy, exercise
Malignant disease, e.g. bronchial, breast, gastric
Metabolic, e.g. renal failure, acidosis
Congenital, e.g. leucocyte adhesion deficiency, hereditary neutrophilia

Table 8.21 Causes of neutropenia

Acquired
Viral infection
Severe bacterial infection, e.g. typhoid
Felty's syndrome
Immune neutropenia – autoimmune, autoimmune neonatal neutropenia
Pancytopenia from any cause, including drug-induced marrow aplasia (see p. 402)
Pure white cell aplasia
Inherited
Ethnic (neutropenia is common in black races)
Kostmann's syndrome (severe infantile agranulocytosis) due to mutation in elastane 2 (ELA 2) gene
Cyclical (genetic mutation in ELA2 gene with neutropenia every 2–3 weeks)
Others, e.g. Schwachman–Diamond syndrome, dyskeratosis congenita, Chédiak–Higashi syndrome

The white cell
Neutrophils
Eosinophils
Basophils
Monocytes
Lymphocytes
Haemostasis and thrombosis
Haemostasis

be noted that black patients may have somewhat lower neutrophil counts. Neutropenia caused by viruses is probably the most common type. Chemotherapy and radiotherapy predictably produce neutropenia; many other drugs have been known to produce an idiosyncratic cytopenia and a drug cause should always be considered.

Clinical features

Infections may be frequent, often serious, and are more likely as the neutrophil count falls. An absolute neutrophil count of less than 0.5×10^9/L is regarded as 'severe' neutropenia and may be associated with life-threatening infections such as pneumonia and septicaemia. A characteristic glazed mucositis occurs in the mouth, and ulceration is common.

Investigations

The blood film shows marked neutropenia. The appearance of the bone marrow will indicate whether the neutropenia is due to depressed production or increased destruction of neutrophils. Neutrophil antibody studies are performed if an immune mechanism is suspected.

Treatment

Antibiotics should be given as necessary to patients with acute severe neutropenia (see p. 461).

If the neutropenia seems likely to have been caused by a drug, all current drug therapy should be stopped. Recovery of the neutrophil count usually occurs after about 10 days. G-CSF (see p. 389) is used to decrease the period of neutropenia after chemotherapy and haemopoietic transplantation. It is also used successfully in the treatment of chronic neutropenia.

Steroids and high-dose intravenous immunoglobulin are used to treat patients with severe autoimmune neutropenia and recurrent infections, and G-CSF has produced responses in some cases.

EOSINOPHILS

Eosinophils are slightly larger than neutrophils and are characterized by a nucleus with usually two lobes and large cytoplasmic granules that stain deeply red. The eosinophil plays a part in allergic responses (see p. 56) and in the defence against infections with helminths and protozoa.

Eosinophilia is $>0.4 \times 10^9$/L eosinophils in the peripheral blood. The causes of eosinophilia are listed in Table 8.22.

Table 8.22 Causes of eosinophilia

Parasitic infestations, such as:
Ascaris
Hookworm
Strongyloides

Allergic disorders, such as:
Hayfever (allergic rhinitis)
Other hypersensitivity reactions, including drug reactions

Skin disorders, such as:
Urticaria
Pemphigus
Eczema

Pulmonary disorders, such as:
Bronchial asthma
Tropical pulmonary eosinophilia
Allergic bronchopulmonary aspergillosis
Churg–Strauss syndrome

Malignant disorders, such as:
Hodgkin's lymphoma
Carcinoma
Eosinophilic leukaemia

Miscellaneous, such as:
Hypereosinophilic syndrome
Sarcoidosis
Hypoadrenalism
Eosinophilic gastroenteritis

BASOPHILS

The nucleus of basophils is similar to that of neutrophils but the cytoplasm is filled with large black granules. The granules contain histamine, heparin and enzymes such as myeloperoxidase. The physiological role of the basophil is not known. Binding of IgE causes the cells to degranulate and release histamine and other contents involved in acute hypersensitivity reactions (see p. 437).

Basophils are usually few in number ($<1 \times 10^9$/L) but are significantly increased in myeloproliferative disorders.

MONOCYTES

Monocytes are slightly larger than neutrophils. The nucleus has a variable shape and may be round, indented or lobulated. The cytoplasm contains fewer granules than neutrophils. Monocytes are precursors of tissue macrophages and dendritic cells and spend only a few hours in the blood but can continue to proliferate in the tissues for many years.

A monocytosis ($>0.8 \times 10^9$/L) may be seen in chronic bacterial infections such as tuberculosis or infective endocarditis, chronic neutropenia and patients with myelodysplasia, particularly chronic myelomonocytic leukaemia.

LYMPHOCYTES

Lymphocytes form nearly half the circulating white cells. They descend from pluripotential stem cells (Fig. 8.1). Circulating lymphocytes are small cells, a little larger than red cells, with a dark-staining central nucleus. There are two main types: T and B lymphocytes (see p. 63).

Lymphocytosis (lymphocyte count $>5 \times 10^9$/L) occurs in response to viral infections, particularly EBV, CMV and HIV, and chronic infections such as tuberculosis and toxoplasmosis. It also occurs in chronic lymphocytic leukaemia and in some lymphomas.

HAEMOSTASIS AND THROMBOSIS

The integrity of the circulation is maintained by blood flowing through intact vessels lined by endothelial cells. Injury to the vessel wall exposes collagen and together with tissue injury sets in motion a series of events leading to haemostasis.

HAEMOSTASIS

Haemostasis is a complex process depending on interactions between the vessel wall, platelets and coagulation and fibrinolytic mechanisms. The formation of the haemostatic plug is shown in Figure 8.33.

Vessel wall

The vessel wall is lined by endothelium which, in normal conditions, prevents platelet adhesion and thrombus formation. This property is partly due to its negative charge but also to:

- thrombomodulin and heparan sulphate expression
- synthesis of prostacyclin (PGI_2) and nitric oxide (NO), which cause vasodilatation and inhibit platelet aggregation
- production of plasminogen activator.

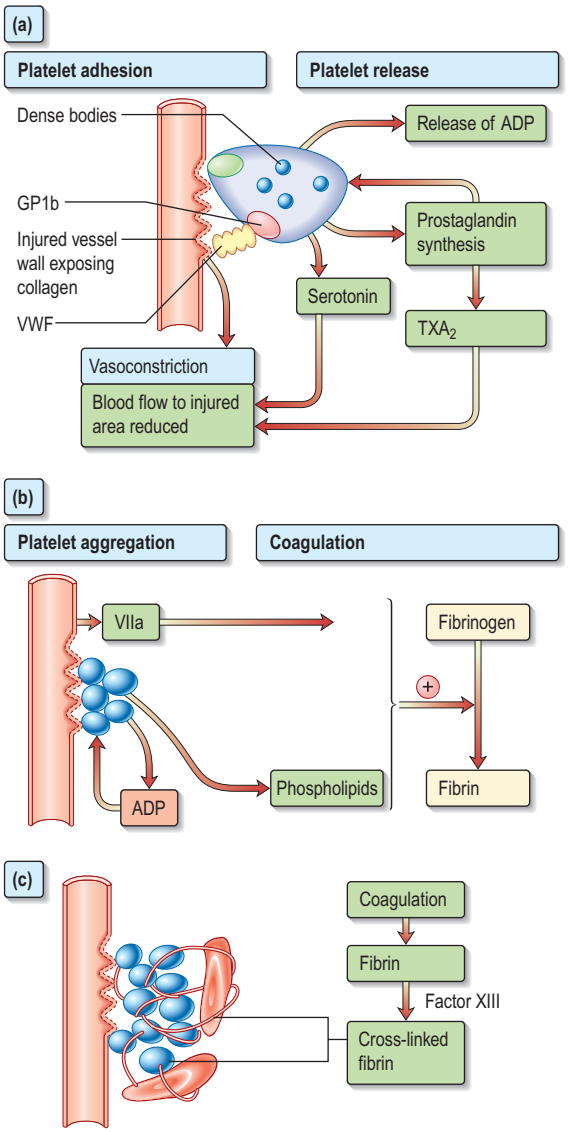

Fig. 8.33 **Formation of the haemostatic plug: sequential interactions between the vessel wall, platelets and coagulation factors.**
(a) Contact of platelets with collagen via the platelet receptor GP1b and factor VWF in plasma activates platelet prostaglandin synthesis which stimulates release of ADP from the dense bodies. Vasoconstriction of the vessel occurs as a reflex and by release of serotonin and thromboxane A_2 (TXA_2) from platelets.
(b) Release of ADP from platelets induces platelet aggregation and formation of the platelet plug. The coagulation pathway is stimulated leading to formation of fibrin.
(c) Fibrin strands are cross-linked by factor XIII and stabilize the haemostatic plug by binding platelets and red cells.

Injury to vessels causes reflex vasoconstriction, while endothelial damage results in loss of antithrombotic properties, activation of platelets and coagulation and inhibition of fibrinolysis (Fig. 8.33).

Platelets

Platelet adhesion. When the vessel wall is damaged, the platelets escaping come into contact with and adhere to collagen and von Willebrand factor that is bound below the endothelium. This is mediated through glycoprotein Ib (GPIb).

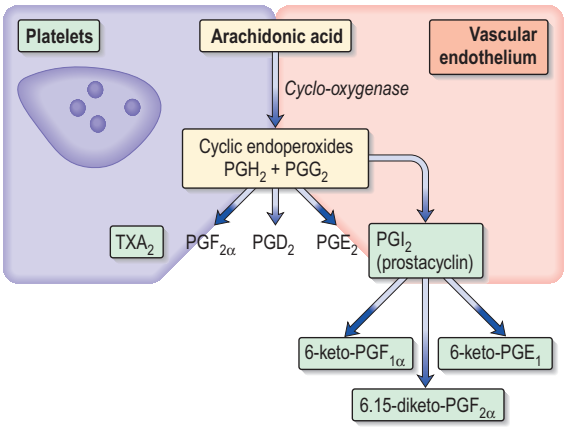

Fig. 8.34 **Prostaglandin synthesis.**

Glycoprotein IIb–IIIa is then exposed, forming a second binding site for VWF. Within seconds of adhesion to the vessel wall platelets begin to undergo a shape change, from a disc to a sphere, spread along the subendothelium and release the contents of their cytoplasmic granules, i.e. the dense bodies (containing ADP and serotonin) and the α-granules (containing platelet-derived growth factor, platelet factor 4, β-thromboglobulin, fibrinogen, VWF, fibronectin, thrombospondin and other factors).

Platelet release. The release of ADP leads to a conformational change in the fibrinogen receptor, the glycoprotein IIb–IIIa complex (GPIIb–IIIa), on the surfaces of adherent platelets allowing it to bind to fibrinogen (see also Fig. 8.41).

Platelet aggregation (Fig. 8.33b). As fibrinogen is a dimer it can form a direct bridge between platelets and so binds platelets into activated aggregates (platelet aggregation) and further platelet release of ADP occurs. A self-perpetuating cycle of events is set up leading to formation of a platelet plug at the site of the injury.

Coagulation. After platelet aggregation and release of ADP, the exposed platelet membrane phospholipids are available for the assembly of coagulation factor enzyme complexes (tenase and prothrombinase); this platelet phospholipid activity has been called platelet factor 3 (PF-3). The presence of thrombin encourages fusion of platelets, and fibrin formation reinforces the stability of the platelet plug. Central to normal platelet function is platelet *prostaglandin synthesis*, which is induced by platelet activation and leads to the formation of TXA_2 in platelets (Fig. 8.34). Thromboxane (TXA_2) is a powerful vasoconstrictor and also lowers cyclic AMP levels and initiates the platelet release reaction. Prostacyclin (PGI_2) is synthesized in vascular endothelial cells and opposes the actions of TXA_2. It produces vasodilatation and increases the level of cyclic AMP, preventing platelet aggregation on the normal vessel wall as well as limiting the extent of the initial platelet plug after injury.

Coagulation and fibrinolysis

Coagulation involves a series of enzymatic reactions leading to the conversion of soluble plasma fibrinogen to fibrin clot (Fig. 8.35). Roman numerals are used for most of the factors, but I and II are referred to as fibrinogen and prothrombin respectively; III, IV and VI are redundant. The active forms are denoted by 'a'. The coagulation factors are primarily synthesized in the liver and are either serine protease enzyme

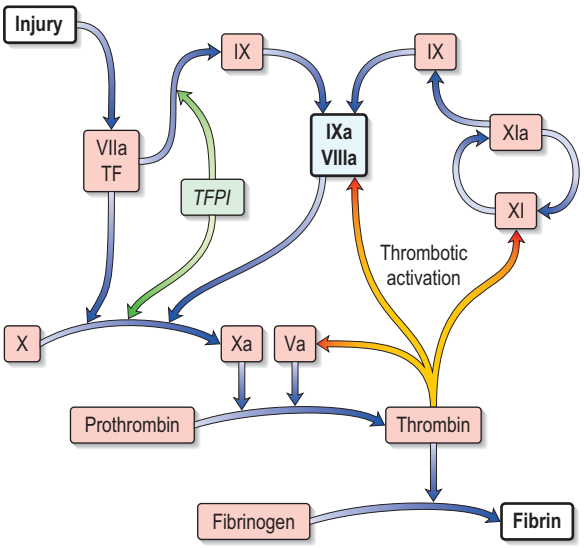

Fig. 8.35 **Coagulation mechanism.** The in vivo pathway begins with tissue factor–factor VIIa complex activating factor X and also factor IX. Factor XI is activated by thrombin. TF, tissue factor; TFPI, tissue factor pathway inhibitor.

precursors (factors XII, XI, X, IX and thrombin) or cofactors (V and VIII), except for fibrinogen, which is degraded to form fibrin.

Coagulation pathway

This enzymatic amplification system was traditionally divided into 'extrinsic' and 'intrinsic' pathways. This concept is useful for the interpretation of clinical laboratory tests such as the prothrombin time (PT) and activated partial thromboplastin time (APTT) (see p. 435) but unrepresentative and an oversimplification of in vivo coagulation. Coagulation is initiated by tissue damage. This exposes tissue factor (TF) which binds to factor VII. The TF–factor VII complex directly converts factor X to active factor Xa and some factor IX to factor IXa. In the presence of factor Xa, tissue factor pathway inhibitor (TFPI) inhibits further generation of factor Xa and factor IXa. Following inhibition by TFPI the amount of factor Xa produced is insufficient to maintain coagulation. Further factor Xa, to allow haemostasis to progress to completion, can only be generated by the alternative factor IX/factor VIII pathway. However, enough thrombin exists at this point to activate factor VIII (and factor V) and together with factor IXa (generated by TF-factor VIIa) further activation of factor X can proceed. The presence of activated factor V dramatically enhances the conversion of prothrombin to thrombin by factor Xa. Without the amplification and consolidating action of factor VIII/factor IX, bleeding will ensue as generation of factor Xa is insufficient to sustain haemostasis.

Thrombin hydrolyses the peptide bonds of fibrinogen, releasing fibrinopeptides A and B, and allowing polymerization between fibrinogen molecules to form fibrin. At the same time, thrombin, in the presence of calcium ions, activates factor XIII, which stabilizes the fibrin clot by cross-linking adjacent fibrin molecules.

Factor VIII consists of a molecule with coagulant activity (VIII:C) associated with von Willebrand factor. Factor VIII increases the activity of factor IXa by ~200000 fold. VWF functions to prevent premature factor VIII:C breakdown and

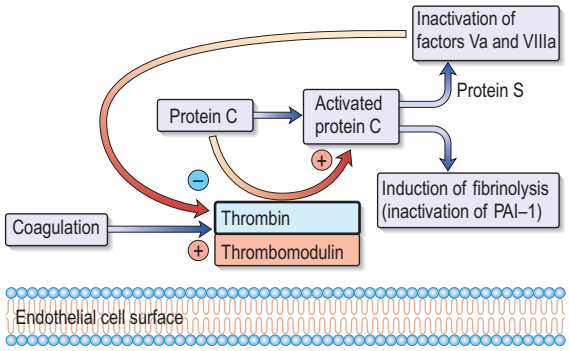

Fig. 8.36 **Activation of protein C.** PAI-1, plasminogen activator inhibitor 1.

locate it to areas of vascular injury. VIII:C has a molecular weight of about 350000.

Von Willebrand Factor (VWF) is a glycoprotein with a molecular weight of about 200000 which readily forms multimers in the circulation with molecular weights of up to 20×10^6. It is synthesized by endothelial cells and megakaryocytes and stored in platelet granules as well as the endothelial cells. The high-molecular-weight multimeric forms of VWF are the most biologically active (see p. 432 and Fig. 8.39).

Physiological limitation of coagulation

Without a physiological system to limit blood coagulation dangerous thrombosis could ensue. The natural anticoagulant mechanism regulates and localizes thrombosis to the site of injury.

Antithrombin. Antithrombin (AT), a member of the serine protease inhibitor (serpin) superfamily, is a potent inhibitor of coagulation. It inactivates the serine proteases by forming stable complexes with them, and its action is greatly potentiated by heparin.

Activated protein C. This is generated from its vitamin K-dependent precursor, Protein C, by thrombin; thrombin activation of protein C is greatly enhanced when thrombin is bound to thrombomodulin on endothelial cells (Fig. 8.36). Activated protein C inactivates factor V and factor VIII, reducing further thrombin generation.

Protein S. This is a cofactor for protein C, which acts by enhancing binding of activated protein C to the phospholipid surface. It circulates bound to C4b binding protein but some 30–40% remains unbound and active (free protein S).

Other inhibitors. Other natural inhibitors of coagulation include α_2-macroglobulin, α_1-antitrypsin and α_2-antiplasmin.

Fibrinolysis

Fibrinolysis is a normal haemostatic response that helps to restore vessel patency after vascular damage. The principal component is the enzyme plasmin, which is generated from its inactive precursor plasminogen (Fig. 8.37). This is achieved principally via tissue plasminogen activator (t-PA) released from endothelial cells. Some plasminogen activation may also be promoted by urokinase, produced in the kidneys. Other plasminogen activators (factor XII and prekallikrein) are of minor physiological importance.

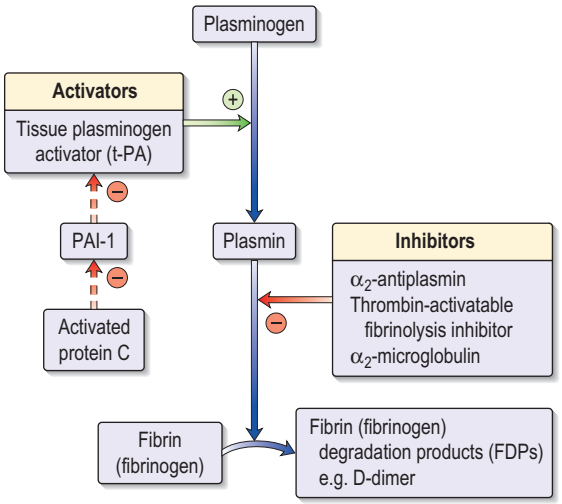

Fig. 8.37 **Fibrinolytic system.** PA-1, plasminogen activator inhibitor-1.

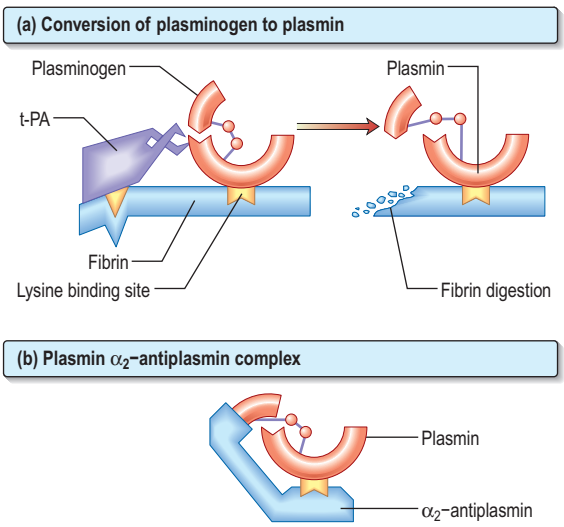

Fig. 8.38 **Fibrinolysis. (a)** The conversion of plasminogen to plasmin by plasminogen activator (t-PA) occurs most efficiently on the surface of fibrin, which has binding sites for both plasminogen and t-PA. **(b)** Free plasmin in the blood is rapidly inactivated by α_2-antiplasmin. Plasmin generated on the fibrin surface is partially protected from inactivation. The lysine-binding sites on plasminogen are necessary for the interaction between plasmin(ogen) and fibrin and between plasmin and α_2-antiplasmin.

Plasmin is a serine protease, which breaks down fibrinogen and fibrin into fragments X, Y, D and E, collectively known as fibrin (and fibrinogen) degradation products (FDPs). D-dimer is produced when cross-linked fibrin is degraded. Its presence in the plasma indicates that the coagulation mechanism has been activated.

The fibrinolytic system is activated by the presence of fibrin. Plasminogen is specifically adsorbed to fibrin and fibrinogen by lysine-binding sites. However, little plasminogen activation occurs in the absence of polymerized fibrin, as fibrin also has a specific binding site for plasminogen activators, whereas fibrinogen does not (Fig. 8.38).

t-PA is inactivated by plasminogen activator inhibitor-1 (PAI-1). Activated protein C inactivates PAI-1 and therefore induces fibrinolysis (Fig. 8.36). Inactivators of plasmin, such as α_2-antiplasmin (Fig. 8.38) and thrombin-activatable fibrinolysis inhibitor (TAFI), also contribute to the regulation of fibrinolysis.

Investigation of bleeding disorders

Although the precise diagnosis of a bleeding disorder will depend on laboratory tests, much information is obtained from the history and physical examination:

- **Is there a generalized haemostatic defect?** Supportive evidence for this includes bleeding from multiple sites, spontaneous bleeding, and excessive bleeding after injury.
- **Is the defect inherited or acquired?** A family history of a bleeding disorder should be sought. Severe inherited defects usually become apparent in infancy, while mild inherited defects may only come to attention later in life, for example with excessive bleeding after surgery, childbirth, dental extractions or trauma. Some defects are revealed by routine coagulation screens which are performed before surgical procedures.
- **Is the bleeding suggestive of a vascular/platelet defect or a coagulation defect?**

Vascular/platelet bleeding is characterized by easy bruising and spontaneous bleeding from small vessels. There is often bleeding into the skin. The term purpura includes both petechiae, which are small skin haemorrhages varying from pinpoint size to a few millimetres in diameter and which do not blanch on pressure, and ecchymoses, which are larger areas of bleeding into the skin. Bleeding also occurs from mucous membranes especially the nose and mouth. *Coagulation disorders* are typically associated with bleeding after injury or surgery, and in more severe forms, haemarthroses and muscle haematomas. There is often a short delay between the precipitating event and overt haemorrhage or haematoma formation.

Laboratory investigations

- **Blood count and film** show the number and morphology of platelets and any blood disorder such as leukaemia or lymphoma. The normal range for the platelet count is 150–400 $\times$ 10^9/L.
- **Bleeding time** measures platelet plug formation in vivo. It is determined by applying a sphygmomanometer cuff to the arm and inflating it to 40 mmHg. Two 1 mm deep, 1 cm long incisions are made in the forearm with a template. Each wound is blotted every 30 seconds and the time taken for bleeding to stop is recorded, normally between 3 and 10 minutes. Prolonged bleeding times are found in patients with platelet function defects, and there is a progressive prolongation with platelet counts less than 100 $\times$ 10^9/L. The bleeding time should not be performed at low platelet counts.
- **Coagulation tests** are performed using blood collected into citrate, which neutralizes calcium ions and prevents clotting.

The *prothrombin time* (PT) (also see p. 445) is measured by adding tissue factor (thromboplastin) and calcium to the patient's plasma. The normal PT is 12–16 seconds and may be expressed as the international normalized ratio, INR (see p. 324) The PT measures VII, X, V, prothrombin and fibrinogen (classic 'extrinsic' pathway) and is prolonged with abnor-

malities of these factors. It may also be abnormal in liver disease, or if the patient is on warfarin.

The *activated partial thromboplastin time* (APTT) is also sometimes known as the PTT with kaolin (PTTK). It is performed by adding a surface activator (such as kaolin), phospholipid (to mimic platelet membrane) and calcium to the patient's plasma. The normal APTT is 30–50 seconds and depends on the exact methodology. The APTT measures XII, XI, IX, VIII, X, V, prothrombin and fibrinogen (classic 'intrinsic' pathway) and is prolonged with deficiencies of one or more of these factors. It is not dependent on factor VII.

The *thrombin time* (TT) is performed by adding thrombin to the patient's plasma. The normal TT is 12–14 seconds, and it is prolonged with fibrinogen deficiency, qualitative defects of fibrinogen (dysfibrinogenaemia) or inhibitors such as heparin or FDPs.

Correction tests can be used to differentiate prolonged times in the PT, APTT and TT due to various coagulation factor deficiencies and inhibitors of coagulation. Prolonged PT, APTT or TT due to coagulation factor deficiencies can be corrected by addition of normal plasma to the patient's plasma. Failure to correct after addition of normal plasma is suggestive of the presence of an inhibitor of coagulation.

Factor assays are used to confirm coagulation defects, especially where a single inherited disorder is suspected.

Special tests of coagulation will often be required to confirm the precise haemostatic defect. Such tests include estimation of fibrinogen and FDPs, platelet function tests such as platelet aggregation and platelet granule contents.

VASCULAR DISORDERS

The vascular disorders (Table 8.23) are characterized by easy bruising and bleeding into the skin. Bleeding from mucous membranes sometimes occurs but the bleeding is rarely severe. Laboratory investigations including the bleeding time are normal. The vascular disorders include the following.

Hereditary haemorrhagic telangiectasia is a rare disorder with autosomal dominant inheritance. Dilatation of capillaries and small arterioles produces characteristic small red spots that blanch on pressure in the skin and mucous membranes, particularly the nose and gastrointestinal tract. Recurrent epistaxis and chronic gastrointestinal bleeding are the major problems which causes chronic iron deficiency anaemia.

Easy bruising syndrome is a common benign disorder occurring in otherwise healthy women. It is characterized by bruises on the arms, legs and trunk with minor trauma, possibly because of skin vessel fragility. It may give rise to the suspicion of a serious bleeding disorder.

Senile purpura and purpura due to steroids are both due to atrophy of the vascular supporting tissue.

Purpura due to infections is mainly caused by damage to the vascular endothelium. The rash of meningococcal septicaemia is particularly characteristic (see p. 136).

Henoch–Schönlein purpura (see p. 592) occurs mainly in children. It is a type III hypersensitivity (immune complex) reaction that is often preceded by an acute upper respiratory tract infection. Purpura is mainly seen on the legs and buttocks. Abdominal pain, arthritis, haematuria and glomerulonephritis also occur. Recovery is usually spontaneous, but some patients develop renal failure.

Episodes of inexplicable bleeding or bruising may represent abuse, either self-inflicted or caused by others. These various forms of artificial or factitious purpura are expressions of severe emotional or psychiatric disturbances.

Table 8.23 Vascular disorders

Congenital
Hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu disease)
Connective tissue disorders (Ehlers–Danlos syndrome, osteogenesis imperfecta, pseudoxanthoma elasticum, Marfan's syndrome)

Acquired
Severe infections:
- Septicaemia
- Meningococcal infections
- Measles
- Typhoid

Allergic
Henoch–Schönlein purpura
Autoimmune disorders (SLE, rheumatoid arthritis)

Drugs
Steroids
Sulphonamides

Others
Senile purpura
Easy bruising syndrome
Scurvy
Factitious purpura

PLATELET DISORDERS

Bleeding due to thrombocytopenia or abnormal platelet function is characterized by purpura and bleeding from mucous membranes. Bleeding is uncommon with platelet counts above 50×10^9/L, and severe spontaneous bleeding is unusual with platelet counts above 20×10^9/L (Table 8.24).

Thrombocytopenia

This is caused by reduced platelet production in the bone marrow, excessive peripheral destruction of platelets or sequestration in an enlarged spleen (Table 8.25). The underlying cause may be revealed by history and examination but a bone marrow examination will show whether the numbers of megakaryocytes are reduced, normal or increased, and will provide essential information on morphology. Specific laboratory tests may be useful to confirm the presence of such conditions as paroxysmal nocturnal haemoglobinuria (PNH) or systemic lupus erythematosus (SLE).

In patients with thrombocytopenia due to failure of production, no specific treatment may be necessary but the underlying condition should be treated if possible. Where the platelet count is very low or the risk of bleeding is very high, then platelet transfusion is indicated.

Table 8.24 Clinical effects caused by different levels of platelet count

Platelet count ($\times 10^9$/L)	Clinical defect
>500	Haemorrhage or thrombosis
500–100	No clinical effect
100–50	Moderate haemorrhage after injury
50–20	Purpura may occur Haemorrhage after injury
<20	Purpura common Spontaneous haemorrhage from mucous membranes Intracranial haemorrhage (rare)

Table 8.25 Causes of thrombocytopenia

Impaired production
Selective megakaryocyte depression:
- Rare congenital defects
- Drugs, chemicals and viruses

As part of a general bone marrow failure:
- Cytotoxic drugs and chemicals
- Radiation

Megaloblastic anaemia
Leukaemia
Myelodysplastic syndromes
Myeloma
Myelofibrosis
Solid tumour infiltration
Aplastic anaemia
HIV infection

Excessive destruction or increased consumption
Immune
- Autoimmune – ITP
- Drug induced, e.g. GP IIb/IIIa inhibitors, pencillins, thiazides
- Secondary immune (SLE, CLL, viruses, drugs, e.g. heparin, bivalirudin)
- Alloimmune neonatal thrombocytopenia
- Post-transfusion purpura

Disseminated intravascular coagulation
Thrombotic thrombocytopenic purpura

Sequestration
Splenomegaly
Hypersplenism

Dilutional
Massive transfusion

Immune thrombocytopenic purpura (ITP)

Thrombocytopenia is due to immune destruction of platelets. The antibody-coated platelets are removed following binding to Fc receptors on macrophages.

ITP in children

This occurs most commonly in children (age 2–6 years). It has an acute onset with mucocutaneous bleeding and there may be a history of a recent viral infection, including varicella zoster or measles. Although bleeding may be severe, life threatening hemorrhage is rare (~ 1%). Bone marrow examination is not usually performed unless treatment becomes necessary on clinical grounds.

ITP in adults

The presentation is usually less acute than in children. Adult ITP is characteristically seen in women and may be associated with other autoimmune disorders such as SLE, thyroid disease and autoimmune haemolytic anaemia (Evans' syndrome), in patients with chronic lymphocytic leukaemia and solid tumours, and after infections with viruses such as HIV. Platelet autoantibodies are detected in about 60–70% of patients, and are presumed to be present, although not detectable, in the remaining patients; the antibodies often have specificity for platelet membrane glycoproteins IIb/IIIa and/or Ib.

Clinical features

Major haemorrhage is rare and is seen only in patients with severe thrombocytopenia. Easy bruising, purpura, epistaxis and menorrhagia are common. Physical examination is normal except for evidence of bleeding. Splenomegaly is rare.

Investigation

The only blood count abnormality is thrombocytopenia. Normal or increased numbers of megakaryocytes are found in the bone marrow (if examination is performed), which is otherwise normal. The detection of platelet autoantibodies is not essential for confirmation of the diagnosis, which often depends on exclusion of other causes of excessive destruction of platelets.

Treatment

Children

Children do not usually require treatment. Where this is necessary on clinical grounds, high-dose prednisolone is effective, given for a very short course. Intravenous immunoglobulin (i.v. IgG) should be reserved for very serious bleeding or urgent surgery. Chronic ITP is rare and requires specialist management.

Adults

Patients with platelet counts greater than 30×10^9/L require no urgent treatment unless they are about to undergo a surgical procedure.

First-line therapy consists of oral corticosteroids 1 mg/kg body weight. Approximately 66% will respond to prednisolone but relapse is common when the dose is reduced. Only 33% of patients can expect a long-term response and long-term remission is seen in only 10–20% of patients following stopping prednisolone. Patients who fail to respond to corticosteroids or require high doses to maintain a safe platelet count should be considered for splenectomy.

Intravenous immunoglobulin (i.v. IgG) is effective. It raises platelet count in 75% and in 50% the platelet count will normalize. Responses are only transient (3–4 weeks) with little evidence of any lasting effect. However, it is very useful where a rapid rise in platelet count is desired, especially before surgery. There are also advocates for high dose corticosteroids for additional therapy.

Second-line therapy involves splenectomy, to which the majority of patients respond – two-thirds will achieve a normal platelet count. Patients who do not have a complete response can still expect some improvement.

Third-line therapy. For those that fail splenectomy, a wide range of other therapies are available. These include high-dose corticosteroids, intravenous immunoglobulin, Rh0(D) immune globulin (anti-D), vinca alkaloids, danazol, immunosuppressive agents such as azathioprine, ciclosporin and dapsone, combination chemotherapy, mycophenolate mofetil. Major difficulties with many third-line therapies are modest response rates and slow onset of action. Consequently there is also interest in the use of specific monoclonal antibodies such as rituximab, as well as recombinant thrombopoietin. However, clinical trials of thrombopoietin were stopped because of thrombocytopenia but eltrombopag, a thrombopoietin receptor agonist (which binds to another point of the thrombopoietin receptor), has been shown to increase platelets in ITP. Romiplostim, a novel thrombopoiesis protein given weekly subcutaneously, has also been shown to significantly increase platelet count in ITP on a long-term basis; there were no major adverse effects in this trial. Platelet transfusions are reserved for intracranial or other extreme haemorrhage, where emergency splenectomy may be justified.

Other immune thrombocytopenias

Drugs cause immune thrombocytopenia by the same mechanisms as described for drug-induced immune haemolytic anaemia (see p. 417). The same drugs can be responsible

for immune haemolytic anaemia, thrombocytopenia or neutropenia in different patients.

Heparin-induced thrombocytopenia. See page 444.

Neonatal alloimmune thrombocytopenia is due to fetomaternal incompatibility for platelet-specific antigens, usually for HPA-1a (human platelet alloantigen), and is the platelet equivalent of haemolytic disease of the newborn (HDN). The mother is HPA-1a-negative and produces antibodies, which destroy the HPA-1a-positive fetal platelets. Thrombocytopenia is self-limiting after delivery, but platelet transfusions may be required initially to prevent or treat bleeding associated with severe thrombocytopenia; platelets are prepared from HPA-1a-negative volunteers or the mother herself. Severe bleeding such as intracranial haemorrhage may also occur in utero.

Antenatal treatment of the mother – usually with high dose IgG and/or steroids – has been effective in preventing haemorrhage in severely affected cases.

Post-transfusion purpura (PTP) is rare, occurring 2–12 days after a blood transfusion. PTP is associated with a platelet-specific alloantibody, usually anti-HPA-1a in an HPA-1a-negative individual. PTP almost invariably occurs in females who have been previously immunized by pregnancy or blood transfusion. The cause of the destruction of the patient's own platelets is not well understood, but they may be destroyed as 'bystanders' during the acute immune response to HPA-1a. PTP is self-limiting, but high-dose intravenous IgG may limit the period of thrombocytopenia.

Thrombotic thrombocytopenic purpura (TTP) *(see p. 599)*

TTP is a rare, but very serious condition, in which platelet consumption leads to profound thrombocytopenia. There is a characteristic symptom complex of florid purpura, fever, fluctuating cerebral dysfunction and haemolytic anaemia with red cell fragmentation, often accompanied by renal failure. The coagulation screen is usually normal but lactic dehydrogenase (LDH) levels are markedly raised as a result of haemolysis. TTP arises due to endothelial damage and microvascular thrombosis. This occurs due to a reduction in ADAMTS 13 (A Disintegrin-like and Metalloproteinase domain with Thrombospondin-type motifs), a protease which is normally responsible for VWF degradation. ADAMTS 13 is needed to break down ultra large von Willebrand factor multimers (UL VWFMs) into smaller haemostatically active fragments that interact with platelets. Reduction in ADAMTS 13 results in the adhesion and aggregation of platelets to UL VWFMs and multiorgan microthrombi. In most sporadic cases there is a true deficiency of the ADAMTS 13, associated with antibodies to ADAMTS 13. In some congenital cases the deficiency is due to mutations in the ADAMTS 13 gene. Secondary causes of acute TTP include pregnancy, oral contraceptives, SLE, infection and drug treatment, including the use of ticlopidine and clopidogrel. Such cases may have a variable ADAMTS 13 activity at presentation and may or may not have associated antibodies to ADAMTS 13.

Treatment consists of plasma exchange as the mainstay of treatment. It provides a source of ADAMTS 13 and removes associated autoantibody in acute TTP. Cryoprecipitate and Solvent-Detergent FFP (fresh frozen plasma) both contain ADAMTS 13. Pulsed intravenous methylprednisolone is given acutely, as is increasingly rituximab as a primary treatment of choice. Disease activity is monitored by measuring the platelet count and serum LDH. Platelet concentrates are contraindicated. The untreated condition has a mortality of up to 90% but modern management has reduced this figure to about 10%. Recurrent and relapsing TTP occurs, often associated with a persistent lack of ADAMTS 13. In secondary TTP cases, identifiable precipitating drugs should be stopped.

Platelet function disorders

These are usually associated with excessive bruising and bleeding and, in some of the acquired forms, with thrombosis. The platelet count is normal or increased and the bleeding time is prolonged. The rare inherited defects of platelet function require more detailed investigations such as platelet aggregation studies and factor VIII:C and VWF assays, if von Willebrand disease is suspected.

Inherited types of platelet dysfunction

- *Glanzmann's thrombasthenia* – lack of the platelet membrane glycoprotein IIb–IIIa complex resulting in defective fibrinogen binding and failure of platelet aggregation.
- *Bernard–Soulier syndrome* – lack of platelet membrane glycoprotein Ib, the binding site for VWF. This causes a failure of platelet adhesion and moderate thrombocytopenia.
- *Storage pool disease* – lack of the storage pool of platelet dense bodies, causing poor platelet function.

Acquired types of platelet dysfunction

- Myeloproliferative disorders
- Renal and liver disease
- Paraproteinaemias
- Drug-induced, such as NSAIDs (aspirin) or other platelet inhibitory drugs.

If there is serious bleeding or if the patient is about to undergo surgery, drugs with antiplatelet activity should be withdrawn and any underlying condition should be corrected if possible.

Bleeding in renal disease is multifactorial, although platelet dysfunction is a major component. The degree of the defect of haemostasis is broadly proportional to the plasma urea concentration – platelet function is impaired by urea, guanidinosuccinic acid and other phenolic metabolites that accumulate in renal failure. Dialysis partially corrects platelet function. The haematocrit should be increased to greater than 0.30 and the use of desmopressin may be helpful. Platelet transfusions may be required if these measures are unsuccessful or if the risk of bleeding is high.

Thrombocytosis

The platelet count may rise above 400 $\times$ 10^9/L as a result of:

- splenectomy
- malignant disease
- inflammatory disorders such as rheumatoid arthritis and inflammatory bowel disease
- major surgery and post haemorrhage
- myeloproliferative disorders
- iron deficiency.

Thus thrombocytosis is part of the acute-phase reaction, although following splenectomy platelet numbers are also elevated because of the loss of a major site of platelet destruction.

Essential thrombocythaemia, a myeloproliferative disorder which is described on page 421, and other myeloproliferative conditions such as polycythaemia vera (PV), myelofibrosis and chronic myeloid leukaemia (CML) may also be associated with a high platelet count.

A persistently elevated platelet count can lead to arterial or venous thrombosis. It is usual to treat the underlying cause of the thrombocytosis but a small dose of aspirin (75 mg) is also sometimes given. In myeloproliferative diseases the primary risk is thrombosis and specific action to reduce the platelet count, usually with hydroxycarbamide (hydroxyurea), is often taken. Paradoxically there is also a risk of abnormal bleeding if the platelet count is very high.

INHERITED COAGULATION DISORDERS

Coagulation disorders may be inherited or acquired. The inherited disorders are uncommon and usually involve deficiency of one factor only. The acquired disorders occur more frequently and almost always involve several coagulation factors; they are considered in the next subsection.

In inherited coagulation disorders, deficiencies of all factors have been described. Those leading to abnormal bleeding are rare, apart from haemophilia A (factor VIII deficiency), haemophilia B (factor IX deficiency) and von Willebrand disease.

Haemophilia A

This is due to a lack of factor VIII. VWF is normal in haemophilia (Fig. 8.39). The prevalence of haemophilia A is about 1 in 5000 of the male population. It is inherited as an X-linked disorder. If a female carrier has a son, he has a 50% chance of having haemophilia, and a daughter has a 50% chance of being a carrier. All daughters of men with haemophilia are carriers and the sons are normal.

The human factor VIII gene is large, constituting about 0.1% of the X chromosome, encompassing 186 kilobases of DNA. Various genetic defects have been found, including deletions, duplications, frameshift mutations and insertions. In approximately 50% of families with severe disease, the defect is an inversion. There is a high mutation rate, with one-third of cases being apparently sporadic with no family history of haemophilia.

Clinical and laboratory features

The clinical features depend on the level of factor VIII. The normal level of factor VIII is 50–150 iu/dL.

- *Levels of less than 1 iu/dL (severe haemophilia)* are associated with frequent spontaneous bleeding from early life. Haemarthroses are common and recurrent bleeding into joints leads to joint deformity and crippling if adequate treatment is not given. Bleeding into muscles is also common, and intramuscular injections should be avoided.
- *Levels of 1–5 iu/dL (moderate haemophilia)* are associated with severe bleeding following injury and occasional spontaneous bleeds.
- *Levels above 5 iu/dL (mild haemophilia)* are associated usually with bleeding only after injury or surgery. It should be noted that patients with mild haemophilia can still bleed badly once haemostasis has failed. Diagnosis in this group is often delayed until quite late in life.

The most common causes of death in people with haemophilia are cancer and heart disease, as for the general population. Cerebral haemorrhage is much more frequent. In recent years, HIV infection and liver disease (due to hepatitis C) have become a more common cause of death. These infections were acquired from blood transfusion by many patients that were treated with factor concentrates prior to 1986. Since 1986 such plasma derived products are all virally inactivated with heat or chemicals.

The main laboratory features of haemophilia A are shown in Table 8.26. The abnormal findings are a prolonged APTT and a reduced level of factor VIII. The PT, bleeding time and VWF level are normal.

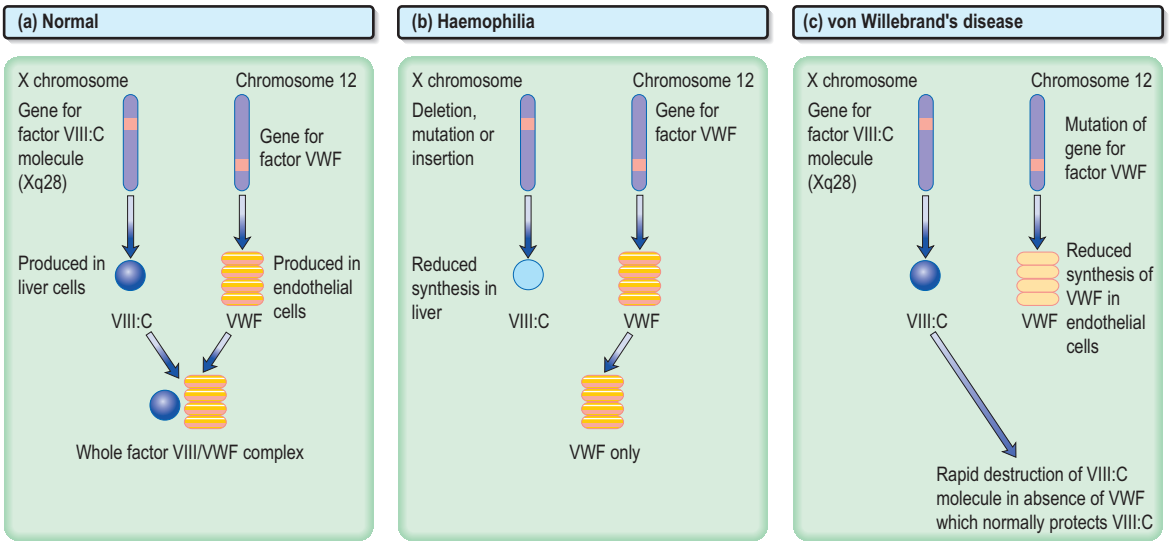

Fig. 8.39 **(a) Normal factor VIII synthesis. (b) Haemophilia A showing defective synthesis of factor VIIIc. (c) von Willebrand disease showing reduced synthesis of VWF.**

Table 8.26 Blood changes in haemophilia A, von Willebrand disease and vitamin K deficiency

	Haemophilia A	von Willebrand disease	Vitamin K deficiency
Bleeding time	Normal	↑	Normal
PT	Normal	Normal	↑
APTT	↑+	↑±	↑
VIII:C	↓++	↓	Normal
VWF	Normal	↓	Normal

Treatment

Bleeding is treated by administration of factor VIII concentrate by intravenous infusion.

- *Minor bleeding*: the factor VIII level should be raised to 20–30 iu/dL.
- *Severe bleeding*: the factor VIII should be raised to at least 50 iu/dL.
- *Major surgery*: the factor VIII should be raised to 100 iu/dL preoperatively and maintained above 50 iu/dL until healing has occurred.

Factor VIII has a half-life of 12 hours and therefore must be administered at least twice daily to maintain the required therapeutic level. Continuous infusion is sometimes used to cover surgery. Factor VIII concentrate is freeze-dried and can be stored in domestic refrigerators at 4°C. This allows it to be administered by the patient immediately after bleeding has started, reducing the likelihood of chronic damage to joints and the need for inpatient care.

Recombinant factor VIII concentrate is well established as the treatment of choice for people with haemophilia, but economic constraints and limited production capacity for recombinant factors have resulted in many patients still being offered treatment with plasma derived concentrates, particularly in developing countries.

To prevent recurrent bleeding into joints and subsequent joint damage, patients with severe haemophilia are given factor VIII infusions regularly three times per week. Such 'prophylaxis' treatment is usually started in early childhood (around 2 years of age).

Synthetic vasopressin (desmopressin – an analogue of vasopressin) – intravenous, subcutaneous or intranasal – produces a 3–5 fold rise in factor VIII and is very useful in patients with a baseline level of factor VIII > 10 iu/dL. It avoids the complications associated with blood products and is useful for treating bleeding episodes in mild haemophilia and as prophylaxis before minor surgery. It is ineffective in severe haemophilia.

People with haemophilia should be registered at comprehensive care centres (CCC), which take responsibility for their full medical care, including social and psychological support. Each person with haemophilia carries a special medical card giving details of the disorder and its treatment.

Complications

Up to 30% of people with severe haemophilia will, during their lifetime, develop antibodies to factor VIII that inhibit its action. Such inhibitors usually develop after the first few treatment doses of factor VIII. The prevalence of inhibitors is, however, only 5–10% because inhibitory antibodies develop only rarely in moderate and mild haemophilia and often disappear spontaneously or with continued treatment.

Management of such patients may be very difficult, as even extremely high doses of factor VIII may not produce a rise in the plasma factor VIII level. Recombinant factor VIIa at very high 'pharmacological' levels can bypass factor IX/VIII activity in the coagulation pathway and is an effective treatment in more than 80% of bleeding episodes in patients with high factor VIII inhibitor levels. Some factor IX concentrates are also deliberately activated to produce factors, which also may 'bypass' the inhibitor and stop the bleeding.

In the longer term the aim of management is to eradicate the inhibitory antibody, particularly in those that have recently developed inhibitors. This is done using immune tolerance induction strategies, sometimes using immunosuppression and immunoabsorption.

The risk of viral transmission has been virtually eliminated in developed countries by excluding high-risk blood donors, testing all donations for HBsAg, HCV and HIV antibodies, and by including steps to inactivate viruses during the preparation of plasma-derived concentrate. However, there is now a concern that the infectious agent that causes variant CJD may be transmissible by blood and blood products. Pooled plasma products are now manufactured solely from plasma drawn from countries with a low incidence of BSE.

Hepatitis A and B *vaccination* is offered routinely to all patients with haemophilia and von Willebrand disease. The clinical consequences of haemophilia patients infected with HIV are similar to other HIV-infected patients (see p. 187), except that Kaposi's sarcoma does not occur. A number of patients with hepatitis C will progress to develop chronic liver disease and cirrhosis (see p. 340).

The use of recombinant factor VIII effectively eliminates any residual risk of transfusion-transmitted infection, and it is safe and effective; but there is a similar incidence of inhibitor development as with plasma-derived factor VIII.

Carrier detection and antenatal diagnosis

Determination of carrier status in females begins with a family history and coagulation factor assays. Female carriers may have a low factor VIII level but the exact value is very variable, partly because of lyonization. Owing to this process early in embryonic life (that is, random inactivation of one chromosome; see p. 37), some carriers have very low levels of factor VIII while others will have normal levels. Carrier detection is best carried out using molecular genetic testing, in the main by direct detection of mutations within the factor VIII gene. Antenatal diagnosis may be carried out by molecular analysis of fetal tissue obtained by chorionic villus biopsy at 11–12 weeks' gestation.

Haemophilia B (Christmas disease)

Haemophilia B is caused by a deficiency of factor IX. The inheritance and clinical features are identical to haemophilia A, but the incidence is only about 1 in 30 000 males. The gene is smaller at 34 kilobases and the half-life of the factor is longer at 18 hours. Haemophilia B is treated with factor IX concentrates, recombinant factor IX being generally available, and prophylactic doses are given twice a week. Desmopressin is ineffective.

Von Willebrand disease (VWD)

In VWD, there is defective platelet function as well as factor VIII deficiency, and both are due to a deficiency or abnormality of VWF (Fig. 8.39). VWF plays a role in platelet adhesion to damaged subendothelium as well as stabilizing factor VIII in plasma (see p. 432).

The VWF gene is located on chromosome 12 and numerous mutations of the gene have been identified. VWD has been classified into three types:

- *Type 1* is partial quantitative deficiency of VWF and significant type 1 VWD is usually inherited as an autosomal dominant.
- *Type 2* is due to a qualitative abnormality of VWF, and it too is usually inherited as an autosomal dominant.
- *Type 3* is recessively inherited and patients have virtually complete deficiency of VWF. Their parents are often phenotypically normal.

Many subtypes of VWD have also been described, particularly type 2, which reflect the specific qualitative changes in the VWF protein.

Clinical features. These are very variable. Type 1 and type 2 patients usually have relatively mild clinical features. Bleeding follows minor trauma or surgery, and epistaxis and menorrhagia often occur. Haemarthroses are rare. Type 3 patients have more severe bleeding but rarely experience the joint and muscle bleeds seen in haemophilia A.

Characteristic laboratory findings are shown in Table 8.26. These also include defective platelet aggregation with ristocetin.

Treatment depends on the severity of the condition and may be similar to that of mild haemophilia, including the use of desmopressin where possible. Some plasma derived factor VIII concentrates contain von Willebrand factor. These specific products are used to treat bleeding or to cover surgery in patients who require replacement therapy, such as those with type 3 (severe) VWD and those who do not respond adequately to desmopressin. Cryoprecipitate can be used as a source of VWF, but should be avoided if possible since it is not a virally inactivated product.

ACQUIRED COAGULATION DISORDERS

Vitamin K deficiency (see also p. 219)

Vitamin K is necessary for the γ-carboxylation of glutamic acid residues on coagulation factors II, VII, IX and X and on proteins C and S. Without it, these factors cannot bind calcium.

Deficiency of vitamin K may be due to:

- *inadequate stores*, as in haemorrhagic disease of the newborn and severe malnutrition (especially when combined with antibiotic treatment) (see p. 324)
- *malabsorption of vitamin K*, a fat-soluble vitamin, which occurs in cholestatic jaundice owing to the lack of intraluminal bile salts
- *oral anticoagulant drugs*, which are vitamin K antagonists.

The PT and APTT are prolonged (Table 8.26) and there may be bruising, haematuria and gastrointestinal or cerebral bleeding. Minor bleeding is treated with phytomenadione (vitamin K_1) 10 mg intravenously. Some correction of the PT is usual within 6 hours but it may not return to normal for 2 days.

Newborn babies have low levels of vitamin K, and this may cause minor bleeding in the first week of life (*classical haemorrhagic disease of the newborn*). Vitamin K deficiency also causes *late haemorrhagic disease of the newborn*, which occurs 2–26 weeks after birth and results in severe bleeding such as intracranial haemorrhage. Most infants with these syndromes have been exclusively breast-fed, and both conditions are prevented by administering 1 mg i.m. vitamin K to all neonates (see p. 219). Concerns about the safety of this are unfounded.

Liver disease

Liver disease may result in a number of defects in haemostasis:

- *Vitamin K deficiency.* This occurs owing to intrahepatic or extrahepatic cholestasis.
- *Reduced synthesis.* Reduced synthesis of coagulation factors may be the result of severe hepatocellular damage. The use of vitamin K does not improve the results of abnormal coagulation tests, but it is generally given to ensure that a treatable cause of failure of haemostasis has not been missed.
- *Thrombocytopenia.* This results from hypersplenism due to splenomegaly associated with portal hypertension or from folic acid deficiency.
- *Functional abnormalities.* Functional abnormalities of platelets and fibrinogen are found in many patients with liver failure.
- *Disseminated intravascular coagulation.* DIC (see below) occurs in acute liver failure.

Disseminated intravascular coagulation (DIC)

There is widespread generation of fibrin within blood vessels, owing to activation of coagulation by release of procoagulant material, and by diffuse endothelial damage or generalized platelet aggregation. Activation of leucocytes, particularly monocytes causing expression of tissue factor and the release of cytokines, may play a role in the development of DIC. There is consumption of platelets and coagulation factors and secondary activation of fibrinolysis leading to production of fibrin degradation products (FDPs), which contributes to the coagulation defect by inhibiting fibrin polymerization (Fig. 8.40). The consequences of these changes are a mixture of initial thrombosis followed by a bleeding tendency due to consumption of coagulation factors and fibrinolytic activation.

Causes of DIC

These include:

- malignant disease
- septicaemia (e.g. Gram-negative and meningococcal)
- haemolytic transfusion reactions
- obstetric causes (e.g. abruptio placentae, amniotic fluid embolism)
- trauma, burns, surgery
- other infections (e.g. falciparum malaria)

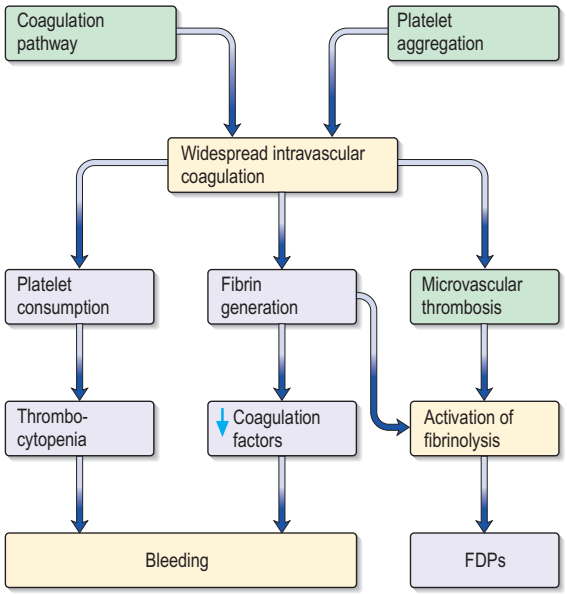

Fig. 8.40 **Disseminated intravascular coagulation.** FDPs, fibrin degradation products.

- liver disease
- snake bite.

Clinical features

The underlying disorder is usually obvious. The patient is often acutely ill and shocked. The clinical presentation of DIC varies from no bleeding at all to profound haemostatic failure with widespread haemorrhage. Bleeding may occur from the mouth, nose and venepuncture sites and there may be widespread ecchymoses.

Thrombotic events occur as a result of vessel occlusion by fibrin and platelets. Any organ may be involved, but the skin, brain and kidneys are most often affected.

Investigations

The diagnosis is often suggested by the underlying condition of the patient.

Severe cases with haemorrhage

- The PT, APTT and TT are usually very prolonged and the fibrinogen level markedly reduced.
- High levels of FDPs, including D-dimer, are found owing to the intense fibrinolytic activity stimulated by the presence of fibrin in the circulation.
- There is severe thrombocytopenia.
- The blood film may show fragmented red blood cells.

Mild cases without bleeding

- Increased synthesis of coagulation factors and platelets
- Normal PT, APTT, TT and platelet counts
- FDPs are raised.

Treatment

The underlying condition is treated and this is often all that is necessary in patients who are not bleeding. Maintenance of blood volume and tissue perfusion is essential. Transfusions of platelet concentrates, FFP, cryoprecipitate and red cell concentrates is indicated in patients who are bleeding. Inhibitors of fibrinolysis such as tranexamic acid should not be used in DIC as dangerous fibrin deposition may result. Activated protein C concentrates have been used in selected cases. In those cases with a dominant thrombotic component the use of heparin seems logical but there is little evidence to suggest any benefit.

Excessive fibrinolysis

Excessive fibrinolysis occurs during surgery involving tumours of the prostate, breast, pancreas and uterus owing to release of tissue plasminogen activators.

Primary hyperfibrinolysis is very rare but activation of fibrinolysis occurs in DIC as a secondary event in response to intravascular deposition of fibrin.

The clinical picture is similar to DIC with widespread bleeding. Laboratory investigations are also similar with a prolonged PT, APTT and TT, a low fibrinogen level, and increased FDPs, although fragmented red cells and thrombocytopenia are not seen, since disseminated coagulation is not present.

If the diagnosis is certain, fibrinolytic inhibitors such as epsilon-aminocaproic acid (EACA) or tranexamic acid can be given but evidence for efficacy is lack.

Massive transfusion

Few platelets and reduced levels of clotting factors are found in stored blood, although there are adequate amounts of the other coagulation factors. During massive transfusion (defined as transfusion of a volume of blood equal to the patient's own blood volume within 24 hours, e.g. approximately 10 units in an adult), the platelet count and PT and APTT should be checked at intervals.

Transfusion of platelet concentrates and FFP should be given if thrombocytopenia or defective coagulation are thought to be contributing to continued blood loss. Other problems of massive transfusion are described on page 905.

Inhibitors of coagulation

Factor VIII autoantibodies arise occasionally in patients without haemophilia but with autoimmune disorders such as SLE, in elderly patients, with malignant disease and sometimes after childbirth. There can be severe bleeding. Immediate bleeding problems are managed as with bypassing factor concentrates (see above). Longer-term therapy is to eliminate the autoantibody using immunosuppression, such as steroids, cyclophosphamide and more recently, in severe cases, rituximab.

Lupus anticoagulant antibodies (see p. 544) are autoantibodies directed against phospholipids (antiphospholipid antibodies) and lead to prolongation of phospholipid dependent coagulation tests, particularly the APTT, but do not inhibit coagulation factor activity.

THROMBOSIS

A thrombus is defined as a solid mass formed in the circulation from the constituents of the blood during life. Fragments of thrombi (emboli) may break off and block vessels downstream. Thromboembolic disease is much more common than abnormal bleeding; nearly half of adult deaths in England and Wales are due to coronary artery thrombosis, cerebral artery thrombosis or pulmonary embolism.

A thrombus results from a complex series of events involving coagulation factors, platelets, red blood cells and the vessel wall.

Arterial thrombosis

This usually occurs in association with atheroma, which tends to form at areas of turbulent blood flow such as the bifurcation of arteries. Platelets adhere to the damaged vascular endothelium and aggregate in response to ADP and TXA_2 to form a 'white thrombus'. The growth of the platelet thrombus is limited at its margins by PGI_2 and NO. Plaque rupture leads to the exposure of blood containing factor VIIa to tissue factor within the plaque, which may trigger blood coagulation and lead to thrombus formation. This results in complete occlusion of the vessel or embolization that produces distal obstruction. The risk factors for arterial thrombosis are related to the development of atherosclerosis (see p. 744).

Arterial thrombi may also form in the heart, as mural thrombi in the left ventricle after myocardial infarction, in the left atrium in mitral valve disease, or on the surfaces of prosthetic valves.

Venous thrombosis

Unlike arterial thrombosis, venous thrombosis often occurs in normal vessels. Major causes are stasis and hypercoagulability. The majority of venous thrombi occur in the deep veins of the leg, originating around the valves as 'red thrombi' consisting mainly of red cells and fibrin. The propagating thrombus is formed of fibrin and platelets and is particularly liable to embolize. Chronic venous obstruction following thrombosis in the deep veins of the leg frequently results in a permanently swollen limb and may lead to ulceration (postphlebitic syndrome).

Risk factors for venous thrombosis are shown in Table 8.27. Venous thrombosis may occur with changes in blood cells such as polycythaemia and thrombocythaemia, and with coagulation abnormalities (thrombophilia; see below).

The clinical features and diagnosis of venous thrombosis are discussed on page 809.

Table 8.27 Risk factors of venous thromboembolism

Patient factors	Disease or surgical procedure
Age	Trauma or surgery, especially of pelvis, hip or lower limb
BMI >30 kg/m^2	Malignancy
Varicose veins	Cardiac or respiratory failure
Continuous travel more than 3 h in preceding 4 weeks	Recent myocardial infarction or stroke
Immobility (bed rest > 4 days)	Acute medical illness/severe infection
Pregnancy and puerperium	Inflammatory bowel disease
Previous deep vein thrombosis or pulmonary embolism	Behçet's disease
Thrombophilia	Nephrotic syndrome
Antithrombin deficiency	Myeloproliferative disorders
Protein C or S deficiency	Paroxysmal nocturnal haemoglobinuria
Factor V Leiden	Paraproteinaemia
Resistance to activated protein C (caused by factor V Leiden variant)	Sickle cell anaemia
Prothrombin gene variant	Central venous catheter in situ
Hyperhomocysteinaemia	
Antiphospholipid antibody/lupus anticoagulant	
Oestrogen therapy including HRT	
Dysfibrinogenaemia	
Plasminogen deficiency	

Thrombophilia

Thrombophilia is a term describing inherited or acquired defects of haemostasis leading to a predisposition to venous or arterial thrombosis. It should be considered in patients with:

- recurrent venous thrombosis
- venous thrombosis for the first time under age 40 years
- an unusual venous thrombosis such as mesenteric or cerebral vein thrombosis
- unexplained neonatal thrombosis
- recurrent miscarriages
- arterial thrombosis in the absence of arterial disease.

Coagulation abnormalities

Factor V Leiden

Factor V Leiden differs from normal factor V by a single nucleotide substitution (Arg506Gln). This variation makes factor V less likely to be cleaved by activated protein C. As factor V is a cofactor for thrombin generation (Fig. 8.33) impaired inactivation by activated protein C (Fig. 8.34) results in a tendency to thrombosis. Factor V Leiden is found in 3–5% of healthy individuals in the western world and in about 20-30% of patients with venous thrombosis.

Factor V Leiden acts synergistically with other acquired thrombosis risk factors, for example in those taking oral contraceptive pills or when pregnant. Thrombosis risk rises 35-fold in those on a combined oral contraceptive pill although the absolute risk for thrombosis remains at significantly less than 0.5% per year for any single individual.

Prothrombin variant

A mutation in the 3′ untranslated region of the prothrombin gene has been described (G20210A). This variant is associated with elevated levels of prothrombin and a two- to threefold increase in the risk of venous thrombosis. There is an interaction with factor V Leiden and contraceptive pill use or pregnancy. The prevalence is 2% in Caucasian populations, 6% in unselected patients with thrombosis.

Antithrombin (AT) deficiency

This deficiency can be inherited as an autosomal dominant. Many variations have been described that lead to a conformational change in the protein. It can also be acquired following trauma, with major surgery and with the contraceptive pill. Low levels are also seen in severe proteinuria (e.g. the nephrotic syndrome). Recurrent thrombotic episodes occur starting at a young age in the inherited variety. Patients are

relatively resistant to heparin as antithrombin is required for its action. Antithrombin concentrates are available.

Protein C and S deficiency

These autosomal dominant conditions result in an increased risk of venous thrombosis, often before the age of 40 years. Homozygous protein C or S deficiency causes neonatal purpura fulminans, which is fatal without immediate replacement therapy. Protein C concentrate and a recombinant activated protein C are available.

Antiphospholipid antibody

See pages 504 and 544.

Homocysteine

When elevated this amino acid is associated with both arterial thrombosis and venous thromboembolism. The mechanism of vascular damage is unclear. Folate, B_{12} and B_6 supplementation are often helpful in reducing levels.

Investigations

Haemostatic screening tests

- **Full blood count** including platelet count
- **Coagulation screen** including a fibrinogen level. These tests will detect erythrocytosis, thrombocytosis, and dysfibrinogenaemia and the possible presence of a lupus anticoagulant.

Testing for specific causes of thrombophilia

- **Assays** for naturally occurring anticoagulants such as AT, protein C and protein S
- **Assay** for activated protein C resistance and molecular testing for factor V Leiden and the prothrombin variant
- **Screen for a coagulation factor** inhibitor including a lupus anticoagulant (and anticardiolipin antibodies) (see p. 544).

Prevention and treatment of arterial thrombosis

Attempts to prevent or reduce arterial thrombosis are directed mainly at minimizing factors predisposing to atherosclerosis. Treatment of established arterial thrombosis includes the use of antiplatelet drugs and thrombolytic therapy.

Antiplatelet drugs

Platelet activation at the site of vascular damage is crucial to the development of arterial thrombosis, and this can be altered by the following drugs (Table 8.28):

- *Aspirin* irreversibly inhibits the enzyme cyclo-oxygenase (COX), resulting in reduced platelet production of TXA_2 (Fig. 8.34). At the low doses used in cardiovascular disease prevention or treatment, there is selective inhibition of the isoform COX-1 found within platelets. This inhibition cannot be repaired and is effective for the life of the circulating platelet, which is about 1 week. In recent years, it has been suggested there may be significant individual variability in the response to aspirin, although there is no clear reason for this. The term 'aspirin resistance' has been loosely applied when the clinical effects of aspirin are less than expected. No large body of clinical trial data is specifically available to correlate clinical events and laboratory findings with respect to aspirin response and so it is difficult to determine if the breakthrough events experienced by patients treated with aspirin represent aspirin resistance or are related to more mundane issues such as aspirin dose, drug interactions or drug non-compliance.
- *Dipyridamole* – which inhibits platelet phosphodiesterase, causing an increase in cyclic AMP with potentiation of the action of PGI_2 – has been used widely as an antithrombotic agent, but there is little evidence that it is effective.
- *Clopidogrel* – irreversibly blockades the ADP ($P2Y_{12}$) receptor on platelet cell membranes, so affecting the ADP-dependent activation of the glycoprotein IIb/IIIa complex. It is similar to ticlopidine but has fewer side-effects. Trials support its use in acute coronary syndromes (see p. 753), particularly if aspirin is contraindicated.
- *Prasugrel*, a novel thienopyridine, is like clopidogrel. It is being trialled in acute coronary syndromes (see p. 753).
- *Glycoprotein IIb/IIIa receptor antagonists* block the receptor on the platelet for fibrinogen and von Willebrand factor (Fig. 8.41). Three classes have been described:
  (a) murine–human chimeric antibodies (e.g. abciximab)
  (b) synthetic peptides (e.g. eptifibatide)
  (c) synthetic non-peptides (e.g. tirofiban).
  They have been used as an adjunct in invasive coronary artery intervention and as primary medical therapy in coronary heart disease. Excessive bleeding has been a problem.
- *Epoprostenol* is a prostacyclin, which is used to inhibit platelet aggregation during renal dialysis (with or without heparin) and is also used in primary pulmonary hypertension.

Table 8.28 Drugs used in the treatment of thrombotic disorders

Antiplatelet	Anticoagulant
Aspirin	Heparin:
Dipyridamole	Unfractionated (or standard)
Clopidogrel	Low molecular weight
GP IIb/IIIa inhibitors, e.g. abciximab, eptifibatide, tirofiban	Hirudin-like, e.g. lepirudin, bivalirudin
Epoprostenol	Fondaparinux
Prasugrel	Warfarin
Thrombolytic	Bivalirudin
Streptokinase	Dabigatran
Tissue-type plasminogen activator (t-PA or alteplase)	Apixaban
Reteplase (r-PA)	Rivaroxaban
Tenecteplase (TNK-tPA)	

The indications for and results of antiplatelet therapy are discussed in the appropriate sections (pp. 753 and 1132).

Thrombolytic therapy

Streptokinase

Streptokinase is a purified fraction of the filtrate obtained from cultures of haemolytic streptococci. It forms a complex with plasminogen, resulting in a conformational change, which activates other plasminogen molecules to form plasmin. Streptokinase is antigenic and the development of streptococcal antibodies precludes repeated use. Activation

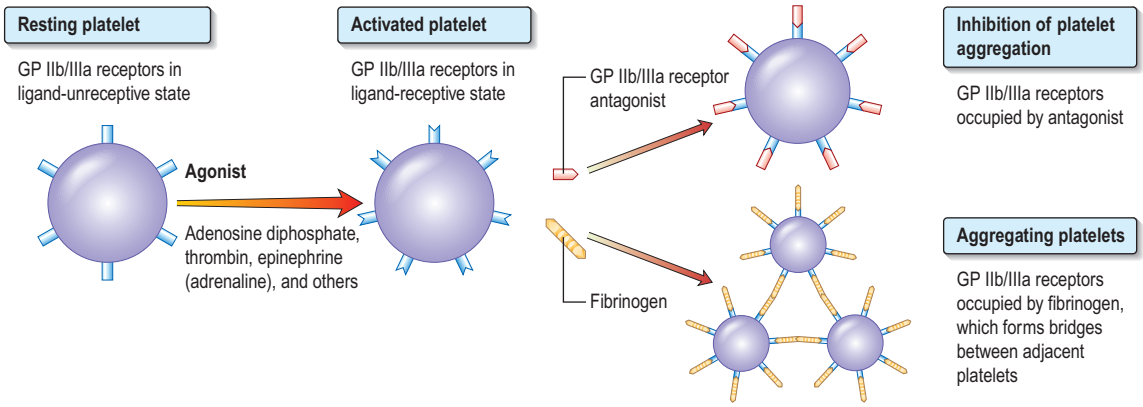

Fig. 8.41 **The role of glycoprotein IIb/IIIa in platelet aggregation and the inhibition of platelet aggregation by inhibitors of glycoprotein IIb/IIIa receptors.** Modified from Lefkovits J, Plow EF, Topol EJ. Mechanisms of disease: platelet glycoprotein IIb/IIIa receptors in cardiovascular medicine. *New England Journal of Medicine* 1995; **332:** 1554, with permission. Copyright © 1995 Massachusetts Medical Society. All rights reserved.

of plasminogen is indiscriminate so that both fibrin in clots and free fibrinogen are lysed, leading to low fibrinogen levels and the risk of haemorrhage.

Plasminogen activators (PA)

Tissue-type plasminogen activators (alteplase (t-PA), tenecteplase (TNK-tPA)) are produced by recombinant technology. Reteplase (r-PA) is also a recombinant plasminogen activator. They are not antigenic and do not give allergic reactions. They are relatively fibrin-specific, have relatively little systemic activity, and short half-lives (~5 minutes). The bleeding complications observed are similar in severity and frequency to those observed with streptokinase, suggesting that fibrin specificity does not confer protection against hemorrhage.

Indications

The use of thrombolytic therapy in myocardial infarction is discussed on page 753. The combination of aspirin with thrombolytic therapy produces better results than thrombolytic therapy alone. The extent of the benefit depends on how quickly treatment is given. They are also used in cerebral infarction (see p. 1131) and occasionally in massive pulmonary embolism. The main risk of thrombolytic therapy is bleeding. Treatment should not be given to patients who have had recent bleeding, uncontrolled hypertension or a haemorrhagic stroke, or surgery or other invasive procedures within the previous 10 days.

Prevention and treatment of venous thromboembolism

Venous thromboembolism is a common problem after surgery, particularly in high-risk patients such as the elderly, those with malignant disease and those with a history of previous thrombosis (Table 8.29). The incidence is also high in patients confined to bed following trauma, myocardial infarction or other illnesses. The prevention and treatment of venous thrombosis includes the use of anticoagulants.

Anticoagulants

Heparin (standard or unfractionated)

Heparin is not a single substance but a mixture of polysaccharides. Commercially available unfractionated heparin consists of components with molecular weights varying from 5000 to 35 000 with an average of about 13 000. It was initially extracted from liver (hence its name) but it is now prepared from porcine gastric mucosa. Heparin acts immediately, binding to antithrombin. This induces a conformational change which increases the inhibitory activity of antithrombin (at least 5000-fold) towards activated serine protease coagulation factors (thrombin, XIIa, XIa, Xa, IXa and VIIa).

Low-molecular-weight heparins (LMW heparins)

These are produced by enzymatic or chemical degradation of standard heparin, producing fractions with molecular weights in the range of 2000–8000. Potentiation of thrombin inhibition (anti-IIa activity) requires a minimum length of the heparin molecule with an approximate molecular weight of 5400, whereas the inhibition of factor Xa requires only a smaller heparin molecule with a molecular weight of about 1700. LMW heparins have the following properties:

- Bioavailability is better than that of unfractionated heparin.
- They have greater activity against factor Xa than against factor IIa, suggesting that they may produce an equivalent anticoagulant effect to standard heparin but have a lower risk of bleeding, although this has not generally been confirmed. In addition, LMW heparins cause less inhibition of platelet function.
- They have a longer half-life than standard heparin and so can be given as a once-daily subcutaneous injection instead of every 8–12 hours.
- They produce little effect on tests of overall coagulation, such as the APTT at doses recommended for prophylaxis. They are not fully neutralized by protamine.

LMW heparins are excreted renally and therefore dose reductions are required in those with renal impairment.

LMW heparins are widely used for antithrombotic prophylaxis, e.g. high-risk surgical patients and for the treatment of established thrombosis (see p. 810).

The main complication of all heparin treatment is bleeding. This is managed by stopping heparin. Very occasionally it is necessary to neutralize unfractionated heparin with protamine. Other complications include osteoporosis with prolonged therapy and thrombocytopenia.

Heparin-induced thrombocytopenia (HIT). HIT is an uncommon complication of heparin therapy and usually occurs 5–

Table 8.29 Classification of risk of deep vein thrombosis and pulmonary embolism for hospital patients (International Consensus Statement Guidelines)

Risk category	General surgery	Gynaecology	Obstetrics*	Medical patients
High	Major general surgery, age > 60 years Major general surgery, age 40–60 years and cancer or history of DVT/PE Thrombophilia Hip/knee arthroplasty	Major gynaecological surgery, age > 60 years Major gynaecological surgery, age 40–60 years and cancer or history of DVT/PE Thrombophilia	History of DVT/PE Thrombophilia	Stroke Age > 70 years Congestive heart failure (CHF) Shock History of DVT/PE Thrombophilia
Moderate	Major general surgery, age 40–60 years without other risk factors† Minor surgery, age > 60 years Minor surgery, age 40–60 years with history of DVT/PE or on oestrogen therapy	Major gynaecological surgery, age 40–60 years Major gynaecological surgery, age < 40 years on oestrogen therapy Minor surgery, age > 60 years	Age > 40 years	Immobilized patient with active disease Cardiac failure
Low	Major general surgery, age < 40 years No other risk factors† Minor surgery, age 40–60 years No other risk factors†	Minor gynaecological surgery, age < 40 without any other risk factors† Minor gynaecological surgery, age 40–60 years without any other risk factors†	Age < 40 years without any other risk factors	Minor medical illnesses

Adapted from Prevention of venous thromboembolism. International Consensus Statement. Guidelines compiled in accordance with the scientific evidence 2001. *International Angiology* **20**: 1–37.
Minor surgery, operations other than abdominal lasting less than 45 minutes. Major surgery, any intra-abdominal operation and all other operations lasting more than 45 minutes.
*The risk of DVT in obstetric patients with pre-eclampsia and the other factors is unknown, but prophylaxis should be considered.
†The risk is increased by infectious disease, presence of varicose veins, general immobility.

14 days after first heparin exposure. It is due to an immune response directed against heparin/platelet factor 4 complexes. All forms of heparin have been implicated but the problem occurs less often with LMW heparins.

HIT is paradoxically associated with severe thrombosis and when diagnosed all forms of heparin must be discontinued, including heparin flush. Unfortunately the diagnosis can be difficult to make because patients on heparin are often very sick and may be thrombocytopenic for many other reasons. Laboratory tests based on bioassay or immunoassay are available but are neither sensitive nor specific and management decisions often have to be made before results are available.

It is necessary to continue some form of anticoagulation in patients with HIT and the choice lies between the heparinoid danaparoid and the direct thrombin inhibitor hirudin. The introduction of warfarin should be covered by one of these agents, as warfarin alone may exacerbate thrombosis as protein C levels fall.

Fondaparinux

This is a synthetic pentasaccharide, which inhibits activated factor X, similar to the LMW heparins. It will now be necessary to establish comparative efficacy (prevention or treatment of thrombosis) against risk of side-effects (bleeding) before the position of fondaparinux becomes clear.

Direct thrombin inhibitors

A recombinant form of hirudin, lepirudin, is available. Hirudins bind directly to thrombin and are effectively irreversible inhibitors. They can be monitored by the use of the APTT and are excreted by the kidney, so must be used with caution in renal failure. *Lepirudin* is used for anticoagulation in patients with HIT.

Bivalirudin is a 20 amino acid synthetic analogue of hirudin. Compared to hirudin it appears to cause less bleeding, is a reversible thrombin inhibitor (as it is broken down by thrombin) and has a shorter half-life. It is used in percutaneous coronary interventions.

Oral anticoagulants

These act by interfering with vitamin K metabolism. There are two types of oral anticoagulants, the coumarins and indanediones. The coumarin warfarin is most commonly used because it has a low incidence of side-effects other than bleeding.

The dosage is controlled by prothrombin tests (PT). Thromboplastin reagents for PT testing are derived from a variety of sources and give different PT results for the same plasma.

It is standard practice to compare each thromboplastin with an international reference preparation so that it can be assigned an international sensitivity index (ISI). The international normalized ratio (INR) is the ratio of the patient's PT to a normal control when using the international reference preparation. Therapeutic ranges using the INR for oral anticoagulation in various conditions are shown in Box 8.4.

Each laboratory can use a chart adapted to the ISI of their thromboplastin to convert the patient's PT to the INR. Suitably selected control plasmas can also be used to achieve the same objective. The use of this system means that PT tests on a given plasma sample using different thromboplastins result in the same INR and that anticoagulant control is comparable in different hospitals across the world.

Contraindications to the use of oral anticoagulants are seldom absolute and include:

Box 8.4 Indications for oral anticoagulation and target INR (British Society for Haematology 2000)

Target INR	
2.5	Pulmonary embolism, proximal and calf deep vein thrombosis, recurrence of venous thromboembolism when no longer on warfarin therapy, symptomatic inherited thrombophilia, atrial fibrillation, cardioversion, mural thrombus, cardiomyopathy
3.5	Recurrence of venous thromboembolism while on warfarin therapy, antiphospholipid syndrome, mechanical prosthetic heart valve, coronary artery graft thrombosis

- severe uncontrolled hypertension
- non-thromboembolic strokes
- peptic ulceration (unless cured by *Helicobacter pylori* eradication)
- severe liver and renal disease
- pre-existing haemostatic defects
- non-compliance.

Oral anticoagulants should be avoided in pregnancy because they are teratogenic in the first trimester and may be associated with fetal haemorrhage later in pregnancy. When anticoagulation is considered essential in pregnancy, specialist advice should be sought. Self-administered subcutaneous heparin should be used as an alternative, although this may not be as effective for women with prosthetic cardiac valves.

Many drugs interact with warfarin (see Ch. 16). More frequent PT testing should accompany changes in medication, which should occur with the full knowledge of the anticoagulant clinic.

An increased anticoagulant effect due to warfarin is usually produced by one of the following mechanisms:

- drugs causing a reduction in the metabolism of warfarin, including tricyclic antidepressants, cimetidine, sulphonamides, phenothiazines and amiodarone
- drugs such as clofibrate and quinidine which increase the sensitivity of hepatic receptors to warfarin
- drugs interfering with vitamin K absorption (such as broad-spectrum antibiotics and colestyramine) which also potentiate the action of warfarin
- displacement of warfarin from its binding site on serum albumin by drugs such as sulphonamides (this is not usually responsible for clinically important interactions)
- drugs that inhibit platelet function (such as aspirin) which increase the risk of bleeding
- alcohol excess, cardiac failure, liver or renal disease, hyperthyroidism and febrile illnesses which result in potentiation of the effect of warfarin.

A decreased anticoagulant effect due to warfarin. This is usually produced by drugs that increase the clearance of warfarin by induction of hepatic enzymes that metabolize warfarin, such as rifampicin and barbiturates.

Anticoagulant related bleeding. Bleeding is the most important serious side-effect of warfarin. Bleeding occurs in up to 4% of patients on oral anticoagulants per year, and is serious in half of these with a 0.5% morbidity associated with it. The benefit of anticoagulants must therefore be notably more than the risk of bleeding. Management of warfarin related bleeding (Emergency Box 8.1) is given dependent upon the INR and the degree of bleeding. Minor bleeding may be treated with cessation of warfarin alone, whilst serious bleeding will require additional use of vitamin K and factor concentrates.

Emergency Box 8.1

Management of bleeding and excessive oral anticoagulation

INR > 3.0 < 6.0 (target INR 2.5)	(1) reduce warfarin dose or stop
INR > 4.0 < 6.0 (target INR 3.5)	(2) restart warfarin when INR < 5.0
INR > 6.0 < 8.0 no bleeding or minor bleeding	(1) stop warfarin
	(2) restart when INR < 5.0
INR > 8.0, no bleeding or minor bleeding	(1) stop warfarin
	(2) restart warfarin when INR < 5.0
	(3) if other risk factors for bleeding give 0.5–2.5 mg of vitamin K (oral)
Major bleeding	(1) stop warfarin
	(2) give prothrombin complex concentrate 50 units/kg or FFP 15 mL/kg if concentrate not available
	(3) give 5 mg of vitamin K (oral or i.v.)

If unexpected bleeding occurs investigate the possibility of a local anatomical cause.

Modified from British Society for Haematology 1998.

New orally active anticoagulant drugs. A number of orally active direct thrombin and Xa inhibitor drugs (e.g. dabigatran, rivaroxaban, apixaban) have been introduced for the prevention of thrombosis. Such drugs have a much broader therapeutic window than warfarin and offer the prospect of fixed drug dosing without the need to monitor coagulation. They do not however have specific antidotes.

Prophylaxis to prevent venous thromboembolism (VTE)

Risk factors for VTE are well defined. Most hospitalized patients have one or more of these risk factors and VTE is common in hospitalized patients. The risk of developing deep vein thrombosis (DVT) after hip replacement surgery has been estimated to be as high as 50% when thromboprophylaxis is not used. Approximately 10% of hospital deaths may be due to pulmonary embolism (PE) and more people die from hospital acquired venous thrombosis than the combined deaths from road traffic accidents, AIDS and breast cancer. PE is the most common preventable cause of hospital death.

Thromboprophylaxis is highly effective and cost effective. Such prophylactic measures include early mobilization, elevation of the legs, compression stockings, intermittent compression devices and use of anticoagulant drugs, such as LMW heparins. All patients, medical and surgical, admitted to hospital should be assessed for thrombotic risk and given

appropriate thromboprophylaxis. Care must be exercised in those patients undergoing neurosurgical procedures.

Low-risk patients (Table 8.29) require no specific measures other than early mobilization.

Moderate and high-risk patients are most effectively managed using graduated compression stockings and LMW heparin subcutaneously daily.

The antithrombin agents dabigatran and rivaroxaban are now being used after lower limb joint replacement surgery. They are as effective as LMW heparins and, as they are given orally, can be used for longer periods.

Treatment of established venous thromboembolism

- The *aim* of anticoagulant treatment is to prevent further thrombosis and pulmonary embolization while resolution of venous thrombi occurs by natural fibrinolytic activity. Anticoagulation is started with heparin as it produces an immediate anticoagulant effect. There is no evidence that it is necessary to use heparin for any longer than it takes for simultaneously administered warfarin to produce an anticoagulant effect (INR 2.5), usually about 5 days.
- *LMW heparin* (e.g. tinzaparin 175 units/kg daily) is equally effective and as safe as unfractionated heparin in the immediate treatment of deep vein thrombosis and pulmonary embolism. This creates the opportunity for treatment of venous thromboembolism without admission to hospital, in compliant patients without coexisting risk factors for haemorrhage.
- *Length of anticoagulation*. This is recommended for at least 6 weeks after isolated calf vein thrombosis and at least 3 months after proximal DVT or PE in patients who have temporary risk factors. For patients with idiopathic VTE or permanent risk factors at least 6 months' anticoagulation is recommended.
- Use of *longer-term anticoagulation* in patients with previous thrombosis. It has been suggested that a lower INR might be safer and equally effective but the current view is that the target INR should be 2.0–3.0 where oral anticoagulation is used. Indefinite anticoagulation is considered appropriate for those with two or more episodes of VTE.
- *Outpatient anticoagulation* is best supervised in anticoagulant clinics. Patients are issued with national booklets for recording INR results and anticoagulant doses. Home monitoring is possible in well-motivated patients.

The role of thrombolytic therapy in the treatment of venous thrombosis is not established. It is used in patients with massive pulmonary embolism who are haemodynamically unstable and in patients with extensive deep venous thrombi.

Thrombolytic therapy should be followed by anticoagulation with heparin for a few days and then by oral anticoagulants to prevent rethrombosis.

Palliative medicine and symptom control 494

The term 'malignant disease' encompasses a wide range of illnesses, including common ones such as lung, breast and colorectal cancer (Table 9.1), as well as rare ones, like the acute leukaemias. Malignant disease is widely prevalent and, in the West, almost a third of the population will develop cancer at some time during their life. It is second only to cardiovascular disease as the cause of death. Although the mortality of cancer is high, many advances have been made, both in terms of treatment, and in understanding the biology of the disease at the molecular level.

Treatment is given with curative or palliative intent, depending upon the evidence from continuing clinical trials. For many people, the word 'cancer' implies certain death, although this is clearly not always the case. Physicians have an obligation to be honest with their patients, combining realism about the prognosis with compassion and understanding so that patients can take an informed part in treatment decisions.

Table 9.1 Epidemiology of cancer by site of origin in England and Wales

Type	% of all cancers (1998)	% of cancer deaths	M:F

AETIOLOGY AND EPIDEMIOLOGY

In most patients the cause of their cancer remains unknown and is probably multifactorial. Several environmental factors have, however, been identified as being associated with the development of malignancy (Table 9.2) and may be amenable to preventative action such as smoking cessation, dietary modification and antiviral immunization.

Tobacco

The incidence of lung cancer in both men and women had increased dramatically in the last 25 years, but is now falling in many developed countries. The association of smoking with lung cancer is indisputable and causative mechanisms have been identified: cigarette tobacco is responsible for one-third of all deaths from cancer in the UK. Smoking not only causes lung cancer, it is also associated with cancer of the mouth, larynx, oesophagus and bladder. Smoking is discussed on page 829.

Alcohol

Alcohol is associated with cancers of the upper respiratory and gastrointestinal tracts (Table 9.2), and it also interacts with tobacco in the aetiology of these tumours. It may be associated with an increased risk of breast cancer.

Table 9.2 Some causative factors associated with the development of cancer

Smoking	Mouth, pharynx, oesophagus, larynx, lung, bladder, lip
Alcohol	Mouth, pharynx, larynx, oesophagus, colorectal
Iatrogenic:	
Alkylating agents	Bladder, bone marrow
Oestrogens	Endometrium, vagina, breast, cervix
Androgens	Prostate
Radiotherapy e.g. mantle radiotherapy	Carcinoma of breast and bronchus
Diet:	
High-fat diet	Colorectal cancer
Environmental/occupation	
Vinyl chloride	Liver (angiosarcoma)
Polycyclic hydrocarbons	Skin, lung, bladder, myeloid leukaemia
Aromatic amines	Bladder
Asbestos	Lung, mesothelium
Ultraviolet light	Skin, lip
Radiation	e.g. leukaemia, thyroid cancer
Aflatoxin	Liver
Biological agents:	
Hepatitis B virus	Liver (hepatocellular carcinoma)
Hepatitis C virus	Liver (hepatocellular carcinoma)
Human T cell leukaemia virus	Leukaemia/lymphoma
Epstein–Barr virus	Burkitt's lymphoma Hodgkin's lymphoma
Human papilloma virus types 16, 18	Cervix Oral cancer (type 16)
Schistosoma japonicum	Bladder
Helicobacter pylori	Stomach

Diet

Dietary factors have been attributed to account for a third of cancer deaths, although it is often difficult to differentiate these from other epidemiological factors. For example, the incidence of stomach cancer is particularly high in the Far East, while breast and colon cancers are more common in the western, economically more developed countries. Many associations have been observed without a causative mechanism being identified between the incidence of cancer and the consumption of dietary fibre, red meat, saturated fats, salted fish, vitamin E, vitamin A and many others. Food and its role in the causation of gastrointestinal cancer is discussed in Chapter 5. Increasing levels of obesity in the developed world have been associated with increases in women of cancers associated with oestrogenic stimulation of the breast and endometrium.

Environmental/occupational

Ultraviolet light is known to increase the risk of skin cancer (basal cell, squamous cell and melanoma). The incidence of melanoma is therefore particularly high in the white Anglo-Celtic population of Australia, New Zealand and South Africa, where exposure to UV light is combined with a genetically predisposed population.

Occupational factors. In 1775, Percival Pott described the association between carcinogenic hydrocarbons in soot and the development of scrotal epitheliomas in chimney sweeps.

The principal causes now are asbestos (lung and mesothelial cancer) and combustion of fossil fuels (see p. 880) releasing polycyclic hydrocarbons (skin, lung, bladder cancers). Organic chemicals such as benzene may cause molecular abnormalities associated with the development of myeloid leukaemia.

Infectious agents

The geographical distribution of a rare malignancy suggests that it might be caused by, or associated with, an infective agent. Chronic persistent infection provides growth stimulation while many viruses contain transforming viral oncogenes. For example, a specific type of T cell leukaemia, seen almost exclusively in residents of the southern island of Japan and in the West Indies, is caused by infection with the retrovirus HTLV-1 (human T cell leukaemia virus) which is endemic in these areas.

Hepatocellular carcinoma occurs in patients with hepatitis B and C virus infections, and Burkitt's lymphoma and nasopharyngeal carcinoma are associated with the Epstein–Barr virus. EBV is also linked with Hodgkin's lymphoma (see p. 476). Patients with HIV infection or immunosuppression from organ transplantation have an increased incidence of EBV-related lymphoma and herpesvirus-8-associated Kaposi's sarcoma. The incidence of cervical cancer had increased among younger women in association with sexually transmitted human papillomavirus infection types 16 and 18 but a vaccine is now available.

Bacterial infection with *Helicobacter pylori* predisposes to the development of gastric cancer and gastric lymphoma, while *Schistosoma japonicum* infection predisposes to the development of squamous carcinomas in the bladder.

Iatrogenic

Drugs. Oestrogens have been implicated in the development of vaginal, endometrial and breast carcinoma. Alkylating agents given, for example, for Hodgkin's lymphoma (see later) are themselves associated with an increased incidence of secondary acute myelogenous leukaemia (AML), bladder and lung cancer. The anthracyclines and the epipodophyllotoxin drug, etoposide, have also been shown to be associated with the development of secondary AML amongst long-term survivors.

Radiation. The nuclear disasters of Hiroshima, Nagasaki and Chernobyl led to an increased incidence of leukaemia after 5–10 years in the exposed population. Increased incidences of thyroid and breast cancer have also been reported. Long-term survivors following radiotherapy used, for example, in ankylosing spondylitis, Hodgkin's lymphoma, testicular germ cell tumours and childhood cancers has led to increased incidences of cancer at the radiation field margins.

Geographical distribution

The incidence and mortality from cancer varies by tumour type and geographical region across the world. The

Ask the authors
www.studentconsult.com

incidence varies according to a number of known factors such as age, since most cancers occur in those over the age of 65 who comprise 3.3% of the population in Africa compared with 15.2% in Europe. Smoking prevalence in the previous 20 years is reflected in the rates of lung, oesophageal and oral cancers, reproductive patterns influence breast cancer, diet is associated with breast, bowel and stomach cancers, and infection with stomach, liver and cervix cancers. Incidence and mortality are closely linked for cancers for which treatment has yet to make significant improvements such as lung, stomach and liver, while in countries with effective screening programmes there is an increasing incidence and decreasing mortality for breast, cervix, bowel, and prostate cancers.

Lung cancer incidence and mortality is highest in eastern Europe (66M + 35F per 100 000 population) with 50–60% smoking prevalence. *Breast cancer* incidence is highest in North America at 97/100 000 but mortality is lower at 17/100 000 than north and western Europe. *Bowel cancer* incidence is highest in Australia and New Zealand (49M + 38F/100 000) but mortality at 20/100 000 is the same as in eastern and western Europe. *East Asia* has the highest incidence (46M + 22F/100 000) and mortality (35M + 15F/100 000) from stomach cancer. The diagnosis of *prostate cancer* has been increased by PSA testing in North America to 120/100 000 but mortality at 15/100 000 is lower than the Caribbean, 28/100 000. *Liver cancer* is most frequent in East Asia (37M + 12F/100 000) related to infection with hepatitis B and C, while in East Africa *cervical cancer* incidence (43/100 000) and mortality (35/100 000) are highest due to HPV infection. *Oesophageal cancer* incidence in East Asia (24M + 8F/100 000) and *oral cancer* in South Central Asia (13M + 8F/100 000) are linked to the consumption of tobacco and beetel.

Environmental factors interact with genetic predisposition. For example, subsequent generations of people moving from countries with a low incidence to those with a high incidence of breast or colon cancer acquire the cancer incidence of the country to which they have moved while northern European stock exposed to strong UV radiation have the highest risk of developing melanoma.

THE BIOLOGY OF CANCER

Most human neoplasms are clonal in origin, i.e. they arise from genetic mutations within a single population of precursor or cancer stem cells. However, over subsequent cell divisions heterogeneity develops with the accumulation of further abnormalities. The genes most commonly affected can be characterized as those controlling cell cycle check points, DNA repair and DNA damage recognition, apoptosis, differentiation and growth signalling. Proliferation may continue at the expense of differentiation, which together with the failure of apoptosis leads to tumour formation with the accumulation of abnormal cells varying in size, shape and nuclear morphology as viewed down the light microscope.

Proliferation

The *kinetics* of cancer cell growth are exponential; however, the doubling times of human tumours are enormously variable. Mutations are common in the genes controlling a series of intracellular proteins, such as the cyclins and cyclin-dependent kinases (see p. 28), and oncogene products such as c-myc, and the ras proteins (see Cancer genetics, p. 49) that regulate proliferation. Proliferation may also be abnormal due to persistence of the nuclear enzyme telomerase which prevents senescence, loss of cell–cell adhesion signalling, abnormal stromal nutrient supply or cytokine signalling.

Epithelial growth factor (EGF), vascular endothelial growth factor and *fibroblast growth factor* and their receptors are overexpressed in many human epithelial tumours, leading to receptor tyrosine kinase signalling and unrestrained growth which has been the target of several new drugs such as imatinib. *Transforming growth factor-β (TGF-β)*, a cytokine which has effects on extracellular matrix proteins, angiogenesis (see below) and immune effector cells, is also often overexpressed in tumour cells, and defects in TGF-β signalling are often found in cancer cells. Defects in tumour suppressor genes such as p53 (encoded by the *TP53* gene located on the short arm of chromosome 17 (17p13.1)) and the less common MADH4 or their regulatory genes are common in most epithelial cancers and form the focus of much research into targeted therapies.

Apoptosis and growth

Tumour cell death may also be dysregulated. Normal cells usually die by an active and tightly regulated process known as apoptosis, or 'programmed cell death' (see p. 28). Apoptosis can occur in response to a number of physiological cell signals or pathological stimuli (tumour necrosis factor, Fas ligand and DNA-damaging cytotoxic drugs) and is mediated within the cell by a family of proteins known as caspases. Caspase activity is, in turn, regulated by intracellular inhibitors such as the Bcl-2 family of proteins and the inhibitor of apoptosis proteins (IAPs). Disturbances in the normal balance of these various proteins have been identified and targetted for treatment in the upregulation of the bcl-2 protein in follicular non-Hodgkin's lymphoma.

Tumour immunology

Tumour cells are usually not recognized and killed by the immune system. There are two main reasons. The *first* is failure to express molecules such as HLA and costimulatory B7 molecules. These are required for activation of cytotoxic, or 'killer', T lymphocytes, since expression of these 'costimulatory' molecules following gene transfection may augment an immune response. *Secondly*, tumours may also actively secrete immunosuppressive cytokines and cause a generalized immunosuppression. This can lead, for example, to the reactivation of latent herpes zoster in shingles associated with malignancy. Research has identified new strategies for antigen presentation for future vaccines (see also immunotherapy, p. 75).

Angiogenesis

For many tumours, there is a progressive slowing of the rate of growth as the tumours become larger. This occurs for many reasons, but outgrowing the blood supply is paramount. New vessel formation (angiogenesis) is stimulated by a variety of peptides produced both by tumour cells and by host inflammatory cells, such as basic fibroblast growth

factor (bFGF), angiopoietin 2 and vascular endothelial growth factors (VEGFs), which are stimulated by hypoxia. Inhibition of angiogenesis is being developed as a method of cancer therapy, to deprive the cancer of nutrients and oxygen, and inhibit haematogenous spread, or metastasis, e.g. bevacizumab, the anti-VEGFR monoclonal antibody

Invasion and metastasis

Cancers spread by both local invasion and by distant metastasis through the vessels of the blood and lymphatic systems. Infiltration into surrounding tissues is associated with loss of cell–cell cohesion which is mediated by active homotypic cell adhesion molecules (CAMs). The cadherin molecules in association with the integrins are transmembrane heterodimeric glycoproteins able to mediate cellular attachment. Epithelial cadherin (E-cadherin) is expressed by many carcinomas, and mutated in some such as familial gastric carcinoma (see p. 264).

Invasion is also determined by the balance of activators to inhibitors of proteolysis. The balance between the expression and activity of the matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) is involved in tumour growth, invasion, metastasis and angiogenesis, and is being targeted in new therapeutic drugs for cancer treatment.

Dissemination of tumour cells occurs through intravasation into the vascular and lymphatic vessels and dissemination to distant sites, partly by chance, but also because of specific interactions between receptors and cytokines found on stromal and tumour cells. Extravasation is followed by angiogenesis to form an established metastasis.

Bone metastases have been extensively investigated because they occur in 75% of patients with advanced breast and prostate cancer but in only 25% of patients with other solid tumours, e.g. lung, GI tract, thyroid, bladder or kidney.

Metastases are either osteolytic or osteoblastic with some patients having both. Prostate cancer is predominantly osteoblastic while most patients with breast cancer and all with multiple myeloma have osteolytic lesions.

Bone is a frequent site of metastases due to:

- high blood flow
- tumour cell production of adhesins which bind them to marrow stromal cells
- growth factors in bone, including TGFβ, insulin-like growth factor (ILG) 1 and 2, platelet-derived growth factor and fibroblastic growth factors.

Osteolytic metastases (Fig. 9.1). The destruction of bone is mediated by osteoclasts driven by the tumour cells production of parathyroid hormone-related peptide, IL-6, prostaglandin E_2, TNF and macrophage colony-stimulating factor (M-CSF). These increase the expression of receptor activity of nuclear factor κB ligand (RANKL) which directly induces formation of osteoclasts and bone resorption. Bone destruction increases calcium levels and release of matrix cytokines, which promote tumour growth and production of PTH-related peptide, so further increasing osteolytic bone destruction in many tumours. In multiple myeloma there is, additionally, inhibition of osteoblast activity (see p. 484). Bisphosphonates prevent or reverse this cascade by inhibiting osteoclasts.

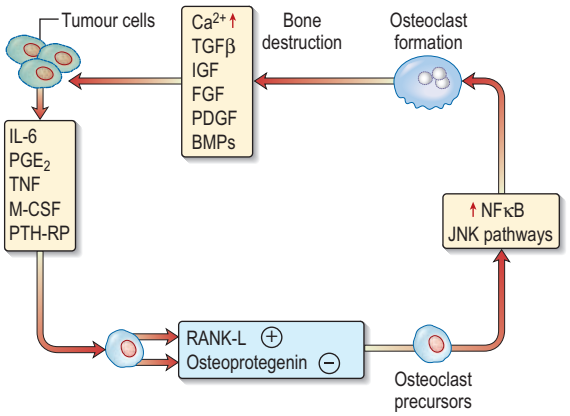

Fig. 9.1 **Mechanisms of osteolytic metastases.** Tumour cells secrete hormones and cytokines as shown. These increase various factors, e.g. RANKL, and lead to increased osteoclastic activity. Bone destruction (resorption) in turn produces factors which increase tumour growth. Osteoprotegerin (see p. 558) has an inhibitory effect on RANKL. BMPs, bone morphogenic proteins; FGF, fibroblast growth factor; IGF, insulin-like growth factor; IL-6, interleukin 6; JNK, jun N-terminal kinase; M-CSF, macrophage colony-stimulating factor; NFκB, nuclear factor kappa B; PDGF, platelet-derived growth factor; PGE_2, prostaglandin E2; PTH-RP, parathyroid hormone-related peptide; RANKL, receptor activator of NFκB ligand; TGF, transforming growth factor; TNF, tumour necrosis factor.

Osteoblastic metastases. The mechanism for this is less clear. It has been suggested that osteoclastic activity precedes osteoblastic activity and bone formation. It is also possible that the vicious circle (as in osteoclastic activity) may be in action, whereby the tumour induces osteoblastic activity and the release of growth factors for osteoblasts, which then increases the growth of tumours. Endothelin 1 has been shown to stimulate bone formation and its levels are increased in, for example, prostate and breast cancers.

Cancer genetics

The development of cancer is a multistep process associated with fundamental genetic changes within the cell. Evidence for the genetic origin of cancer is based on the following:

- Some cancers show a familial predisposition.
- Most known carcinogens act through induced mutations.
- Susceptibility to some carcinogens depends on the ability of cellular enzymes to convert them to a mutagenic form.
- Genetically determined traits associated with a deficiency in the enzymes required for DNA repair are associated with an increased risk of cancer.
- Some cancers are associated with chromosome 'instability' because of deficiencies in mismatch repair genes.
- Many malignant tumours represent clonal proliferations of neoplastic cells.
- Many malignancies contain well-described cytogenetic abnormalities, which involve mutated or abnormally regulated oncogenes and tumour suppressor genes with transforming activity in cell lines.

Table 9.3 Familial cancer syndromes

	Gene	Neoplasms
Autosomal dominant		
Retinoblastoma	*RB1*	Eye
Wilms' tumour	*WT1*	Kidney
Li–Fraumeni	*p53*	Sarcoma/brain/ leukaemia
Neurofibromatosis type 1	*NF1*	Neurofibromas
Familial adenomatous polyposis (FAP)	*APC*	Colon
Hereditary non-polyposis colon cancer (HNPCC)	*MLH1* and *MSH2*	Colon, endometrium
Hereditary diffuse gastric cancer syndrome	*E-cadherin*	Stomach
Breast ovary families	*BRCA1* *BRCA2* *p53*	Breast/ovary
Melanoma	*p16*	Skin
Von Hippel–Lindau	*VHL*	Renal cell carcinoma and haemangio-blastoma
Multiple endocrine neoplasia Type 1	*MEN1*	Pituitary, pancreas, parathyroid
Multiple endocrine neoplasia Type 2	*RET*	Thyroid, adrenal medulla
Autosomal recessive		
Xeroderma pigmentosa	*XP*	Skin
Ataxia telangiectasia	*AT*	Leukaemia, lymphoma
Fanconi's anaemia	*FA*	Leukaemia, lymphoma
Bloom's syndrome	*BS*	Leukaemia, lymphoma

Mutations may occur in the germline and therefore be present in every cell in the body, or they may occur by somatic mutation in response, for example, to carcinogens, and therefore be present only in the cells of the tumour.

Expression of the mutation and hence carcinogenesis will depend upon the penetrance (due to level of expression and presence of other genetic events) of the gene and whether the mutated allele has a dominant or recessive effect. There are a small group of autosomal dominant inherited mutations such as RB (in retinoblastoma) and a small group of recessive mutations (Table 9.3). Carriers of the recessive mutations are at risk of developing cancer if the second allele becomes mutated, leading to 'loss of heterozygosity' within the tumour, although this is seldom sufficient as carcinogenesis is a multistep process.

Malignant transformation may result from a gain in function as cellular proto-oncogenes become mutated (e.g. *ras*), amplified (e.g. *HER2*) or translocated (e.g. *BCR-ABL*). However, these mutations are insufficient to cause malignant transformation by themselves. Alternatively, there may be a loss of function of tumour suppressor genes such as P53 that normally suppress growth. Loss or gain of function may also involve alterations in the genes controlling the transcription of the oncogenes or tumour suppressor genes (e.g. p. 49) (Tables 9.3 and 9.4).

Table 9.4 Examples of acquired/somatic mutations and proto-oncogenes

Point mutation	
K-*ras*	Pancreatic cancer
DNA amplification	
myc	Neuroblastoma
HER2-neu	Breast cancer
Chromosome translocation	
BCR-ABL	CML, ALL
PML-RAR	APML
Bcl-2/IgH	Follicular lymphoma
c-myc and Ig	Burkitt's lymphoma

CML, chronic myeloid leukaemia; ALL, acute lymphoblastic leukaemia; APML, acute promyelocytic leukaemia.

DNA repair

Autosomal dominant

The following are examples of cancer syndromes that exhibit dominant inheritance (Table 9.3):

- *Retinoblastoma* is an eye tumour found in young children. It occurs in both hereditary (40%) and non-hereditary (60%) forms. The 40% of patients with the hereditary form have a germline mutation on the long arm of chromosome 13 that predisposes to retinoblastoma. In addition to the latter, children inheriting this mutation at the so-called *RB1* locus are at risk for developing other tumours, particularly osteosarcoma.
- *Breast and ovarian cancer*. Two genes have been identified – *BRCA1* and *BRCA2*. A strong family history along with germline mutation of these genes accounts for most cases of familial breast cancer and over half of familial ovarian cancers. BRCA1 and 2 proteins bind to the DNA repair enzyme Rad51 to make it functional in repairing DNA breaks. Mutations in the *BRCA* genes will lead to accumulation of unrepaired mutations in tumour-suppressor genes and crucial oncogenes.
- *Neurofibromatosis*. Inactivation of the *NF1* gene will lead to constitutive activation of ras proteins.
- *Multiple-endocrine-adenomatosis syndromes* (see p. 1026). Multiple endocrine neoplasia type 1 is associated with the *MEN1* gene and type 2 (*MEN2*) is associated with mutations in the *RET* proto-oncogene on chromosome 10 and as such are the exception to all the other syndromes which involve tumour suppressor genes.

Autosomal recessive

Some relatively rare autosomal recessive diseases associated with abnormalities of DNA repair predispose to the development of cancer (Table 9.3).

- *Xeroderma pigmentosum*. There is an inability to repair DNA damage caused by ultraviolet light and by some chemicals, leading to a high incidence of skin cancer.
- *Ataxia telangiectasia*. Mutation results in an increased sensitivity to ionizing radiation and an increased incidence of lymphoid tumours.
- *Bloom's syndrome and Fanconi's anaemia*. An increased susceptibility to lymphoid malignancy is seen.

It is not known why these chromosome-break syndromes predispose to tumours of lymphatic tissue.

THE DIAGNOSIS OF MALIGNANCY

Most common cancers (but not the haematological cancers) start as focal microscopic clones of transformed cells, and diagnosis only becomes likely once sufficient tumour bulk has accumulated to cause symptoms or signs. In order to try to make an earlier diagnosis and increase the curative possibilities, an increasing number of screening programmes are being developed which target the asymptomatic or preinvasive stages of the cancer as in cervix, breast and colon or use serum tumour markers as in prostate and ovarian cancers.

Screening

Genetic screening can be used to target screening to groups at most risk of developing cancer, e.g. *BRCA1* positive and breast cancer. The aim of screening programmes is to improve individual and/or population survival by detecting cancer at its very early stages when the patient is asymptomatic. This strategy is dependent upon finding tests that are sufficiently sensitive and specific, using detection methods that identify cancer before it has spread, and having curative treatments that are practical and consistent with maintenance of a normal lifestyle and quality of life.

Screening is provided to populations, e.g. for breast, cervical and colon cancer in the UK, and also to individuals via annual check-ups, or opportunistic when patients see their doctor for other reasons.

Unfortunately, earlier diagnosis does not necessarily mean longer survival. The patient is merely treated at an earlier date and hence the survival appears longer, death still occurs at the same time from the point of genesis of the cancer. This is called lead time bias (Fig. 9.2). With length time bias, a greater number of slowly growing tumours are detected when screening asymptomatic individuals leading to a false impression of an improvement in survival.

An effective screening procedure should:

- be affordable to the healthcare system
- be acceptable to all social groups so that they attend for screening
- have a good discriminatory index between benign and malignant lesions
- show a reduction in mortality from the cancer.

Cervical cancer. The smear test is cheap and safe though seen as unacceptably invasive by some women. Cervical smears require a well-trained cytologist to identify the early changes (dyskaryosis and cervical intraepithelial neoplasia (CIN)). However developments in liquid cytology and DNA testing for human papillomavirus (HPV) have been introduced. The introduction of this test reduces the incidence and mortality from cervical cancer though it has not been subject to randomized trials. Future screening may be linked to the introduction of vaccination against HPV infection for women before they become sexually active.

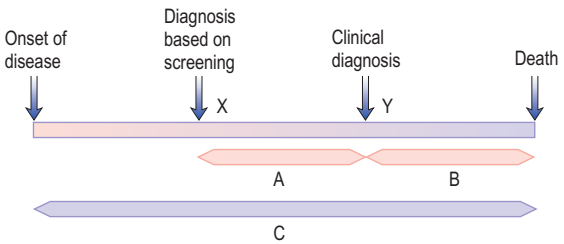

Fig. 9.2 **Lead time bias.** Earlier diagnosis, at X, made by screening tests before the clinical diagnosis, at Y, suggests an increased survival time of A + B. The actual survival time (C) remains unchanged.

Breast cancer. The UK NHS Breast Screening Programme (i.e. biplanar mammography every 3 years) for women aged 50–70 years has been shown to reduce mortality from breast cancer in randomized control studies. The test is acceptable to most women with 75% of women attending for screening.

The cost is estimated to be between £250 000 and £1.3 million per life saved, money which, according to critics of screening, could be used more appropriately in better treatment.

Women from families with *BRCA1*, *BRCA2* and *p53* mutations require intensive screening starting at an earlier age.

Colorectal cancer (CRC). Faecal occult blood is an acceptable and cheap test for the detection of CRC. The false-positive rates are high, meaning many unnecessary colonoscopies (see p. 270). The UK has recently introduced a national screening programme for colorectal cancer using faecal occult blood in patients 60–64 years. This will be evaluated over the coming years.

Other population-based screening programmes that are being used or are in trials are:

Prostate cancer. Serum prostate-specific antigen (PSA) can be used for the detection of this cancer, which is on the increase. The natural history of the disease is unclear. Many men over 70 have evidence of prostate cancer at post mortem with no symptoms of the disease and it has been suggested that over 75-year-olds should not have screening PSAs. The test must be interpreted with caution due to the natural increase in PSA with age, benign prostatic hypertrophy, and with prostatitis.

Treatment may be associated with unacceptable side-effects (see p. 646) and no overall survival advantage has yet been shown in population studies. It may be life saving for the individual diagnosed with a high grade tumour that is still amenable to curative treatment.

Epithelial ovarian cancer. Serum CA125 can be used for the early detection of this cancer and is the subject of ongoing trials. An improvement in survival of a screened population can be shown but at the cost of many unnecessary laparotomies so that further enhancements are being investigated by serial testing and in combination with transvaginal ultrasound scans.

Symptoms of cancer

Patients often present with a history of tumour site-specific symptoms, e.g. pain, and physical signs, e.g. a mass, which readily identify the primary site of the cancer. On the other hand, many seek medical attention when more systemic and non-specific symptoms occur such as weight loss, fatigue

and anorexia. These usually indicate a more advanced stage of the disease except in some paraneoplastic and ectopic endocrine syndromes (see below). Other patients are only diagnosed upon the discovery of established metastases such as the abdominal distension of ovarian cancer, the back pain of metastatic prostatic cancer or the liver enlargement of metastatic gastrointestinal cancer.

Other indirect effects of the cancer manifest as paraneoplastic syndromes (Box 9.1) that are often associated with specific types of cancer and are reversible with treatment of the cancer. The effects and mechanisms can be very variable. For example in the Lambert–Eaton syndrome (see p. 1181) there is cross-reactivity between tumour antigens and the normal tissues, e.g. the acetylcholine receptors at neuromuscular junctions.

The *coagulopathy of cancer* may present with thrombophlebitis, deep venous thrombosis and pulmonary emboli, particularly in association with cancers of pancreas, stomach and breast. Some 18% of patients with recurrent pulmonary embolus will be found to have an underlying cancer and cancer patients are also at risk of a pulmonary embolus following diagnosis.

Other symptoms are related to peptide or hormone release, e.g. carcinoid or Cushing's syndrome.

Cachexia of advanced cancer is thought to be due to release of chemokines such as tumour necrosis factor (TNF), as well as the fact that patients have a loss of appetite.

Cancer-associated immunosuppression can lead to reactivation of latent infections such as herpes zoster.

Physical examination

A general examination should be performed to include:

- main symptomatic areas, e.g. site, size of mass and associated lymphadenopathy
- precursor lesions, e.g. solar keratosis, dysplastic naevi
- general signs, e.g. jaundice, clubbing
- functional capacity (see Table 9.6).

Histology

The diagnosis of cancer may be suspected by both patient and doctor but advice about treatment can usually only be given on the basis of a tissue diagnosis. This may be obtained by surgical biopsy or on the basis of cytology (e.g. lung cancer diagnosed by sputum cytology). Malignant lesions can be distinguished morphologically from benign by the pleomorphic nature of the cells, increased numbers of mitoses, nuclear abnormalities in size, chromatin pattern and nucleolar organization, and evidence of invasion into surrounding tissues.

The degree of differentiation (or conversely of anaplasia) of the tumour has prognostic significance: generally speaking, more differentiated tumours have a better prognosis than poorly differentiated ones.

Box 9.1 Paraneoplastic syndromes

Syndrome	Tumour	Serum antibodies
Neurological		
Lambert–Eaton syndrome	Lung (small-cell) lymphoma	Anti VGLC
Peripheral sensory neuropathy	Lung (small-cell), breast and ovary lymphoma	Anti Hu
Cerebellar degeneration	Lung (particularly small-cell) lymphoma	Anti Yo
Opsoclonus/myoclonus (p. 1109)	Breast, lung (small-cell)	Anti Ri
Stiff man syndrome	Breast, lung (small-cell)	Anti-amphiphysin
Limbic, hypothalamic, brain stem encephalitis	Lung	Anti Ma protein
	Testicular	Anti-NMDAR
Endocrine/metabolic		
SIADH	Lung (small-cell)	
Ectopic ACTH secretion	Lung (small-cell)	
Hypercalcaemia	Renal, breast	
Musculoskeletal		
Hypertrophic pulmonary osteoarthropathy	Lung (non-small-cell)	
Clubbing	Lung	
Skin		
Dermatomyositis/polymyositis	Lung and upper GI	
Acanthosis nigricans	Mainly gastric	
Hyperpigmentation	Lung (small-cell)	
Pemphigus	Non-Hodgkin's lymphoma, CLL	
Haematological		
Erythrocytosis	Renal cell carcinoma, hepatocellular carcinoma, cerebellar haemangioblastoma	
Migratory thrombophlebitis	Pancreatic adenocarcinoma	
DIC	Adenocarcinoma	

SIADH, syndrome of inappropriate antidiuretic hormone secretion; ACTH, adrenocorticotrophic hormone; CLL, chronic lymphocytic leukaemia; DIC, disseminated intravascular coagulation; NMDAR, N-methyl-D-aspartate receptors.

Tissue tumour markers: Immunocytochemistry, using monoclonal antibodies against tumour antigens, is very helpful in differentiating between lymphoid and epithelial tumours and between some subsets of these, for example T and B cell lymphomas, germ cell tumours, prostatic tumours, neuroendocrine tumours, melanomas and sarcomas. However, there is much overlap in the expression of many of the markers and some adenocarcinomas and squamous carcinomas do not bear any distinctive immunohistochemical markers that are diagnostic of their primary site of origin.

There are several tests for genetic markers in tissue sections. For example, fluorescent in situ hybridization (FISH, see p. 41) can be used to look for characteristic chromosomal translocations, e.g. in lymphoma and leukaemia, deletions or amplifications, e.g. in breast cancer (see genetic basis of cancer, p. 49). Tissue microarrays can identify patterns of multiple genomic alterations and single nucleotide polymorphisms (SNPs), e.g. in breast cancer and lymphoma (see p. 35), with prognostic and predictive relevance. Increasingly genomics and proteomics are being investigated in order to target new (and expensive) therapies, e.g. imatinib in CML and GIST, trastuzumab and lapatinib in breast cancer, and erlotinib in lung cancer, but it is still unclear which of the many gene signatures are most reliable and reproducible.

Staging

Before a decision about treatment can be made, not only the type of tumour but also its extent and distribution need to be established. Various 'staging investigations' are therefore performed before a treatment decision is made. To be useful clinically the staging system must subdivide the patients into groups of different prognosis which can guide treatment selection.

The staging systems vary according to the type of tumour and may be site specific (see Hodgkin's lymphoma, p. 476), or the TNM (tumour, node, metastases) classification shown in Table 9.5 which can be adapted for application to most common cancers.

Performance status

In addition to anatomical staging, the person's age and general state of health need to be taken into account when planning treatment. The latter has been called 'performance status' and is of great prognostic significance for all tumour types (Table 9.6). Performance status reflects the effects of the cancer on the patient's functional capacity. An alternative performance rating scale is by Karnowsky. With a performance status ≥ 2, response to and survival following treatment are greatly reduced for most tumour types.

Table 9.5 TNM classification as used for lung cancer

T = extent of primary tumour; N = extent of regional lymph node involvement; M = presence of distant metastases

Tx	Positive cytology only
T1	<3 cm diameter
T2	>3 cm/extends to hilar region/invades visceral pleura/partial atelectasis
T3	Involvement of chest wall, diaphragm, pericardium, mediastinum, pleura, total atelectasis
T4	Involvement of heart, great vessels, trachea, oesophagus, malignant effusion
N1	Peribronchial, ipsilateral hilar lymph node involvement
N2	Ipsilateral mediastinal
N3	Contralateral mediastinal, scalene or supraclavicular
M0	No distant metastases
M1	Metastases present

Table 9.6 Eastern Cooperative Oncology Group (ECOG) performance status scale

Status	Description
0	Asymptomatic, fully active and able to carry out all predisease performance without restrictions
1	Symptomatic, fully ambulatory but restricted in physically strenuous activity and able to carry out performance of a light or sedentary nature, e.g. light housework, office work
2	Symptomatic, ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours: in bed less than 50% of day
3	Symptomatic, capable of only limited self-care, confined to bed or chair more than 50% of waking hours, but not bedridden
4	Completely disabled. Cannot carry out any self-care. Totally bedridden

Serum tumour markers (Table 9.7)

Tumour markers are intracellular proteins or cell surface glycoproteins released into the circulation and detected by immunoassays. Examples are given in Table 9.7. Values in the normal range do not necessarily equate with the absence of disease and a positive result must be corroborated by histology as these markers can be seen in many benign conditions. They are most useful in the serial monitoring of response to treatment.

Cancer imaging

Radiological investigation by experts is required at various stages: at initial diagnosis and staging of the disease, during the monitoring of treatment efficacy, at the detection of recurrence, and for the diagnosis and treatment of complications.

Table 9.7 Serum tumour markers

α-Fetoprotein	Hepatocellular carcinoma, and non-seminomatous germ cell tumours of the gonads
β-Human chorionic gonadotrophin (β-HCG)	Choriocarcinomas, germ cell tumours (testicular) and lung cancers
Prostate-specific antigen (PSA)	Carcinoma of prostate
Carcinoma embryonic antigen (CEA)	Gastrointestinal cancers
CA-125	Ovarian cancer
CA-19-9	Gastrointestinal cancers particularly pancreatic cancer
CA-15-3	Breast cancer
Osteopontin	Many cancers including mesothelioma

The choice of investigations needs to be guided by the patient's symptoms and signs, site and histology of the cancer, the curative or palliative potential of treatment, and the utility of the information in guiding treatment. The investigations are described under each tumour type.

Plain X-ray allied to *ultrasonography* is quick and relatively cheap and widely available.

Cross-sectional imaging by computed tomographic scanning (*CT scan*), or magnetic resonance imaging (*MRI scan*) has greater anatomical detail, while functional imaging with radioactive nucleides for thyroid cancer is both diagnostic and therapeutic.

Contrast agents are used for increased structural discrimination and can be further enhanced with functional specificity for metabolically active tissue with ^{19}fluorodeoxyglucose uptake and CT-positron emission tomography (CT-PET scan) as used extensively in head and neck cancer, lung cancer and lymphoma. *Radionuclide imaging* of sentinel lymph nodes is used to guide lymphatic surgery in breast cancer and melanoma while paramagnetic iron particles taken up by macrophages can enable MRI lymphography for pelvic tumours. Tumour targeted contrast agents can improve detection rates such as the radiolabelled MAb rituximab for lymphoma or radiolabelled small molecules such as octreotide for neuroendocrine tumours. Research into the use of reporter agents which become visible only upon activation within the tumour environment holds the promise of greater sensitivity and specificity in the future.

CANCER TREATMENT

Aims of treatment

Cancer treatment requires the cooperation of a multidisciplinary team to coordinate the delivery of the appropriate treatment (surgery, chemotherapy, radiotherapy and biological/endocrine therapy), supportive and symptomatic care, and psychosocial support. While all members will have the patient's care as their central concern, someone, often the oncologist, has to take responsibility for the coordination of the many professionals involved. Central to this endeavour is the involvement of the patient, through education as to the nature of their disease and the treatment options available. An informed choice can then be made, even if in the end it is simply to abide by the decisions made by the professionals. Good communication embodies a humane approach which preserves hope at an appropriate level through empathy and understanding of the patient's position (see p. 12).

Curing cancer

For most solid tumours local control is necessary but not sufficient for cure because of the presence of systemic (microscopic) disease, while haematological cancers are usually disseminated from the outset. Improvement in the rate of cure of most cancers is thus dependent upon earlier detection to increase the success of local treatment and effective systemic treatment. The likelihood of cure of the systemic disease depends upon the type of cancer and its expression of appropriate treatment targets, its drug sensitivity and tumour bulk (microscopic or clinically detectable). A few rare cancers are so chemosensitive that even bulky metastases can be cured, e.g. leukaemia, lymphoma, gonadal germ cell tumours and choriocarcinoma. For most common solid tumours such as lung, breast and colorectal cancer, there is no current cure of bulky (clinically detectable) metastases, but micrometastatic disease treated by adjuvant systemic therapy (see below) after surgery can be cured in 10–20% of patients.

Adjuvant therapy for solid tumours

This is defined as treatment given, in the absence of macroscopic evidence of metastases, to patients at risk of recurrence from micrometastases, following treatment given for the primary lesion. *'Neoadjuvant' therapy* is given before primary therapy, to both shrink the tumour to improve the local excision and treat any micrometastases as soon as possible.

Micrometastatic spread by lymphatic or haematological dissemination often occurs early in the development of the primary tumour, and can be demonstrated by molecular biological methods capable of detecting the small numbers (1 in 10^6) of circulating cells. Studies correlating prognosis with histological features of the primary cancer, e.g. differentiation, or presence of early metastatic invasion of blood vessels or regional lymph nodes, have led to an increasing ability to predict which patients are at high risk of local or distant recurrence from micrometastatic disease.

Trials of treatment with local radiotherapy or endocrine, biological or chemotherapy systemic treatments have shown a significant improvement in survival in common adult cancers such as breast, bowel, prostate, head and neck, cervical cancer, choriocarcinoma and gonadal germ cell cancers. Central to these studies has been the careful selection of patients according to defined risk criteria, and the reduction of treatment toxicity to reach a balanced risk/benefit ratio. Relative risk reductions in the order of 12–25% and absolute improvements in 5- to 10-year survival of 5–10% (dependent upon the pre-existing risk) have been achieved in common epithelial cancers such as lung, bowel, breast and prostate, with greater absolute improvements of 25% in the more sensitive germ cell tumours.

While these improvements currently translate into many lives saved from common diseases at a public health level, the majority who receive such treatment do not benefit because they were already cured, or because the cancer is resistant to the treatment. Better tests in the future will identify those with the micrometastases who really need treatment. On an individual patient basis the decision on whether adjuvant treatment will be worthwhile must include consideration of other factors such as the patient's life expectancy, concurrent medical conditions and lifestyle priorities.

Treatment of metastases in the CNS

When metastatic disease has spread to the CNS it may not be accessible to conventional drug therapy. Examples of this are leukaemic infiltration of the meninges with acute lymphoblastic leukaemia, small-cell lung cancer and breast cancer. Because of the blood–brain barrier, chemotherapy agents and especially monoclonal antibodies do not enter the subarachnoid space in sufficient quantity, and are therefore ineffective in treating meningeal infiltration. In order to treat these cells, intrathecal chemotherapy and/or cranial irradiation are required for patients at risk (see p. 471).

Palliation

When cure is no longer possible, palliation, i.e. relief of tumour symptoms and prolongation of life, is possible in many cancers in proportion to their drug and radiation sensitivity. There is on average a 2- to 18-month prolongation in median life expectancy with treatments for solid tumours and up to 5–8 years for some leukaemias and lymphomas, with those with the most responsive tumours experiencing the greatest benefit. The development of more effective chemotherapeutic drugs, targeted biological agents and better supportive care such as antiemetics has done much to reduce the side-effects of systemic therapy and to improve the cost/benefit ratio for the patient receiving palliative treatment. In addition, through early assessment during treatment, it is possible to stop if there is no evidence of benefit within 6–8 weeks of starting, so as to minimize exposure to toxic and unsuccessful treatment.

Measuring response to treatment

A measurable response to treatment can serve as a useful early surrogate marker when assessing whether to continue a given treatment for an individual patient. Trials to assess response to treatment in advanced disease have identified active agents for use in the more curative setting of adjuvant treatment of early stage disease

Response to treatment can be subjective or objective. *A subjective response* is one perceived by the patient in terms of, for example, relief of pain and dyspnoea, or improvement in appetite, weight gain or energy. Such subjective response is a major aim of most palliative treatments. Quantitative measurements of these subjective symptoms form a part of the assessment of response to chemotherapy, especially in those situations where cure is not possible and where the aim of treatment is to provide prolongation of good-quality life. In these circumstances, measures of quality of life enable an estimate of the balance of benefit and side-effects to be made.

Objective response to treatment is measured either as a complete response, which is a complete disappearance of all detectable disease clinically and radiologically, or partial response, which is conventionally defined as more than a 50% reduction in the area of the tumour. The terms used to evaluate the responses of tumours are given in Box 9.2. As an alternative the RESIST convention uses a 30% reduction in the sum of all measurable lesion diameters to indicate a partial response. The term '*remission*' is often used synonymously with '*response*', which if complete means an absence of detectable disease without necessarily implying a cure of the cancer.

Box 9.2 Definitions of response

Complete response	Complete disappearance of all detectable disease
Partial response	More than 50% reduction in the product of the bidimensional diameters of the tumour
Stable disease	No change, or <50% reduction and <25% increase
Progressive disease	Increase in size of tumour by at least 25% at any site

Oncological emergencies

Superior vena caval obstruction can arise from any upper mediastinal mass but is most commonly associated with lung cancer and lymphoma. The patient presents with difficulty breathing and/or swallowing, with stridor, swollen, oedematous facies and arms with venous congestion in the neck and dilated veins in the upper chest and arms. Treatment is with immediate steroids, vascular stents, anticoagulation and mediastinal radiotherapy or chemotherapy. Some tumours, e.g. lymphomas, small-cell lung cancers and germ cell tumours, are so sensitive to chemotherapy that this is preferred to radiotherapy, as the masses are likely to be both large and associated with more disseminated disease elsewhere. An early decision is necessary on the patient's likely prognosis, as ventilatory support may be required until treatment has had time to relieve the obstruction.

Spinal cord compression (see p. 1163) needs to be rapidly diagnosed and urgent treatment arranged within 24 hours of onset of paresis to salvage as much functional capacity as possible. Early neurological clinical features may be incomplete, more subjective than objective and gradual in onset. MR scanning is the investigation of choice. Treatment should begin with high-dose steroids followed by surgical decompression and radiotherapy to the affected vertebrae to achieve the best disease control and palliation.

Neutropenic sepsis (see p. 461).

Acute lysis syndrome This occurs if treatment produces a massive breakdown of tumour cells, leading to increased serum levels of urate, potassium and phosphate. Urate deposition in the renal tubules can cause renal failure (hyperuricaemic nephropathy) requiring dialysis. The xanthine oxidase inhibitor allopurinol is given before treatment is started. Intravenous rasburicase, a recombinant urate oxidase, is occasionally used for prophylaxis and treatment but is very expensive.

Acute hypercalcaemia presents with vomiting, confusion, constipation and oliguria. Treatment is by resuscitation with intravenous fluids until a saline diuresis is established, followed by i.v. bisphosphonate, e.g. pamidronate, clodronate, or the more potent zolendronate (Emergency Box 18.2).

Raised intracranial pressure due to intracerebral metastases presents classically with headache, nausea and vomiting. There are often no localizing neurological signs and almost never papilloedema until very late in the disease. However, for many there is a slower onset with non-specific symptoms such as drowsiness or mental deterioration. Treatment is by high-dose steroids and investigation by MRI as to whether surgery is appropriate or chemotherapy and radiotherapy are required.

Hyperviscosity affects those with a very high haematocrit (>50), white cell count ($>100 \times 10^9$/L) or platelet cell count ($>1000 \times 10^9$/L) from untreated acute leukaemia, or polycythaemia. Treatment is by leucopheresis and plasmapheresis followed by chemotherapy treatment for the underlying malignancy.

Pulmonary embolus is a common complication of the coagulopathy of cancer and as a side-effect of chemotherapy.

Frequently it does not present with classical signs but as unexplained breathlessness with episodic exacerbations from multiple small emboli. A low index of suspicion should be kept in any cancer patient with hypoxia, especially if immobilized in bed in hospital. Prophylaxis with subcutaneous low molecular weight heparin is indicated in all patients if there is no contraindication from tumour bleeding.

Cardiac tamponade from a malignant pericardial effusion usually presents with a fall in cardiac output and symptoms of shortness of breath, drowsiness and hypotension that can be dramatically reversed by the ultrasound-guided percutaneous drainage of the fluid. More sustained improvement may require the surgical formation of a pericardial window and time for chemotherapy to take effect.

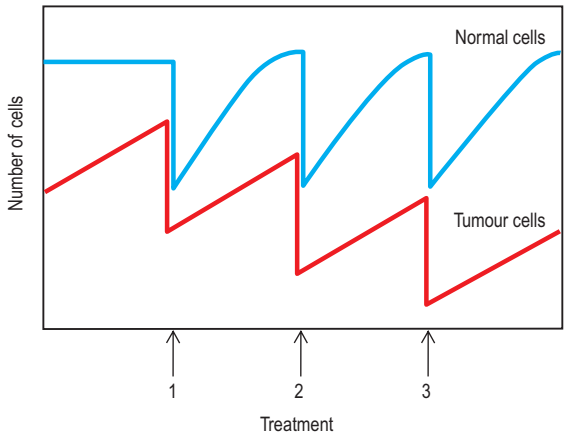

Fig. 9.3 **Effects of multiple courses of cytotoxic chemotherapy.**

PRINCIPLES OF CHEMOTHERAPY

Chemotherapy employs systemically administered drugs that directly damage cellular DNA (and RNA). It kills cells by promoting apoptosis and sometimes frank necrosis. There is a narrow therapeutic window between effective treatment of the cancer and normal tissue toxicity, because the drugs are not cancer specific (unlike some of the biological agents), and the increased proliferation in cancers is not much greater than in normal tissues (see tumour growth and failure of apoptosis, p. 27). The dose and schedule of the chemotherapy is limited by the normal tissue tolerance, especially in those more proliferative tissues of the bone marrow and gastrointestinal tract mucosa. All tissues can be affected, however, depending upon the pharmacokinetics of the drug and affinity for particular tissues (e.g. heavy metal compounds for kidneys and nerves).

The therapeutic effect on the cancer is achieved by a variety of mechanisms which seek to exploit differences between normal and transformed cells. While most of the drugs have been derived in the past by empirical testing of many different compounds, e.g. alkylating agents, the new molecular biology is leading to targeting of particular genetic defects in the cancer (see tyrosine kinase inhibitors, p. 464).

Toxicity to normal tissue can be limited in some instances by supplying growth factors such as granulocyte colony-stimulating factor (G-CSF) or by the infusion of stem cell preparations to diminish myelotoxicity. The use of more specific biological agents with relatively weak pro-apoptotic effects in combination with the general cytotoxics has also improved the therapeutic ratio (see trastuzumab and breast cancer, p. 488).

Most tumours rapidly develop resistance to single agents given on their own. For this reason the principle of intermittent combination chemotherapy was developed. Several drugs are combined together, chosen on the basis of differing mechanisms of action and non-overlapping toxicities. These drugs are given over a period of a few days followed by a rest of a few weeks, during which time the normal tissues have the opportunity for regrowth. If the normal tissues are more proficient at DNA repair than the cancer cells, it may be possible to deplete the tumour while allowing the restoration of normal tissues between chemotherapy cycles (Fig. 9.3).

In many experimental tumours it has been shown that there is a log–linear relationship between drug dose and number of cancer cells killed and that the maximum effective dose is very close to the maximum tolerated dose at which dose-limiting toxicity is reached. With a chemosensitive tumour, relatively small increases in dose may have a large effect on tumour cell kill. It is therefore apparent that where cure is a realistic option the dose administered is critical and may need to be maintained despite toxicity. In situations where cure is not a realistic possibility and palliation is the aim, a sufficient dose to exceed the therapeutic threshold, but not cause undue toxicity, is required as the short-term quality of life becomes a major consideration.

Classification of cytotoxic drugs

(Table 9.8)

DNA damaging

Alkylating agents act by covalently binding alkyl groups, and their major effect is to cross-link DNA strands, interfering with DNA synthesis and causing strand breaks. Despite being among the earliest cytotoxic drugs developed, they maintain a central position in the treatment of cancer. Melphalan is one of the original nitrogen mustards and is used in multiple myeloma. Chlorambucil is used in Hodgkin's lymphoma and chronic lymphocytic leukaemia. Other common alkylating agents include cyclophosphamide and ifosfamide,

Table 9.8 Chemotherapy: some cytotoxic drugs

DNA damaging

Free radicals – alkylators, e.g. cyclophosphamide

DNA cross-linking – platinum, e.g. cisplatin, carboplatin, oxaliplatin

Antimetabolites

Thymidine synthesis, e.g. 5-fluorouracil, methotrexate, cytarabine and mercaptopurine

DNA repair inhibitors

Topoisomerase inhibitors – epipodophyllotoxins, e.g. etoposide; campothecins, e.g. irinotecan

DNA intercalation – anthracyclines, e.g. doxorubicin

Antitubulin

Tubulin binding – alkaloids, e.g. vincristine, vinorelbine

Taxanes – e.g. paclitaxel, docetaxel

as well as the nitrosoureas, carmustine (BCNU), lomustine (CCNU) and busulfan used in chronic myeloid leukaemia. Tetrazines also alkylate DNA; dacarbazine is used in malignant melanoma and temozolomide in malignant gliomas.

Platinum compounds Cisplatin, carboplatin and oxaliplatin cause interstrand cross-links of DNA and are often regarded as non-classical alkylating agents. They have transformed the treatment of testicular cancer (cisplatin) and have a major role against many other tumours, including lung, ovarian and head and neck (cis or carbo-platin), and gastrointestinal (oxaliplatin) cancer. Toxicity, as for other heavy metals, includes renal and peripheral nerve damage.

Antimetabolites

Antimetabolites are usually structural analogues of naturally occurring metabolites that interfere with normal synthesis of nucleic acids by falsely substituting purines and pyrimidines in metabolic pathways. Antimetabolites can be divided into:

Folic acid antagonist, e.g. methotrexate. This is structurally very similar to folic acid and binds preferentially to dihydrofolate reductase, the enzyme responsible for the conversion of folic acid to folinic acid. It is used widely in the treatment of solid tumours and haematological malignancies. Folinic acid is often given to 'rescue' normal tissues from the effects of methotrexate.

Pyrimidine antagonists. 5-Fluorouracil (5-FU) consists of a uracil molecule with a substituted fluorine atom. It acts by blocking the enzyme thymidylate synthase, which is essential for pyrimidine synthesis. 5-Fluorouracil has a major role in the treatment of solid tumours, particularly gastrointestinal cancers. Oral capecitabine is metabolized to 5-FU, and tegafur with uracil and calcium folinate are used in gastrointestinal and breast cancers.

Arabinosides inhibit DNA synthesis by inhibiting DNA polymerase. Cytosine arabinoside (cytarabine) is used almost exclusively in the treatment of acute myeloid leukaemia where it remains the backbone of therapy, while its analogue gemcitabine is proving useful in a number of solid cancers such as lung, breast, pancreas and ovary. Fludarabine is used in the treatment of B cell chronic lymphocytic leukaemia; it is also used in reduced intensity stem cell transplantation (see p. 473) because of its immunosuppressive effect.

Purine antagonists, e.g. 6-mercaptopurine and 6-thioguanine, which are both used almost exclusively in the treatment of acute leukaemia.

DNA repair inhibitors

Epipodophyllotoxins. These are semisynthetic derivatives of podophyllotoxin which inhibit topoisomerase. Topoisomerases allow unwinding and uncoiling of supercoiled DNA. Etoposide is a drug used in a wide range of cancers and works by maintaining DNA strand breaks by inhibiting the enzyme topoisomerase II. Topoisomerase I inhibitors such as irinotecan and topotecan have also proved active against lung, colon, ovary and cervix cancer.

Cytotoxic antibiotics. The anthracyclines act by intercalating adjoining nucleotide pairs on the same strand of DNA and by inhibiting topoisomerase II DNA repair. They have a wide spectrum of activity in haematological and solid tumours. Doxorubicin and its cogener epirubicin are two of the most widely used of all cytotoxic drugs but have cumulative toxicity to the myocardium. Pegylated liposomal doxorubicin is used for Kaposi's sarcoma and as second-line treatment for advanced ovarian cancer with reduction of cardiotoxicity, but increased toxicity to the skin on the palms of the hands and soles of the feet. Amsacrine is a similar drug used occasionally in acute myeloid leukaemia. Bleomycin and mitomycin are also intercalating agents which promote the cleavage of DNA and RNA. Bleomycin has a particular toxicity to the lung causing interstitial fibrosis.

Antitubulin agents

Vinca alkaloids. Drugs such as vincristine, vinblastine and vinorelbine act by binding to tubulin and inhibiting microtubule formation (see p. 24). They are used in the treatment of haematological (vincristine and vinblastine) and non-haematological cancers (vinorelbine). They are associated with neurotoxicity due to their anti-microtubule effect and must never be given intrathecally.

Taxanes. Paclitaxel and docetaxel bind to tubulin dimers and prevent their assembly into microtubules. They are active drugs against many cancers such as ovarian, breast and lung cancer. Taxanes can cause neurotoxicity and hypersensitivity reactions and patients should be premedicated with steroids, H_1 and H_2 histamine antagonists prior to treatment.

Side-effects of chemotherapy

Chemotherapy carries many potentially serious side-effects and should be used only by trained practitioners. The four most common side-effects are vomiting, hair loss, tiredness and myelosuppression (Table 9.9). Side-effects are much more directly dose related than anticancer effects and it has been the practice to give drugs at doses close to their maximum tolerated dose, although this is not always necessary to achieve their maximum anticancer effect. Common combination chemotherapeutic regimens are shown in Table 9.10.

Extravasation of intravenous drugs. Cytotoxic drugs should only be given by trained personnel. They cause severe local tissue necrosis if leakage occurs outside the vein. Stop the

Table 9.9 Side-effects of chemotherapy

Common
Nausea and vomiting
Hair loss
Myelosuppression
Mucositis
Fatigue
Drug-specific
Cardiotoxicity, e.g. anthracyclines
Pulmonary toxicity, e.g. bleomycin
Neurotoxicity, e.g. cisplatinum, vinca alkaloids, taxanes

Skin plantar–palmar dermatitis, e.g. 5-fluorouracil
Sterility, e.g. alkylating agents, anthracyclines, docetaxel
Secondary malignancy, e.g. alkylating agents, epipodophyllotoxins

Table 9.10 Some common chemotherapy regimens

Hodgkin's lymphoma	ABVD	Doxorubicin, bleomycin, vinblastine, dacarbazine
	BEACOPP	Bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisolone
Non-Hodgkin's lymphoma	CHOP	Cyclophosphamide, hydroxy-doxorubicin, vincristine, prednisolone
Breast	CMF	Cyclophosphamide, methotrexate, 5-fluorouracil
	EC-T	Epirubicin, cyclophosphamide, paclitaxel
	FEC-D	5FU, epirubicin, cyclophosphamide, docetaxel
Lung	PE	Cisplatin, etoposide
	GC	Gemcitabine, carboplatin
Stomach	ECF	Epirubicin, cisplatin, 5-fluorouracil
Colorectal	FolFOx	Oxaliplatin, 5FU, folinic acid
	OX	Oxaliplatin, capecitabine

NB. Some abbreviations are related to trade names.

infusion immediately and institute local measures, e.g. aspirate as much of the drug from the cannula, infiltrate area with 0.9% saline and apply warm compresses. Antihistamines and corticosteroids may give symptomatic relief. Dexrazoxane is used for anthracycline-induced extravasation as an antidote.

Nausea and vomiting. The severity of this common side-effect varies with the cytotoxic and it can be eliminated in 75% of patients by using modern antiemetics. Nausea and vomiting are particular problems with platinum analogues and with doxorubicin. A stepped policy with antiemetics such as metoclopramide and domperidone followed by 5-HT_3 serotonin antagonists (e.g. ondansetron, granisetron) combined with dexamethasone should be used to match the emetogenic potential of the chemotherapy. Aprepitant, a neurokinin receptor antagonist, is helpful in preventing acute and delayed nausea and vomiting. It is used with dexamethasone and a 5-HT_3 antagonist. Drugs such as cyclizine, haloperidol and levomepromazine, and benzodiazepines can be used to control persistent nausea.

Hair loss. Many but not all cytotoxic drugs are capable of causing hair loss. Scalp cooling can sometimes be used to reduce hair loss but in general this side-effect can only be avoided by selection of drugs where this is possible. Hair always regrows on completion of chemotherapy.

Bone marrow suppression and immunosuppression. Suppression of the production of red blood cells, white blood cells and platelets occurs with most cytotoxic drugs and is a dose-related phenomenon. Severely myelosuppressive chemotherapy may be required if treatment is to be given with curative intent despite the potential for rare but fatal infection or bleeding. Anaemia and thrombocytopenia are managed by red cell or platelet transfusions.

Box 9.3 Febrile neutropenia treatment

IMMEDIATE INTERVENTION IS ESSENTIAL

Resuscitation with intravenous fluids to restore circulatory function, e.g. urine output, followed by cultures of blood, urine, sputum and stool and empirical antibiotics:

- Commonly used antibiotics should include activity against pseudomonas, e.g. ceftazidime or ticarcillin with gentamicin
- May require antibiotics against *Staph. aureus* especially with indwelling venous access lines, e.g. flucloxacillin or vancomycin for MRSA.

If the patient deteriorates clinically and/or temperature still elevated after 48 hours, change antibiotics according to culture results or empirically increase Gram-negative and Gram-positive cover.

- Consider adding treatment for opportunistic infections if fever not responding to broad-spectrum antibiotics, e.g. amphotericin B
  - liposomal amphotericin B or voriconazole (latter two are very expensive) or caspofungin – fungus
  - high-dose co-trimoxazole – pneumocystis
  - clarithromycin – mycoplasma.

Neutropenic patients are at high risk of bacterial and fungal infection, often from enteric bowel flora. Patients must be warned of the possibility of neutropenia occurring. Those with a fever > 37.5°C and less than 0.5×10^9 neutrophils/L are managed by the immediate introduction of broad-spectrum antibiotics intravenously for the treatment of infection (Box 9.3). Initial empirical therapy should be reviewed following microbiological results. Prophylactic antibiotic levofloxacin during the period of myelosuppression has been shown to reduce infection in solid tumour patients but can raise the risk of *Clostridium difficile* colitis. Haemopoietic growth factors such as G-CSF and peripheral blood stem cells can reduce the duration of neutropenia significantly, benefiting patients at high risk of infectious complications.

Mucositis. This common side-effect of chemotherapy reflects the sensitivity of the mucosa to antimitotic agents. It causes severe pain in the oropharyngeal region and problems with swallowing and nutrition. Mucositis can be generalized throughout the intestinal track when it can cause life threatening diarrhoea. Treatment is with antiseptic and anticandidal mouthwash and, if severe, fluid and antibiotic support, as the mucosa is a portal for entry of enteric organisms. Folinic acid is used to prevent and treat mucositis from methotrexate. A keratinocyte growth factor (palifermin) is helpful.

Cardiotoxicity. This is a rare side-effect of chemotherapy, usually associated with anthracyclines such as doxorubicin. It is dose-related and can largely be prevented by restricting the cumulative total dose of anthracyclines within the safe range (equivalent to 450 mg/m^2 body surface area cumulative doxorubicin dose). Cardiotoxicity can also be reduced by using the analogue epirubicin or by reducing peak drug concentrations through delayed release preparations such as liposomal doxorubicin or employing fractionated administration schedules. Whether these strategies affect the antitumour efficacy is still debated. 5-Fluorouracil and its prodrug capecitabine cause cardiac ischaemia.

FURTHER READING

Hesketh PJ. Chemotherapy induced nausea and vomiting. *New England Journal of Medicine* 2008; **358**: 2482–2492.

Neurotoxicity. This occurs predominantly with the vinca alkaloids, taxanes and platinum analogues (but not carboplatin). It is dose-related and cumulative. Chemotherapy is usually stopped before the development of a significant polyneuropathy, which once established is only partially reversible. Vinca alkaloids such as vincristine must never be given intrathecally as the neurological damage is progressive and fatal.

Nephrotoxicity. Cisplatin (but not oxaliplatin or carboplatin), methotrexate and ifosfamide can potentially cause renal damage. This can usually be prevented by maintaining an adequate diuresis during treatment to reduce drug concentration in the renal tubules and careful monitoring of renal function.

Sterility and premature menopause. Some anticancer drugs, particularly alkylating agents, but also anthracyclines, and docetaxel may cause gonadal damage resulting in sterility and in women the loss of ovarian oestrogen production, which may be irreversible.

In males the storage of sperm prior to chemotherapy should be offered to the patient when chemotherapy is given with curative intent.

In females it may be possible to collect oocytes to be fertilized in vitro and cryopreserved as embryos for subsequent implantation. Cryopreservation of ovarian tissue and retrieval of viable oocytes for subsequent fertilization is still experimental. The recovery of gonadal function is dependent upon the status before treatment, and in women this is mostly related to age since menarche, with those under the age of 40 having significantly more ovarian reserve.

Secondary malignancies. Anticancer drugs have mutagenic potential and the development of secondary malignancies, predominantly acute leukaemia, is an uncommon but particularly unwelcome long-term side-effect in patients otherwise cured of their primary malignancies. The alkylating agents, anthracyclines, and epipodophyllotoxins are particularly implicated in this complication.

Drug resistance

Drug resistance is one of the major obstacles to curing cancer with chemotherapy. Some tumours have an inherently low level of resistance to currently available treatment and are often cured. These include gonadal germ cell tumours, Hodgkin's lymphoma and childhood acute leukaemia. Solid tumours such as small-cell lung cancer, breast cancer and ovarian cancer initially appear to be chemosensitive, with the majority of patients responding, but most patients eventually relapse with resistant disease. In oesophageal, gastric and colorectal cancers there is an intermediate degree of sensitivity while in other tumours such as pancreatic cancer, non-small-cell lung cancer and melanoma the disease is largely chemoresistant from the start.

Most resistance occurs as a result of genetic mutation and becomes more likely as the number of tumour cells increases. It has also been shown that anticancer drugs can themselves increase the rate of mutation to resistance. Resistance to cytotoxic drugs is often multiple and is then known as multidrug resistance (MDR), e.g. resistance to doxorubicin is often associated with resistance to vinca alkaloids and epipodophyllotoxins, and is mediated through increased expression of P-glycoprotein (a 170 kDa membrane phosphoglycoprotein), which mediates the efflux of cytotoxic drugs out of the cells. Many other mechanisms may also be involved in resistance to chemotherapy, such as the upregulation of anti-apoptotic proteins Bcl-2 and Bax and DNA repair pathways.

High-dose therapy

Most anticancer drugs have a sigmoid dose–response relationship which suggests that, up to a point, a higher dose of a cytotoxic drug will induce a greater response. However, increasing cytotoxic drug doses is often not possible, owing to toxicity. For those chemotherapeutic agents with a dose-limiting toxicity of bone marrow failure, infusion of previously harvested haemopoietic stem cells is able to restore the lymphohaemopoietic system and permit the use of higher doses to overcome resistance.

Haemopoietic stem cell transplantation

Bone marrow or peripheral blood cells may be:

- autologous – from self
- syngeneic – from identical twin
- allogeneic – from non-identical donor (matched or sometimes mismatched)
- from umbilical cord blood. This is increasingly being used for adult and childhood leukaemia.

It usually takes 2–3 weeks for engraftment to take and during this time patients need supportive care with nursing in isolated cubicles with air filtration.

Autologous stem cell transplantation

Autologous stem cells are used as rescue from myeloablative chemotherapy. Haemopoietic stem cells are collected from the patients' bone marrow, or more commonly by leucopheresis from peripheral blood following administration of the growth factor granulocyte colony-stimulating factor (G-CSF) prior to chemotherapy. They are stored by cryopreservation. These cells are then re-infused intravenously after an intensive, myeloablative chemotherapy regimen. This approach has been particularly effective in relapsed leukaemias, lymphomas, myeloma and germ cell tumours. There is no risk of graft rejection or graft-versus-host disease (GVHD) but the graft-versus-tumour effect is lost (see below).

Allogeneic stem cell transplantation

Allogeneic transplants combine the cytotoxic effect of high-dose therapy with a potent immunotherapy effect. Historically, the transplantation of donor haemopoietic cells has been combined with myeloablative chemotherapy ± radiotherapy with the dual effects of treating the malignancy as well as immunosuppression that allows the graft 'to take'. Anti-T cell antibodies are often given to reduce graft-versus-host disease and immune-related infection. The engraftment of the donor immune system, with antitumour activity (graft versus tumour), is primarily responsible for the increased effectiveness of this approach. In general, ideal donors are fully matched at the major HLA antigens. Thus siblings are more likely to be found to be potential donors than unrelated volunteers. Some degree of HLA antigen mismatch may be

tolerated in children, but is problematic in adults. Allogeneic transplantation has been successfully used in acute and chronic leukaemias, and myeloma.

Complications include '*graft-versus-host disease*', an immune reaction of the donor cells against normal host organs, which can affect 30–50% of transplant recipients and is potentially fatal in some cases. Immunosuppression, both from conditioning therapy and from the immunosuppressive drugs (ciclosporin or tacrolimus) given to prevent graft-versus-host disease, results in a high incidence of opportunistic infections. All patients receive prophylactic antibacterial, antifungal and antiviral drugs but infections still occur. *Mortality* therefore from conventional allogeneic stem cell transplantation is a major problem, with 20–40% at risk of dying from the procedure, depending on the age and status of the recipient, and the degree of HLA compatibility of the donor (see also immunotherapy, p. 75).

Non-myeloablative allogeneic stem cell transplantation. This has been developed using conditioning therapy with drugs such as fludarabine which is sufficiently immunosuppressant without radiation therapy. This maintains the anticancer effect of the stem cell transplantation without the complications of conventional allogeneic stem cell transplantation. Mortality (mainly GVHD) is lower, and the technique is being used more widely, particularly in the elderly.

PRINCIPLES OF ENDOCRINE THERAPY

Oestrogens are capable of stimulating the growth of breast and endometrial cancers, and androgens the growth of prostate cancer. Removal of these growth factors by manipulation of the hormonal environment may result in apoptosis and regression of the cancer. Endocrine therapy can be curative in a proportion of patients treated for micrometastatic disease in the adjuvant setting for breast and prostate cancer and provides a minimally toxic non-curative (palliative) treatment in advanced/metastatic disease. The presence of detectable cellular receptors for the hormone is strongly predictive of response. However this is also modified by the many molecular interactions between the activation pathways of, for example, EGFR and oestrogen receptor (ER). Figure 9.4 shows the binding of the hormone to the receptor.

Anti-oestrogens and progestogens

In premenopausal women hormonal manipulation can be achieved by the reduction of endogenous oestrogen by oophorectomy or via pituitary downregulation using a gonadotrophin-releasing hormone (GnRH) analogue such as goserelin.

Tamoxifen is a mixed agonist and antagonist of oestrogen action on the ER while the more recent drug fulvestrant is a more selective oestrogen receptor modulator (SERM). Tamoxifen is used as an adjuvant therapy in breast cancer and both are used in advanced metastatic breast disease (see p. 487).

Synthetic progestogens, e.g. medroxyprogesterone acetate and megestrol acetate, have a direct effect on breast tumour cells through progesterone receptors, as well as effects on the pituitary/ovarian (premenopausal) and adrenal/pituitary axis (postmenopausal). They can be as effective as tamoxifen in metastatic breast cancer and have a role in endometrial adenocarcinoma, with response rates of up to 25%. Trials to date with adjuvant progestogens have not been successful in increasing survival.

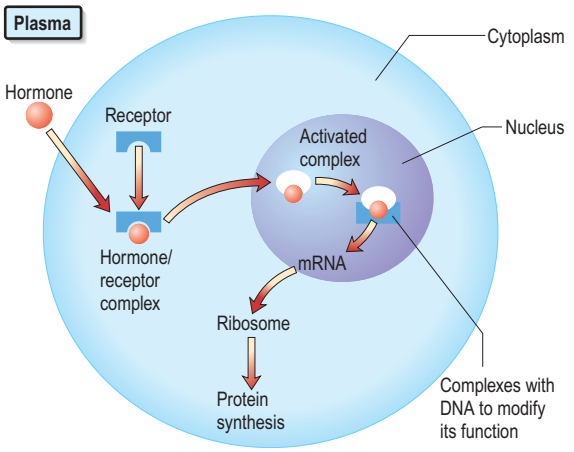

Fig. 9.4 **Mechanism of the interaction between a steroid hormone and its receptor.** This interaction modifies DNA activity and hence cell growth and replication.

In postmenopausal women, androgens are synthesized by the adrenal glands and converted in subcutaneous fat to estrone by the enzyme aromatase. *Aromatase inhibitors*, for example anastrozole, letrozole and exemestane, reduce circulating oestrogen levels and oestrogen synthesis in tumour cells and have shown greater efficacy than tamoxifen in the treatment of metastatic breast cancer (see p. 487) and equivalence in the adjuvant setting.

Side-effects are those of oestrogen deprivation hot flushes, emotional lability, vaginal dryness and loss of libido, plus specific effects such as tamoxifen coagulopathy and endometrial hyperplasia, progestogen fluid retention, and aromatase inhibitor arthralgia and osteoporosis.

Androgen deprivation

- *GnRH agonists*, e.g. goserelin and leuprorelin, and orchidectomy, are equally effective in lowering circulating androgens and inducing responses in prostate cancer. However, in the first week this produces a rise in LH and testosterone which can result in a tumour flare. Therefore goserelin is given in combination with an antiandrogen, e.g. flutamide, initially. In the adjuvant setting, the addition of androgen deprivation to prostatic radiotherapy or surgery has improved survival.
- *Androgen receptor blockers* such as flutamide and abiraterone, an inhibitor of CYP17 which is necessary for androgen production, are also effective.

PRINCIPLES OF BIOLOGICAL THERAPY

Interferons

Interferons are naturally occurring cytokines that mediate the cellular immune response. They are both antiproliferative and stimulate humoral and cell-mediated immune responses to the tumour that can result in an antitumour effect if the host effector mechanisms are fully competent.

Alpha-interferon (IFN-α) has been used to treat advanced melanoma and renal cell carcinoma. In renal cell carcinoma alpha-interferon has a low (10–15%) but significant anticancer effect and prolongation of survival.

Treatment with IFN has side-effects (see p. 341), most commonly flu-like symptoms which tend to diminish with time, and fatigue which generally does not and can be treatment limiting. IFN was given as a daily subcutaneous injection, but conjugation with polyethylene glycol (PEG interferon) has led to a reduction in frequency of injection and severity of side-effects.

Interleukins

Originally described for their activity in modulating leucocyte activation, these cytokines have widespread activity in coordinating cellular activity in many organs. Interleukin 2, a recombinant protein, is used to activate T cell responses, often in conjunction with interferon-stimulated B cell activation. Antitumour activity has been observed in renal cell carcinoma and melanoma with responses in 10–20% of patients, occasionally for prolonged periods. Toxicity is common; acutely this includes the capillary leak syndrome with hypotension, and pulmonary oedema, whilst autoimmune thyroiditis and vitiligo occur later.

Haemopoietic growth factors

Erythropoietin is given for anaemia. Granulocyte (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF) are used:

- to reduce the duration of cytopenia following chemotherapy
- with or without chemotherapy, to stimulate the proliferation of haemopoietic progenitor cells in the marrow so that they enter the circulation and can be collected from the peripheral blood to support high-dose chemotherapy treatment, particularly in myeloma (see p. 486).

Monoclonal antibodies (Table 9.11)

Monoclonal antibodies (Mab) directed against tumour cell surface antigens are 'humanized' by being genetically engineered as a chimera comprising a human constant region with the murine heavy and light chains of the antigen-combining site, to reduce formation of blocking human anti-mouse antibodies when used in patients. Uses include:

- In vitro, in conjunction with complement, they are occasionally used to deplete autologous bone marrow of tumour cells in patients with leukaemia and lymphoma receiving high-dose treatment with autologous haemopoietic progenitor cell support.
- In vitro in immunoadsorption columns to select the CD34-positive (stem cell) fraction from peripheral blood progenitor cell or autologous bone marrow collections, to support high-dose treatment in haematological and other malignancies. (Used rarely.)
- As direct treatment for B cell lymphoid malignancy (e.g. rituximab anti-CD20 surface antigen). Tumour cell lysis occurs by both complement- and antibody-dependent cellular cytotoxicity.
- As a carrier molecule to target toxins or radioisotopes to the tumour cells, e.g. anti-CD20 conjugated to radioactive iodine is being used as treatment for non-Hodgkin's lymphoma.
- As anti-growth factor agents added to chemotherapy. They act by inhibiting dimerization of the extracellular receptor molecules, e.g. *trastuzumab* (a member of the epidermal growth factor receptor (EGFR) family), against the Her2/Neu or c-erbB2 antigen to increase the apoptotic response to cytotoxics in breast cancer. They are also used with *bevacizumab* anti VEGF receptor in colorectal and breast cancer, and *cetuximab* anti EGFR for head and neck and colorectal cancers.

Table 9.11 Some biological therapies

Drug	Function	Malignancy
Dasatinib	Tyrosine kinase inhibitor	AML, ALL
Imatinib	Tyrosine kinase inhibitor	Stromal cell tumour, chronic myeloid leukaemia
Sunitinib	Tyrosine kinase inhibitor	Renal cancer
Sorafenib	Tyrosine kinase inhibitor	Renal cancer
Gefitinib	EGF tyrosine kinase inhibitor	Non-small-cell lung cancer, pancreatic cancer
Bexarotene	Retinoid X receptor agonist	Cutaneous T-cell lymphoma
Erlotinib	EGF tyrosine kinase inhibitor	Non-small-cell lung cancer
Cetuximab	Anti-EGF receptor	Colorectal cancer
Bevacizumab	Anti-VEGFR	Colorectal cancer
Rituximab	Anti-CD20 on B cells	Lymphoma
Alemtuzumab	Anti-CD52 on lymphocytes	Chronic lymphocytic leukaemia
Trastuzumab	Binds to HER-2/neu receptor	Breast cancer
Bortezomib	Proteosome inhibitor	Leukaemia, myeloma

EGF, epidermal growth factor; VEGF, vascular endothelial growth factor.

Side-effects are those of hypersensitivity to the foreign protein, and specific cross-reactivities, e.g. trastuzumab for the myocardium, bevacizumab for the mucosa and renal tubule, and cetuximab for the skin follicles.

Intracellular signal inhibitors (Table 9.11)

Many cancer cells are transformed by the activity of the protein products of oncogenes that signal growth by phosphorylation of tyrosine residues on the intracellular portion of growth factor receptors. Small molecule inhibitors have many pharmacokinetic advantages over the Mab inhibitors. The first example was the tyrosine kinase inhibitor (TKi) imatinib, which specifically inhibits the BCR-ABL fusion oncoprotein cKit. This compound is an extremely effective treatment for chronic myeloid leukaemia, and gastrointestinal stromal tumours (GIST) which are also characterized by the presence of the cKit target. The less specific TKi's sunitinib and sorafenib which inhibit signalling by EGFR and VEGFR have proved effective in metastatic renal cancer, while lapatinib which inhibits Her2 has increased survival in metastatic breast cancer. Erlotinib and gefitinib on the other hand have shown only limited activity in lung cancer. Many other similar molecules are in preclinical or early clinical development.

Immunotherapy

Activation of the immune system using Bacille Calmette–Guérin (BCG) for bladder cancer induces responses in 60% of patients. Certain antigens that are specific to cancer cells, such as sequences of tumour immunoglobulin from B cell lymphomas or melanoma antigens, have been used as tumour vaccines. Antigen-presenting cells (dendritic cells) from the patient can be genetically engineered to present both antigen and cytokines such as interleukin 2 or granulocyte–macrophage colony-stimulating factor, and clinical responses have been observed. Another approach has used dendritic cells to further improve the vaccination strategy by engineering them to display the full range of HLA and B7 costimulatory molecules.

The use of non-myeloablative haemopoietic stem cell and donor lymphocyte infusions with allogeneic BMT, while losing some of the specificity, has produced the strongest evidence for the efficacy of immunotherapy via graft versus tumour activity at the risk of great toxicity.

Gene therapy

Antisense oligonucleotides are short sequences of DNA bases which specifically inhibit complementary sequences of either DNA or RNA. As a result, they can be generated against genetic sequences which are specific for tumour cells. Their clinical development has been hampered by poor uptake by tumour cells and rapid degradation by natural endonucleases. However, one antisense sequence directed against the *Bcl-2* oncogene has been shown to have an antitumour effect in patients with non-Hodgkin's lymphoma. Viral vectors for the transfection of tumour cells in vivo are being tested as a way of delivering specific replacement gene therapy in head and neck cancers.

PRINCIPLES OF RADIATION THERAPY

Radiation delivers energy to tissues, causing ionization and excitation of atoms and molecules. The biological effect is exerted through the generation of single- and double-strand DNA breaks, inducing apoptosis of cells as they progress through the cell cycle, and through the generation of short-lived free radicals, particularly from oxygen, which damage proteins and membranes. This partly explains why a lack of oxygen confers some degree of radio resistance to cells.

External beam (or teletherapy) from a linear accelerator source produces X-rays. The energy is transmitted as photons and is the most commonly used form of radiotherapy. Cobalt-60 generators can also provide gamma rays and high-energy photons, but are being gradually phased out.

Brachytherapy is the use of radiation sources in close contact with the tissue to provide intense exposure over a short distance to a restricted volume.

Systemic radionuclides, e.g. iodine-131, or radioisotope-labelled monoclonal antibodies and hormones, can be administered by intravenous or intracavitary routes to provide radiation targeted to particular tissue uptake via surface antigens or receptors.

The radiation dose is measured in Gray (Gy), where 1 Gray = 1 joule absorbed per kilogram of absorbing tissue and 1 centigray (cGy) = 1 rad. The biological effect is dependent upon the dose rate, duration, volume irradiated and the tissue sensitivity. Sensitivity to photon damage is greatest during the G2–M phase of the cell cycle and is also dependent upon the DNA repair capacity of the cell. *Fractionation* is the delivery of the radiation dose in increments separated by at least 4–6 hours to try to exploit any advantage in DNA repair between normal and malignant cells. Radiation dose is thus described by three factors:

- total dose in Gy
- number of fractions
- time for completion.

Most external beam treatments that are given with curative intent are delivered in 1.5 to 2 Gy fractions daily for 5 days per week. *Hyperfractionation* is when more than one fraction per day is given and this approach has been shown to improve outcome in head and neck and lung cancer. The treatment can also be accelerated, i.e. the total dose is given in a shorter overall time. For example a standard curative treatment taking 6.5 weeks can be accelerated so that the same dose is delivered in 5.5 weeks.

The radiation effect will also depend upon the intensity of the radiation source, measured as the linear energy transfer or frequency of ionizing events per unit of path, which is subject to the inverse square law as the energy diminishes with the distance from the source.

The generation of free radicals depends upon the degree of oxygenation/hypoxia in the target tissues. This can affect the biological effect by up to threefold and is the subject of continuing research for hypoxic cell sensitizers to overcome the reduced efficacy of radiation for hypoxic tumours. Hypoxia, however, may also drive a more malignant potential further, so reduced efficacy is only part of the solution to the hypoxia problem.

The depth of penetration of biological tissues by the photons depends upon the energy of the beam. Low-energy photons from an 85 kV source are suitable for superficial treatments, while high-energy 35 MV sources produce a beam with deeper penetration, less dose at the initial skin boundary (skin sparing), sharper edges, and less absorption by bone. Superficial radiation may be also delivered by electron beams from a linear accelerator that has had the target electrode that generates the X-rays removed.

Radiotherapy treatment planning involves both detailed physics of the applied dose and knowledge of the biology of the cancer and whether the intention is to treat the tumour site alone, or include the likely loco-regional patterns of spread. Normal tissue tolerance will determine the extent of the side-effects and therefore the total achievable dose. A balanced decision is made according to the curative or palliative intent of the treatment and the likely early or late side-effects.

The cancers for which radiotherapy is usually employed as primary curative when the tumour is anatomically localized are listed in Table 9.12, along with those in which radiotherapy has curative potential when used in addition to surgery (adjuvant radiotherapy). Palliative treatments are frequently used to provide relief of symptoms to improve quality if not duration of survival (Box 9.4). Palliative treatment is usually given in as few fractions as possible over as short a time as possible.

Radiotherapy planning, by the use of CT scanning guidance, has been complemented by the introduction of

Table 9.12 Curative radiotherapy treatment

Primary modality	Adjuvant to primary surgery
Retina	Lung
CNS	Breast
Skin	Uterus
Pharynx and larynx	Bladder
Cervix and vagina	Rectum
Prostate	Testis-seminoma
Lymphoma	Sarcoma

Box 9.4 Palliative benefits of radiotherapy

- Pain relief, e.g. bone metastases
- Reduction of headache and vomiting in raised intracranial pressure from CNS metastases
- Relief of obstruction of bronchus, oesophagus, ureter, and lymphatics
- Preservation of skeletal integrity from metastases in weight-bearing bones
- Reversal of neurological impairment from spinal cord or optic nerve compression by metastases

intensity modulated radiotherapy (IMRT) which can deliver curved dose distributions to enable an improved therapeutic ratio. This allows a greater differential in dose between the tumour and critical normal structures, in turn allowing dose escalation or a reduced risk of toxicity.

Combination chemo-radiotherapy

The local efficacy of radiotherapy can be increased by the simultaneous but not serial addition of chemotherapy with agents such as cisplatin, mitomycin and 5FU for cancers of the head and neck, lung, oesophagus, stomach, rectum, anus and cervix. Reduced local recurrence rates have translated into survival benefits and further research is investigating the concurrent use of biological agents (e.g. epidermal growth factor receptor inhibitors) with radiation.

Side-effects of radiotherapy

Early radiotherapy side-effects may occur within days to weeks of treatment when they are usually self-limiting but associated with general systemic disturbance (Table 9.13). The side-effects will depend upon tissue sensitivity, fraction size and treatment volume and are managed with supportive measures until normal tissue repair occurs. The toxicity may also be enhanced by exposure to other radiation-sensitizing agents, especially some cytotoxics, e.g. bleomycin, actinomycin, anthracyclines, cisplatin and 5-fluorouracil.

Later side-effects occur from months to years later, unrelated to the severity of the acute effects because of their different mechanism. Late effects reflect both the loss of slowly proliferating cells and a local endarteritis which produces ischaemia and proliferative fibrosis. The risks of late side-effects are related to the fraction size and total dose delivered to the tissue.

Table 9.13 Side-effects of radiotherapy

Acute temporary side-effects/dependent on region being treated	
Anorexia, nausea, malaise	
Mucositis, oesophagitis, diarrhoea	
Alopecia	
Myelosuppression	
Late side-effects	
Skin	Ischaemia, ulceration
Bone	Necrosis, fracture, sarcoma
Mouth	Xerostomia, ulceration
Bowel	Stenosis, fistula, diarrhoea
Bladder	Fibrosis
Vagina	Dyspareunia, stenosis
Lung	Fibrosis
Heart	Pericardial fibrosis, cardiomyopathy
CNS	Myelopathy
Gonads	Infertility, menopause
Second malignancies	e.g. Leukaemia, cancer, e.g. thyroid

Growth may be arrested if bony epiphyses are not yet fused and are irradiated, leading to distorted skeletal growth in later life.

Secondary malignancies following radiotherapy may appear 10–20 years after the cure of the primary cancer. Haematological malignancies tend to occur sooner than solid tumours from the irradiated tissues. The latter are very dependent upon the status of the tissue at the time of treatment, e.g. the pubertal breast is up to 300 times more sensitive to malignant transformation than the breast tissues of a woman in her thirties. Patients who smoke are more liable to develop lung cancer. Treatment of these secondary cancers can be successful providing there is normal bone marrow to reconstitute the haemopoietic system or the whole tissue at risk (e.g. thyroid after mantle radiotherapy for lymphoma) can be resected.

HAEMATOLOGICAL MALIGNANCIES

The leukaemias, the lymphomas and multiple myeloma are an interrelated spectrum of malignancies of the myeloid and lymphoid systems. They are uncommon but not rare, the lymphomas alone being the fifth commonest cancer in the UK. The aetiology of these diseases for the most part is unknown, although viruses, irradiation, cytotoxic poisons and immune suppression have been implicated in a small proportion of cases (see p. 467). The pathogenesis involves at least one or usually more molecular abnormalities, and non-random chromosomal abnormalities have been detected in several leukaemias and lymphomas. Classification has become increasingly complex, with the universally applied WHO scheme demanding morphological, cytogenetic and sometimes molecular criteria to be fulfilled. Treatment options are multiple. Patients need to be supported through treatment involving prolonged myelosuppression and immuno-

www.studentconsult.com
Ask the authors

suppression. These are potentially life-threatening but can also be curative. This has given rise to the need for highly skilled staff and specialist facilities; patients should be referred to these centres for treatment.

In the management of these diseases it is critical that patients are appraised of the natural history, its potential modification by treatment and the risks of both severe morbidity and mortality. It must be made clear from the outset whether a curative or palliative strategy is most appropriate and why. If cure is to be pursued, the patient must be appraised of the approximate probability of success and its potential price. The possibility of failure needs to be addressed at the outset and not at the last minute.

THE LEUKAEMIAS

These are relatively uncommon diseases with an incidence of about 10 per 100 000 per year; which can occur at any age. They are classified as being acute (short natural history) or chronic (long natural history), and of myeloid or lymphoid origin. More than half of the leukaemias present acutely (ALL, AML) with the remainder being chronic types (CLL, CML). The type of leukaemia varies with age; acute lymphoblastic leukaemia (ALL) is mainly seen in childhood and chronic lymphocytic leukaemia (CLL) is a disease of the elderly. The myelodysplastic syndromes are considered pre-leukaemic and are discussed on page 422. Leukaemia can be diagnosed by examination of a stained slide of peripheral blood and bone marrow, but immune phenotyping, cytogenetics and molecular genetics are essential for complete subclassification and prognostication.

General classification

The characteristics of leukaemic cells can be assessed by light microscopy, expression of cytosolic enzymes and expression of surface antigens. These will reflect the lineage and degree of maturity of the leukaemic clone. Thus, leukaemia can be divided on the basis of the speed of evolution of the disease into acute or chronic; each of these is then further subdivided into myeloid or lymphoid, according to the cell type involved.

- acute myeloid leukaemia (AML)
- acute lymphoblastic leukaemia (ALL)
- chronic myeloid leukaemia (CML)
- chronic lymphocytic leukaemia (CLL).

Aetiology

In the majority of patients this is unknown but several factors have been associated:

- *Radiation*. This can induce genetic damage to haemopoietic precursors and ALL, AML and CML have been seen in increased incidences in survivors of Hiroshima and Nagasaki and in patients treated with ionizing radiation.
- *Chemical and drugs*. Exposure to benzene used in industry may lead to marrow damage. AML occurs after treatment with alkylating agents (e.g. melphalan) and topoisomerase II inhibitors (e.g. etoposide).
- *Genetic*. Leukaemia risk is highly elevated in a number of germline conditions that result in genetic instability or bone marrow failure. These include Fanconi anaemia, ataxia telangiectasia and Li–Fraumeni syndrome. The risk is elevated some 30 times in people with trisomy 21. There is a high degree of concordance among monozygotic twins.
- *Viruses*. Leukaemias are associated with human T cell lymphotropic virus type 1 (HTLV-1), which is found particularly in Japan and the Caribbean.

Genetic abnormalities in leukaemia

Leukaemic cells often have a somatically acquired cytogenetic abnormality, which may be of prognostic, as well as diagnostic, significance.

These genetic alterations change the normal cell regulating process by interfering with the control of normal proliferation, blocking differentiation, maintaining an unlimited capacity for self-renewal and, lastly, promoting resistance to death signals, i.e. decreased apoptosis.

The first non-random chromosomal abnormality to be described was the Philadelphia (Ph) chromosome, which is associated with CML in 97% of cases. The Ph chromosome is also found in ALL, the incidence in the latter illness increasing with age. The translocation is shown schematically in Figure 9.5. The Ph chromosome is an abnormal chromosome 22, resulting from a reciprocal translocation between part of the long arm of chromosome 22 and chromosome 9. The resulting karyotype is described as t(9;22)(q34;q11). The molecular consequences of the translocation are that part of the Abelson proto-oncogene (*c-ABL*) normally present on chromosome 9 is translocated to chromosome 22, where it comes into juxtaposition with a region of chromosome 22 named the 'breakpoint cluster region' (BCR). The translocation creates a hybrid transcription unit consisting of the 5′ end of the *BCR* gene and the *c-ABL* proto-oncogene.

The new 'fusion' gene *BCR-ABL* is capable of being expressed as a chimeric messenger RNA which has been identified in cells from patients with CML. When translated, this produces a fusion protein that has tyrosine kinase

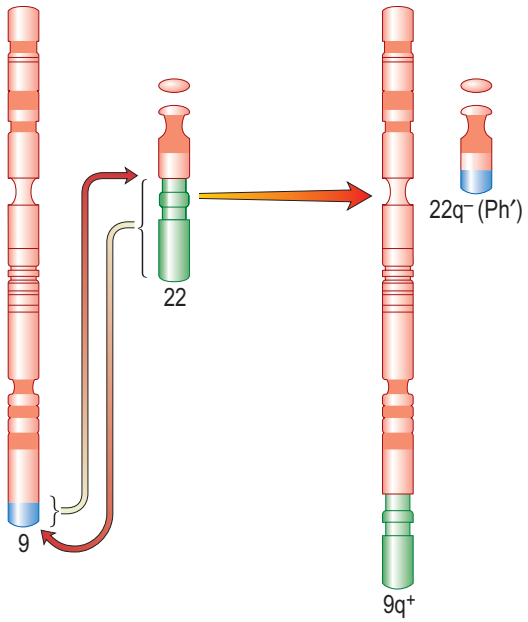

Fig. 9.5 **The Philadelphia chromosome (Ph).** The long arm (q) of chromosome 22 has been shortened by the reciprocal translocation with chromosome 9.

activity and enhanced phosphorylating activity compared with the normal protein, resulting in altered cell growth, stromal attachment and apoptosis. The breakpoint differs in CML and Ph-positive ALL, leading to the production of two different tyrosine kinase proteins with molecular weights of 210 kDa and 190 kDa respectively. It is unclear whether the presence of *BCR-ABL* is sufficient for the development of the disease. It has been shown that normal subjects can carry low levels of the *BCR-ABL* fusion gene in their blood without developing leukaemia.

Almost all patients with acute promyelocytic leukaemia (APML), a subtype of acute myelogenous leukaemia, have the t(15;17) reciprocal translocation, which occurs at the q25 band on chromosome 15 and the q22 band on chromosome 17. The breakpoint on chromosome 17 occurs in the gene encoding the retinoic acid receptor, fusing it with part of the PML gene (PML/RAR-alpha fusion gene). This is to some extent the explanation for the responsiveness of patients with APML to all-*trans*-retinoic acid (ATRA, see p. 471). Other genetic and cytogenetic abnormalities are often seen in leukaemic cells (Table 9.14).

Cell surface markers

These can be used to classify acute leukaemias. Immature myeloid cells have cell surface markers, e.g. CD13, CD14, CD33, CD34, which can be identified using monoclonal antibodies. The majority of patients with ALL (60%), for example, show the common ALL antigen (CALLA – CD10).

ACUTE LEUKAEMIAS

The acute leukaemias increase in incidence with advancing age. Acute myeloid (myeloblastic, myelogenous) leukaemia (AML) has a median age at presentation of 65 years and may arise 'de novo' or against a background of myelodysplasia, either of unknown aetiology or related to cytotoxic chemotherapy. Acute lymphoid (lymphoblastic) leukaemia (ALL) has a substantially lower median age at presentation and in addition is the commonest malignancy in childhood. The WHO classification is shown in Table 9.14.

Table 9.14 WHO classification of acute leukaemia

(a) Acute myeloid leukaemia

AML with recurrent genetic abnormalities

AML with t(8;21)(q22;q22), (AML1/ETO)

AML with abnormal bone marrow eosinophils and inv(16)(p13;q22) or t(16;16)(p13;q22), (CBFβ/MYH11)

Acute promyelocytic leukaemia with t(15;17)(q22;q12), PML/RAR-alpha and variants

AML with 11q23 (MLL) abnormalities

AML with multilineage dysplasia

Following MDS or MDS/MDP

Without antecedent MDS or MDS/MDP, but with dysplasia in at least 50% of cells in two or more myeloid lineages

AML and myelodysplastic syndromes, therapy related

Alkylating agent/radiation-related type

Topoisomerase II inhibitor-related type

Other

AML, not otherwise categorized*

AML, minimally differentiated

AML without maturation

AML with maturation

Acute myelomonocytic leukaemia

Acute monoblastic/acute monocytic leukaemia

Acute erythroid leukaemia (erythroid/myeloid and pure erythroleukaemia variants)

Acute megakaryoblastic leukaemia

Acute basophilic leukaemia

Acute panmyelosis with myelofibrosis

Myeloid sarcoma

(b) Acute lymphoid leukaemia

Precursor B cell acute lymphoblastic leukaemia

t(9;22)(q34;q11); BCR/ABL fusion gene

t(4;11)(q21;q23); MLL-AF4 fusion gene

t(1;19)(q23;p13.3); E2A/PBX1 fusion gene

t(12;21)(p13;q22); TEL/AMLI

Precursor T cell acute lymphoblastic leukaemia

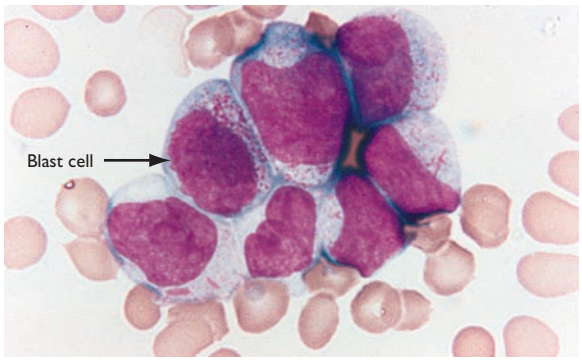
Burkitt-cell leukaemia

MDS, myelodysplastic syndromes; MPD, myeloproliferative diseases.
*The entities included in this group are defined almost identically to the corresponding entity in the French–American–British (FAB) classification.
Modified from Jaffe ES, Harris NL, Stein H, Vardiman JW (eds). *World Health Organization Classification of Tumours. Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues.* Lyon: IARC Press, 2001, with permission of the World Health Organization.

Clinical features

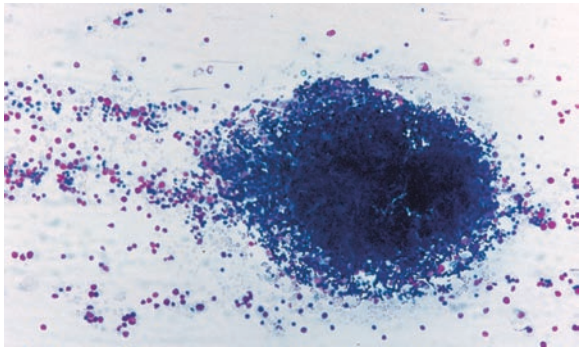
The majority of patients with acute leukaemia, regardless of subtype, present with symptoms reflecting inadequate haematopoiesis secondary to leukaemic cells infiltration of the bone marrow:

- anaemia – shortness of breath on effort, excessive tiredness, weakness
- leucopenia – recurrent infections
- thrombocytopenia – bleeding and bruising (particularly acute promyelocytic leukaemia)
- marrow infiltration – bone pain.



Examination may be unremarkable, but features include:

- pallor
- fever (due to infection, not the disease itself)
- petechiae, purpura, bruises, fundal haemorrhage (particularly acute promyelocytic leukaemia)
- lymphadenopathy, hepatosplenomegaly (more notable in lymphoblastic leukaemia)
- violaceous skin lesions (acute myelomonocytic leukaemia)
- testicular enlargement (acute lymphoblastic leukaemia)
- cranial nerve palsies occasionally found (acute lymphoblastic leukaemia).



Investigations

Confirmation of diagnosis (Fig. 9.6)

- **Blood count**. Hb low, WBC raised usually (sometimes low), platelets low.
- **Blood film**. Blast cells almost invariably seen, (Fig. 9.6a), lineage identified morphologically, confirmed with immunophenotyping.
- **Bone marrow aspirate**. Increased cellularity, reduced erythropoiesis, reduced megakaryocytes, sometimes trilineage dysplasia. Replacement by blast cells > 20%

(a)

(b)

Fig. 9.6 **Acute leukaemia. (a) Peripheral blood film showing characteristic blast cells.** The arrow points to the abnormal blast cell. **(b) Bone marrow aspirate showing particle with increased cellularity.** Courtesy of Dr Manzoor Mangi.

(often approaching 100%) (Fig. 9.6b). Lineage confirmation by immunophenotyping (FISH), cytogenetic and molecular genetics, e.g. AML – CD33 or CD13, and ALL – CD10 and CD19.

- **Chest X-ray**. Mediastinal widening often present in T lymphoblastic leukaemia.
- **Cerebrospinal fluid examination**. Performed when blasts have been cleared from the peripheral blood in all patients with ALL, as the risk of CNS involvement is high. It is less critical in AML, except in cases where there is a monoblast/monocytic component.

For planning therapy

- Biochemistry, serum urate, renal and liver biochemistry.
- Cardiac function; ECG and direct tests of left ventricular function, e.g. echocardiogram/cardiac magnetic resonance (see p. 706).

Principles of management

Untreated acute leukaemia is invariably fatal, most often within months, though with judicious palliative care it may be extended to perhaps a year. Treatment with curative intent may be successful, or may fail, either because the leukaemia cannot be eradicated or because the patient cannot sustain the therapy, death occurring as early as if treatment had not been initiated.

At initial presentation, acute leukaemias range from being probably curable (most favourable risk – childhood acute lymphoblastic leukaemia) through possibly curable (de novo low-risk AML) to probably incurable (AML with adverse cytogenetic features in the elderly, secondary AML, recurrent acute leukaemia). Since curative treatment even for 'low-risk' acute leukaemia carries considerable morbidity and potential mortality and that for 'high-risk' acute leukaemia even more, it is essential that the 'risk/benefit' ratio is clearly understood by physician and patient alike.

In AML, patients with t(15;17) t(8;21) or inv(16) (or its variant t16;16), i.e. low risk, do not benefit from allogeneic stem cell transplantation during their first complete remission because the risks outweigh benefits. Patients with adverse factors (high risk) – (5/del5q), -7, abnormal 3q26 or a complex karyotype – should have stem cell transplantation because they respond poorly to conventional chemotherapy. Other poor prognostic factors (high risk) include developing the disease over 60 years of age, leukaemia following myelodysplastic syndrome (MDS), relapsed disease, secondary leukaemia and extramedullary disease.

Palliative therapy

Every attempt should be made to ensure that the patients are at home as much as possible, whilst making available the full range of supportive care. Palliation may well include both chemotherapy and irradiation in addition to blood product support. 'Moral' support is invaluable.

Curative therapy

The decision to treat with curative intent, particularly if successful, implies severe disruption of normality for the patient and family for at least 6 months and often up to a year, and, regardless of success, life is never quite the same again. In the short term, it may demand transfer to another hospital, as acute leukaemia should only be treated in units seeing at least 10 such cases per year. It is highly likely to involve admission to hospital for up to a month in the first instance, with further, partly predictable, subsequent admissions of several days' to weeks' duration, requiring discussions and decisions about work or education.

The decision to treat with curative intent implies that cure is possible, and that the chance of cure justifies the risks of the therapy. It does not imply that cure is guaranteed or even expected. The failure rate may be high, and the patient must know that he or she will be told if cure becomes an unrealistic goal. Treating with curative intent may well involve rapid decisions about resuscitation with transfer to the intensive care unit, the possibility of which is discussed in advance.

Active therapy

Supportive care

This forms the basis of treatment whether for cure or palliation:

- Avoidance of symptoms of anaemia (haemoglobin > 10 g/dL) – repeated transfusion of packed red cells (sometimes irradiation of cells is required).
- Prevention or control of bleeding (platelet count < 10×10^9/L in the uninfected, and 20×10^9/L in the infected patient).
- Treatment of infection (see Box 9.3):
  (a) *Prophylactically*. Education of patients, relatives and staff about hand washing and isolation facilities. The use of selected antibiotics and antifungals.
  (b) *Therapeutically*. Management of fever with protocol/algorithm of antibiotic and antifungal combinations.

- Control of hyperuricaemia with hydration, prophylactic allopurinol and very occasionally rasburicase (see p. 458).

Specific treatment

The initial requirement of therapy is to return the peripheral blood and bone marrow to normal (complete remission; CR). This '*induction chemotherapy*' is tailored to the particular leukaemia and the individual patient's risk factors. Since this treatment is not leukaemia specific but also impairs normal bone marrow function, it leads to a major risk of life-threatening infection, which increases the risk of early death in the short term. Since infection is the major problem, it is necessary to conduct the early therapy in hospital, the patient sleeping in a single room with en-suite lavatory and washing facilities ('some' isolation). An indwelling venous catheter inserted at the time of diagnosis secures venous access for the administration of cytotoxics, blood product support and antimicrobial therapy.

Successful *remission induction* is always followed by further treatment (*consolidation*). The details of this are determined by the type of leukaemia, the patient's risk factors and the patient's tolerance of treatment. Recurrence is almost invariable if 'consolidation' therapy is not given. This reflects the lack of sensitivity of the definition of 'complete remission', which has been solely morphological. Cytogenetics and molecular genetic techniques can however identify residual leukaemic cells not detected morphologically, and they are highly predictive of recurrence. Recommendations have recently been made to modify the definition of remission to reflect this. Failure to achieve morphological CR with two cycles of therapy carries almost as bad a prognosis as the untreated leukaemia. If CR can be achieved, e.g. by new experimental approaches, cure may still be possible with stem cell transplantation (see p. 462).

Acute myeloid leukaemia (AML; excluding APML, p. 471)

Treatment with *curative intent* is undertaken in the majority of adults below the age of 60 years, provided there is no significant co-morbidity. Risk of failure is based on the cytogenetic pattern (Fig. 9.7). Those at 'low risk' are treated with moderately intensive combination chemotherapy. This always includes an anthracycline such as daunorubicin and cytosine arabinoside (cytarabine) and consolidation with a minimum of four cycles of treatment given at 3- to 4-week intervals. Those at 'high risk' may only be treated with curative intent if an HLA-identified sibling is available for stem cell transplantation.

Those at 'intermediate risk' are a heterogeneous group. When possible they should be given consolidating chemotherapy to induce remission followed by sibling-matched allogeneic transplantation, despite its attendant risks.

For those with a favourable risk profile, allogeneic transplantation is not recommended to consolidate first remission. In this group the potential morbidity from the procedure outweighs the potential risk of relapse.

The initial treatment of the *older patient* is much more contentious. Intuitively, biological age should determine the management of the individual patient. Unfortunately 'high-risk AML' is commoner with increasing age, but is only curable with allogeneic transplantation, and the toxicity of this treatment increases dramatically with age.

Complete remission will be achieved in about three-quarters of patients under the age of 60, failure being due to either resistant leukaemia or death due to infection or (rarely) bleeding. Approximately 50% of those entering complete remission will be cured. (i.e. approximately 30% overall) (Fig. 9.8). The management of recurrence is undertaken on an individual basis, since the overall prognosis is very poor despite

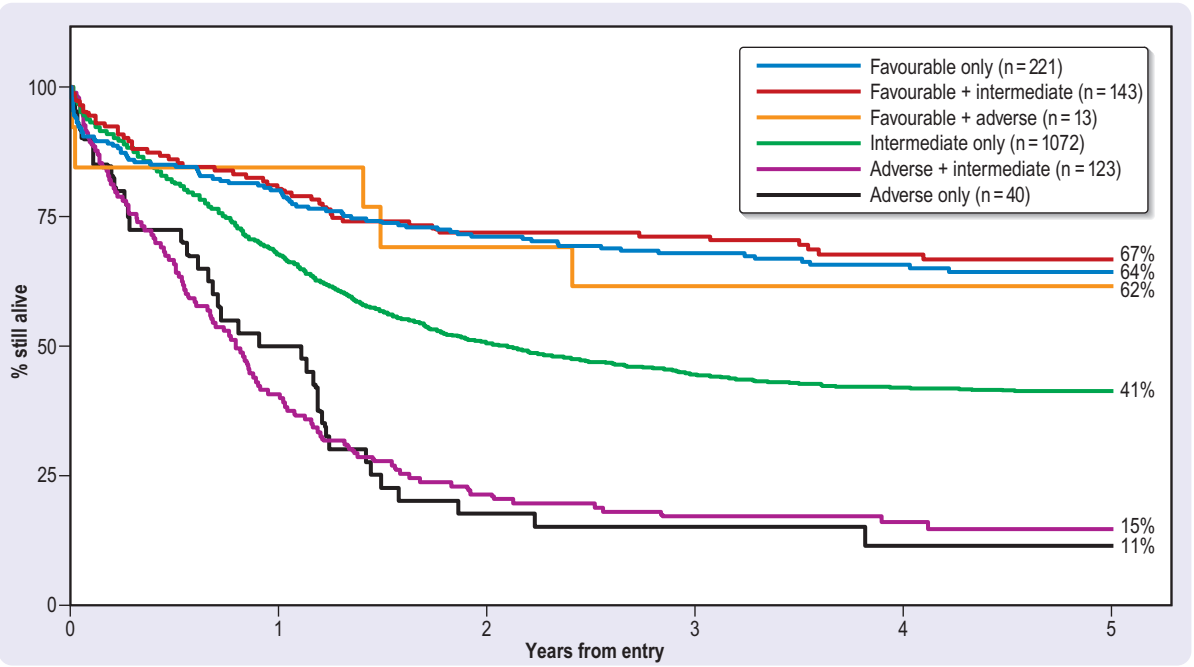


Fig. 9.7 **Influence of cytogenetic risk groups on overall survival in AML.** This research was originally published in *Blood*. Grimwade, Walker H, Oliver F et al. The importance of diagnostic cytogenetics on outcome in AML: analysis of 1612 patients entered into the MRC AML 10 Trial. *Blood* 1998; **92**: 2322–2333. © American Society of Hematology.

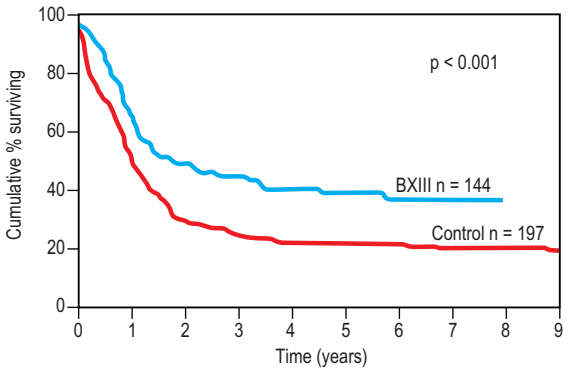

Fig. 9.8 **Acute myeloid leukaemia: overall survival with or without myeloablative therapy.** BXIII, treatment group. From Rohatiner AZS, Gregory WM, Bassan R et al. High-dose treatment with autologous bone marrow support as consolidation of first remission in younger patients with acute myelogenous leukaemia. *Annals of Oncology* 2000; **11:** 1007–1015 by permission of Oxford University Press.

the fact that second remissions may be achieved. Long survival following recurrence is rarely achieved without allogeneic transplantation. Experimental therapy should be considered.

Acute promyelocytic leukaemia (APML)

This is an uncommon variant of AML characterized by the translocation t(15;17) and with particular morphological features (see p. 467). There is an almost invariable coagulopathy, which was a major cause of death. The empirical discovery that all-*trans*-retinoic acid (ATRA) causes differentiation of promyelocytes and rapid reversal of the bleeding tendency was a major breakthrough. APML is treated with ATRA combined with chemotherapy and, following successful remission induction, with maintenance ATRA. Allogeneic transplantation may be necessary either if the leukaemia is not eliminated at the molecular level, or following a second remission after recurrence. Arsenic trioxide, which induces apoptosis via activation of the caspase cascade (see p. 28), is used with resistant or relapsed disease.

Complete remission and molecular remission occur in at least 80% of younger adults with APML (it is uncommon in the elderly). At least 60% will expect to be cured. In contrast to the other subtypes of AML, the prognosis after recurrence is quite favourable with prolonged second remissions being possible with further blocks of ATRA and chemotherapy even if allogeneic transplant is not able to be performed, although it is the treatment of choice.

Acute lymphoblastic leukaemia (ALL)

The overall strategy for the treatment of ALL differs in detail from that for AML. Remission induction is undertaken with combination chemotherapy including vincristine, a glucocorticoid, an anthracycline and asparaginase (crisantaspase). Daunorubicin is perhaps the most frequently used anthracycline, and dexamethasone is replacing prednisolone as the glucocorticoid of choice. Once remission is achieved, the details of consolidation will be determined by the anticipated risk of failure. Intensive consolidation of remission with variable numbers of chemotherapy cycles comprising cytotoxics with different mechanisms of action has been standard practice, including the administration of high-dose methotrexate. Consolidation high-dose chemotherapy and autologous stem cell rescue is probably equivalent to standard consolidation but is rarely used. In those patients with high-risk features (see below), allogeneic transplantation is recommended upon achieving first complete remission.

The other major difference between therapy for ALL and AML is the need for central nervous system directed therapy. Prophylaxis should be given with intrathecal chemotherapy under platelet cover if necessary, as soon as blasts are cleared from the blood. Depending upon risk this may be continued for up to 2 years, and complemented by high doses of systemic cytosine arabinoside (cytarabine) or methotrexate. Cranial irradiation was previously given to all patients to reduce the risk of relapse within the central nervous system; some risk adapted strategies now reserve this only for those patients at very high risk (Fig. 9.9).

After intensive induction and consolidation, maintenance therapy for 2 years is required to reduce the risk of disease recurrence in certain subtypes. This typically comprises 2 years of treatment with methotrexate and mercaptopurine, although more intensive regimens are used by some groups. During this period of time chemotherapy dosing/scheduling is adjusted to maintain a target white cell count of 3 $\times 10^9$/L.

Prognostic factors

A number of clinical and laboratory features are determinants of treatment response and survival in ALL. Increasingly therapeutic strategies, based upon prognostic risk, are being used in the management of the disease.

- *Age*. Overall survival decreases with increasing age in adult ALL.
- *White cell count*. High white cell counts at the time of diagnosis (>30 000 $\times 10^9$/L); associated with high risk of CNS relapse.
- *Immunophenotype*. The immunophenotype is characterized at presentation and can be used to divide ALL patients into risk groups. B cell ALL represents 75% of ALL, with the remainder of T cell lineage. In the former, Pro-B ALL is considered a poor prognostic group compared to the more common Pre B-ALL form. T-ALLs are associated with the presence of a mediastinal mass although they may have superior outcomes to those of B-cell lineage.
- *Cytogenetic aberrations*. Chromosomal abnormalities are detected in 60% of adult ALL patients. The presence of t(9;22)or t(4;11) is associated with a poor prognosis, the former being particularly unfavourable. It is unclear yet what the role of imatinib will be in this setting.
- *Time to response*. Early clearance of blasts is favourable, with failure to achieve a CR within 3–4 weeks being adverse
- *Minimal residual disease*. Highly sensitive techniques have been employed to detect low level leukaemic populations in the morphologically normal bone marrow. These include flow cytometry, PCR quantitative assessment of immunoglobulin gene rearrangement and of chromosomal translocation. This identifies patients with high levels of minimal residual disease who may be at high risk of relapse and thus suitable for therapeutic intensification.

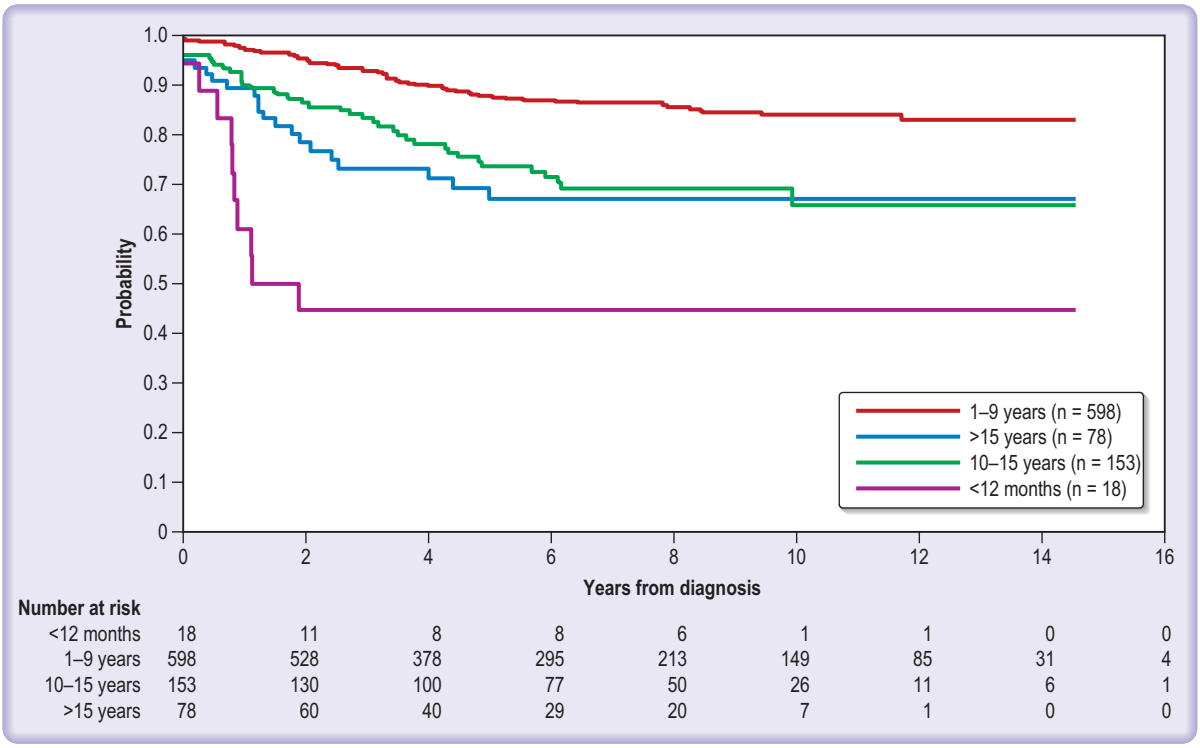

Fig. 9.9 **Overall survival in 2628 children with newly diagnosed ALL** participating in consecutive studies conducted at St Jude Children's Research Hospital from 1962 to 2005. From Pui C-M, Robinson LL, Lock T. Acute lymphoblastic leukaemia. *Lancet* 2008; **371:** 1030–1043, figure 3 with permission from Elsevier.

Prognosis (Fig. 9.9)

The prognosis of ALL in childhood is now excellent: complete remission is achieved in almost all, with up to 80% being alive without recurrence at 5 years. Failure occurs most frequently in those with high blast count and t(9;22) translocation.

The situation is far less satisfactory for adults, the prognosis getting worse with advancing years. Co-morbidity and t(9;22) translocation increases in frequency with age. Overall the complete remission rate is 70–80%, failure being due partly to resistant leukaemia and partly to failure of supportive care. Failure to achieve complete remission with first-line therapy carries a very poor prognosis. If CR can be achieved with new therapies, it should be consolidated with sibling or possibly even unrelated donor transplantation despite the high risk of graft-versus-host disease. Between 30% and 40% of patients continue in durable first remissions, resulting in approximately 25–30% overall patient cure.

As with AML, most recurrences occur within the first 3 years and the outcome is extremely poor. Second remissions, though usually achieved, are rarely durable except following allogeneic transplantation. Isolated extramedullary recurrences, however, may be cured.

CHRONIC LEUKAEMIAS

Chronic myeloid leukaemia (CML)

Chronic myeloid leukaemia (CML), which accounts for about 14% of all leukaemias, is almost exclusively a disease of adults with the peak of presentation being between 40 and 60 years and is characterized by the presence of the Philadelphia chromosome (Fig. 9.10). Unlike the acute leukaemias which are either rapidly reversed or rapidly fatal,

Fig. 9.10 **Philadelphia chromosome.** This is formed by a reciprocal translocation of part of the long arm (q) of chromosome 22 to chromosome 9. It is seen in 90–95% of patients with chronic myeloid leukaemia. The karyotype is expressed as 46XX, (9;22)(q34;q11).

CML has a more slowly progressive course which if not initially cured will be followed eventually by blast crisis (90% myeloid, 20% lymphoid) or myelofibrosis and death after 3–4 years.

Clinical features

CML usually presents in the chronic phase and some patients have no symptoms. Symptoms include:

- symptomatic anaemia (e.g. shortness of breath)
- abdominal discomfort due to splenomegaly

- weight loss
- fever, sweats, in the absence of infection
- headache (occasionally) due to hyperleucocytosis
- bruising, bleeding (uncommon), priapism.

Signs include:

- pallor
- splenomegaly, often massive
- lymphadenopathy (uncommon, when found suggests blast crisis)
- retinal haemorrhage due to leucostasis.

Investigations

- **Blood count**. Hb low (normochromic and normocytic) or normal, WBC raised (usually >100 × 10^9/L), platelets low, normal or raised.
- **Blood film**. Neutrophilia with the whole spectrum of myeloid precursors including occasional blasts. Elevated basophils and eosinophils.
- **Bone marrow aspirate**. Increased cellularity, increased myeloid precursors. Cytogenetics reveals t(9;22) translocation (the Philadelphia chromosome) (Fig. 9.10).
- **Fluorescein-in-situ hybridization (FISH)** or reverse transcriptase polymerase chain reaction (RT-PCR) are used to demonstrate the cytogenetic/molecular abnormality. These are also used to quantitatively monitor response to therapy.
- **Leukocyte alkaline phosphatase** is usually reduced.

Management

Imatinib, a tyrosine kinase inhibitor that specifically blocks the enzymatic action of the BCR-ABL fusion protein, is first-line treatment for the chronic phase. It has replaced alpha-interferon. Imatinib produces a complete haematological response in over 95% of patients, and 70–80% of these have no detectable BCR-ABL transcripts in the blood. Event-free, and overall, survival appear to be better than for other treatments. Imatinib can be continued indefinitely.

In the acute phase (blast transformation) most patients have only a short-lived response to imatinib, and other chemotherapy as for acute leukaemia is used in the hope of achieving a second chronic phase.

Side-effects of imatinib, which usually are well tolerated, include nausea, headaches, rashes and cytopenia. Resistance to imatinib as a single agent may develop as a result of secondary mutations beyond the t(9;22). The use of second generation tyrosine kinase inhibitors, dasatinib and nilotinib, may restore haematological or molecular remissions in those patients in the chronic phase that have primary or acquired resistance to imatinib.

Stem cell transplantation (SCT)

Allogeneic haemopoietic stem cell transplantation can cure approximately 70% of chronic phase CML patients. SCT was choice therapy for young patients with an HLA matched donor, but this has changed in the light of the success of imatinib therapy. It is now only used in those with an inadequate response to imatinib or those that have disease progression on therapy. There are many potential complications with an allogeneic transplantation approach; death may occur as a result of graft-versus-host disease (GVHD) or opportunistic infection, and the decision to proceed is based upon a balance of risk.

Factors making complications more likely include:

- increasing age
- SCT in acute phase
- prolonged interval from diagnosis to transplantation
- degree of histocompatibility between donor and recipient.

Graft-versus-leukaemia effect plays a role in the increased survival following SCT so that reduced-intensity transplantation is being more frequently used.

Chronic lymphocytic leukaemia (CLL)

This is the commonest leukaemia, occurring predominantly in later life and increasing in frequency with advancing years (median age of presentation between 65 and 67 years). It results from the clonal expansion of small lymphocytes and is almost invariably (95%) B cell in origin. The majority of patients are asymptomatic, identified as a chance finding on a blood count performed for another indication. Other patients, however, present with the features of marrow failure or immunosuppression. The median survival is about 10 years, and prognosis correlates with various clinical features at presentation (Table 9.15). These clinical features simply represent differences in the biology of the disease, and a number of cytogenetic and molecular abnormalities are now recognized as being of prognostic significance (see below). A pre-malignant condition, *monoclonal B cell lymphocytosis* (MBL), occurs where there are less than the 5 × 10^9/L B cells required for a diagnosis of CLL. Some of these have CLL phenotype and may progress to CLL.

Clinical features

The majority of patients are asymptomatic at presentation. Common symptoms are:

- recurrent infection because of (functional) leucopenia and immune failure (reduced immunoglobulins)
- anaemia due to haemolysis or marrow infiltration
- painless lymphadenopathy
- left upper quadrant discomfort (from splenomegaly).

The commonest findings on examination are:

- anaemia
- fever (due to infection)
- generalized lymphadenopathy (may involve single area)
- hepatosplenomegaly, sometimes massive.

However, none of these may be present.

Investigations

- **Blood count**. Hb normal or low; WBC raised, and may be very high; with lymphocytosis (criteria for diagnosis > 5 × 10^9/L), platelets normal or low.
- **Blood film**. Small or medium sized lymphocytes. May see smudge cells in vitro.
- **Bone marrow**. Reflects peripheral blood, often very heavily infiltrated with lymphocytes.
- **Immunophenotyping** shows mainly $CD19^+$, $CD5^+$, $CD23^+$ with a weak expression of CD20 and CD79b and surface immunoglobulin (kappa and lambda light chains).
- **Cytogenetics/FISH analysis** are not essential for diagnosis but may help in the assessment of prognosis.

Table 9.15 The Rai and Binet staging systems for chronic lymphocytic leukaemia*

System and stage	Risk	Manifestations	Percent of patients	Median survival (years)	Recommended treatment
Rai staging system					
0	Low	Lymphocytosis	31	>10	Watch and wait
I	Intermediate	Lymphadenopathy	35	9	Treat only with progression†
II	Intermediate	Splenomegaly, lymphadenopathy, or both	26	7	Treat only with progression†
III	High	Anaemia, organomegaly	6	5	Treatment indicated in most cases
IV	High	One or more of the following: anaemia, thrombocytopenia and organomegaly	2	5	Treatment indicated in most cases
Binet staging system					
A	Low	Lymphocytosis, <3 lymphoid areas enlarged‡	63§	>10	Watch and wait
B	Intermediate	≥3 Lymphoid areas enlarged‡	30	7	Treatment indicated in most cases
C	High	Anaemia, thrombocytopenia or both	7	5	Treatment indicated in most cases

*Lymphocytosis is present in all stages of the disease.
†Progression is defined by weight loss, fatigue, fever, massive organomegaly and a rapidly increasing lymphocyte count.
‡Enlarged lymphoid areas may include the cervical, axillary and inguinal lymph nodes; the spleen or liver may be enlarged.
§Stage A includes all patients with Rai stage 0 disease, two-thirds of patients with Rai stage I disease and one-third of those with Rai stage II.
From Dighiero G, Binet JL. When and how to treat chronic lymphocytic leukaemia. *New England Journal of Medicine* 2000; **343**: 1800. Copyright © Massachusetts Medical Society. All rights reserved.

- **Coombs' test**. May be positive if there is haemolysis.
- **Immunoglobulins**. Low or normal.

Prognostic factors

The clinical course of CLL is variable. Several serum markers, e.g. β_2 microglobulin, soluble CD23 and thymidine kinase, have been shown to predict progression and survival. Variations in predictor cut-off levels have limited their widespread application. Cytogenetic abnormalities are detected in >90% of cases. Patients with an isolated deletion at 13q have an excellent prognosis, in contrast to those with either 11q deletions or 17p deletions (the sites of the tumour suppressor genes *ATM* and *TP53* respectively) who tend to have a rapidly evolving clinical course. Trisomy of 12 is frequently observed and similarly conveys risk of progression. In those tumours that demonstrate a high level of mutation within the variable region of the rearranged immunoglobulin heavy chain (*IgVH*) the clinical course is more indolent than those where the *IgVH* sequence more closely resembles that of the germ line. Such assessments are technically demanding; expression of ZAP70, a 70 kDa tyrosine kinase protein, correlates well with mutational status. Patients with <20% expression of ZAP70 have median 10-year survival of ≥50%; in >20% expression the median survival was <5 years. High expression of CD38 on leukaemic cells may also indicate adverse prognosis.

Management

In CLL, the major consideration is when to treat, indeed 30% of patients will never require intervention. Treatment depends on the 'stage' (Table 9.15) of the disease and the prognostic biomarkers. Choice of therapy will depend upon patient-related factors such as age and co-morbidity, adverse prognostic features and anticipated response and toxicities to therapy. Intervention, when indicated, usually causes improvement in symptoms and in the blood count. The effect on survival is unclear. More aggressive treatments, particularly combinations of cytotoxic chemotherapy with antibody therapy, result in better quality remission of longer duration. These improvements may translate into a survival advantage, to accompany the improvement in quality of life afforded by good supportive care.

Early-stage disease is usually managed expectantly, advanced-stage disease is always treated immediately and the approach to the intermediate stage is variable. The absolute indications for treatments are:

- marrow failure manifest by worsening anaemia and/or thrombocytopenia
- recurrent infection
- massive or progressive splenomegaly or lymphadenopathy
- progressive disease manifest by doubling of the lymphocyte count in 6 months
- systemic symptoms (fever, night sweats or weight loss)
- presence of haemolysis or other immune mediated cytopenias.

General/supportive treatment

Anaemia due to haemolysis is treated with steroids. If it is refractory or recurrent, or if splenic discomfort is a problem, a splenectomy is performed. Anaemia and thrombocytopenia due to marrow infiltration is treated with chemotherapy and, when necessary, transfusion. Erythropoietin (see p. 390) may avoid the need for transfusions, particularly in patients receiving chemotherapy.

Infection is treated with antibiotics, with prophylactic therapy being given during periods of chemotherapy. Immunoglobulin replacement may be helpful.

Allopurinol is given to prevent hyperuricaemia.

Specific treatment

- Chlorambucil, given in modest doses, usually reduces the blood count and decreases lymphadenopathy and splenomegaly, and successfully palliates the disease. The bone marrow rarely returns to normal. Treatment is usually limited to a few months' duration and then withheld until progression. In asymptomatic patients without an indication for therapy, early use of chlorambucil does not provide a survival advantage over expectant management.
- *Purine analogues, fludarabine* alone or in combination with *cyclophosphamide* or *mitoxantrone* (with or without steroids), have had a much greater impact on the bone marrow and can induce complete or molecular complete remission although they are not helpful in 17p-deletion or p53 mutations.
- Combination therapy with *rituximab* (relatively ineffective alone) shows a dramatic improvement in the response rate and has become *standard choice first-line therapy*. Alemtuzumab, a humanized monoclonal antibody targeting CD52 which is highly expressed on B-CLL, may be used in those patients that progress after fludarabine.
- Allogeneic stem cell transplantation with non-myeloablative conditioning regimens is undergoing investigation, particularly for the younger patient.

Lymphomatous transformation

CLL may undergo lymphomatous (Richter's) transformation in 5–10% of cases, most typically to diffuse large B-cell lymphoma, although Hodgkin's like transformation is recognized. In the main, response to cytotoxic chemotherapy is unsatisfactory and survival short.

Hairy cell leukaemia (HCL)

HCL is a clonal proliferation of abnormal B (or very rarely T) cells which, as in CLL, accumulate in the bone marrow and spleen. It is a rare disease, median age at presentation is 52 years old and the male to female ratio is 4:1. The bizarre name relates to the appearance of the cells on a blood film and in the bone marrow – they have an irregular outline owing to the presence of filament-like cytoplasmic projections. They show a strong acid phosphatase reaction that is resistant to tartaric acid. The cells express many cellular differentiation markers including CD19, 20 and 103 but not CD21 or 5.

Clinical features

Clinical features include anaemia, fever and weight loss. Splenomegaly occurs in 80%, lymphadenopathy is uncommon. Anaemia, neutropenia, thrombocytopenia and low monocyte counts are found.

Treatment

The purine analogues 2-chloroadenosine acetate (2-CDA) (cladribine) and pentostatin have specific activity in this condition; complete remission is achieved in 90% with just one cycle of treatment. The remissions sometimes last for several years and patients can be retreated. Rituximab is used in cases who do not respond to the above drugs.

Prolymphocytic leukaemia

Prolymphocytic leukaemia is another rare disorder, often mistaken for CLL. It may be of B or of T cell lineage. It is characterized by bone marrow failure (anaemia, neutropenia and thrombocytopenia) and – as in HCL – splenomegaly. Treatment generally comprises chlorambucil as for CLL, although splenectomy may be indicated and fludarabine can be useful.

THE LYMPHOMAS

The lymphomas are commoner than the leukaemias and are increasing in incidence for reasons which are unclear. They arise as the result of abnormal proliferation of the lymphoid system, and hence occur at any site where lymphoid tissue is found. Most commonly they are manifest by the development of lymphadenopathy at single or multiple sites, although primary extranodal presentations account for up to 20% of non-Hodgkin's lymphoma. The prognosis is determined by the specific subtype of lymphoma and the anatomical extent of disease and its bulk, the clinical course ranging from months to years.

The guiding principles of management are broadly the same as for the leukaemias. The precise diagnosis is established, appropriate further investigation is conducted to allow a management plan to be formulated, both for the short and long term, and the situation is clearly explained to the patient.

Lymphomas are currently classified on the basis of histological appearance into:

- Hodgkin's lymphoma
- non-Hodgkin's lymphoma.

The distinction between lymphoid leukaemia and lymphoma is not always clear.

HODGKIN'S LYMPHOMA (HL)

This is a rare disease involving primarily the lymph nodes. The incidence in the UK and North America is approximately 3/100 000, although this is less in populations derived from Eastern Asia. It occurs slightly more frequently in males than females with a ratio of 1.3:1. Over 90% will occur in adults between 16 and 65 years with the peak incidence in the third decade. The incidence is stable.

Aetiology

There is epidemiological evidence linking previous infective mononucleosis with HL and up to 40% of patients with HL have increased EBV antibody titres at the time of diagnosis and several years prior to the clinical development of HL. EBV DNA has been demonstrated in tissue from patients with HL. These data suggest a role for EBV in pathogenesis. Other viruses have not been detected. Other environmental and occupational exposures to pathogens have been postulated.

Pathology

The hallmark of HL is the presence of the clonal malignant Reed–Sternberg cell in a lymph node biopsy or (rarely) extranodal tissue (Fig. 9.11). There is a paucity of such malignant cells, surrounded by abundant bystander cells. The Reed–Sternberg cells are usually derived from germinal centre B cells or, rarely, peripheral T cells. CD30 and CD15 are almost always expressed in the majority of cases of classical HL. It is clear that several pathways may lead to HL but the central issue must be that lymphocytes of the B-cell lineage not expressing immunoglobulins somehow escape apoptosis.

The WHO classification of HL is shown in Table 9.16. Classical HL (representing 95% of cases) can be divided into:

- *Nodular sclerosing HL* (70% of cases) demonstrates a nodular growth pattern with many fibrotic bands present. This type is typically seen in young adults, without sex predominance. It involves particularly cervical and supraclavicular lymph nodes and the anterior mediastinum.
- *Lymphocyte-rich HL* appears in 5% and is characterized by an infiltrate of many small lymphocytes and Reed–Sternberg cells. It often occurs in peripheral lymph nodes. It is often an indolent disease which presents at a higher median age.
- *Mixed cellularity HL*. Approximately 25% of cases have mixed cellularity with lymphocytes, eosinophils, neutrophils and histiocytes. Reed–Sternberg cells are present but no fibrotic bands. It is more common in men and is associated with B symptoms (see below).
- *Lymphocyte-depleted HL* is rare and there is lack of cellular infiltrate with numerous Reed–Sternberg cells. It typically presents with advanced stage and B symptoms. It is seen in HL associated with HIV.

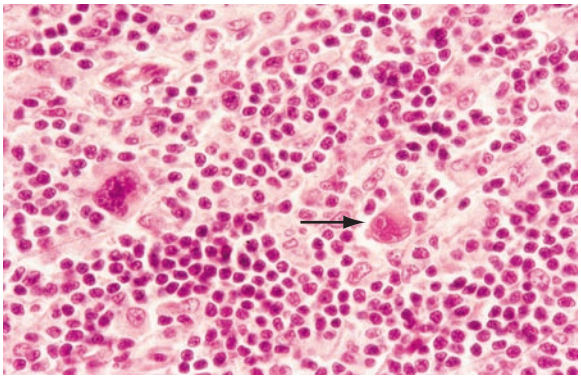

Fig. 9.11 **Histological appearance of Hodgkin's lymphoma.** There is a background rich in benign small lymphocytes and histiocytes together with scattered mononuclear Hodgkin's cells and a classical malignant binucleate Reed–Sternberg cell (arrow) to the right of centre. Courtesy of Dr AJ Norton.

Phenytoin

Primary lymph node malignancies
Hodgkin's lymphoma
Non-Hodgkin's lymphoma
Chronic lymphocytic leukaemia
Acute lymphoblastic leukaemia

Secondary malignancies
Nasopharyngeal
Thyroid
Laryngeal
Lung
Breast
Stomach

Miscellaneous
Kawasaki's syndrome
Kikuchi's disease (histiocytic necrotizing lymphadenitis)

In addition to classical HL, nodular lymphocyte-predominant HL (5% of cases) contains malignant L and H cells (lymphocytic and/or histiocytic Reed–Sternberg cell variants, also called 'popcorn' cells) which are positive for CD20, CD45, BCL6, CD79a without expressing CD15 or CD30.

Clinical features

- Lymph node enlargement, most often of the cervical nodes (other causes are shown in Table 9.17); these are usually painless and with a rubbery consistency. The pattern of spread is usually contiguous.
- Enlargement of the spleen/liver.
- Systemic 'B' symptoms: fever, (25%) drenching night sweats, weight loss of >10% bodyweight (see Table 9.18).

- Other constitutional symptoms, such as pruritus, fatigue, anorexia and, occasionally, alcohol-induced pain at the site of enlarged lymph nodes.
- Symptoms due to involvement of other organs (e.g. mediastinum – cough and breathlessness).

Investigations

(i) Standard

- **Lymph node biopsy** is required for a definitive diagnosis (Fig. 9.11).
- **Blood count** may be normal, or there can be a normochromic, normocytic anaemia. Lymphopenia and occasionally eosinophilia are present.
- **Erythrocyte sedimentation rate (ESR)** is usually raised and is an indicator of disease activity.
- **Liver biochemistry** is often abnormal, with or without liver involvement.
- **Serum lactate dehydrogenase**; raised level is adverse prognostic factor.
- **Uric acid** is normal or raised.
- **Chest X-ray** may show mediastinal widening, with or without lung involvement (Fig. 9.12).
- **CT scans** show involvement of intrathoracic nodes in 70% of cases. Abdominal or pelvic lymph nodes are also found. It is the investigation of choice for staging (Table 9.18).
- **Bone marrow aspirate and trephine biopsy** are seldom done but show involvement in patients with advanced disease. This is unusual at initial presentation (5%).

(ii) Almost standard

- **Positron emission tomography (PET)** is increasingly being used for staging, assessment of response and direction of therapy (Fig. 9.13). Despite the fact that the evidence base is still quite small, and many hypotheses remain to be validated, there can be no doubt that it is a major advance in the management of lymphoma.

Prognostic features

The presence of B symptoms confers an adverse prognosis as does advanced stage. The Hasenclever score, based on seven clinical parameters, is used to determine prognosis in advanced stage disease (Box 9.5).

Table 9.18 Cotswolds modification of Ann Arbor staging classification

Stage	Description
Stage I	Involvement of a single lymph-node region or lymphoid structure (e.g. spleen, thymus, Waldeyer's ring) or involvement of a single extralymphatic site
Stage II	Involvement of two or more lymph-node regions on the same side of the diaphragm (hilar nodes, when involved on both sides, constitute stage II disease); localized contiguous involvement of only one extranodal organ or site and lymph-node region(s) on the same side of the diaphragm (IIE). The number of anatomic regions involved should be indicated by a subscript (e.g. II_3)
Stage III	Involvement of lymph-node regions on both sides of the diaphragm (III), which may also be accompanied by involvement of the spleen (IIIS) or by localized involvement of only one extranodal organ site (IIIE) or both (IIISE)
III1	With or without involvement of splenic, hilar, coeliac or portal nodes
III2	With involvement of para-aortic, iliac and mesenteric nodes
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph-node involvement
Designations applicable to any disease state	
A	No symptoms
B	Fever (temperature > 38°C), drenching night sweats, unexplained loss of more than 10% of body weight within the previous 6 months
X	Bulky disease (a widening of the mediastinum by more than one-third of the presence of a nodal mass with a maximal dimension greater than 10 cm)
E	Involvement of a singe extranodal site that is contiguous or proximal to the known nodal site

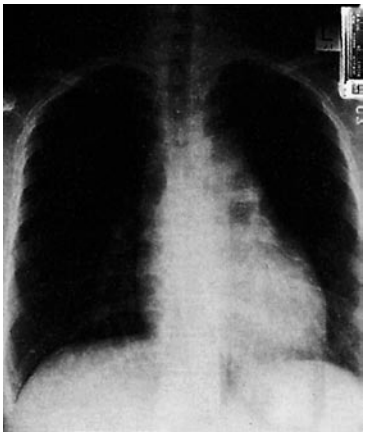

Fig. 9.12 **Chest X-ray of a large mediastinal mass that is due to Hodgkin's lymphoma.**

Management

Treatment is almost always recommended and undertaken with curative intent and considerable expectation of success (Fig. 9.14). Expectant management may be reasonable in some cases of lymphocyte-predominant Hodgkin's lymphoma, although the rationale for this must be made clear to the patient and there needs to be close early surveillance.

Specific treatment is based otherwise on the anatomical distribution of disease, its 'bulk' and the presence or absence of 'B' symptoms. ('stage': Table 9.18).

'Early stage' (IA, IIA no bulk)

The treatment of choice is brief chemotherapy followed by involved field irradiation. Large field irradiation has come under criticism because of a significantly increased incidence

of breast cancer in young women, lung cancer in smokers and cardiac disease following supradiaphragmatic 'mantle' field irradiation. 'Moderate' chemotherapy ABVD (Table 9.10, p. 461), 2–4 cycles (i.e. non-sterilizing and low secondary cancer risk) followed by involved field irradiation (20–30 Gy) has become standard care. Current trials are evaluating the role of PET scanning to see if patients who become 'PET' negative can be spared irradiation altogether.

Advanced disease

This is also curable for a significant proportion of patients, the median survival exceeding 5 years. Cyclical combination chemotherapy with irradiation at sites of bulk disease has been standard at many centres for years. Increasingly, the data from therapeutic strategies incorporating PET scanning during and after therapy have suggested that PET-negative residual masses are likely to represent fibrous tissue, and that irradiation may be omitted (Fig. 9.13). This is a major advance. Thus it may be that the 50–60% cure rate with this

Lymphopenia	$>0.6 \times 10^9$/L	$\leq 0.6 \times 10^9$/L

Cumulative number of points associated with increased adverse prognosis, freedom from progression at 5 years

Score 0	84%	7% (of all patients)
Score 1	77%	22%
Score 2	67%	29%
Score 3	60%	28%
Score 4	51%	12%
Score 5	42%	7%

approach may be achieved with a considerable reduction in the number of patients receiving irradiation. The major short-term toxicity of the therapy relates to myelosuppression, the mortality being around 1%, and the long-term risks being to the heart and lungs. Infertility and second malignancy are uncommon.

The above approach fails for about 25% of patients. More intensive treatment programmes have been tested, e.g. BEACOPP (Table 9.10), with better results, but with greater toxicity profiles (and greater expense), and are clearly not necessary for the majority of patients. The challenge remains to identify those who need it prior to initiation of therapy, which has proven difficult. An alternative is to develop a 'risk-adapted' therapy relying on an early assessment of response to 'minimal' therapy (ABVD) and escalating as appropriate. Trials are in prospect to direct therapy as a consequence of the result of the PET scan after 1 or 2 cycles of therapy.

Recurrent Hodgkin's lymphoma, certainly after 'conventional'-dose chemotherapy, is potentially very serious though not necessarily fatal. Hopefully, it is a declining problem. The median survival from the first recurrence is more than 10 years; it may be influenced by the duration of first remission: it may not be so good if failure occurs after more intensive initial therapy. Second and third remissions are achieved, more often than not with 'appropriate' re-induction chemotherapy. It is conventional to consolidate remission in this group when possible, with high-dose therapy and peripheral blood cell progenitor rescue (PBPCR). Registry data suggest that this may be curative in up to 50%, although follow-up does not extend beyond 15 years.

Experimental approaches for recurrent and refractory disease include new cytotoxic drugs, monoclonal antibodies and reduced-intensity allogeneic transplantation. Limited success with myeloablative chemotherapy with haemopoietic stem cell rescue has been reported in those with 'refractory disease'.

NON-HODGKIN'S LYMPHOMA (NHL)

These are malignant tumours of the lymphoid system classified separately from Hodgkin's lymphoma. Most (70%) are of B cell origin with 30% of T cell origin.

The incidence of these tumours is approximately 15/100 000 per year in developed countries, an incidence which has increased over the last 20–30 years for reasons largely unknown. There is a slight male predominance.

Aetiology

The cause is unknown. There is wide geographical variation which probably reflects different environmental factors. A number of infective agents are associated with the development of NHL.

- EBV virus DNA is observed in between 10% and 30% of tumours and is strongly associated with endemic Burkitt's lymphoma of sub-Saharan Africa, but is present in only about 20% of the sporadic cases observed in the Western world.
- The human T cell lymphotropic virus which is prevalent in Japan, Africa, South America and the Caribbean is a major risk factor for adult T cell lymphoma/leukaemia.
- Herpesvirus 8 is associated with primary effusion lymphomas and Castleman's disease.
- There is an increase in lymphoma in patients with HIV infection and more specifically primary brain lymphoma, immunoblastic diffuse large B-cell lymphoma and Burkitt's lymphoma are AIDS defining illnesses.
- *Helicobacter pylori* is an aetiological factor in gastric MALT lymphoma.

Epidemiological studies have documented an association between farming and NHL which may be a result of pesticide exposure. In addition organic solvents and hair dyes used prior to 1980 have been implicated.

Lymphomas also occur in a number of congenital immunodeficiency states. Acquired immunodeficiency, as a result of organ transplantation, is strongly associated with NHLs. These are commonly extranodal and most frequently occur in the first year after transplantation. In autoimmune disorders an elevated risk of NHL is reported, attributed to disturbances in immune function (e.g. Sjögren's syndrome and extranodal marginal zone lymphoma). A number of familial cancer syndromes are also associated with NHL (Table 9.3, p. 453).

Pathogenesis

There is a malignant clonal expansion of lymphocytes which occurs at different stages of lymphocyte development. In general, neoplasms of non-dividing mature lymphocytes are indolent whereas those of proliferating cells (e.g. lymphoblasts, immunoblasts) are much more aggressive. This malignant transformation is usually due to errors in gene rearrangements which occur during the class switch, or gene recombinations for immunoglobulins and T cell receptors. Thus, many of the errors occur within immunoglobulin loci or T cell receptor loci. For example, an abnormal gene translocation may lead to the activation of a proto-oncogene next to a promoter sequence for the immunoglobulin heavy chains (Ig-H).

Cytogenetic features (Table 9.19)

Burkitt's lymphoma was the first tumour in which a cytogenetic change was shown to involve the translocation of a specific gene. The most frequent change is a translocation between chromosomes 8 and 14 in which the *myc* oncogene moves from chromosome 8 to a position near the constant region of the immunoglobulin heavy chain gene on chromosome 14, resulting in upregulation of myc. Similar rearrangements involving the light chain loci are seen in the alternative Burkitt's lymphoma translocations between chromosome 8 and either chromosome 2 or 22. Other somatic cytogenetic abnormalities associated with human lymphoma are the t(14;18) in follicular lymphoma, involving upregulation of the Bcl-2 gene, or the upregulation of the cell cycle regulator cyclin D1 as a result of t(11;14) in mantle cell lymphoma. Gene expression profiling and other molecular techniques are increasingly revealing aberrations or patterns of aberration which are associated specifically with one or other subtype of lymphoma and have led to the identification of

Table 9.19 Chromosome translocations in non-Hodgkin's lymphoma

Type	Translocation	Genes	Function
Follicular	t(14;18)	*Bcl-2/Ig*	Suppresses apoptosis
Lymphoplasmacytic	t(9;14)	*PAX5*	Transcription factor
Mantle cell	t(11;14)	*Bcl-1* (cyclin D1)	Cell cycle regulator
Diffuse large B cell	t(3;4)	*Bcl-6*	Cell cycle regulator
Burkitt's	t(8;14) t(2;8)	*c-myc* and Ig	Transcription factor
Anaplastic	t(2;5)	*NPM1/ALK*	Tyrosine kinase
MALT	t(11;18)	*BIRC3/MALT1 fusion protein*	Suppresses apoptosis

MALT, mucosal associated lymphoid tissue.

new molecular subclasses of lymphoma. Such studies have also resulted in the identification of genes of prognostic significance.

Immunophenotypes

All NHL B cells express CD20 and surface immunoglobulin. Individual lymphomas vary in their expression, e.g. follicular lymphomas express CD10, mantle cell CD43, while the diffuse large B cell lymphoma expresses both CD10 and CD43. They can be used in the classification. T cell lymphomas do not express CD20 but variably express CD3, 4, 8 and 30.

Classification

The WHO classification (2001) which is based on the Revised European American Lymphoma (REAL) system is shown in Table 9.20. Previous classifications have divided lymphomas into indolent (or low grade) and aggressive (or high grade), and the WHO classification has been modified to include aggressive or highly aggressive lymphomas. NHL can also be staged in a similar way to Hodgkin's lymphoma (Table 9.18).

Clinical features

- *Peripheral lymphadenopathy*. Most patients present with painless, superficial lymph node enlargement.
- *Systemic symptoms (B symptoms).* Fever, sweats and weight loss.
- *Extranodal presentation*. This is more common than in HL and may involve the gastrointestinal tract, lung, brain, testes, thyroid and skin. Abdominal involvement may reveal hepatosplenomegaly. Skin involvement (T cell lymphomas) presents as mycosis fungoides (see p. 1260) and Sézary syndrome (see p. 1260).
- *Oropharyngeal involvement* occurs rarely.

Investigations

- **Full blood count**. Normochromic, normocytic anaemia, an elevated white cell count or neutropenia and thrombocytopenia are suggestive of bone marrow infiltration.
- **ESR** may be elevated.
- **Urea and electrolytes**. Patients may have renal impairment as a consequence of ureteric obstruction secondary to intra-abdominal or pelvic lymph node enlargement.
- **Serum uric acid** level may be raised.

Table 9.20 Modified WHO classification of lymphoid neoplasms other than ALL (2001)

B cell lymphomas	
Precursor B cell lymphoma	Precursor B lymphoblastic lymphoma/leukaemia (*highly aggressive*)
Mature B cell lymphoma	Chronic lymphocytic leukaemia/small lymphocytic lymphoma
	Lymphoplasmacytic lymphoma
	Splenic marginal zone lymphoma
	Extranodal marginal zone B cell lymphoma of mucosa-associated lymphoid tissue (MALT-lymphoma)
	Nodal marginal zone B cell lymphoma
	Follicular lymphoma (*aggressive*)
	Mantle cell lymphoma
	Diffuse large B cell lymphoma (*aggressive*)
	Mediastinal (thymic) large B cell lymphoma
	Intravascular large B cell lymphoma
	Primary effusion lymphoma
	Burkitt's lymphoma/leukaemia (*highly aggressive*)
T/NK cell lymphomas	
Precursor T cell lymphoma	Precursor T cell lymphoblastic leukaemia/lymphoma (*highly aggressive*)
	Blastic NK cell lymphoma
Mature T/NK cell lymphoma	Adult T cell leukaemia/lymphoma (*very aggressive*)
	Extranodal NK/T cell lymphoma, nasal type
	Enteropathy-type T cell lymphoma
	Hepatosplenic T cell lymphoma
	Subcutaneous panniculitis-like T cell lymphoma
	Mycosis fungoides
	Sézary syndrome
	Primary cutaneous anaplastic large cell lymphoma
	Peripheral T cell lymphoma, unspecified (*aggressive*)
	Angioimmunoblastic T cell lymphoma
	Anaplastic large cell lymphoma (*aggressive*)

NK, natural killer.

Modified from Jaffe ES, Harris NL, Stein H, Vardiman JW (eds). *World Health Organization Classification of Tumours. Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues.* Lyon: IARC Press, 2001 with permission of the World Health Organization.

- **Liver biochemistry**. This may be abnormal if there is hepatic involvement.
- **Serum lactate dehydrogenase and β_2-microglobulin** are prognostic indicators.
- **Serum immunoglobulins.** Decreased levels may occur with paraproteinaemia.
- **Chest X-ray, CT scans** of chest, abdomen and pelvis. PET and gallium scans help in staging.
- **Bone marrow aspirate and trephine biopsy** are always performed.
- **Lymph node biopsy** (or Trucut needle biopsy, often under radiological guidance, in the case of surgically inaccessible nodes). Immunophenotyping and cytogenetic/molecular analysis (DNA microarray analysis), to distinguish type of NHL.

At the completion of staging investigations, it is possible to assign a clinical prognostic index score, at least for follicular lymphoma (FLIPI, see later) and 'large cell lymphoma' (IPI).

Follicular lymphoma

These comprise 20% of all B cell lymphomas. Most patients with follicular lymphoma present feeling well but with painless lymphadenopathy. Investigation usually reveals multiple sites of disease: involvement of the bone marrow is common. Managed conservatively it is a remitting and recurring disease with a clinical course running over a median of 10 (1–20 years) years during which there will be about three 'episodes' of relapse. Death occurs because of resistant disease, transformation to diffuse large B cell lymphoma (LBCL) or the effects of therapy.

The 'well' patient should be managed with no specific therapy until progression is documented. Repeat biopsy should be performed at this time in case there has been histological transformation to LBCL as this has specific implications for therapy and prognosis.

The indications for the initiation of therapy are:

- *Stage I presentation* single lymph node field (10–15%). This is treated with 'involved' field mega voltage irradiation, which almost invariably induces 'complete remission'. The median time to progression is 10–15 years. Some patients may be cured. The therapy has a low morbidity and mortality.
- Advanced disease with:
  - constitutional 'B' symptoms
  - 'organ impairment', i.e. bone marrow failure
  - 'bulky' disease, i.e. lymph node mass > 10 cm
  - progressive disease after expectant management, documented if necessary on two scans 3 months apart
  - histological transformation.
- Philosophy of patient and physician.

A specific follicular lymphoma international prognostic index (FLIPI) has been formulated, defining 'low', 'intermediate' and 'high' risk groups. This may provide a more objective basis for the decision to begin therapy, and with what. Box 9.6 shows the prognostic factors in non-Hodgkin's lymphoma, which are very similar.

A study has shown that survival can be predicted by the different genes expressed on accompanying T cells and dendritic cells (not tumour cells) identified by gene expression microarray analysis of tumour tissue.

Management

Follicular lymphoma has been a recurring remitting disease, treated intermittently, but with a high risk over time of transformation to diffuse large B-cell lymphoma, the median survival being about 10 years. An increase in the therapeutic options has coincided over the past 10 years with an apparent improvement in the prognosis. There is now a possibility of cure, particularly after allogeneic stem cell haematopoietic transplantation.

Treatment

Chemo-immunotherapy

This has become the treatment of choice for follicular lymphoma since the demonstration in large randomized phase II clinical trials that the anti-CD20 antibody, *rituximab*, added to cyclical combination chemotherapy, improves the response rate, freedom from progression and overall survival. There is only circumstantial evidence that one chemotherapy combination is better than another. Indeed, for the long term, it has not been shown that there is any advantage of combination over single agent chemotherapy. The duration of antibody therapy after chemotherapy has been completed remains under investigation.

Other options

- **Rituximab alone**. This is being investigated in the setting of the patient 'not needing therapy', and may also be valuable in patients with progressive disease, for whom chemotherapy is inappropriate. It induces remission, mainly partial, in 30–60% of patients depending on how much previous therapy has been received.
- **Chemotherapy alone.** Both mono- and combination chemotherapy are now only being used alone when there is evidence that antibody therapy has failed.
- **Myeloablative chemo-(immunotherapy) with peripheral blood progenitor cell rescue.** This has been shown to result in very long freedom from recurrence in phase II trials when performed in second remission, and to have a survival advantage also in a phase III trial. For many physicians, it is the treatment of choice in second remission, although there are some alternative compelling data for 'maintenance rituximab'.

Box 9.6 Prognostic factors in non-Hodgkin's lymphoma

Adverse factors:

- Age > 60 years
- Stage III or IV, i.e. advanced disease
- High serum lactate dehydrogenase level
- Performance status (ECOG 2 or more)
- More than one extranodal site involved

ECOG, Eastern Cooperative Oncology Group.

Ask the authors
www.studentconsult.com

- **Irradiation for stage 1 disease** (see p. 465). Targeted irradiation, ^{131}I or ^{90}Y being delivered with anti-CD20 as a carrier is being used.
- **Allogeneic haematopoietic stem cell transplantation (HSCT).** Data suggests that this may be curative. Reduced intensity conditioning HSCT is the subject of many phase II trials. The design of phase III trials is difficult.

Lymphoplasmacytic lymphoma

This is an uncommon B cell lymphoma often presenting with extensive bone marrow infiltration, and is almost the only lymphoma to be diagnosed on bone marrow biopsy alone. There is frequently splenomegaly and anaemia, and in some an associated paraprotein. This IgM (a large pentameric molecule which at high concentrations increases plasma viscosity) is associated with immune paresis (*Waldenström's macroglobulinaemia*; WM). Patients in this group are usually older and commonly present with the symptoms of bone marrow failure or hyperviscosity. It may be a chance diagnosis.

Management may be expectant, the indications for treatment being:

- symptomatic anaemia
- recurrent infection
- symptoms of hyperviscosity, e.g. headache, visual disturbance, mucosal haemorrhage, heart failure
- progression.

Treatment is supportive in the first instance. Transfusion and/or erythropoietin is given for the anaemia, particularly if chemotherapy is being given. Plasmapheresis is an excellent means of controlling the paraproteinaemia both in the short and longer term.

Chlorambucil is the conventional treatment, the 'response criteria' for WM being different from those of the rest of the lymphomas. The paraprotein will be reduced by 50% in 50–70% of cases in the short term. Progression is the rule but as with follicular lymphoma there may be further response to treatment. The purine analogue fludarabine is also 'effective'. Rituximab is being used increasingly.

It is not clear how much the use of chemotherapy has actually influenced overall survival, and quality of life is poorly recorded. The median survival is several years.

A heightened awareness of this relatively uncommon but symptomatic lymphoma has led to more enthusiastic exploration of the new therapies being tested on the other B cell lymphomas (see above).

Mantle cell lymphoma

This is an uncommon lymphoma (6% of non-Hodgkin's lymphoma) with a median survival of 3–4 years. It occurs predominantly in the elderly and is almost always widely disseminated at presentation, with lymphadenopathy and frequent involvement of the bone marrow and gastrointestinal tract. Treatment is often compromised by co-morbidity.

Combination chemotherapy is the most usual first-line therapy, if possible: the response rate may be above 50% but the complete remission rate is low. The addition of rituximab has little effect and has not increased survival. Intensifying chemotherapy does not appear to improve survival and bortezomib, the proteasome inhibitor, is being used after failure of other therapy.

Diffuse large B cell lymphoma (DLBCL)

This is the commonest lymphoma and is almost invariably fatal without therapy within months, and was previously classified as aggressive or high-grade lymphoma. Now >50% of young patients are cured. The only indications for a palliative approach at the initial presentation are extreme co-morbidity and the will of the patient. Expectant management is inappropriate. Patients present with rapidly progressive lymphadenopathy and progressive infiltration of many organs, e.g. spinal cord, gastrointestinal tract.

Treatment

Treatment decisions are based on the stage and may be tailored by the International Prognostic Index (Box 9.6). PET scanning is useful in judging the response to treatment.

In the absence of relevant co-morbidity all patients should receive cyclical combination chemo-immunotherapy, the gold standard being cyclophosphamide, hydroxydaunorubicin, vincristine, prednisolone and rituximab (CHOP + R). Between 60% and 70% of those with early stage disease (I, IIA without bulk) may expect to be cured either with 6 cycles or 3 cycles followed by involved field irradiation. Those with more extensive disease conventionally receive 6–8 cycles. There has been a suggestion that decreasing the interval between cycles may be feasible (with growth factor support), and this may improve the results. There are conflicting reports about the advantages of increasing the intensity of initial treatment for those perceived to be at 'high risk'. There is also controversy about the indications for central nervous system prophylaxis and which form it should take.

For those with advanced disease the cure fraction, which was about 30%, has been increased with the incorporation of rituximab as standard therapy, by 15%.

Progression during therapy or failure of the initial treatment to achieve complete remission has a very poor prognosis. Second-line therapy, e.g. platinum compounds or gemcitabine, should be initiated with a view, if possible, to high-dose therapy and peripheral blood progenitor cell rescue (PBPCR) if further response is achieved. This is not usually possible and long-term success is rare. Proper consideration should be given to palliation or experimental therapy. By contrast, recurrence after a disease-free interval is potentially still curable. The complete remission rate after a second treatment is 40–50%: it is conventional to consolidate such remissions with high-dose therapy which will cure perhaps half (i.e. 25% 'cure' overall of the selected younger patients in whom curative therapy is attempted).

Burkitt's lymphoma

This is an uncommon lymphoma in the western world. It is endemic to Africa in the mosquito belt: there is a close association with the Epstein–Barr virus and it is a disease with a very high proliferative index which is very rapidly fatal without therapy.

The clinical presentation worldwide is usually that of lymphadenopathy, often with an abdominal mass and fre-

quently with bone marrow infiltration (and 'leukaemia'). Central nervous system involvement is common, up to 30% having meningitis at the time of presentation. In Africa, by far the two commonest presentations are the abdominal mass or a large tumour involving the jaw (Fig. 9.15); the bone marrow and central nervous system are also frequently involved.

Treatment

Treatment, whilst undoubtedly toxic with both morbidity and mortality, is much less dangerous than the disease. It relieves symptoms and is potentially curative in a high proportion of cases.

Supportive care is with hydration and prevention of hyperuricaemia with allopurinol associated with rapid tumour lysis. Rasburicase (see p. 485) is a major advance.

Drug therapy

Cyclical combination chemotherapy, incorporating at least high doses of cyclophosphamide and methotrexate as well as vincristine and doxorubicin, is followed by further cycles including high-dose cytarabine depending on the extent of disease at presentation. Up to 6 cycles must be given at about monthly intervals. While both the high-dose systemic methotrexate and cytarabine cross the blood–brain barrier in tumoricidal doses, many prefer to supplement them with intrathecal chemotherapy also. The role of cranial irradiation is unclear. In Africa, treatment can be difficult to coordinate but is based on the same principles.

This treatment will be tolerated quite well by the majority of patients, who tend to be young. The reported complete remission rate is very high, 70–90% depending on age (and excluding those with concurrent HIV infection), with very few recurrences occurring after 1 year. Hence 60–70% may be cured. Demonstrating improvements on this will be difficult but rituximab may have a role.

The management of progression despite treatment is difficult and rarely successful. Remission induction with alternative therapy, possibly including cisplatin, is the first line of attack. If achieved, it is consolidated with high-dose therapy or allogeneic transplantation.

T cell lymphomas

These are much less common than the B cell counterparts. In the main, the overall treatment strategies are the same, but success is much more limited.

Fig. 9.15 **A child with Burkitt's lymphoma.**

Primary extranodal lymphoma

The WHO classification does not distinguish between primarily nodal or extranodal at the time of presentation if the histological picture is the same.

Primary cerebral lymphoma

This is a very aggressive disease with survival untreated measured in months. It is particularly dangerous within the setting of HIV infection. Irradiation plus corticosteroids has, until recently, been the treatment of first choice. It is rarely curative, and may be associated with severe cerebral toxicity when given in high enough doses to eliminate lymphoma, particularly in the elderly. Even following irradiation, the median time to progression is less than a year. Subsequent management is palliative.

A very aggressive approach, involving sequential very high doses of methotrexate followed by cytarabine, may obviate the need for irradiation and be curative in a proportion of cases. Followed by irradiation this treatment may eliminate lymphoma in an even higher proportion of cases, but the potential central nervous system toxicity is considered by most to be unacceptable.

Primary gastric lymphoma

In a high proportion of cases, particularly in Northern Italy, lymphoma is associated with *Helicobacter pylori* infection (see p. 262). Biopsy of the gastric lesion usually shows lymphoma ('low-grade' B cell pathologically, of extranodal marginal zone type) and *H. pylori* is usually detected. Treatment to eradicate *H. pylori* is with antibiotics (and a proton pump inhibitor) for 2 weeks (see p. 261). Symptomatic relief is usually rapid. Provided there is no evidence of disease outside the stomach, further treatment is not given but surveillance endoscopy is performed, first at 3 months then 6-monthly. Partial or complete remission is the rule, but may take many months to achieve. Treatment of progression (always confirmed by biopsy) is with more antibiotics initially. Both irradiation and alkylating agent therapy are effective. Rituximab is being investigated. There is no role for surgery in the management of gastric lymphoma.

Primary cutaneous lymphoma (see p. 1260)

This is much commoner than generally perceived. It must be carefully distinguished from cutaneous infiltration with lymphocytes in a patient with nodal disease. It is usually of T cell origin (*Sézary syndrome, mycosis fungoides*). It is often multifocal and responds well to local therapy even when it appears histologically aggressive. Survival may be very long without chemotherapy, and in many cases treatment may only serve to disrupt the quality of life.

Lymphoma in HIV disease

NHL is the most common AIDS defining malignancy, and with the declining incidence of opportunistic infection due to highly active antiretroviral therapies has become the most common AIDS defining illness. In the main they are of B cell origin, have an aggressive course and present at unusual extranodal locations (e.g. body cavity, anogenital, sinus). The most common are Burkitt's lymphoma and the immunoblastic subtype of large B cell lymphoma; the indolent lymphomas are much less common. Those patients presenting with advanced stage disease, low CD4 counts at diagnosis, aged

> 35 or with an elevated serum lactate dehydrogenase have an inferior prognosis.

Primary CNS lymphoma, a common site, may be difficult to distinguish from toxoplasmosis on radiological assessment.

Primary effusion lymphoma (PEL), a lymphoma of the coelomic cavities, presents with pericardial and pleural effusions or ascites. Median survival even with chemotherapy is short.

Multicentric Castleman's disease is a polyclonal lymphoproliferative disorder presenting with fever, lymphadenopathy, organomegaly that frequently progresses to malignant lymphoma. It is associated with HIV and HHV-8 infection.

Treatment is difficult but CHOP therapy is usually the first-line option. This is followed by rituximab with reports of great efficacy. Antivirals, e.g. ganciclovir, are used but are palliative only.

Hodgkin's disease is increased in HIV-infected patients, although this is not an AIDS defining illness. Patients are more likely to present with B symptoms and marrow involvement.

MYELOMA

Myeloma is a malignant disease of the plasma cells of bone marrow, accounting for 1% of all malignant disease. There is a clonal expansion of abnormal, proliferating plasma cells producing a monoclonal paraprotein, mainly IgG (55%) or IgA (20%) and rarely IgM and IgD. The paraproteinaemia may be associated with excretion of light chains in the urine (Bence Jones protein), which are either kappa or lambda. In approximately 20% there is no paraproteinaemia, only light chains in the urine. Rarely, patients produce no paraprotein or light chains (<10%).

Clinicopathological features

Myeloma is a disease of the elderly, the median age at presentation being over 60 years. It is rare under 40 years of age. The annual incidence is 4 per 100000 and it is commoner in males and in black Africans but less common in Asians. There is:

- *Bone destruction*, often causing fractures of long bones or vertebral collapse (which can cause spinal cord compression) and hypercalcaemia. Soft tissue plasmacytomas also occur and they are the usual cause of spinal cord compression in myeloma.
- *Bone marrow infiltration* with plasma cells, resulting in anaemia, neutropenia, thrombocytopenia, together with production of the paraprotein which may (rarely) result in symptoms of hyperviscosity.
- *Renal impairment* (see p. 422) owing to a combination of factors – deposition of light chains in the renal tubules, hypercalcaemia, hyperuricaemia, use of NSAIDs and (rarely), deposition of amyloid.

In addition there is a reduction in the normal immunoglobulin levels (immuneparesis), contributing to the tendency for patients with myeloma to have recurrent infections, particularly of the respiratory tract.

Cytogenetics

With fluorescent in situ hybridization and microarray techniques abnormalities are found in most cases of myeloma. Abnormalities of chromosome 13 and hypodiploidy (<45 chromosomes) have been shown to be associated with poor survival, as have t(4;14), t(14;16) and p53 (17p) deletions. t(11:14) and hyperdiploidy (>50 chromosomes) are associated with a better prognosis.

Bone disease

There is dysregulation of bone remodelling which leads to the typical lesions, usually seen in the spine, skull, long bones and ribs. In myeloma there is increased osteoclastic activity with no increased osteoblast formation of bone. Bisphosphonates that inhibit osteoclast activity are useful in myeloma but surprisingly there is no increase in bone deposition (see below).

Adhesion of stromal cells to myeloma cells stimulates the production of RANKL, IL-6, and also VEGF (which plays a role in angiogenesis). RANKL also stimulates osteoclast formation and the lytic lesions (see Fig. 9.1). Myeloma cells also produce dickkopf-1 (DKK1) which inhibits osteoblast activity and therefore production of new bone. This occurs because DKK1 binds to the Wnt co-receptor, lipoprotein receptor-related protein 5 (LRP5), inhibiting Wnt signalling and osteoblast differentiation.

Symptoms

- Bone pain – most commonly backache owing to vertebral involvement (60%)
- symptoms of anaemia
- recurrent infections
- symptoms of renal failure (20–30%)
- symptoms of hypercalcaemia
- rarely, symptoms of hyperviscosity and bleeding due to thrombocytopenia.

Patients can be asymptomatic, the diagnosis being suspected by 'routine' abnormal blood tests. Life-threatening complications are shown in Box 9.7.

Investigations

- *Full blood count*. Hb, WCC and platelet count are normal or low.
- *ESR*. This is almost always high.
- *C-reactive protein* is almost always raised.

Fig. 9.16 **Myeloma affecting the skull.** Note the rounded lytic translucencies produced by infiltration of the skull with myeloma cells.

Box 9.7 Life-threatening complications of myeloma

- Renal impairment – often a consequence of hypercalcaemia – requires urgent attention and patients may need to be considered for long-term peritoneal or haemodialysis.
- Hypercalcaemia should be treated by rehydration and use of bisphosphonates such as pamidronate.
- Spinal cord compression due to myeloma is treated with dexamethasone, followed by radiotherapy to the lesion delineated by a magnetic resonance imaging (MRI) scan.
- Hyperviscosity due to high circulating levels of paraprotein may be corrected by plasmapheresis.

- *Blood film*. There may be rouleaux formation as a consequence of the paraprotein.
- *Urea and electrolytes*. There may be evidence of renal failure (see above)
- *Serum β_2-microglobulin* > 2.5 mg/L – useful in prognosis.
- *Serum lactate dehydrogenase* (LDH) raised – useful in prognosis.
- *Serum calcium* is normal or raised.
- *Serum alkaline phosphatase* is usually normal.
- *Total protein* is normal or raised.
- *Serum albumin* is normal or low – useful in prognosis.
- *Serum protein electrophoresis* and immunofixation characteristically shows a monoclonal band.
- *Serum free light chain assay.*
- *Uric acid* is normal or raised.
- *Skeletal survey*. This may show characteristic lytic lesions, most easily seen in the skull (Fig. 9.16). CT, MRI and PET are used in plasmacytomas (bone or soft tissue deposits). MRI spine is useful if there is back pain – may show imminent compression/collapse.
- *24-hour urine electrophoresis and immunofixation* is used for assessment of light-chain excretion.
- *Bone marrow aspirate* or trephine shows characteristic infiltration by plasma cells (Fig. 9.17). Amyloid may be found.

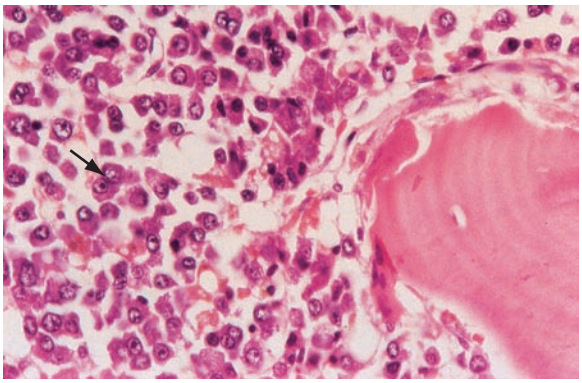

Fig. 9.17 **Multiple myeloma.** Histology shows replacement of the medullary cavity by abnormal plasma cells with some binucleate forms (arrow). A residual bony trabeculum is present towards the right. Courtesy of Dr AJ Norton.

Box 9.8 International prognostic index based on serum albumin + β_2 microglobulin (β_2M)

Stage	Median survival (months)
Stage 1 – β_2M < 3.5 mg/L and s albumin ≥ 35 g/L	62
Stage 2 – not stage 1 or 3	44
Stage 3 – β_2M ≥ 5.5 mg/L	29

Diagnosis

Two out of three diagnostic features should be present:

- paraproteinaemia or Bence Jones protein
- radiological evidence of lytic bone lesions
- an increase in bone marrow plasma cells.

For symptomatic myeloma, evidence of end organ failure should also be present, i.e. anaemia, lytic lesions, renal impairment, hypercalcaemia, recurrent infections.

An international prognostic index based on serum albumin + β_2 microglobulin (β_2M) at diagnosis is used for prognostic information (Box 9.8).

Monoclonal gammopathy of unknown significance (MGUS). MGUS describes an isolated finding of a monoclonal paraprotein in the serum, usually in the elderly; 20–30% go on to develop multiple myeloma over a 25-year period.

Treatment

With good supportive care and chemotherapy with autologous or allogeneic stem cell transplantation, median survival is now 5 years with some patients surviving to 10 years. Young patients receiving more intensive therapy may live longer. The conversion of asymptomatic to symptomatic myeloma is related to the level of myeloma protein in the blood and number of plasma cells in the bone marrow.

Supportive therapy

- Anaemia should be corrected; blood transfusion may be required. Erythropoietin often helps. Transfusion should be undertaken cautiously in patients with hyperviscosity.
- Infection should be treated promptly with antibiotics. Give yearly flu vaccinations.

- Bone pain can be helped most quickly by radiotherapy and systemic chemotherapy or high-dose dexamethasone. NSAIDs are usually avoided because of the risk of renal failure. Bisphosphonates, e.g. zoledronate, which inhibit osteoclast activity, reduce progression of bone disease.
- Pathological fractures may also be prevented by prompt orthopaedic surgery (kyphoplasty) with pinning of lytic bone lesions seen on the skeletal survey. Kyphoplasty and vertebroplasty may be useful in treating vertebral fractures.

Specific therapy

Myeloma remains incurable. Therapy is aimed at treatment of specific complications, prevention of these and prolongation of overall survival. In older or less fit patients, melphalan and prednisolone is the standard of care, with a median survival of 29–37 months; complete remissions are rare. Recent phase III studies suggest that this combined with thalidomide results in improved response rates and overall survival, albeit with increased toxicity. In younger patients (<65–70 years) a high-dose dexamethasone based induction followed by high-dose melphalan with peripheral blood stem cell rescue (autotransplantation) has a significantly higher response rate with 40% of patients achieving a CR with median survival increasing to 6 years. The role of allogeneic transplant is currently unclear.

Thalidomide has activity as a single agent and is now widely used in relapsed myeloma. Lenalidomide is a thalidomide analogue, which has recently obtained marketing authorization in the USA and Europe for relapsed myeloma. It has greater potency than thalidomide with less toxicity. Bortezomib is a proteosome inhibitor which is also licensed for relapsed myeloma. Thalidomide, lenalidomide and bortezomib all show synergy with dexamethasone, and chemotherapy and several phase II studies have shown very promising activity in newly diagnosed patients. One phase III study has shown that bortezomib plus melphalan and prednisolone is superior to the latter two alone.

COMMON SOLID TUMOUR TREATMENT

Common solid cancer mortality is listed in Table 9.1; the improvements in treatment over the past 10 years have come from advances in both prevention, diagnosis and treatment. The presentation, diagnosis and natural history of the common cancers are described in the relevant organ system chapters. In this section the systemic therapy of the common cancers is described, and in addition the treatment of germ cell tumours illustrates what can be achieved when chemotherapy resistance is overcome. The decision to treat and the aim of that treatment, whether for palliation or cure, require knowledge of the natural history of the disease, prognostic and predictive factors, the patient's performance status, and the potential efficacy of treatment. Management should be carried out by multidisciplinary teams, usually led by an oncologist.

Lung cancer (see p. 880)

Presentation, diagnosis and surgery are discussed on page 881.

Prognostic factors

Lung cancer histology is divided into two main types: *small-cell (neuroendocrine) lung cancers* (SCLC), which tend to disseminate early in their development, and *non-small-cell lung cancers* (NSCLC), which are more likely to be diagnosed in a localized form. Tumour stage and patient performance status are used in selecting treatment and predicting response and prognosis. While overall 5-year survival has remained approximately 15%, treatment is beginning to have an impact in selected groups and the multidisciplinary team can greatly aid in the appropriate application of treatment and the avoidance of nihilism.

Non-small-cell lung cancer

The staging is classified according to the TNM system (Table 9.5), by which the disease can be divided into local, locally advanced and advanced stages with 5-year survival varying from 55–67%, to 23–40%, to 1–3% respectively. The addition of CT and PET scanning has increased the accuracy of staging and improved the selection of patients for surgery and adjuvant therapy.

Treatment

In operable disease stages T1N0 to T3N2 (stage I to IIIa) adjuvant radiotherapy and chemotherapy following surgery can improve prognosis in patients of good performance status as shown by the international adjuvant lung cancer trial and a meta-analysis of 12 randomized controlled trials. Cisplatin-based combination chemotherapy induced a response in 60% and produced a relative risk reduction of 11% with an absolute improvement in 5-year survival for stage II and IIIa disease of 4% from 40.4% to 44.5%.

For unresectable disease, the combination of concurrent cisplatin with radiotherapy (chemoradiation) when compared with radiotherapy alone has increased the resection rate and 3-year survival from 11% to 23% at the expense of greater oesophageal toxicity.

In advanced disease cisplatin or carboplatin in combination with one other drug such as paclitaxel or gemcitabine for 12 weeks produces a symptomatic improvement in 40%, and increases median survival from 6 to 10 months compared with best supportive care, with 10–20% alive at 1 year. Erlotinib inhibits the EGFR tyrosine kinase and can induce responses in 10% of NSCLC particularly in adenocarcinoma in non-smoking women. However gene profiling has yet to be developed to be able to predict responses and target the use of this drug to those patients most likely to benefit.

Small-cell lung cancer

Prognostic factors

The staging of small-cell lung cancer is divided into limited and extensive disease according to whether or not it is confined to a single anatomical area or radiation field. Systemic therapy is the primary therapeutic modality because of the usually disseminated nature of the disease.

Treatment

Limited disease is present in approximately 30% of patients and is best treated with concurrent chemo- and radiotherapy using a combination of cisplatin and etoposide or irinotecan, which increases the survival at 5 years from 15% to 25% compared with radiotherapy alone. A similar degree of

- Oestrogen and progesterone receptor negative
- Positive nodes

improvement can also be achieved with hyperfractionated radiotherapy. Prophylactic whole-brain radiation to prevent cerebral metastases can reduce symptomatic CNS disease and improve overall survival by 5%.

Extensive disease can be palliated with the combination of carboplatin and etoposide or irinotecan, which when compared with best supportive care can increase median survival from 6 months to 9–13 months and 2-year survival to 20%.

Breast cancer

Breast cancer is the most common cancer in women who do not smoke. The screening programme in the UK, with biplanar digital mammography every 3 years in women aged 50–70 and improvements in multimodality treatment, have improved overall survival and rates of cure, while breast-conserving surgery has greatly ameliorated the psychosexual impact of the disease.

Aetiology and pathology

The majority of breast cancers arise from the epithelial cells of the milk ducts and reproduce their histological features in a variety of patterns (Table 9.21), of which the most common is an infiltrating ductal carcinoma. For many cancers it is thought that there is an identifiable precursor in situ stage which is confined within the basement membrane and is still truly localized and detectable by its trade mark microcalcification on a screening mammogram. For others this stage may be so brief or non-existent as to not be detectable and invasive disease is present from very early in development with a consequently worse prognosis. Approximately 10% of women with breast cancer have detectable mutations in the *BRCA 1* and *2* genes and TP53, which account for < 5% of breast cancer (Table 9.22). The hormonal environment exerts a major effect on the expression of the breast cancer potential and is related to reproductive behaviour, diet, exercise, weight, and exogenous hormones from oral contraception and postmenopausal hormone replacement therapy.

Symptoms and signs

Most women with symptomatic rather than screen-detected breast cancer present with a painless increasing mass which may also be associated with nipple discharge, skin tethering, ulceration and, in inflammatory cancers, oedema and erythema. In developing countries, 80% are likely to present with advanced disease and metastases.

Investigations

The triple assessment of any symptomatic breast mass by palpation, radiology (mammography, ultrasound and MRI scan) and fine-needle aspiration cytology is the most reliable way to differentiate breast cancer from the 15 times more common benign breast masses. Large bore core needle biopsy should follow to provide histological confirmation and predictive factors such as grade and oestrogen, progesterone and Her2 receptor status to inform the subsequent decision-making process. Assessment should be carried out in a dedicated one-stop clinic able to provide the appropriate support and referral accordingly. Staging is both surgical with respect to tumour size and axillary lymph node status and, in advanced disease, by investigation of common sites of metastasis by chest X-ray, CT/MRI, bone and liver scan. At present, only 20% of patients are diagnosed with no evidence of microscopic nodal metastases.

Prognostic factors

The following are all significant independent predictors of risk of recurrence: size of the primary tumour; the histological subtype (most are infiltrating ductal carcinoma); histological grade/differentiation; oestrogen and progesterone receptor (ER, PR) status; patient age and menopausal status. Expression of Her2 like ER and PR is a predictor of treatment response.

Gene expression profiles have identified sets of up to 50 genes, the pattern of expression of which can identify low- and high-risk subsets on which to decide adjuvant therapy. However the definitive trial to test the gene-directed therapy has yet to be conducted, in part through the continuing difficulties with the technology and inability to provide reproducible results across different laboratories.

Early breast cancer

The prognosis (10-year survival) can be predicted from the combined effect of the independent prognostic factors in Box 9.9. Survival probability and benefit from adjuvant treatment can be calculated using the website www.adjuvantonline.com that is based on the American Surveillance Epidemiology and End Results (SEER) database and has been validated on independent data sets from British

Columbia and Finland. The estimated 10-year survival probability will vary from 93–99% for small (<1 cm) low-grade node-negative tumours to only 10% for large high-grade tumours with more than nine axillary nodes involved without adjuvant therapy.

Local treatment

Surgery may vary from wide local excision or segmental mastectomy and breast conservation for masses < 4 cm in diameter, to simple mastectomy with or without reconstruction. The choice is dictated by the location and extent of the breast mass in relation to the breast size, and patient preferences. Surgery of the axilla is by sentinel lymph node guided sampling (after dye injection) in the absence of clinical or radiological (usually ultrasound) evidence of lymphadenopathy, or full dissection to level 3 if there are clinically involved nodes in order to gain local control and provide prognostic information to guide adjuvant treatment. The greater the amount of axillary surgery the more the risk of post-operative lymphoedema.

Radiotherapy is given to the conserved breast after wide local excision to reduce local recurrence, and to the chest wall after mastectomy if there are risk factors such as proximity to surgical margins or lymph node metastases, to complete the local control measures. Radiotherapy to the axilla and supraclavicular fossa can be added after sampling but not full dissection of the axilla because the combination raises the risk of severe lymphoedema to 30%. Adjuvant radiotherapy reduces the risk of local recurrence by 25% and improves 10-year survival by 3%.

Recent data suggest that women over 70 years with oestrogen receptor positive cancers up to 2 cm diameter may be offered surgery and tamoxifen alone without radiotherapy, without compromising outcome.

Adjuvant systemic treatment

Endocrine

In about one-third of patients the breast cancer will express receptors for oestrogen and progesterone. Tamoxifen (see p. 463) adjuvant therapy immediately following surgery for *receptor-positive disease* reduces the 10-year relative risk of women dying from breast cancer by about 25% and the absolute 10-year death rate by 12% for all stages.

For *postmenopausal women* with oestrogen and/or progesterone receptor-positive disease, adjuvant tamoxifen or aromatase inhibitors (AIs) such as anastrozole given for 5 years reduces the risk of death from breast cancer by a similar 25%.

The choice between AIs and tamoxifen is the subject of continuing controversy and trials. AIs avoid the adverse effects of tamoxifen on the uterus and venous thromboembolism but add risks of arthralgia and osteoporosis (Table 9.23). Aromatase inhibitors achieve a greater reduction in contralateral breast cancers than tamoxifen and in some trials a reduction in distant metastases contributing to an overall improvement in relapse-free survival which has not as yet produced a survival advantage except in one study of sequential tamoxifen and exemestane. Both tamoxifen and aromatase inhibitors cause symptoms of oestrogen deprivation such as hot flushes and vaginal dryness, but whereas tamoxifen has a beneficial effect upon serum lipid profiles the reverse is true of AIs leading to concerns over their long-term effects on women's cardiovascular health. It is recommended that the choice should be discussed for each patient taking the individual co-morbidities into account.

Table 9.23 Side-effects of endocrine agents for breast cancer in order of frequency

Tamoxifen	Aromatase inhibitors
Hot flushes	Hot flushes
Weight gain	Vaginal dryness
Mood changes	Arthralgia
Vaginal discharge	Skin rash
Thromboembolism	Osteoporosis
Endometrial hyperplasia and neoplasia	Adverse lipid profile

Chemotherapy and biological therapy

A meta-analysis of all randomized trials of adjuvant therapy in breast cancer has shown that for women with high-risk features (Box 9.9) (including receptor-negative), adjuvant chemotherapy with first generation regimens such as CMF (cyclophosphamide, 5-fluorouracil plus methotrexate) for 6 months, reduces the absolute 10-year death rate by about 10% and the relative risk of death by 20%. Ovarian ablation by GnRH analogue for 2 years is equally as effective as CMF chemotherapy in premenopausal women. More effective second generation regimens with epirubicin, (Epi-CMF – cyclophosphamide, methotrexate, 5-fluorouracil) or FEC100 (5-fluorouracil, epirubicin, cyclophosphamide) increase this to 25%. A third generation regimen with a taxane (AC-T (doxorubicin, cyclophosphamide, paclitaxel), FEC-D (fluorouracil, epirubicin, cyclophosphamide followed by docetaxel), TAC (paclitaxel, doxorubicin, carboplatin)) (Table 9.10) gives a 33% relative risk reduction but has increased toxicity. The effects of endocrine therapy are additive to those of chemotherapy and most effective given following, not concurrently with, the chemotherapy.

Menopausal status does not affect the relative efficacy of chemotherapy; however, since the risk of recurrence is lower after the menopause, the absolute improvement in survival is less. Toxicity may also be higher in this age group so that treatment decisions may need to be more individualized in discussion between the patient and her doctors. The combined effect of radiotherapy, chemotherapy and tamoxifen or aromatase inhibitor approximately halves the risk of dying of breast cancer for appropriately selected patients.

Her2/cerbB2 targeted therapy

Three recent trials of the addition of adjuvant IV trastuzumab for a further year to chemotherapy for the treatment of the 25% of patients in whom the breast cancer overexpresses Her2 have all shown a significant reduction in risk of mortality: 25% for trastuzumab alone, and 33% when administered concurrently with a taxane. Trastuzumab has been rapidly adopted as standard of care for these patients but many questions remain to be asked about the schedule of administration, toxicity to the myocardium and comparison with the oral small molecule inhibitors of EGFR such as lapatinib. Trastuzumab has a direct toxic effect upon the myocardium that is additive to pre-existing myocardial damage, especially that caused by anthracyclines, and cannot be given concurrently with them. Left ventricular ejection fraction must be monitored before and during treatment to avoid potentially severe congestive heart failure.

Neoadjuvant and primary systemic treatment

The application of systemic treatment with either endocrine or chemotherapeutic agents as above before surgery has been investigated, on the premise that it would improve survival by preventing the peri-operative release of viable tumour cells into the circulation. However randomized trials have failed to demonstrate a survival advantage when compared with postoperative treatment, i.e. the advantage over surgery alone was the same, but have identified the benefit in either rendering inoperable tumours operable (called primary systemic therapy) or large tumours smaller and suitable for breast conserving surgery in about one-third of such patients (called neoadjuvant therapy).

Advanced breast cancer

Patients with established metastatic disease may require endocrine therapy, chemotherapy and radiotherapy. The treatment is not curative but may be of great palliative benefit and consistent often with many years of good-quality life. Little additional benefit has been gained by adding endocrine and chemotherapy together, although the addition of anti-HER2 (antibodies) to chemotherapy has produced a modest survival advantage. In general, therefore, the serial use of intermittent courses of the different endocrine and chemotherapies starting with the least toxic most effective treatment seems most consistent with maintaining a good quality of life for as long as possible.

Endocrine therapy (see p. 463)

Women who have high levels of oestrogen receptors (ER) and progesterone receptors (PR) in their tumour have a greater chance of responding to endocrine treatments (i.e. 60% versus 10% for ER negative disease).

Endocrine therapy is usually tried first in those patients who have characteristics suggesting they are likely to respond and who do not have immediately life-threatening disease. Remission lasts on average 2 years and is consistent with an excellent quality of life. When relapse occurs, further treatment with alternative agents may produce another remission.

Chemotherapy (see p. 459)

Chemotherapy is used for patients who are unlikely to respond to hormonal treatment or who fail to respond to endocrine therapy or who require a rapid response if at risk of, for example, liver or respiratory failure. If chosen carefully, chemotherapy can provide good-quality palliation and prolongation of life. The drugs listed below are all able to induce objective responses in metatastatic disease and patients in whom the disease responds are likely to experience further serial responses to subsequent treatment at relapse. There is no advantage in combining more than two drugs at a time, and considerable uncertainty over the advantages of combinations with higher response rates but only rarely better survival (e.g. DC vs D) compared with single agent regimens which have the advantage of preserving more options for future use. There is very little difference in efficacy between the different regimens for metastatic disease, with response rates varying from 40% to 60% for median duration of 8–10 months. The most common regimens used include:

- MM – mitoxantrone and methotrexate
- AC/EC – doxorubicin or epirubicin and cyclophosphamide
- DC – docetaxel and capecitabine
- PG – paclitaxel and gemcitabine
- VC – vinorelbine and capecitabine.

The addition of trastuzumab and more recently lapatinib to the cytotoxic drugs (except the anthracyclines – see above) has significantly improved survival for those women whose tumour overexpresses the *c-erbB2/Her2* oncogene. For the remainder current research has identified responses to the inhibition of EGFR and VEGFR by bevacizumab and sunitinib when added to chemotherapy.The regimens do differ in toxicity, with MM being one of the least toxic. The multiple regimens provide the possibility of avoiding drug resistance over several episodes of treatment interspersed with treatment-free periods so that the disease can be palliated, often for several years.

Bisphosphonate therapy

Bone metastases are a common problem in the management of breast cancer, and the bisphosphonates have a major role in reducing the incidence of osteolytic deposits, bone pain and fracture when used preventatively, and in treating pain and hypercalcaemia from established metastases. Second generation bisphosphonates pamidronate and oral clodronate are often sufficient. The more potent third generation drugs such as zoledronate and oral ibandronate may be more effective and require less frequent administration (once every 6 months) but can be associated with impaired bone healing and osteonecrosis of the jaw (see p. 565).

Gastrointestinal cancer

Presentation, diagnosis and local treatments are described in Chapter 6.

Oesophageal cancer

Prognostic factors

Histology, stage, age and performance status are critical prognostic factors for treatment decisions, which should be made by a multidisciplinary team in designated units. The prognosis for the majority of symptomatic patients is poor, 50% have distant metastases at the time of diagnosis and the majority of the remainder will have loco-regional spread into adjacent mediastinal structures. CT-PET scans have improved the selection of patients with truly localized disease for whom curative treatment may be attempted.

Treatment

Neoadjuvant therapy for potentially resectable squamous carcinomas with cisplatin, 5-fluorouracil and concurrent radiotherapy achieves complete remission in 20–40% with a median survival of 19 months and 25–35% of patients alive 5 years after surgery. There is an increased perioperative mortality. Pre- and postoperative chemotherapy with epirubicin, cisplatin and 5FU for adenocarcinomas at the oesophago-gastric junction has improved overall survival for those patients with resectable disease and good performance status with a relative risk reduction of 25% and absolute improvement in 5-year survival by 13% from 23% to 36%.

Locally advanced or metastatic disease can be palliated with 5-fluorouracil or capecitabine chemotherapy in approximately 30%, increasing to 45–55% with the addition of oxaliplatin or irinotecan for a median duration of 6–8 months. Distressing symptomatic problems with dysphagia can be

partially relieved by endoscopic insertion of expanding metal stents to support enteral feeding or percutaneous endoscopic gastrostomy tubes and endoscopic ablation to help control bleeding. In deciding upon such measures the patient and their family understand that it does not improve survival beyond that dictated by the underlying cancer.

Gastric cancer

Presentation and diagnosis and local treatment are described on page 265.

Prognostic factors

The histological grade and staging with respect to the presence of serosal involvement (T3) and nodal involvement (N1–2), and performance status, are the main factors in prognosis. For the majority of patients with node-positive disease the 5-year survival is only 20% following surgery alone.

Treatment

Adjuvant postoperative chemo-radiotherapy with cisplatin and 5-fluorouracil compared with surgery alone showed significantly increased median survival from 28 to 35 months and 3-year survival from 41% to 50%. This was achieved mainly through improvement in loco-regional control but is suitable only for good performance status patients.

Advanced disease may be palliated with chemotherapy such as epirubicin or docetaxel combined with cisplatin and infusional 5-fluorouracil, or oxaliplatin and capecitabine in 40–50% of patients for a median of 8–10 months in good performance status patients. Supportive care for patients with upper GI cancers more than any other site must include careful attention to nutrition with the use of endoscopic stents to relieve obstruction, nasojejunal and percutaneous gastrostomy feeding tubes, and occasionally parenteral nutrition. When the disease progresses beyond active anticancer treatment management of the distressing obstructive symptoms can be helped with palliative medication to reduce secretions and at times a venting gastrostomy.

Colorectal cancer

Presentation and diagnosis and local treatment are described on page 304.

Prognostic factors

The site of the disease, above or below the pelvic peritoneal reflection, TNM stage and performance status are the main prognostic factors (see Table 6.20).

Treatment

Neoadjuvant chemo-radiation treatment of rectal cancers using cisplatin and 5-fluorouracil with radiotherapy has increased the proportion of locally advanced tumours able to be resected with clear surgical margins and reduced local relapse rate but has not improved overall survival compared with postoperative adjuvant treatment. However the preoperative use has much reduced toxicity to the other pelvic structures due to the preservation of the normal anatomical relations.

Adjuvant chemotherapy with 5-fluorouracil and folinic acid or with capecitabine for rectal and colonic adenocarcinoma significantly increases 5-year survival for node-positive disease stage III (Dukes' C) by 5% from 40% to 45%. A further 6% improvement in a recent trial was achieved by the addition of oxaliplatin, and trials are examining the addition of monoclonal antibody to the EGF receptor (cetuximab) or VEGF receptor (bevacizumab).

Advanced colorectal cancer is successfully palliated with little toxicity by 5-fluorouracil and folinic acid regimens in approximately 30% of patients for a median of 12–14 months. The addition of irinotecan or oxaliplatin increases the proportion who benefit to 55% but with increased toxicity. The monoclonal antibody bevacizumab (and possibly cetuximab) increases the response rate to chemotherapy and in one trial the median survival from 14 to 21 months.

Liver metastases are a common problem with colorectal cancers and local treatment can be accomplished with a variety of methods from surgical resection to radiofrequency, and cryo-ablation, or hepatic artery embolization or chemoembolization with chemotherapy laden microspheres. Appropriate selection of the patients who are most likely to benefit through careful restaging by MRI and PET-CT scans to exclude those with extra-hepatic disease and poor performance status is required. Small lesions can be ablated, larger lesions are best managed by partial hepatectomy, or a combination approach so that embolization is followed by hepatic regeneration before final resection. Long-term survival without recurrence is reported in up to 20% of patients at 5 years with a single < 4 cm lesion amenable to resection presenting more than a year from initial diagnosis. Current trials are examining preoperative chemotherapy before hepatic resection.

Epithelial ovarian cancer

Aetiology and pathology

There is uncertainty over the *epithelial tissue* of origin that gives rise to the 80% of all ovarian cancers that are epithelial (Table 9.24). The ovarian surface epithelium of the serosal peritoneum is most likely but others include the epithelial lining of the fallopian tubes. There is a consistent relationship between the risk of epithelial ovarian cancer (EOC) and the frequency and duration of ovulation. While not mechanistically explained this has provided a successful rationale for reducing risk of EOC by up to one-third through early pregnancy and the use of the oral contraceptive pill. The remainder are of germ cell or stromal origin although molecular

biological markers have shown that the category of mixed müllerian sarcoma is misnamed being an entirely epithelial tumour with metaplastic stromal elements.

Symptoms and signs

Ovarian cancer typically causes few specific symptoms, sometimes there is a sensation of a pelvic mass, which may become (acutely) painful, often there is only vague abdominal distension and epigastric discomfort. On examination the majority of patients present with a pelvic mass and advanced stage III (spread within the peritoneal cavity) or IV (extraperitoneal) disease. Screening (see p. 454) by serum CA125 tumour marker and transvaginal ultrasound scan can detect some early cancers and improve survival but at the cost of too many negative laparotomies and is thus still considered a research tool.

Investigation

Pelvic examination should be complemented by a transvaginal ultrasound and serum CA125. MRI is the definitive imaging technique for the pelvis while CT-PET scans assist in staging the patient.

Prognostic factors

Histological subtype (clear cell and mucinous are worse), grade/differentiation, stage, extent of residual disease following surgery, and performance status are all significant independent prognostic factors for survival.

Treatment

Surgery (with total abdominal hysterectomy, bilateral salpingo-oophorectomy and omentectomy) has a major role in the treatment of ovarian cancer. For patients in whom the disease is confined to the ovary, i.e. stage I, the surgery can be curative in 80–90% if the histology is well to moderately differentiated. For patients with poorly differentiated or more advanced disease, with spread throughout the peritoneal cavity, surgery still has a major role in staging the patient and improving survival when it is possible to debulk optimally to <1 cm residual. *Primary chemotherapy and delayed surgery* is an alternative approach currently under investigation and is able to render approximately one-third of inoperable patients fit for optimal debulking surgery.

Carboplatin, which is associated with fewer side-effects than cisplatin, has become the mainstay of epithelial ovarian cancer treatment. Response is achieved in approximately two-thirds of patients. Paclitaxel has been shown to improve the survival of many patients when added to a platinum-based treatment.

Adjuvant treatment with carboplatin and paclitaxel for stage I high-risk disease increases the absolute 5-year survival by 9% from 70% to 79%, and for combined stages I–III completely debulked disease by 19% from 60 to 79%, a relative risk reduction of 29%.

In more advanced disease 75% of patients will respond to combination chemotherapy and the median survival is approximately 3 years. At recurrence further palliative responses can be achieved with carboplatin and paclitaxel if the treatment free interval is >6 months, or liposomal doxorubicin, etoposide and gemcitabine are all active drugs in recurrent disease. Up to 30% of those with metastatic disease may be alive after 5 years, although this falls to 5–10% if the cancer is not able to be debulked at operation or has spread outside the peritoneal cavity. Promising new drugs being investigated are bevacizumab and erlotinib in combination with carboplatin.

Epithelial ovarian cancer tends to remain within the peritoneal cavity often exclusively which has lead to new intraperitoneal routes of administration of treatment with potentially improved survival. However at recurrence bulk disease in the peritoneum commonly causes progressive bowel obstruction which may require palliative operation or expert palliative care support to manage the terminal phases of the illness.

Prostate cancer

Early prostate cancer

Presentation and diagnosis are described on page 645.

Prognostic factors

Diagnosis is usually made on a raised serum PSA (prostate-specific antigen) followed by a transrectal ultrasound guided needle biopsy. The histological appearances are graded and accorded a Gleason Score which together with the height of the serum PSA plus accurate staging of the local extent of disease with pelvic MRI and transrectal ultrasound can identify prognostic groups (Table 9.25). This allows the selection of patients with good prognosis for no active treatment who may reasonably choose to be kept under surveillance and, like 75% of men over the age of 80, die with, but not because of, their prostate cancer.

Treatment

Patients with localized disease requiring treatment can be managed by curative surgery (radical prostatectomy), or external beam radiotherapy, or brachytherapy implants which can achieve equivalent survival rates but differ in the spectrum of unwanted side-effects with respect to incontinence and sexual dysfunction. In appropriately selected series of patients a 5-year survival of 85% can be achieved. Discussion between patient and clinician is vital to enable a treatment choice that is most appropriate to the patient's circumstances.

Adjuvant androgen deprivation treatment such as monthly depot goserelin has not improved the survival following surgery but when given before and during radiotherapy can improve the overall survival at 3 years from 62% to 78%.

Advanced prostate cancer

Treatment

Metastatic prostate cancer with either local or most often osteoblastic skeletal spread is rapidly and effectively palliated in 70% of patients by androgen deprivation through orchidectomy, monthly depot injection of GNRH analogues goserelin or leuprorelin, or androgen receptor blockade with oral flutamide or abiraterone (see p. 646). The median duration of response is 2 years. However, on the development of androgen insensitivity, prostate cancer management must be further tailored to the patient's age, performance status and bone marrow function. These measures include simple steroids and bisphosphonates or docetaxel chemotherapy which can be guided by PSA response to provide some further palliation. Radiotherapy provides very effective palliation for the common problem of painful skeletal metastases and can be delivered by external beam therapy or systemically by intravenous bone-seeking strontium-labelled bisphosphonate for patients with multiple affected sites.

Bone pain can also be reduced with bisphosphonates such as zolendronate, as the metastatic sites comprise a combination of increased osteoclastic and osteoblastic activity.

Testicular and ovarian germ cell tumours

Germ cell tumours are the most common cancers in men aged 15–35 years but comprise only 1–2% of all cancers. They are much less common in women. There are two main histological types, seminoma (dysgerminoma in women) and teratoma. Teratomas may comprise varying proportions of mature and immature elements. Mature teratomas in women present as dermoid cysts with low malignant potential. Germ cell tumours may rarely occur in extragonadal sites in the midline from pituitary, mediastinum or retroperitoneum but should be treated in a similar manner (Table 9.26).

Symptoms and signs

Most men present with a testicular mass which is often painful, some with symptoms of metastases to the para-aortic lymph nodes with back pain. In women the mass presents with vague pelvic symptoms but at a younger age than the more common epithelial ovarian cancers.

Investigations and surgery

- Ultrasound or MRI scanning of the testicle or ovary is required.
- Assay of serum tumour markers, α-fetoprotein (AFP) and β-human chorionic gonadotrophin (β-HCG), and lactic dehydrogenase (LDH).
- CT or MRI scan for distant metastases.
- Surgery for men is by the inguinal approach to avoid spillage of highly metastatic tumour in the scrotum.
- Surgery in women for diagnosis and staging should always be conservative compared to the approach in epithelial ovarian cancer with preservation of fertility because of the efficacy of chemotherapy.

Table 9.26 Germ cell histology: WHO classification

Seminoma
Embryonal cancer
Teratoma mature, immature, or with malignant differentiation
Choriocarcinoma
Endodermal sinus tumour
Mixed teratoma

Treatment

Seminomas

Seminomas are the least common of these tumours and are very radiosensitive and chemosensitive. Seminomas are associated with a raised serum LDH but only rarely a mildly raised HCG and never a raised AFP. Stage I disease limited to the gonad is associated with a 30% risk of recurrence with surgery alone. Adjuvant therapy with either chemotherapy or radiotherapy to the para-aortic lymph nodes leads to greater than 95% cure in early-stage disease but chemotherapy with single-agent cisplatin or carboplatin does not have the long-term risks of secondary malignancy associated with radiotherapy. Combination chemotherapy (e.g. cisplatin, etoposide and bleomycin) will cure 90% of those with visible metastatic disease.

Teratomas

The risk of relapse with stage I disease varies from 5% to 40% depending upon the prognostic factors of histological differentiation and extent of local invasion.

Adjuvant chemotherapy for those at moderate to high risk (e.g. cisplatin, etoposide and bleomycin) leads to a 95% cure rate.

Metastatic disease commonly involves para-aortic lymph nodes and lungs but may spread rapidly (especially if there are trophoblastic (HCG-producing) elements present) and cause life threatening respiratory or other organ failure. HCG is associated with gynaecomastia and should be tested by the urinary pregnancy test in any young male to enable rapid institution of potentially life-saving treatment. About 80% of teratomas will express either HCG or AFP and almost all metastatic disease will be associated with an elevation of the less-specific serum marker LDH.

Chemotherapy cure for metastatic teratoma varies from over 90% for those with small-volume to 40% for those with large-volume metastases and associated rises of AFP > 10 000 and β-HCG > 100 000 IU/L.

Although approximately 20% of men will be infertile due to azoospermia at the time of diagnosis, the majority of the remainder will retain their fertility after chemotherapy and be able to father normal children. Similarly, most women retain their fertility, although less is known about the association with infertility at presentation owing to the much lower frequency of germ cell tumours in women.

Metastatic cancer of unknown primary

Patients presenting with symptoms of their metastases or with an incidental finding on imaging without a clinically obvious primary after investigation represent a common clinical problem and comprise 5–10% of patients in a specialist oncological centre. As a result of several systematic studies, some with post-mortem follow-up, the following guidance

Box 9.10 Adenocarcinoma with unknown primary: primary sites with major treatment benefits

- Breast, e.g. isolated axillary lymphadenopathy
- Ovary, e.g. peritoneal carcinomatosis
- Prostate, e.g. pelvic lymphadenopathy

should aid the choice of appropriate investigation and treatment.

Diagnosis

Diagnosis requires histology first and foremost, as it will lead to the identification of several distinct groups.

1. *Squamous cancers* – mostly presenting in the lymph nodes of the cervical region, 80% will be associated with an occult head and neck primary, the remainder arising from the lung. Inguinal nodes point usually to a primary of the genital tract or anal canal. Treatment with radiotherapy and chemotherapy may have curative potential especially in the head and neck area even in the absence of an identifiable primary on pan endoscopy.
2. *Poorly differentiated or anaplastic cancers* – this group will contain the majority of the curable cancers such as high-grade lymphomas and germ cell tumours identifiable by their immunocytochemistry and tumour markers. Gene markers such as *ip*12 for germ cell tumours and Bcl-2 for lymphomas are increasingly available to aid this diagnosis. Treatment and prognosis is as outlined in the respective primary sites.
3. *Adenocarcinomas* form the majority, and their investigation should be guided by the desire to identify the most treatable options and the knowledge that the largest proportion will have arisen from the lung or pancreas, with relatively poor treatment prospects (Box 9.10). Tissue tumour markers can be helpful (Table 9.27). Investigations should therefore comprise a chest X-ray and abdominal CT scan with, in men, serum PSA and rectal ultrasound to identify prostate cancers, and in women, mammography to identify occult breast cancer, and pelvic CT or MRI to identify ovarian cancer. For good prognosis patients wishing to have palliative chemotherapy, investigations such as endoscopy to identify lung, colon or stomach primaries are indicated to guide the choice of chemotherapy agents, although the diagnostic yield of 4–5% must be set against the discomfort and risks. Serum tumour markers for other solid cancers, although highly sensitive, are too non-specific to be useful as diagnostic aids in this situation.

Further investigation may require MRI for breast and ovarian masses, PET for head and neck, lung and possibly other primaries, and radioisotope scans for thyroid and carcinoid tumours.

Prognosis

The histological type and extent of the disease, and performance status of the patient are the key factors. Most large series report an overall median survival of 12 weeks but considerably better survival amongst the special subgroups such as patients presenting with isolated nodal metastases who have a significantly better prognosis than the majority with visceral and/or bone metastases and may warrant more extensive investigation.

Table 9.27 Adenocarcinoma of unknown primary (ACUP): immunohistochemistry markers of most probable but not exclusive tissue of origin

EMA (epithelial membrane antigen)	Epithelial
LCA (leucocyte common antigen)	Lymphoid
CEA (carcino-embryonic antigen)	Gastrointestinal cancer
CA125 peritoneal antigen	Ovarian cancer
Cytokeratin 7	Positive in breast and ovary, negative in colorectal cancer
Cytokeratin 20	Positive in colorectal, negative in breast and ovary cancer
TTF-1 (thyroid transcription factor)	Lung cancer and thyroid cancer
Thyroglobulin	Thyroid cancer
ER and PR & Her2 receptors	Breast cancer
S100, melanin and HMB45	Melanoma
Myosin, desmin and factor VIII	Soft tissue sarcoma
Chromogranin and NSE (neurone specific enolase)	Neuroendocrine cancers
AFP (alpha fetoprotein)	Germ cell tumours and hepatocellular carcinoma
βHCG (beta human chorionic gonadotrophin)	Germ cell and trophoblastic tumours
CD117	Gastrointestinal stromal tumours

Treatment

In women, an isolated axillary lymph node metastasis should be treated as for lymph-node-positive breast cancer with a similar prospect for long-term cure. Malignant ascites in women should have a trial of chemotherapy as for epithelial ovarian cancer. The prognosis for those responding to the therapeutic trial is similar to the disease of known primary origin. Primary chemotherapy that achieves an excellent response by imaging and CA125 criteria should be followed by debulking surgery with, if successful, a median survival in excess of 4 years.

For men, the occasional occult prostatic cancer found from a raised serum PSA offers some palliative treatment prospects. For the patient presenting with hepatomegaly due to metastases there is an increasing choice and efficacy of chemotherapy agents for gastrointestinal cancers that have the potential to improve their palliation unless due to melanoma.

If there is an excellent response, suitable patients may even be considered for hepatic ablation or resection. If after all efforts no primary has been identified, palliative chemotherapy treatment can achieve responses in 20–40% in highly selected series, with median survivals of 9–10 months and 5–10% surviving to 5 years.

PALLIATIVE MEDICINE AND SYMPTOM CONTROL

Palliative care may be defined as the active total care of patients with advanced, progressive life-shortening disease. The goal of care is to achieve the best possible quality of life for patients and their carers by managing not only physical symptoms, but also psychological, social and spiritual problems. Death is accepted as a normal process and the need to provide support for the family and friends in bereavement is also recognized.

Basic palliative care should be a core skill for all healthcare providers. There is increasing recognition that good palliative and supportive care can be given alongside disease-specific treatments, for example, radio/chemotherapy in patients with cancer or cardiac medication in patients with heart failure. An 'either/or' approach should be avoided. A problem-based approach that would ensure patients' access to support services, including the multi-professional specialist palliative care services for symptoms with complex aetiology, is preferred. This seems to be a major factor in appropriate supportive and palliative care in patients with non-malignant disease where referral is often left too late if palliative care is only seen as relevant for the immediate end-of-life.

In malignant disease, there is good evidence that integration of palliative care and antitumour management earlier on in the course of disease reduces long-term distress.

Good communication between doctor, patient, carer and members of the healthcare team is vital, with a shared understanding of the problems that underpin the whole approach. Assessment of the patient's understanding of disease and their wishes for future care, with acknowledgment of their concerns, will help the team plan effective support for the future. The aim is to enable the patient to be cared for and to die in the place of their choice. Good liaison between hospital, primary care and hospice is needed to allow this to happen. It is also necessary to recognize that patients will have differing needs for information, and will deal with bad news in different ways, some ways more helpful than others. A sensitive approach respecting the individual is key.

The importance of symptom assessment

A patient's symptoms are often multifactorial and a holistic assessment is imperative in order to manage them properly. The following section deals primarily with just the physical treatments.

Pain

Pain is a feared symptom and at least two-thirds suffer significant pain throughout the course of their disease. Pain may be due to a number of different causes and not all pains respond equally well to opioid analgesics (Fig. 9.18). The pain may not be directly related to the tumour, but rather indirectly, for example due to weight loss or pressure sores, or due to a co-morbidity such as arthritis. Remember that emotional and spiritual distress may be expressed as, or exacerbate, physical pain, and therefore are unlikely to respond well to opioid analgesics.

The concept of 'total pain' indicates that pain can be due to or made worse by various factors:

- Biological – from the cancer itself, therapy (drugs, surgery, radiotherapy).
- Social – financial problems from loss of job, anxiety in family and friends, loss of independence.
- Psychological – fear of dying, pain or being in hospital; anger that you are dying or at the process of diagnosis and delays; depression from all of above.

The WHO analgesic ladder

The cancer pain relief ladder guides the choice of analgesic according to pain *severity*:

Box 9.11 Drugs used for adjuvant pain relief

Drugs	Indication
NSAIDs, e.g. diclofenac	Bone pain, inflammatory pain
Anticonvulsants, e.g. gabopentin/pregabalin	Neuropathic pain
Tricyclic antidepressants, e.g. amitriptyline	Neuropathic pain, depression
Bisphosphonates, e.g. disodium pamidronate	Metastatic bone disease
Dexamethasone	Headache from cerebral oedema due to brain tumour

- *Mild pain*: non-opioid, e.g. paracetamol, ± adjuvant (Box 9.11)
- *Moderate pain*: simple analgesic, e.g. paracetamol, + weak opioid, e.g. codeine or tramadol.
- *Severe pain*: strong opioids, e.g. morphine, ± non-opioid ± adjuvant.

If regular use of optimum dosing (such as paracetamol 1 g × 4 daily for step 1) does not control the pain then an analgesic from the next step should be given. As pain may be due to different physical *aetiologies*, an appropriate adjuvant analgesic may be needed in addition to, or instead of, an analgesic ladder drug, for example, neuropathic pain may need a tricyclic antidepressant adjuvant (see below) such as amitriptyline (Box 9.11).

Strong opioid drugs

Morphine is the drug of choice and in most circumstances should be given regularly by mouth. The dose should be tailored to the individual's needs by allowing 'as required' doses; morphine does not have a 'ceiling' effect. If a patient has needed additional doses to the regular doses, then the amount can be included in the following day's regular dose until that requirement is stable – a process called 'titration'. When the stable daily dose requirement is established, the morphine can be changed to a sustained-release preparation. For example:

20 mg morphine elixir 4-hourly
=120 mg morphine per day
=60 mg twice-daily of a 12-hour preparation
or 120 mg daily of a 24-hour preparation

The starting dose of morphine will be between 5 and 10 mg every 4 hours depending on patient size, renal function and whether they are already taking a weak opioid. If there is significant renal dysfunction, morphine should be used in low doses because of the risk of metabolite accumulation (it is renally excreted). In this circumstance an alternative opioid such as fentanyl can be given by the buccal or transdermal route, e.g. 72 hour self-adhesive patches. This can be used for breakthrough pain.

If a patient is unable to take medication due to weakness, swallowing difficulties or nausea and vomiting, the opioid should be given parenterally. For cancer patients who are likely to need continuous analgesia, continuous subcutaneous infusion is the preferred route. Diamorphine is used most commonly in the UK because its high solubility enables syringe volumes to be kept to a convenient level even with high doses.

Doctors are often worried about addiction to opioids and therefore do not prescribe adequate analgesia for pain. In fact, addiction is very rare with the risk of iatrogenic addiction being <0.01%.

Side-effects and toxicity

The most common side-effects are of *nausea and vomiting*. In the majority of patients this can be managed or prevented with antiemetics (such as metoclopramide). Some of these can be given mixed with the diamorphine, e.g. haloperidol, metoclopramide, cyclizine in the same syringe, although precipitation can occur with high doses. Constipation is common and nearly always occurs with opioids and should be anticipated with lactulose, senna or co-danthramer administration. Unacceptable side-effects may persist in a small proportion of patients, and a change to a different opioid may be needed.

Confusion, persistent and undue *drowsiness, myoclonus, nightmares* and *hallucinations* indicate opioid toxicity. Sometimes this is due to over-rapid dose escalation and usually responds to dose reduction and slower re-titration. It may be due to poorly opioid responsive pain and indicates a need for adjuvant analgesics. Antipsychotics such as haloperidol may help settle the patient's distress whilst waiting for resolution of toxicity. Some patients will tolerate an alternative opioid better, e.g. oxycodone, or, if necessary by subcutaneous injection.

Adjuvant analgesics (Box 9.1)

Not all pains respond completely to opioids and additional or alternative approaches are required. The most commonly used adjuvants are:

- Non-steroidal anti-inflammatory drugs (NSAIDs) used in addition to opioids in bone pain.
- Tricyclic antidepressants (e.g. amitriptyline 10–75 mg daily) and anticonvulsants (e.g. gabapentin 600–2400 mg daily or pregabalin 150 mg at start, increasing up to 600 mg daily) for neuropathic pain.
- Steroids for nerve and inflammatory pains such as liver capsule pain. It may also be used to help the headache of raised intracranial pressure.
- Other headache treatments such as radio/chemotherapy, anaesthetic or neurosurgical intervention, acupuncture and TENS may be useful in selected patients.

Regular review is necessary to achieve optimal pain control, including regular assessment to distinguish pain severity from pain distress.

Gastrointestinal symptoms

- ***Anorexia, weight loss, malaise and weakness*** form the troublesome cancer-cachexia syndrome of advanced disease which carries a poor prognosis. Although attention to nutrition is necessary, the syndrome is mediated through chronic stimulation of the acute phase response, and specifically secreted tumour substances (e.g. lipid mobilizing factor and proteolysis inducing factor). Thus calorie-protein support alone gives very limited benefit, and parenteral feeding has

Ask the authors
www.studentconsult.com

been shown to make no difference to patient survival or quality of life. There is a small and evolving evidence base for specific therapies such as eicosapentanoic acid (EPA) fish oil, COX inhibition with an NSAID and antioxidant treatment, but currently, unless the patient is fit enough for, and responds to antitumour therapy, management is supportive. Some patients may benefit from a trial of a food supplement that contains EPA and antioxidants. Until very recently progesterones or corticosteroids were recommended and are still commonly used as an appetite stimulant, but it is increasingly recognized that weight gain is usually fluid, and particularly in the case of corticosteroids, muscle catabolism is accelerated. Also any benefit in appetite stimulation tends to be short-lived. Thus their use should be limited to short-term only, if at all, for this indication.

- ***Nausea and vomiting***. This is a common symptom, often due to opioid therapy being given without an antiemetic such as haloperidol 1.5 mg × 1–2 daily or metoclopramide 10–20 mg × 3 daily. When associated with chemotherapy, patients should have an antiemetic, starting with metoclopramide, but if the risk of nausea and vomiting is high, give a specific $5HT_3$ antagonist, e.g. ondansetron 8 mg orally or by slow i.v. injection. For most chemical causes of these symptoms, e.g. due to hypercalcaemia, haloperidol 1.5–3 mg daily is the first choice. Metoclopramide is also a prokinetic and therefore useful for emesis due to gastric stasis or constipation. Cyclizine 50 mg × 3 daily is also used.
- ***Gastric distension*** due to pressure on the stomach by the tumour (squashed stomach syndrome) is treated with an antacid and an antiflatulent, e.g. simeticone or with domperidone 10 mg × 3 daily.
- ***Persistent hiccups*** are treated with metoclopramide.
- ***Bowel obstruction***. Metoclopramide should be avoided in complete bowel obstruction where an antispasmodic such as hyoscine butylbromide (60–120 mg/24 hours) is the preferred choice. Control of vomiting in bowel obstruction may also need the addition of octreotide (a somatostatin analogue) to dry up gut secretions thus reducing the volume of vomitus, or physical measures such as defunctioning colostomy or placing of a venting gastrostomy. Occasionally, a lower bowel obstruction may be amenable to resolution by insertion of a stent, or transrectal resection of tumour. Steroids may shorten the length of episodes of obstruction if resolution is possible. In a palliative situation the patient should be allowed to drink and take small amounts of soft diet as they wish. With good mouth care, the sensation of thirst is often avoidable, thus preventing the need for parenteral fluids.

For any cause of vomiting, it may be necessary to start antiemetic therapy parenterally by continuous subcutaneous infusion to gain control of the symptom, and if the patient has gastrointestinal obstruction, this route may need to be continued.

Respiratory symptoms

Breathlessness remains one of the most distressing symptoms in palliative care. Full assessment and active treatment of all reversible conditions, such as drainage of pleural effusions, optimization of treatment for heart failure or chronic pulmonary disease is mandatory. There is often a panic–breathlessness cycle and many patients fear they will die in an acute episode. Reassurance that this is unlikely should be given. Non-pharmacological approaches such as pacing, prioritizing, breathing training, anxiety management and the use of a hand-held fan are helpful. There is little evidence to suggest that correction of hypoxaemia helps the *sensation of breathlessness* and oxygen should only be used with careful consideration of an individual patient rather than used as a blanket panacea. Opioid drugs have been shown to be useful although current evidence suggests there is no advantage with nebulized opioids. Likewise, if panic/anxiety plays a significant part, a quick-acting benzodiazepine such as lorazepam (used sublingually for rapid absorption) may be useful. Care should be taken because of the risk of poor memory and falling. The risk of respiratory depression appears to be less of a concern than previously thought.

Persistent unproductive *cough* is another troublesome symptom that can be helped by opioids (codeine or morphine elixir) due to an antitussive effect. Methadone linctus should be avoided because of its long duration of action. Excessive respiratory secretions can be treated with hyoscine hydrobromide 400–600 µg every 4–8 hours but does give a dry mouth. Glycopyrronium is also useful by subcutaneous infusion of 0.6–1.2 mg in 24 hours.

Other physical symptoms

Patients with cancer may develop other physical symptoms that are caused directly by the tumour (e.g. hemiplegia due to brain secondaries) or indirectly (e.g. bleeding or venous thromboembolism due to disturbances in coagulation). Symptoms may also result from treatment, such as lymphoedema following treatment for breast or vulval cancer, or heart failure secondary to anthracycline chemotherapy. The principles of holistic assessment, reversal of reversible factors and appropriate involvement of the multiprofessional team should be applied.

Non-physical issues

Depression is a common feature of life-limiting and disabling illness and is often missed or dismissed as ‘understandable’. However, it may well respond to usual drug and/or non-drug measures such as cognitive behavioural therapy, and make a big difference to quality of life and the ability of the patient to cope with their situation.

Extending palliative care to patients with non-malignant disease

Specialist palliative care services have traditionally grown up around cancer patients. There is increasing recognition that patients with chronic non-malignant disease such as organ failures (heart, lung and kidney), degenerative neurological disease and infectious disease (HIV) have a similar need, and benefit from a palliative care approach and access to specialist services for complex problems. There may be a less clear end-stage of disease, but the principles of symptom control are the same: holistic assessment,

reversal of reversible factors and multiprofessional support. The management as outlined above is largely transferable with some exceptions (e.g. amitriptyline and NSAIDs are contraindicated in heart failure). Joint working with the relevant consultant involved, e.g. cardiologist, allows optimization of tolerated disease-directed medication as well as palliative care. Clear communication about the stage of disease allows patients the ability to make choices about the end-of-life and to access supportive and palliative care. Discussion of difficult choices is particularly helpful for patients with neurological disease where the question of gastrostomy feeding in the event of loss of swallowing is easier to answer if this is addressed before the patient loses the ability to speak clearly, or loses mental competence to make decisions about their own healthcare.

The patient-orientated principles of palliative medicine can be usefully applied throughout all medical practice so that all patients, irrespective of care setting (home, hospital or hospice) receive appropriate care from the staff looking after them, and have access to specialist palliative services for complex issues.

In summary:

- Patients should always be involved in decisions about their care.
- The quality of life is increased when the goals of treatment are clearly understood by everyone including the patient and carer.
- The multidisciplinary team can provide a high standard of care but there must be realism and honesty at what can be achieved.
- Hospitalization is sometimes necessary but end-of-life care is often delivered in hospices.
- However care at home should be encouraged for as long as possible.

RHEUMATOLOGICAL AND MUSCULOSKELETAL DISORDERS

Many common locomotor problems are short-lived and self-limiting or settle with a course of simple analgesia and/or physical treatment; for example, physiotherapy or osteopathy. However, they represent 20–30% of the workload of the primary care physician, where non-inflammatory problems predominate. Recognition and appropriate early treatment of many painful rheumatic conditions may help reduce the incidence of chronic pain disorders. Early recognition and subsequent treatment of inflammatory arthritis by specialist multidisciplinary teams leads to better symptom control and prevents long-term joint damage and disability. A wide selection of pamphlets and websites offer helpful advice for patients, and their use should be encouraged. Most of the musculoskeletal diseases are seen world-wide, although the prevalence of individual conditions varies.

THE NORMAL JOINT

There are three types of joints – fibrous, fibrocartilaginous and synovial.

Fibrous and fibrocartilaginous joints

These include the intervertebral discs, the sacroiliac joints, the pubic symphysis and the costochondral joints. Skull sutures are fibrous joints.

Synovial joints (Fig. 10.1)

These include the ball-and-socket joints (e.g. hip) and the hinge joints (e.g. interphalangeal).

They possess a cavity and permit the opposed cartilaginous articular surfaces to move painlessly over each other. Movement is restricted to a required range, and stability is maintained during use. The load is distributed across the surface, thus preventing damage by overloading or disuse.

Synovium and synovial fluid. The joint capsule, which is connected to the periosteum, is lined with synovium which is a few cells thick and vascular. Its surface is smooth and non-adherent and is permeable to proteins and crystalloids. As there are no macroscopic gaps, it is able to retain normal joint fluid even under pressure. Macrophages and fibroblast-like synoviocytes form the synovial layer by cell-to-cell interactions mediated by cadherin-II. The synoviocytes release hyaluronan into the joint space, which helps to retain fluid in the joint. Synovial fluid is a highly viscous fluid secreted by the synovial cells and has a similar consistency to plasma. Glycoproteins ensure a low coefficient of friction between the cartilaginous surfaces. Tendon sheaths and bursae are also lined by synovium.

Juxta-articular bone

The bone which abuts a joint (epiphyseal bone) differs structurally from the shaft (metaphysis) (see Fig. 10.31). It is highly

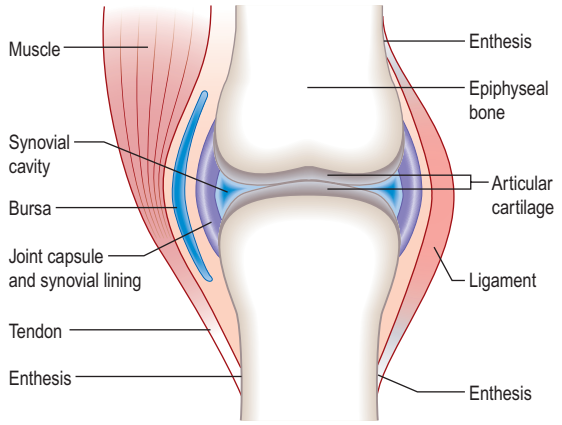

Fig. 10.1 **Normal synovial joint.**

vascular and comprises a light framework of mineralized collagen enclosed in a thin coating of tougher, cortical bone. The ability of this structure to withstand pressure is low and it collapses and fractures when the normal intra-articular covering of hyaline cartilage is worn away – as, for example, in osteoarthritis (OA). Loss of surface cartilage also leads to the abnormalities of bone growth and remodelling typical of OA (see p. 518).

Hyaline cartilage

This forms the articular surface and is avascular. It relies on diffusion from synovial fluid for its nutrition. It is rich in type II collagen that forms a meshwork enclosing giant macromolecular aggregates of proteoglycan. These heterogeneous macromolecules comprise protein chains (aggrecans) to which are attached side-chains of the carbohydrates keratan and chondroitin sulphate. These molecules retain water in the structure by producing a dynamic tension between the retaining force of the collagen matrix and the expansive effect of osmotic pressure. Intermittent pressure from 'loading' of the joint is essential to normal cartilage function and encourages movement of water, minerals and nutrients between cartilage and synovial fluid. Chondrocytes secrete collagen and proteoglycans and are embedded in the cartilage. They migrate towards the joint surface along with the matrix they produce.

Ligaments and tendons

These structures stabilize joints. Ligaments are variably elastic and this contributes to the degree of stiffness or laxity of joints (see p. 554). Tendons are inelastic and transmit muscle power to bones. The joint capsule is formed by intermeshing tendons and ligaments. The point where a tendon or ligament joins a bone is called an *enthesis* and may be the site of inflammation.

Components of extracellular matrix

All connective tissues contain an extracellular matrix of macromolecules – collagens, elastins, non-collagenous glycoproteins and proteoglycans – in addition to cells, e.g. synoviocytes. There are several different types of cell surface receptors that bind extracellular matrix proteins including the integrins, CD44 and the proteoglycan family of receptors, e.g. *syndecans*.

Collagens. Collagens consist of three polypeptide chains (alpha chains) wound into a triple helix. These alpha chains contain repeating sequences of Gly–x–y triplets, where x and y are often prolyl and hydroxyprolyl residues. Collagen fibres show considerable genetic heterogeneity, with genes on at least 12 chromosomes. The majority of collagen in the body is type I – the major component of bone, tendon, ligament, skin, sclera, cornea, blood vessels and the hollow organs. Types III, V and VI are also present in most tissues although little collagen type III is found in bone or cartilage. Other types of collagen are tissue specific, i.e. types II, IX, X and XI are found in hyaline cartilage, type IV and XVII in basement membrane and type VII in anchoring structures at junctions between epithelium and mesenchyme. There are several classes of collagen genes, based on their protein structures, and abnormalities of these may lead to specific diseases (see p. 568).

Elastin is an insoluble protein polymer and is the main component of elastic fibres. Tropoelastin, its precursor, is synthesized by vascular smooth muscle cells and skin fibroblasts. Cross-linkages with desmosine and isodesmosine are specific to elastin fibres.

Glycoproteins. Fibronectin is the major non-collagenous glycoprotein in the extracellular matrix. Its molecule contains a number of functional domains, or cell recognition sites that bind ligands and are involved in cellular adhesion. A peptide sequence (*Arg–Gly–Asp*), which mimics some of the functions of fibronectin, is also found in other adhesion proteins (e.g. vitronectin, laminin and collagen type VI). Fibronectin plays a major role in tissue remodelling. Its production is stimulated by interferon-gamma and by transforming growth factor-beta and inhibited by tumour necrosis factor and interleukin-1.

Proteoglycans. These proteins contain glycosaminoglycan (GAG) side-chains and are of variable form and size. Many have been identified at different sites in connective tissue, e.g. aggrecan, biglycan, fibromodulin, decorin (in extracellular matrix), syndecan, CD44, fibroglycan (on cell surfaces), cerebroglycan (in brain), serglycan (in intracellular tissues) and perglycan (in basement membranes). Their function is to bind extracellular matrix together, retain soluble molecules in the matrix and assist with cell binding. Abnormalities of any of these structures may lead to periarticular or articular symptoms and/or predispose to the development of arthritis.

Joint sensation

The ligaments, periosteum, synovial tissue and capsule of the joint are richly supplied by blood vessels and nerves. Pain usually derives from inflammation of these sites because the synovial membrane is relatively insensitive.

Connective tissue degradation

Connective tissue undergoes repair and re-modelling by enzymes (mainly matrix metalloproteinases, MMPs) which require zinc and act at a neutral pH. There are several MMPs which act on different collagens, e.g. the gelatinases (MMP-2 and -9), which degrade denatured collagen. MMPs also act on non-collagen proteins, e.g. the stromelysins (MMP-3, -10, -11), which degrade proteoglycans and fibronectin. Other members of the MMP group include ADAMs (**a** **d**isintegrin **a**nd a **m**etalloproteinase) which are localized to the cell surface and play a role in matrix degradation.

The turnover of normal collagen is initiated by cytokines, e.g. interleukin-1 synthesized by chondrocytes. Activation of latent MMPs and tissue plasminogen activator then occurs.

Two inhibitors, TIMP (**t**issue **i**nhibitor of **m**etallo**p**roteinase) and plasminogen activator inhibitor-1 (PAI-1), inhibit degradation during matrix remodelling.

Skeletal muscle

This consists of bundles of myocytes containing actin and myosin molecules. These molecules interdigitate and form myofibrils which cause muscle contraction in a similar way to myocardial muscle (p. 683). Bundles of myofibrils (fasciculi) are covered by connective tissue, the perimysium, which merges with the epimysium (covering the muscle) and forms the tendon which attaches to the bone surface (enthesis).

CLINICAL APPROACH TO THE PATIENT

TAKING A MUSCULOSKELETAL HISTORY

The following questions are helpful in assessing the problem and making a diagnosis. A history can often lead to a diagnosis as pattern recognition is the key to diagnosis in rheumatic diseases.

Pain

- *Where is it? Is it localized or generalized?* The pattern of joint involvement is a useful clue to the diagnosis (e.g. distal interphalangeal joints in osteoarthritis).
- *Is it arising from joints, the spine, muscles or bone?* Soft tissue lesions and inflamed joints are locally tender.
- *Could it be referred from another site?* Joint pain is localized but may radiate distally – shoulder to upper arm; hip to thigh and knee.
- *Is it constant, intermittent or episodic? How severe is it – aching or agonizing?* For example, the pain of gout, or of septic arthritis in a previously fit, non-immunocompromised patient is agonizing. Joint pain and swelling lasting a day or so may indicate palindromic rheumatism, whilst longer bouts of a few days are typical of untreated gout or pseudogout. Constant pain, especially pain at night, may be due to an underlying malignancy.
- *Are there aggravating or precipitating factors?* For example:
  - Mechanical problems are made worse by activity and eased by rest.
  - Inflammatory joint and spine pain are worse after rest and improve with activity.
  - Trauma is a common cause of musculoskeletal pain.
- *Are there any associated neurological features?* Numbness, pins and needles and/or loss of power suggest 'nerve' involvement. Examples include carpal tunnel syndrome (see p. 508) or a spinal problem such as disc prolapse (p. 510). Nerve root pain, such as that due to a disc prolapse, reflects the anatomical distribution of the affected root.

Stiffness

- *Is it generalized or localized*? Spine or joint stiffness is common after injury.
- *Does it affect the limb girdles or periphery?*
- *Is it worse in the morning and relieved by activity?* Joints that are stiff for more than 15 minutes each morning are usually inflamed – think of rheumatoid arthritis (RA) (see p. 525) or another cause of inflammatory arthritis. Spinal stiffness and pain which is much worse in the morning may indicate ankylosing spondylitis (p. 533), especially in patients in their twenties or thirties. Shoulder and pelvic girdle stiffness and pain, which are worse in the morning in a patient over 55 years, may be polymyalgia rheumatica (p. 549).

Swelling

- *Is it of one joint, or of several*? Look for symmetry or asymmetry, and/or a peripheral or proximal pattern; these are clues to the type of arthritis. Rheumatoid arthritis is typically polyarticular. An acute monoarthritis may be due to trauma, gout (in a middle-aged male) or sepsis (fever or immunosuppression).
- *Is it constant or episodic*?
- *Are episodes of swelling short-lived, or longer*?
- *Is there associated inflammation (redness and warmth)*?

Gender

Gout (see p. 536), reactive arthritis (p. 535) and ankylosing spondylitis (p. 532) are more common in men. Rheumatoid arthritis and other autoimmune rheumatic diseases are more common in women.

Age

- *Is the person young, middle-aged or older?* Injury is common in young people but can occur at any age.
- *How old was the patient when the problem first started?* Osteoarthritis (see p. 518) and polymyalgia rheumatica (p. 549) rarely affect the under-fifties. Rheumatoid arthritis starts most commonly in women aged 20–50 years.

General health

- *Is there any associated ill-health or other worrying feature, such as weight loss or fever?* Systemic illness is a common feature of many rheumatic diseases. If there is weight loss and/or fever, think of autoimmune rheumatic disease, sepsis (joint infection may be due to septicaemia and is a medical emergency) or malignancy.
- *Are there other associated medical conditions that may be relevant?* Psoriasis (see p. 1240) or inflammatory bowel disease is associated with asymmetrical arthritis. Charcot's joints (p. 555) are seen in diabetics.

Medication

Could a drug be a cause? Diuretics may precipitate gout in men and older women. Hormone replacement therapy or the oral contraceptive pill may precipitate systemic lupus erythematosus (SLE) (p. 541). Steroids can cause avascular necrosis. Some drugs cause a lupus-like syndrome (p. 542).

Race

Is this relevant? Sickle cell disease causes joint pain in young black Africans, but osteoporosis (see p. 560) is uncommon in older black Africans.

Past history

Have there been any similar episodes or is this the first? Are there any clues from previous medical conditions? Gout is

recurrent; the episodes settle without treatment in 7–10 days. Acute episodes of palindromic rheumatism may predate the onset of rheumatoid arthritis (see p. 525).

Family history

Does anyone in the family have a similar problem or another related disorder? Osteoarthritis may be familial. Seronegative spondyloarthropathies (see p. 532) are seen in families with a history of arthritis, psoriasis, ankylosing spondylitis, iritis or inflammatory bowel disease. Autoimmunity has a familial tendency.

Occupational history

What job does the patient do? This can be a factor in soft tissue problems and osteoarthritis (e.g. in heavy labourers and dancers). Work-related problems, particularly in those who use a keyboard, are becoming more common and are complained of more.

Psychosocial history

The biopsychosocial model of disease is highly relevant to many rheumatic disorders:

- *Has there been any recent major stress in family or working life? Could this be relevant?* Stress rarely causes rheumatic disease but may precipitate a flare-up of inflammatory arthritis. Stress also tends to reduce a person's ability to cope with pain or disability. Remember that the diagnosis of a chronic arthritis has a major influence on the lifestyle of patients and their families. The extent of disability should be noted.
- *Has there been an injury for which a legal case for compensation is pending*?

Extent of disability

The World Health Organization describes the impact of disease on an individual in terms of:

- *Impairment*: any loss or abnormality of psychological or anatomical structure or function.
- *Disability* (activity limitation): any restriction or lack of ability to perform an activity in the manner or within the range considered normal for a human being.
- *Handicap* (participation restriction): a disadvantage for an individual resulting from an impairment or disability that limits or prevents the fulfilment of a role that is normal for that individual.

The patient's own perception of limitation must be taken into account during assessment, as well as the impact of physical causes due to disease. Subjective and objective assessments must be made. Quality of life (QoL) involves physical and psychosocial factors. The aim of treatment is to reduce or cure physical and/or psychological disease and to reduce the impact of any impairment or disability on the individual. A variety of different standard questionnaires can be used to assess pain, disease impact and outcome (e.g. Health Assessment Questionnaire (HAQ), Arthritis Impact Measurement Scale (AIMS)).

EXAMINATION OF THE JOINTS

Always observe a patient, looking for disabilities, as he or she walks into the room and sits down. General and neurological examinations are often necessary. Guidelines for rapid examinations of the limbs and spine are shown in Practical box 10.1.

Examining an individual joint involves three stages – looking, feeling and moving:

- *Appearance*. Look at it for swelling, rash or erythema, muscle wasting, deformity such as a distal bone displaced laterally as in knock knees (genu valgus) or bowed legs (genu varus), fixed flexion or hyperextension, loss of normal range and lack of fluidity of movement, and any pain caused by movement.
- *Feel* it for tenderness, warmth (indicates inflammation) and swelling which may be due to fluid, soft tissue or bone. Common descriptors are 'fluctuant' (fluid), 'firm' or 'boggy' (swelling of the synovium), and 'hard' (bony).

Practical Box 10.1 Rapid examinations of the limb and spine

Rapid examination of the upper limbs

- *Raise arms sideways to the ears (abduction). Reach behind neck and back.* Difficulties with these movements indicate a shoulder or rotator cuff problem.
- *Hold the arms forward, with elbows straight and fingers apart, palm up and palm down.* Fixed flexion at the elbow indicates an elbow problem. Examine the hands for swelling, wasting and deformity.
- *Place the hands in the 'prayer' position with the elbows apart.* Flexion deformities of the fingers may be due to arthritis, flexor tenosynovitis or skin disease. Painful restriction of the wrist limits the person's ability to move the elbows out with the hands held together.
- *Make a tight fist.* Difficulty with this indicates a loss of flexion or grip. Grip strength can be measured.

Rapid examination of the lower limbs

- *Ask the patient to walk* a short distance away from and towards you, and to stand still. Look for abnormal posture or stance.
- *Ask the patient to stand on each leg.* Severe hip disease causes the pelvis on the non-weight-bearing side to sag (positive Trendelenburg test).
- *Watch the patient stand and sit,* looking for hip and/or knee problems.
- *Ask the patient to straighten and flex each knee.*
- *Ask the patient to place each foot in turn on the opposite knee with the hip externally rotated.* This tests for painful restriction of hip or knee. Abnormal hips or knees must be examined lying.
- *Move each ankle up and down.* Examine the ankle joint and tendons, medial arch and toes whilst standing.

Rapid examination of the spine

Stand behind the patient.

- *Ask the patient to (a) bend forwards to touch the toes with straight knees, (b) extend backwards, (c) flex sideways, and (d) look over each shoulder, flexing and extending and side-flexing the neck.* Observe abnormal spinal curves – scoliosis (lateral curve), kyphosis (forward bending) or lordosis (backward bending). A cervical and lumbar lordosis and a thoracic kyphosis are normal. Muscle spasm is worse whilst standing and bending. Leg length inequality leads to a scoliosis which decreases on sitting or lying (the lengths are measured lying).
- *Ask the patient to lie supine.* Examine any restriction of straight-leg raising (see disc prolapse, p. 511).
- *Ask the patient to lie prone.* Examine for anterior thigh pain during a femoral stretch test (flexing knee whilst prone), which indicates a high lumbar disc problem.
- *Palpate* the spine and buttocks for tender areas.

- *Movement*. Move it to assess the passive range of movement (e.g. flexion, extension, abduction, adduction and rotation), any instability, or the production of pain and crepitus (grating) seen with cartilage damage. The normal range varies between individuals. Comparing right with left and asking the patient about any change in range help to assess whether the endpoints are normal or not. A screening examination of the locomotor system, known by the acronym GALS (global assessment of the locomotor system) has been devised.

X-ray of the joint often forms an integral part of the examination.

INVESTIGATIONS

Investigations are unnecessary in many of the common regional musculoskeletal problems and osteoarthritis (OA); the diagnosis is clear from the history and examination findings. Tests help to exclude another condition and to reassure the patient or their primary care physician.

Useful blood screening tests

- **Full blood count**
  Haemoglobin. Normochromic, normocytic anaemia occurs in chronic inflammatory and autoimmune diseases. Hypochromic, microcytic anaemia indicates iron deficiency, sometimes due to non-steroidal anti-inflammatory drug (NSAID) induced gastrointestinal bleeding.
  White cell count. Neutrophilia is seen in bacterial infection (e.g. septic arthritis). It also occurs with corticosteroid treatment. Lymphopenia occurs with viral illnesses or active systemic lupus erythematosus (SLE). Neutropenia may reflect drug-induced bone marrow suppression. Eosinophilia is seen in the Churg–Strauss syndrome (p. 870).
  Platelets. Thrombocythaemia occurs with chronic inflammation. Thrombocytopenia is seen in drug-induced bone marrow suppression.
- **Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).** An increase of these reflects inflammation and acute phase reactants. Plasma viscosity is also raised in inflammatory disease and measured in some laboratories in place of the sedimentation rate.
- **Bone and liver biochemistry.** A raised serum alkaline phosphatase may indicate liver or bone disease. A rise in liver enzymes is seen with drug-induced toxicity. For other investigations of bone, see page 559.

Other blood and urine tests

- *Protein electrophoretic strip (and/or immunofixation) and urinary Bence Jones protein* – to exclude myeloma as a cause of a raised ESR.
- *Serum uric acid* – for gout.
- *Antistreptolysin-O titre* – in rheumatic fever.

Serum autoantibody studies

- **Rheumatoid factors (RFs)** (see also p. 524)**.** IgM rheumatoid factors were detected by agglutination tests using IgG-coated latex particles (the Rose–Waaler test) or sensitized sheep red cells (sheep cell agglutination test or SCAT) but increasingly the ELISA technique is being used. RFs are antibodies (usually IgM, but also IgG or IgA) against the Fc portion of IgG. They are detected in 70% of patients with rheumatoid arthritis (RA), but are not diagnostic. RFs are detected in many autoimmune rheumatic disorders (e.g. SLE), in chronic infections, and in asymptomatic older people (Table 10.1).
- **Cyclic citrullinated peptide antibodies (anti-CCP).** These are measured by an ELISA technique and are present in up to 80% of patients with RA. They have a high specificity for RA (90% with a sensitivity of 60%). They are helpful in early disease when the RF is negative to distinguish it from acute transient synovitis (see Box 10.6, p. 525). Both RF and anti-CCP are positive in established RA in more than 90% of patients.
- **Antinuclear antibodies (ANAs).** These are detected by indirect immunofluorescent staining of fresh-frozen sections of rat liver or kidney or Hep-2 cell lines. Different patterns reflect a variety of antigenic specificities that occur with different clinical pictures (see Box 10.11, p. 544). ANA is used as a screening test for SLE, but low titres occur in RA and chronic infections and in normal individuals, especially the elderly (Table 10.2).
- **Anti-double-stranded DNA (dsDNA) antibodies.** These are usually detected by a precipitation test (Farr assay), by ELISA, or by an immunofluorescent test using *Crithidia luciliae* (which contains double-stranded DNA). They are diagnostic of active SLE but may be negative in mild or inactive disease. High titres of IgG anti-dsDNA indicate a poor prognosis and are specific to SLE. They are probably pathogenic. Anti-single-stranded DNA antibodies are non-specific.
- **Anti-extractable nuclear antigen (ENA) antibodies** (see Box 10.11, p. 544)**.** These produce a speckled ANA fluorescent pattern, which can also be distinguished by ELISA.

There are seven types of antibodies to tRNA synthetase enzymes but only a few are available for routine analysis. *Anti*

Table 10.1 Conditions in which rheumatoid factor is found in the serum

Autoimmune rheumatic diseases	**RF (IgM) %**
Rheumatoid arthritis	70
Systemic lupus erythematosus	25
Sjögren's syndrome	90
Systemic sclerosis	30
Polymyositis/dermatomyositis	50
Juvenile idiopathic arthritis	Variable
Viral infections	**Hyperglobulinaemias**
Hepatitis	Chronic liver disease
Infectious mononucleosis	Sarcoidosis
Cryoglobulinaemia	
Chronic infections	**Normal population**
Tuberculosis	Elderly
Leprosy	Relatives of patients with RA
Infective endocarditis	
Syphilis	

Table 10.2	Conditions in which serum antinuclear antibodies (%) are found
Systemic lupus erythematosus	95
Systemic sclerosis	70
Sjögren's syndrome	80
Polymyositis and dermatomyositis	40
Rheumatoid arthritis	30
Juvenile idiopathic arthritis	Variable
Other diseases	
Autoimmune hepatitis	100
Drug-induced lupus	>95
Myasthenia gravis	50
Idiopathic pulmonary fibrosis	30
Diabetes mellitus	25
Infectious mononucleosis	5–10
Normal population	8

Jo-1 antibodies are found in polymyositis and dermatomyositis. *Anti-RNA polymerase antibodies I and III* are present in systemic sclerosis. *Anti-topoisomerase 1 (ScL-70) antibodies* are seen in systemic sclerosis.

- **Anti-neutrophil cytoplasmic antibodies (ANCAs)** (see p. 551)**.** These are predominantly IgG autoantibodies directed against the primary granules of neutrophil and macrophage lysosymes. Two major clinically relevant ANCA patterns are recognized on *immunofluorescence*:
  - proteinase 3 (PR3-ANCA), also called cytoplasmic or cANCA, producing a granular immunofluorescence
  - myeloperoxidase (MPO-ANCA), also called perinuclear or pANCA, producing a perinuclear stain.

Both are strongly associated with small-vessel vasculitides: PR3-ANCA in Wegener's granulomatosis, and MPO-ANCA in e.g. microscopic polyarteritis (polyangiitis) and Churg–Strauss syndrome. An MPO-ANCA is also found in inflammatory bowel disease.

- **Antiphospholipid antibodies** (see p. 599)**.** These are detected in the antiphospholipid syndrome (see p. 544).
- **Immune complexes.** Immune complexes are infrequently measured, largely because of variability between assays and difficulty in interpreting their meaning. Assays based on the polyethylene glycol precipitation method (PEG) or C1q binding are available commercially.
- **Complement.** Low complement levels indicate consumption and suggest an active disease process in SLE.

FURTHER READING

Male D, Brostoff J, Roth DB, Roitt I. *Immunology,* 7th edn. St Louis: Elsevier, 2006.

Joint aspiration (Practical box 10.2)

Examination of joint (or bursa) fluid is used mainly to diagnose septic, reactive or crystal arthritis. The nature of the fluid is an indicator of the level of inflammation. Clear fluid indicates little inflammation in the joint, whereas translucent or opaque fluid indicates increasing cellularity and underlying inflammation. Purulent fluid is seen in septic arthritis, but crystal arthritis and reactive arthritis may also produce a highly cellular effusion. The procedure is often undertaken in combination with injection of a corticosteroid. Aspiration alone is therapeutic in crystal arthritis.

Practical Box 10.2 Joint aspiration

This is a sterile procedure which should be carried out in a clean environment

Explain the procedure to the patient; obtain consent.

1. Decide on the site to insert the needle and mark it.
2. Clean the skin and your hands scrupulously; remove rings and wristwatch. Put on gloves.
3. Draw up local anaesthetic (and corticosteroid if it is being used) and then use a new needle.
4. Warn the patient, insert the needle, injecting local anaesthetic as it advances and, if a joint effusion is suspected, attempt to aspirate as you advance it.
5. If fluid is obtained, change syringes and aspirate fully.
6. Examine the fluid in the syringe and decide whether or not to proceed with a corticosteroid injection (if fluid clear or slightly cloudy).
7. Cover the injection site and advise the patient to rest the affected area for a few days. Warn the patient that the pain may increase initially but to report urgently if this persists beyond a few days, if the swelling worsens, or if they become febrile, since this might indicate an infected joint.

Examination of synovial fluid

Aspiration and analysis of synovial fluid are always indicated when an infected or crystal induced arthritis is suspected, particularly a monoarthritis. Normal fluid is straw coloured and contains <3000 WCC/mm^3. Inflammatory fluid is cloudy, viscous and contains >3000 WCC/mm^3. Septic fluid is opaque and less viscous (it contains hyaluronidase ++) and contains up to 75 000 WCC/m^3. There is much overlap.

Polarized light microscopy is performed for crystals.

- Gout – negatively birefringent, needle-shaped crystals of sodium urate.
- Pyrophosphate arthropathy (pseudogout) – rhomboidal, weakly positively birefringent crystals of calcium pyrophosphate.

Gram staining is essential if septic arthritis is suspected and may identify the organism immediately. Joint fluid should be cultured and antibiotic sensitivities requested.

Diagnostic imaging and visualization

- **X-rays** can be diagnostic in certain conditions (e.g. established rheumatoid arthritis) and are the first investigation in many cases of trauma. X-rays can detect joint space narrowing, erosions in rheumatoid arthritis, calcification in soft tissue, new bone formation, e.g. osteophytes and decreased bone density (osteopenia) or increased bone density (osteosclerosis):
  (a) In acute low back pain, X-rays are indicated only if the pain is persistent, recurrent, associated with neurological symptoms or signs, or worse at night. They should also be performed if the pain is associated with such symptoms as fever or weight

loss (red flags), which might indicate a more serious underlying pathology.

(b) Radiological changes are common in older people and may not indicate symptomatic osteoarthritis or spondylosis.

(c) X-rays are of little diagnostic value in early inflammatory arthritis but are useful as a baseline from which to judge later change.

- **Ultrasound (US)** is particularly useful for periarticular structures, soft tissue swellings and tendons. It is increasingly used to examine the shoulder and other structures during movement, e.g. shoulder impingement syndrome (see p. 507). US with Doppler measures blood flow and hence inflammation. US can be used to guide local injections. It is also used to assess bone density.
- **Magnetic resonance imaging (MRI)** shows bone changes and intra-articular structures in striking detail. Visualization of particular structures can be enhanced with different resonance sequences. T_1 weighted is used for anatomical detail, T_2 weighted for fluid detection and short tau inversion recovery (STIR) for the presence of bone marrow oedema. It is more sensitive than X-rays in the early detection of articular and peri-articular disease. It is the investigation of choice for most spinal disorders but is inappropriate in uncomplicated mechanical low back pain. Gadolinium injection enhances inflamed tissue. MRI can also detect muscle changes, e.g. myositis.
- **Computerized axial tomography (CT)** is useful for detecting changes in calcified structures.
- **Bone scintigraphy** utilizes radionuclides, usually ^{99m}Tc, and detects abnormal bone turnover and blood circulation and, although non-specific, helps in detecting areas of inflammation, infection or malignancy. It is best used in combination with other anatomical imaging techniques.
- **DXA scanning** uses very low doses of X-irradiation to measure bone density and is used in the screening and monitoring of osteoporosis.
- **Positron emission tomography (PET) scanning** uses radionuclides which decay by emission of positrons. ^{18}F-Fluorodeoxyglucose uptake indicates areas of increased glucose metabolism. It is used to locate tumours and demonstrate large vessel vasculitis, e.g. Takayasu's arteritis (see p. 809). PET scans are combined with CT to improve anatomical details.
- **Arthroscopy** is a direct means of visualizing a joint, particularly the knee or shoulder. Biopsies can be taken, surgery performed in certain conditions (e.g. repair or trimming of meniscal tears), and loose bodies removed.

COMMON REGIONAL MUSCULOSKELETAL PROBLEMS (Fig.10.2)

Analgesic and anti-inflammatory drugs used for treatment of musculoskeletal problems are discussed on page 517.

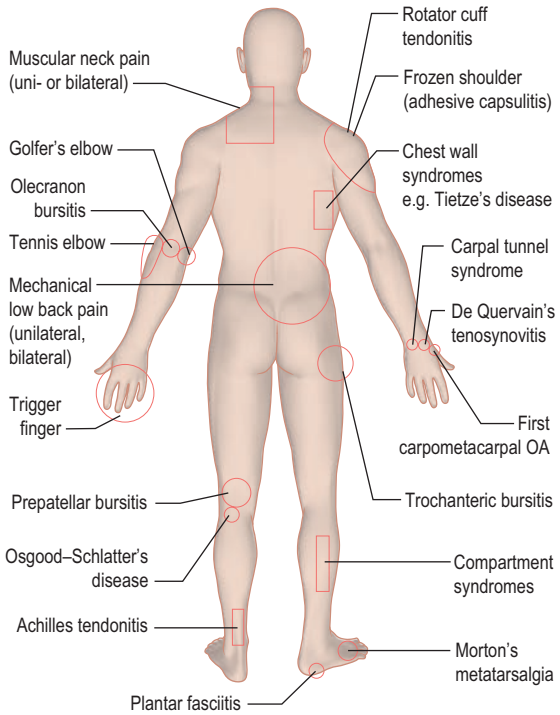

Fig. 10.2 **Common regional musculoskeletal problems.**

PAIN IN THE NECK AND SHOULDER
(Table 10.3)

Mechanical or muscular neck pain (shoulder girdle pain)

Unilateral or bilateral muscular-pattern neck pain is common and usually self-limiting. It can follow injury, falling asleep in an awkward position, or prolonged keyboard working. Chronic burning neck pain occurs because of muscle tension from anxiety and stress.

Spondylosis (see p. 506) seen on X-ray increases after the age of 40 years, but it is not always causal. Spondylosis can, however, cause stiffness and increases the risk of mechanical or muscular neck pain. Muscle spasm can be palpable, is tender and may lead to abnormal neck posture

Table 10.3 Pain in the neck and shoulder

Trauma (for example, a fall)
Mechanical or muscular neck pain
Whiplash injury
Disc prolapse – nerve root entrapment (p. 510)
Ankylosing spondylitis
Shoulder lesions:
Rotator cuff tendonitis
Calcific tendonitis or bursitis
Impingement syndrome or rotator cuff tear
Adhesive capsulitis (true 'frozen' shoulder)
Inflammatory arthritis or osteoarthritis
Polymyalgia rheumatica
Fibromyalgia (chronic widespread pain)
Chronic (work-related) upper limb pain syndrome
Tumour

(e.g. acute torticollis). *Muscular-pattern neck pain* is not localized but affects the trapezius muscle, the C7 spinous process and the paracervical musculature (shoulder girdle pain). Pain often radiates upwards to the occiput but rarely laterally to the tip of the shoulder. It is commonly associated with unilateral or bilateral tension headaches; pain radiating over the head to the temple and eye, described as like a pressure or tight band. These features are also seen in chronic widespread pain (see p. 516).

Treatment

Patients are given short courses of analgesic therapy along with reassurance and explanation. Physiotherapists can help to relieve spasm and pain, teach exercises and relaxation techniques, and improve posture. An occupational therapist can advise about the ergonomics of the workplace if the problem is work-related (see p. 516).

Nerve root entrapment

This is caused by an acute cervical disc prolapse or pressure on the root from spondylotic osteophytes narrowing the root canal.

Acute cervical disc prolapse presents with unilateral pain in the neck, radiating to the interscapular and shoulder regions. This diffuse, aching dural pain is followed by sharp, electric shock-like pain down the arm, in a nerve root distribution, often with pins and needles, numbness, weakness and loss of reflexes (see Table 10.4).

Cervical spondylosis occurs in the older patient with postero-lateral osteophytes compressing the nerve root and causing root pain (see Fig. 21.46, p. 1176), commonly at C5/C6 or C6/C7; it is seen on oblique radiographs of the neck. An MRI scan shows facet joint OA, root canal narrowing and any associated disc prolapse clearly.

Treatment

A support collar, rest, analgesia and sedation are used as necessary. Patients should be advised not to carry heavy items. It usually recovers in 6–12 weeks. MRI is the investigation of choice if surgery is being considered or the diagnosis is uncertain (Fig. 10.3). A cervical root block administered under direct vision by an experienced pain specialist may relieve pain while the disc recovers. Neurosurgical referral is essential if the pain persists or if the neurological signs of weakness or numbness are severe or bilateral. Bilateral root pain is a neurosurgical emergency because a central disc prolapse may compress the cervical spinal cord. Posterior osteophytes may cause spinal claudication and cervical myelopathy (see p. 1177).

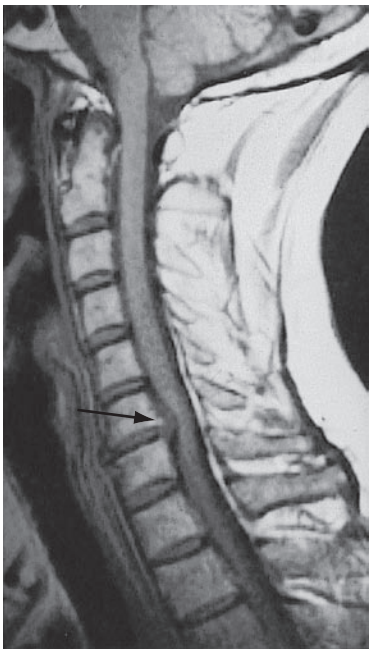

Fig. 10.3 **MRI of cervical spine**, showing a large central disc prolapse impinging on the spinal cord (arrow) at the C6/7 level.

Table 10.4 **Cervical nerve root entrapment – symptoms and signs**

Nerve root	Sensory changes	Reflex loss	Weakness
C5	Lateral arm	Biceps	Shoulder abduction Elbow flexion
C6	Lateral forearm	Biceps	Elbow flexion
	Thumb and index finger	Supinator	Wrist extension
C7	Middle finger	Triceps	Elbow extension
C8	Medial forearm	None	Finger flexion
	Little and ring fingers		
T1	Medial upper arm	None	Finger ab- and adduction

Whiplash injury

Whiplash injury results from acceleration–deceleration forces applied to the neck, usually in a road traffic accident when the car of a person wearing a seat belt is struck from behind. Delayed recovery depends in part upon the severity of the initial injury. A simple decision plan based on clinical criteria helps to distinguish those most at risk and who warrant radiography. There is a low probability of serious bony injury if there is no midline cervical tenderness, no focal neurological deficit, normal alertness, no intoxication and no other painful distracting injury. CT scans are reserved for those with bony injury. MRI scans occasionally show severe soft tissue injury. Whiplash injuries commonly lead to litigation.

Whiplash injury is a common cause of chronic neck pain, although most people recover within a few weeks or months. The pattern of chronic neck pain is often complex, involving pain in the neck, shoulder and arm. Headache, dizziness, and loss of memory and poor concentration sometimes accompany this. The subjective nature of these symptoms has led to controversy about their cause. The problem is more commonly seen in industrialized countries. It has often been suggested that the syndrome is caused in part by the prospect of financial compensation. This may not be wholly conscious and may be contributed to in part by the conflictive nature of the compensation process. There appears to be a direct relationship between poor prognosis and potential for compensation – elimination of compensation for pain and suffering due to this type of injury may lead to an improved prognosis.

Treatment is with reassurance (as the patient may be very anxious), analgesia, a short-term support collar and physiotherapy. Pain may take a few weeks or months to settle and the patient should be warned of this.

PAIN IN THE SHOULDER

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff (Fig. 10.4) which is part of the joint capsule. It comprises the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly and teres major and subscapularis anteriorly. The rotator cuff (particularly supraspinatus) prevents the humeral head blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning moment. This permits the greater tuberosity to glide under the acromion without impingement.

Specific diagnoses are difficult to make clinically and are best made by *ultrasound investigation*. In the short term, however, this may not matter for pain management. Ultrasound should be reserved for patients whose pain persists.

Pain in the shoulder can sometimes be due to problems in the neck. The differential diagnosis of this is shown in Box 10.1. Although the term 'frozen shoulder' is commonly used for any painful stiff shoulder, true frozen shoulder (adhesive capsulitis) is uncommon – see below. A painful, stiff shoulder can result from rotator cuff lesions and is also seen following hemiplegia, chest or breast surgery or myocardial infarction. Painful shoulders may also be the initial presentation of RA, less commonly a seronegative spondyloarthropathy, and of polymyalgia rheumatica in the elderly.

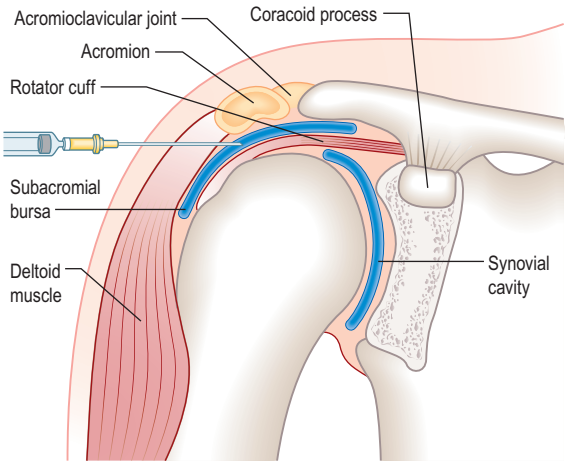

Fig. 10.4 **The shoulder region**, showing site of injection and subacromial space.

Box 10.1 Differential diagnosis of 'shoulder' pain

- Rotator cuff tendonitis pain is worse at night and radiates to the upper arm.
- Painful shoulders produce secondary muscular neck pain.
- Muscular neck pain (also known as shoulder girdle pain) does not radiate to the upper arm.
- Cervical nerve root pain is usually associated with pins and needles or neurological signs in the arm.

Management. Ultrasound examination can distinguish shoulder problems accurately and an ultrasound-guided corticosteroid injection can be given if required.

Rotator cuff (supraspinatus) tendonosis

This is a common cause of painful restriction of the shoulder at all ages. It follows trauma in 30% of cases and is bilateral in under 5%. The pain radiates to the upper arm and is made worse by arm abduction and elevation, which are often limited. The pain is often worse during the middle of the range of abduction, reducing as the arm is raised fully and the painful part of the tendon rotates through to the proximal side of the acromion – a so-called 'painful arc syndrome'. When examined from behind, the scapula rotates earlier than usual during elevation. Passive elevation reduces impingement and is less painful. Severe pain virtually immobilizes the joint, although some rotation is retained (cf. adhesive capsulitis, see below). There is also painful spasm of the trapezius. There may be an associated subacromial bursitis. Isolated subacromial bursitis occurs after direct trauma, falling on to the outstretched arm or elbow.

X-rays or ultrasound are necessary only when rotator cuff tendonosis is persistent or the diagnosis is uncertain.

Treatment

Analgesics or NSAIDs may suffice, but severe pain responds to an injection of corticosteroid into the subacromial bursa (Fig. 10.4). Patients should be warned that 10% will develop worse pain for 24–48 hours after injection. Seventy per cent improve over 5–20 days and mobilize the joint themselves. Physiotherapy helps persistent stiffness but therapeutic ultrasound is of unproven value. Further injections may be needed.

Torn rotator cuff

This is caused by trauma in the young but also occurs spontaneously in the elderly and in rheumatoid arthritis (RA). It prevents active abduction of the arm, but patients learn to initiate elevation using the unaffected arm. Once elevated, the arm can be held in place by the deltoid muscle. In younger people, the tear is repaired surgically but this is rarely possible in the elderly or in RA. Repeated trauma of the cuff between humerus and acromion/acromioclavicular joint causes osteophyte and cyst formation.

Shoulder impingement syndrome causes pain and crepitus on abduction and rotation. Some patients require arthroscopic surgery.

Calcific tendonosis and bursitis

Calcium pyrophosphate deposits in the tendon are visible on X-ray, but they are not always symptomatic. The pathogenesis is unclear, although ischaemia may play a part. The deposit is usually just proximal to the greater tuberosity. It may lead to acute or chronic recurrent shoulder pain and restriction of movement. A local corticosteroid injection may relieve the pain. The calcification may persist or resolve. Aspiration of the deposit under X-ray or ultrasound control may be required for persistent pain. Rarely, arthroscopic removal is necessary.

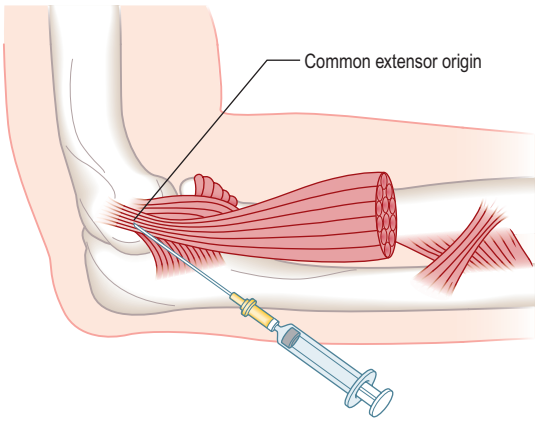

Fig. 10.5 **Injection for tennis elbow.**

Shedding of crystals into the subacromial bursa causes a bursitis with severe pain and shoulder restriction. The shoulder feels hot and is swollen, and an X-ray will show a diffuse opacity in the bursa. The differential diagnosis of calcific bursitis is gout, pseudogout or septic arthritis.

Aspiration and injection with corticosteroid can help.

Adhesive capsulitis (true 'frozen' shoulder)

This is uncommon. Severe shoulder pain is associated with complete loss of all shoulder movements, including rotation. High doses of NSAIDs and intra-articular injections of local anaesthetic and corticosteroids are helpful. Once the pain settles, arthroscopic release speeds functional recovery. When untreated, it recovers in 1–2 years.

PAIN IN THE ELBOW

Pain in the elbow can be due to epicondylitis, inflammatory arthritis or occasionally osteoarthritis.

Epicondylitis

Two common sites where the insertions of tendons into bone become inflamed (enthesitis) are the insertions of the wrist extensor tendon into the lateral epicondyle ('tennis elbow') and the wrist flexor tendon into the medial epicondyle ('golfer's elbow'). Both are usually unrelated to either sporting activity.

There is local tenderness. Pain radiates into the forearm on using the affected muscles – typically, gripping or holding a heavy bag in tennis elbow or carrying a tray in golfer's elbow. Pain at rest also occurs.

Treatment

Advise rest and arrange review by a physiotherapist. A local injection of corticosteroid at the point of maximum tenderness is helpful when the pain is severe (Fig. 10.5). Avoid the ulnar nerve when injecting golfer's elbow. Both conditions settle spontaneously eventually, but occasionally become disabling.

PAIN IN THE HAND AND WRIST (Table 10.5)

Hand pain is commonly caused by injury or repetitive work-related use. When associated with pins and needles or numbness it suggests a neurological cause arising at the wrist, elbow or neck. Pain and stiffness that are worse in the morning are due to tenosynovitis or inflammatory arthritis. The distribution of hand pain often indicates the diagnosis.

Table 10.5 Pain in the hand and wrist – causes

All ages	Older patients
Trauma/fractures	Nodal OA:
Tenosynovitis:	DIPs (Heberden's nodes)
Flexor with/without triggering	PIPs (Bouchard's nodes)
Dorsal	First carpometacarpal joint
De Quervain's	Trauma – scaphoid fracture
Carpal tunnel syndrome	Pseudogout
Ganglion	Gout:
Inflammatory arthritis	Acute
Raynaud's syndrome (p. 809)	Tophaceous
Chronic regional pain syndrome type I (p. 517)	

DIPs, PIPs, distal and proximal interphalangeal joints.

Tenosynovitis

The finger flexor tendons run through a series of synovial sheaths and under loops which hold them in place. Inflammation occurs with repeated or unaccustomed use, or in inflammatory arthritis when the thickened sheaths are often palpable.

Flexor tenosynovitis causes finger pain when gripping and stiffness of the fingers in the morning. Occasionally a tendon causes a trigger finger, when the finger remains flexed in the morning or after gripping and has to be pulled straight. A tendon nodule is palpable, usually in the distal palm.

Dorsal tenosynovitis is less common except in rheumatoid arthritis. The swelling is on the back of the hand and wrist.

De Quervain's tenosynovitis causes pain and swelling around the radial styloid where the abductor pollicis longus tendon is held in place by a retaining band. There is local tenderness, and the pain at the styloid is worsened by flexing the thumb into the palm (Finkelstein's sign).

Treatment

Resting, splinting and NSAIDs are used. Therapeutic ultrasound helps some people. Local corticosteroids are used and injected alongside the tendon under low pressure (not into the tendon itself). Occasionally surgery is needed if symptoms persist after six months.

Carpal tunnel syndrome

This is due to median nerve compression in the limited space of the carpal tunnel. Thickened ligaments, tendon sheaths or bone enlargement can cause it, but it is usually idiopathic. Causes are discussed on page 1172. The history is usually typical and diagnostic with the patient waking with numbness, tingling and pain in a median nerve distribution. The pain radiates to the forearm. The fingers feel swollen but usually are not. Wasting of the abductor pollicis brevis develops with sensory loss in the palm and radial three and a half fingers. Tinel's sign may be positive, i.e. reproduction of the pain on tapping the nerve in the carpal tunnel. Phalen's test is pain of the palm on maximal wrist flexion.

Treatment is with a splint to hold the wrist in dorsiflexion overnight. This relieves the symptoms and is diagnostic; used nightly for several weeks it may produce full recovery. If it does not, a corticosteroid injection into the carpal tunnel (N.B. not into the nerve!) helps in about 70% of cases, although it may recur. Persistent symptoms or nerve damage require nerve conduction studies showing prolonged latency across the carpal tunnel and surgical decompression of the carpal tunnel.

Other conditions causing pain

Inflammatory arthritis. This may present with pain, swelling and stiffness of the hands. In RA the wrists, proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joints are affected symmetrically. In psoriatic arthritis and reactive arthritis a finger may be swollen (dactylitis) or the distal interphalangeal (DIP) joints and nails are affected asymmetrically.

Nodal osteoarthritis. This affects the DIP and less commonly PIP joints, which are initially swollen and red. The inflammation and pain settle but bony swellings remain. There is often a strong family history and it rarely presents before 50 years of age. Reassurance and local treatment are all that is needed.

First carpometacarpal osteoarthritis. This causes pain at the base of the thumb when gripping, or painless stiffness at the base of the thumb, often in persons with nodal osteoarthritis.

Scaphoid fractures. These cause pain in the anatomical snuffbox. They may not be seen immediately on X-ray. If untreated, scaphoid fractures can eventually cause pain because of failed union.

Ganglion. A ganglion is a jelly-filled, often painless swelling caused by a partial tear of the joint capsule. The wrist is a common site. Treatment is not essential as many resolve or cause little trouble. They rarely respond to injection, and surgical excision is the best option.

Dupuytren's contracture

This is a painless, palpable fibrosis of the palmar aponeurosis, with fibroblasts invading the dermis. It causes puckering of the skin and gradual flexion of the affected fingers, usually the ring and little fingers. It is more common in males, Caucasians, in diabetes mellitus and in those who abuse alcohol. A similar fibrosis occurs in the feet in a younger age group. It is often more aggressive. It is also associated with Peyronie's disease of the penis – a painful inflammatory disorder of the corpora cavernosa, leading eventually to painless fibrosis and angulation of the penis during erection. Intralesional steroid injections may help in early disease and some advocate transcutaneous needle aponeurotomy. Plastic surgical release of the contracture is restricted to those with severe deformity of the fingers.

PAIN IN THE LOWER BACK

Low back pain is a common symptom. It is often traumatic and work-related, although lifting apparatus and other mechanical devices and improved office seating are used to avoid it. Episodes are generally short-lived and self-limiting, and patients attend a physiotherapist or osteopath more often than a doctor. Chronic back pain is the cause of 14% of long-term disability in the UK. The causes are listed in Table 10.6, and the management of back pain is summarized in Box 10.2.

Table 10.6 Pain in the back (lumbar region) – causes

Mechanical
Trauma
Muscular and ligamentous pain
Fibrositic nodulosis
Postural back pain (sway back)
Lumbar spondylosis

Osteomalacia (see p. 567)
Paget's disease (see p. 565)
Neoplastic (see p. 555)
Metastases
Multiple myeloma
Primary tumours of bone
Referred pain

Box 10.2 Management of back pain

- Most back pain presenting to a primary care physician needs no investigation.
- Pain between the ages of 20 and 55 years is likely to be mechanical and is managed with analgesia, brief rest if necessary and physiotherapy.
- Patients should stay active within the limits of their pain.
- Early treatment of the acute episode, advice and exercise programmes reduce long-term problems and prevent chronic pain syndromes.
- Physical manipulation of uncomplicated back pain produces short-term relief and enjoys high patient satisfaction ratings.
- Psychological and social factors may influence the time of presentation.
- Appropriate early management reduces long-term disability.

Investigations

- **Spinal X-rays** are required only if the pain is associated with certain 'red flag' symptoms or signs, which indicate a high risk of more serious underlying problems:
  (a) starts before the age of 20 or after 50 years
  (b) is persistent and a serious cause is suspected
  (c) is worse at night or in the morning, when an inflammatory arthritis (e.g. ankylosing spondylitis), infection or a spinal tumour may be the cause

(d) is associated with a systemic illness, fever or weight loss

(e) is associated with neurological symptoms or signs.

- **MRI** is preferable to CT scanning when neurological signs and symptoms are present. CT scans demonstrate bony pathology better.
- **Bone scans** are useful in infective and malignant lesions but are also positive in degenerative lesions.
- **Full blood count, ESR and biochemical tests** are required only when the pain is likely to be due to malignancy, infection or a metabolic cause.

Mechanical low back pain

Mechanical low back pain starts suddenly, may be recurrent and is helped by rest. Mechanical back pain is often precipitated by an injury and may be unilateral or bilateral. It is usually short-lived.

Examination and management

The back is stiff and a scoliosis may be present when the patient is standing. Muscular spasm is visible and palpable and causes local pain and tenderness. It lessens when sitting or lying. Patients with spondylosis on X-ray probably have an increased risk of developing mechanical back pain but changes are often absent in the young and may be coincidental in the elderly. Pain relief and physiotherapy are helpful. Excessive rest should be avoided. The patient needs to be re-educated in lifting and shown exercises to prevent recurrent attacks of pain. Once a patient has presented to a general practitioner with low back pain, although the episode itself is usually self-limiting, there is a significantly increased risk of further back pain episodes. Risk factors for recurrent back pain include female sex, increasing age, pre-existing chronic widespread pain (fibromyalgia) and such psychosocial factors as high levels of psychological distress, poor self-rated health and dissatisfaction with employment. Chronic low back pain is a major cause of disability and time off work and is reduced by appropriate early management.

Spinal movement occurs at the disc and the posterior facet joints, and stability is normally achieved by a complex mechanism of spinal ligaments and muscles. Any of these structures may be a source of pain. An exact anatomical diagnosis is difficult, but some typical syndromes are recognized (see below). They are often associated with but not necessarily caused by radiological spondylosis (see p. 1176).

Postural back pain develops in individuals who sit in poorly designed, unsupportive chairs.

Lumbar spondylosis. The fundamental lesion in spondylosis occurs in an intervertebral disc, a fibrous joint whose tough capsule inserts into the rim of the adjacent vertebrae. This capsule encloses a fibrous outer zone and a gel-like inner zone. The disc allows rotation and bending.

Changes in the discs may start in teenage years or early twenties and increase with age. The gel changes chemically, breaks up, shrinks and loses its compliance. The surrounding fibrous zones develop circumferential or radial fissures. In the majority this is initially asymptomatic but visible on MRI as decreased hydration. Later the discs become thinner and less compliant. These changes cause circumferential bulging of the intervertebral ligaments.

Reactive changes develop in adjacent vertebrae; the bone becomes sclerotic and osteophytes form around the rim of the vertebra (Fig. 10.6). The most common sites of lumbar spondylosis are L5/S1 and L4/L5. In young people, disc prolapse through an adjacent vertebral endplate produces a Schmorl's node on X-ray. This is painless but may accelerate disc degeneration.

Spondylosis may be symptomless, but it can cause:

- episodic mechanical spinal pain
- progressive spinal stiffening
- facet joint pain
- acute disc prolapse, with or without nerve root irritation
- spinal stenosis
- spondylolisthesis.

Facet joint syndrome. Lumbar spondylosis also causes secondary osteoarthritis of the misaligned facet joints. Pain is typically worse on bending backwards and when straightening from flexion. It is lumbar in site, unilateral or bilateral and radiates to the buttock. The facet joints are well seen on MRI and may show osteoarthritis, an effusion or a ganglion cyst. Diagnostic local anaesthetic injections into the joints (under X-ray vision) can be followed by a corticosteroid injection. The long-term value of this is unclear but many patients find the procedure helpful. Physiotherapy to reduce hyperlordosis and reducing weight are helpful.

Fibrositic nodulosis. This causes unilateral or bilateral low back pain, radiating to the buttock and upper posterior thigh. There are tender nodules in the upper buttock and along the iliac crest. Such nodules are relevant only if they are tender and associated with pain. They are probably traumatic. Local, intralesional corticosteroid injections help.

Postural back pain and sway back of pregnancy. Low back pain is common in pregnancy and reflects altered spinal posture and increased ligamentous laxity. There is usually a hyperlordosis on examining the patient standing. Weight control and pre- and postnatal exercises are helpful, and the pain usually settles after delivery. Analgesics and NSAIDs are best avoided during pregnancy and breast-feeding. Epidurals during delivery are not associated with an increased incidence of subsequent back pain. Poor posture causes a similar syndrome in the non-pregnant, owing to obesity or muscular weakness. Poor sitting posture at work is a frequent cause of chronic low back pain.

Treatment of mechanical back pain

Adequate analgesia to allow normal mobility and avoid bed rest is best, combined with physical treatments. The evidence base for physiotherapy, back muscle training regimens and manipulation is not good. Manipulation produces more rapid pain relief in some patients. Acupuncture may help. A positive approach probably reduces the development of chronic pain. A comfortable sleeping position should be adopted using a mattress of medium (not hard) firmness.

Acute lumbar disc prolapse

The central disc gel may extrude into a fissure in the surrounding fibrous zone and cause acute pain and muscle spasm, which in turn leads to a forwards and sideways tilt when standing. These events are often self-limiting. A disc prolapse occurs when the extrusion extends beyond the

Ask the authors
www.studentconsult.com

limits of the fibrous zone (Fig. 10.6). The weakest point is posterolateral, where the disc may impinge on emerging spinal nerve roots in the root canal.

The episode starts dramatically during lifting, twisting or bending and produces a typical combination of low back pain and muscle spasm, and severe, lancinating pains, paraesthesia, numbness and neurological signs in one leg (rarely both). The back pain is diffuse, usually unilateral and radiates into the buttock. The muscle spasm leads to a scoliosis that reduces when lying down. The nerve root pain develops with, or soon after, the onset. The site of the pain and other symptoms is determined by the root affected (Table 10.7). A central high lumbar disc prolapse may cause spinal cord compression and long tract signs (i.e. upper motor neurone). Below L2/L3 it produces lower motor neurone lesions.

On examination, the back often shows a marked scoliosis and muscle spasm. The straight-leg-raising test, whilst lying, is positive in a lower lumbar disc prolapse – raising the straight leg beyond 30 degrees produces pain in the leg. Slight limitation or pain in the back limiting this movement is seen with mechanical back pain. Pain in the affected leg produced by a straight raise of the other leg suggests a large or central disc prolapse. Look for perianal sensory loss and urinary retention, which indicate a cauda equina lesion – a neurosurgical emergency. An upper lumbar disc prolapse produces a positive femoral stretch test – pain in the anterior thigh when the knee is flexed in the prone position.

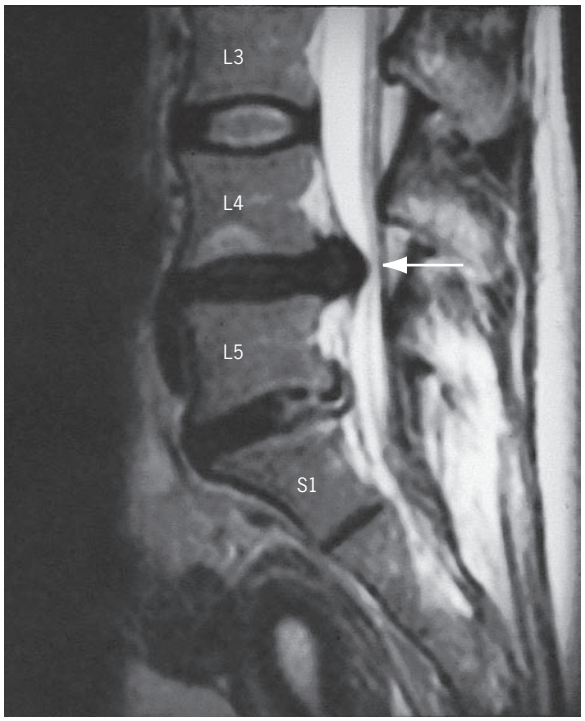

Fig. 10.6 **MRI of lumbar spine**, showing a central disc prolapse at the L4/L5 level (arrow). The signal from the L4/L5 and L5/S1 discs indicates dehydration, while the L3/L4 signal appearance is normal.

Treatment

Advise a short period (2–3 days) of bed rest – lying flat for a lower disc but semi-reclining for a high lumbar disc – and prescribe analgesia and muscle relaxants. Once the pain is tolerable, encourage the patient to mobilize and refer to a physiotherapist for exercises and preventative advice. An X-ray-guided epidural or nerve root canal injection by a pain specialist reduces pain rapidly, although the evidence that it speeds resolution or prevents surgery is unclear. Caudal epidural injections are less effective than lumbar ones. Resuscitation equipment must be available for these procedures. Referral to a surgeon for possible microdiscectomy or hemilaminectomy is necessary if the neurological signs are severe, if the pain persists and is severe for more than 6–10 weeks, or if the disc is central. If bladder or anal sphincter tone is affected it becomes a neurosurgical emergency.

Spinal and root canal stenosis

Progressive loss of disc height, OA of the facet joints, posterolateral osteophytes and buckling of the ligamentum flavum all contribute to root canal stenosis. This causes nerve root pain or spinal root claudication – pain and paraesthesiae in a root distribution brought on by walking and relieved slowly by rest. The associated sensory symptoms, slow recovery when the patient rests, and presence of normal foot pulses distinguish this from peripheral arterial claudication. Severe cervical spondylosis may also produce spinal claudication, often with arm symptoms and signs.

Spinal canal stenosis at more than one level is often associated with severe spondylosis and a congenitally narrow spinal canal. It causes buttock and bilateral leg pain, paraesthesiae and numbness when walking. Rest helps, as does bending forwards, a manoeuvre that opens the spinal canal. Specialist surgical advice is necessary.

Spondylolisthesis

This occurs in adolescents and young adults when bilateral congenital pars interarticularis defects cause instability and permit the vertebra to slip, with or without preceding injury.

Table 10.7 **Lumbar nerve root entrapment – symptoms and signs**

Nerve root	Sensory changes	Reflex loss	Weakness	Usual disc prolapse
L2	Front of thigh	None	Hip flexion/adduction	L2/3
L3	Inner thigh and knee	Knee	Knee extension	
L4	Inner calf	Knee	Knee extension	L3/4
L5	Outer calf	None	Inversion of foot	L4/5
	Upper, inner foot		Dorsiflexion of toes	
S1	Posterior calf	Ankle	Plantar flexion of foot	L5/S1
	Lateral border of foot			

Rarely a cauda equina syndrome with loss of bladder and anal sphincter control and saddle-distribution anaesthesia develops (p. 1177). It is diagnosed radiologically. Low back pain in adolescents warrants investigation, and spondylolisthesis requires orthopaedic assessment. It needs careful monitoring during the growth spurt.

A degenerative spondylolisthesis may also develop in older people with lumbar spondylosis and osteoarthritis of the facet joints.

Diffuse idiopathic skeletal hyperostosis (DISH)

DISH (Forrestier's disease) affects the spine and extraspinal locations. It causes bony overgrowths and ligamentous ossification and is characterized by flowing calcification over the anterolateral aspects of the vertebrae. The spine is stiff but not always painful, despite the dramatic X-ray changes. Ossification at muscle insertions around the pelvis produces radiological 'whiskering'. Similar changes occur at the patella and in the feet.

Treatment is with analgesics or NSAIDs for pain, and exercise to retain movement and muscle strength.

Osteoporotic crush fracture of the spine

Osteoporosis is asymptomatic but leads to an increased risk of fracture of peripheral bones, particularly neck of femur and wrist, and thoracic or lumbar vertebral crush fractures. Such vertebral fractures develop without trauma, after minimal trauma, or as part of a major accident. They may develop painlessly or cause agonizing localized pain that radiates around the ribs and abdomen. Multiple fractures lead to an increased thoracic kyphosis ('widow's stoop'). The diagnosis is confirmed by X-rays, showing loss of anterior vertebral body height and wedging, with sparing of the vertebral endplates and pedicles. Bone oedema on MRI indicates that a fracture is recent.

Treatment

Advise bed rest and analgesia until the severe pain subsides over a few weeks, then gradual mobilization. It may warrant hospitalization, and intravenous bisphosphonates or subcutaneous calcitonin are given to relieve pain. There may be some residual pain and deformity. Bone density measurement and preventative treatment of osteoporosis are essential (see p. 563).

Septic discitis

Septic discitis may cause severe pain and rapid adjacent vertebral destruction. It requires urgent neurosurgical referral.

Ankylosing spondylitis (see also p. 532)

Buttock pain and low back stiffness in a young adult suggests ankylosing spondylitis, especially if it is worse at night and in the morning.

PAIN IN THE HIP (Table 10.8)

'Hip' refers to a wide area between the upper buttock, trochanter and groin. It is useful to ask the patient to point to the site of pain and its field of radiation. Pain arising from the hip joint itself is felt in the groin, lower buttock and anterior thigh, and may radiate to the knee. Occasionally and inexplicably, hip arthritis causes pain only in the knee.

Table 10.8 Pain in the hip – causes

Hip region problems	Main sites of pain
Osteoarthritis of hip	Groin, buttock, front of thigh to knee
Trochanteric bursitis (or gluteus medius tendonopathy)	Lateral thigh to knee
Meralgia paraesthetica	Anterolateral thigh to knee
Referred from back	Buttock
Facet joint pain	Buttock and posterior thigh
Fracture of neck of femur	Groin and buttock
Inflammatory arthritis	Groin, buttock, front of thigh to knee
Sacroiliitis (AS)	Buttock(s)
Avascular necrosis	Groin and buttocks
Polymyalgia rheumatica	Lumbar spine, buttocks and thighs

AS, ankylosing spondylitis.

Osteoarthritis (OA) (see also p. 518)

OA is the most common cause of hip joint pain in a person over the age of 50 years. It causes pain in the buttock and groin on standing and walking. Stiff hip movements cause difficulty in putting on a sock and may produce a limp.

Trochanteric bursitis and gluteus medius tendonopathy

This may be due to trauma or unaccustomed exercise, but sometimes has an unknown cause. It also occurs in inflammatory arthritis. The pain over the trochanter is worse going up stairs and when abducting the hip, and the trochanter is tender to lie on. A local corticosteroid injection onto the surface of the trochanter is helpful. A tear of the gluteus medius tendon at its insertion into the trochanter causes a similar syndrome, but does not respond to injection. MRI scans have demonstrated this new syndrome. Its best management is unclear.

Meralgia paraesthetica (see also p. 1172)

This causes numbness and burning dysaesthesia (increased sensitivity to light touch) over the anterolateral thigh and may be precipitated by a sudden increase in weight, an injury or during pelvic surgery. It is usually self-limiting but can be helped by amitriptyline 10 mg at night or gabapentin starting with 300 mg.

Fracture of the femoral neck

This usually occurs after a fall, occasionally spontaneously. There is pain in the groin and thigh, weight-bearing is painful or impossible, and the leg is shortened and externally rotated. Occasionally a fracture is not displaced and remains undetected. X-rays are diagnostic. Anyone with a hip fracture, especially after minimal trauma, should be reviewed for osteoporosis (see p. 562).

Table 10.9 Pain in the knee

- Trauma and overuse
  - Periarticular problems
    - Anterior knee pain or medial knee pain
  - Internal derangements – meniscal tears or cruciate ligament tears
- Osteoarthritis
- Inflammatory arthritis
  - Acute monoarthritis
    - Gout, pseudogout, Reiter's disease or septic arthritis
  - Pauciarticular (<4 joints)
    - Seronegative spondyloarthropathy or atypical rheumatoid arthritis
  - Polyarticular
    - Rheumatoid arthritis
- Popliteal (Baker's) cyst/ruptured cyst
- Osteochondritis dissecans
- Hypermobility syndrome
- Referred from hip joint

Avascular necrosis (osteonecrosis) of the femoral head

This is uncommon but occurs at any age. There is severe hip pain. X-rays are diagnostic after a few weeks, when a well-demarcated area of increased bone density is visible. In the femur this lies at the upper pole of the femoral head. The affected bone may collapse. Early, the X-ray is normal but bone scintigraphy or MRI demonstrates the lesion. Risk factors include treatment with corticosteroids or heparin, exposure to high barometric pressures (divers and tunnellers), excessive alcohol consumption, and sickle cell disease.

Inflammatory arthritis of the hip

This produces pain in the groin and stiffness, which are worse in the morning. Rheumatoid arthritis (RA) rarely presents with hip pain, although the hip is involved eventually in severe RA. Ankylosing spondylitis and other seronegative spondyloarthropathies cause inflammatory hip arthritis in younger people.

Polymyalgia rheumatica (see also p. 549)

Bilateral hip, buttock and thigh pain and stiffness that are worse in the morning in an elderly patient may be attributable to polymyalgia rheumatica. Neck and shoulder pain and stiffness are usually also present.

PAIN IN THE KNEE (Table 10.9)

The knee depends on ligaments and quadriceps muscle strength for stability. It is frequently injured, particularly during sports. Trauma or overuse of the knee leads to a variety of peri- and intra-articular problems. Some are self-limiting; others require physiotherapy, local corticosteroid injections or surgery.

The knee is also a common site of inflammatory arthritis and osteoarthritis. Minor radiographic changes of osteoarthritis (see Fig. 10.9, p. 519) are common in the over-fifties and often coincidental, the cause of the pain being periarticular. Knee pain should not be attributed to osteoarthritis until other causes have been excluded. Symptomatic osteoarthritis of the knee correlates poorly with the severity of the radiological changes.

Common periarticular knee lesions

Medial knee pain

There may be medial or lateral ligament strain, but the medial ligament is more commonly affected. There is pain at the ligament's insertion into the upper medial tibia, which is worsened by standing or stressing the affected ligament.

Anserine bursitis causes pain and localized tenderness 2–3 cm below the posteromedial joint line in the upper part of the tibia at the site of the bursa. It occurs in obese women, often with valgus deformities, and in breast-stroke swimmers.

Treatment is with physiotherapy and a local corticosteroid injection.

Anterior knee pain

Anterior knee pain is common in adolescence. In many cases no specific cause is found despite careful investigation. This is called 'anterior knee pain syndrome' and settles with time. Isometric quadriceps exercises and avoidance of high heels both help the condition. Patient and parents often need firm reassurance. Abnormal patellar tracking may be a cause and need surgical treatment. Hypermobility of joints causes joint pain, maltracking and rarely recurrent patellar dislocation (see also p. 554).

Pre- and infrapatellar bursitis are caused by unaccustomed kneeling ('housemaid's knee'). There is local pain, tenderness and fluctuant swelling. Avoidance of kneeling and a local corticosteroid injection are helpful. Septic bursitis can occur.

Chondromalacia patellae is diagnosed arthroscopically. The retropatellar cartilage is fibrillated. In most cases the pain settles eventually. When there is patellar misalignment it may need surgery, as does recurrent patellar dislocation in adolescent girls.

Osgood–Schlatter disease (p. 554) causes pain and swelling over the tibial tubercle. It is a traction apophysitis of the patellar tendon and occurs in enthusiastic teenage sports players.

Enthesitis may occur at the patellar end of the tendon (jumper's knee).

Common intra-articular traumatic lesions of the knee

Torn meniscus

The menisci are partially attached fibrocartilages that stabilize the rounded femoral condyles on the flat tibial plateaux. In the young they are resilient but this decreases with age. They can be torn by a twisting injury, commonly in sports that involve twisting and bending. The history is usually diagnostic. There is immediate medial or lateral knee pain and dramatic swelling within a few hours. The affected side is tender. If the tear is large the knee may lock flexed. The immediate treatment is to apply ice. MRI demonstrates the tear (Fig. 10.7). In most circumstances, especially in active sportsmen, early arthroscopic repair or trimming of the torn meniscus is essential. Surgical intervention reduces recurrent pain, swelling and locking but not the risk of secondary osteoarthritis. The long-term benefit of repairing tears is not

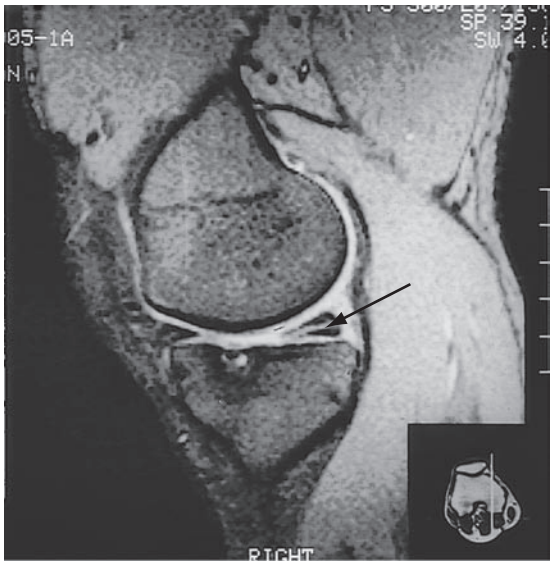

Fig. 10.7 **MRI of a knee**, showing a complete tear of the posterior horn of the medial meniscus, extending to its lower surface (arrow).

yet known. Post-surgical quadriceps exercises aid a return to sport and other activities.

Torn cruciate ligaments

Torn cruciate ligaments account for around 70% of knee haemarthroses in young people. They often coexist with a meniscal tear. Partial cruciate tears are difficult to diagnose clinically. On flexing the knee to 90 degrees, a torn anterior cruciate allows the tibia to be pulled forwards on the femur. MRI is the investigation of choice. Such injuries need urgent orthopaedic referral. There is a significant incidence of secondary OA.

Osteochondritis dissecans

This occasionally causes knee pain and swelling in adolescents and young adults, more commonly males. It is probably traumatic, possibly with hereditary predisposing factors. A fragment of bone and its attached cartilage detach by shearing, most commonly from the lateral aspect of the medial femoral condyle.

There is aching pain after activity and, if the fragment becomes loose, locking or 'giving way' occurs. The lesion is seen on a tunnel-view X-ray, but MRI is more sensitive, especially if the fragment is undisplaced. Undisplaced lesions are treated with rest, then isometric quadriceps exercises. Loose fragments can be fixed arthroscopically or removed. A similar lesion affecting the lateral femoral condyle occurs in older people.

Knee joint effusions

An effusion of the knee causes swelling, stiffness and pain. The pain is more severe with an acute onset and with increasing inflammation, because of stretching of the capsule that contains the pain receptors. A full clinical history and examination must include a past medical, family and drug history.

Inflammatory arthritis affects the knees and causes warmth and swelling. An acute inflammatory monoarthritis of the knee is a common presentation of a seronegative spondyloarthropathy and occasionally is the first sign of RA.

Monoarthritis of the knee, associated with severe pain and marked redness, may be due to septic arthritis, or gout in the middle-aged male, or to gout or pseudogout in an older male or female. A cool, clear, viscous effusion is seen in elderly patients with moderate or severe symptomatic OA (see p. 518).

Examination

A large and tense effusion is easily seen and felt on each side of the patella and in the suprapatellar pouch, and is fluctuant. The effusion delays the patella tapping against the femur when it is pressed firmly and quickly (the 'patellar tap' sign) with the knee held straight and relaxed. Small effusions also demonstrate the 'bulge' sign when the patient is lying with the quadriceps relaxed. For this, apply a gentle sweeping pressure, first to the medial side of the joint and then, watching the medial dimple, to the lateral side. Slightly delayed bulging of the medial dimple indicates fluid in the joint.

Investigations

These are (a) blood tests, and (b) aspiration and examination of the knee effusion. The basic technique of aspiration is described in Practical box 10.2 on page 504.

If there is a flexion deformity, externally rotate the leg or support the knee. Stand on the side opposite the joint and insert the needle between the patella, just proximal to its midpoint, and the medial femoral condyle. Angle the needle slightly backwards and inject small volumes of local anaesthetic, advancing until aspiration detects fluid. Then change the syringe for a larger one and aspirate as much fluid as possible. Examine the fluid and decide whether to inject corticosteroid or arrange microbiological tests.

Haemarthrosis of the knee

This is caused by:

- trauma – meniscal, cruciate or synovial lining tear
- clotting or bleeding disorders, such as haemophilia, sickle cell disease or von Willebrand's disease.

Popliteal cyst (Baker's cyst). In approximately 5% of patients with a knee effusion, a swollen, painful popliteal cyst develops. This is usually due to a bursa (usually the semimembranosus bursa), which in some individuals has a valve-like connection to the knee. This allows the effusion to flow into the bursa but not back. Occasionally there is a synovial herniation through the posterior joint capsule. The cyst is best seen and felt in the popliteal fossa with the patient standing.

Ruptured popliteal cyst. A popliteal cyst may rupture if the patient is mobile, particularly on standing up quickly or climbing stairs. Fluid escapes into the soft tissue of the popliteal fossa and upper calf, causing sudden and severe pain, swelling and tenderness of the upper calf. Dependent oedema of the ankle develops and the knee effusion reduces dramatically in size and may be undetectable.

A history of previous knee problems and the sudden onset of pain and tenderness high in the calf suggest a ruptured cyst rather than a deep vein thrombosis (DVT). However, the diagnosis is often missed and treated inappropriately

with anticoagulants. A diagnostic ultrasound examination distinguishes a ruptured cyst from a DVT (see p. 809). Analgesics or NSAIDs, rest with the leg elevated, and aspiration and injection with corticosteroids into the knee joint are required.

PAIN IN THE FOOT AND HEEL (Table 10.10)

The feet are subjected to extreme pressures by weight-bearing and inappropriate shoes. They are commonly painful. Broad, deep, thick-soled shoes are essential for sporting activities, prolonged walking or standing, and in people with congenitally flat or arthritic feet.

There are two common types of foot deformity:

- *Flat feet* – stress the ankle and throw the hindfoot into a valgus (everted) position. A flat foot is rigid and inflexible
- *High-arched feet* – place pressure on the lateral border and ball of the foot.

The foot is affected by a variety of inflammatory arthritic conditions. After the hand, the foot joints are the most commonly affected by rheumatoid arthritis. The diagnosis depends upon careful assessment of the distribution of the joints affected, the pattern of other joint problems, or by finding the associated condition (e.g. psoriasis, see p. 1240).

Hallux valgus

The great toe migrates laterally. In the congenital form the first metatarsal bone is displaced medially (metatarsus primus varus). The shape of modern shoes causes later onset of hallux valgus. It is a common complication of RA.

Hallux rigidus

Osteoarthritis of the first metatarsophalangeal (MTP) joint in a normally aligned or valgus joint causes hallux rigidus – a stiff, dorsiflexed and painful great toe. Careful choice of footwear and the help of a podiatrist suffice for most cases, but some require surgery.

Metatarsalgia

This is common, especially in women who wear high heels, after trauma and in those with hammer toes. The ball of the foot is painful to walk and stand on. Callosities and pressure-induced bursae develop under the metatarsal heads. Rheumatoid arthritis causes misalignment of the metatarsal bones and severe metatarsalgia.

Treatment is with podiatry and the wearing of appropriate shoes. Surgery is occasionally needed, particularly in the rheumatoid forefoot.

Morton's metatarsalgia is due to a neuroma, usually between the third and fourth metatarsal heads. It causes pain, burning and numbness in the adjacent surfaces of the affected toes when walking. It is helped by wearing wider, cushioned-soled shoes. Occasionally a steroid injection is necessary.

Stress (march) fractures

These cause sudden, severe, weight-bearing pain in the distal shaft of the fractured metatarsal bone. They occur after unaccustomed walking or with new shoes. There is local tenderness and swelling, but initially X-rays are normal and diagnosis delayed. A radioisotope bone scan or MRI reveals the fracture earlier than X-rays. Reduced weight-bearing for a few weeks usually suffices.

Tarsal tunnel syndrome

This is an entrapment neuropathy of the posterior tibial nerve as it rounds the medial malleolus. It produces burning, tingling and numbness of the toes, sole and medial arch. The nerve is tender below the malleolus and, when tapped, produces a shock-like pain (Tinel's sign). A local steroid injection under the retinaculum, between the medial malleolus and calcaneum, is helpful.

Pain under the heel

Plantar fasciitis is an enthesitis at the insertion of the tendon into the calcaneum. It produces localized pain when standing and walking, and tenderness in the midline. It occurs alone or in seronegative spondyloarthropathy.

Plantar spurs are traction lesions at the insertion of the plantar fascia in older people and are usually asymptomatic. They become painful after trauma.

Calcaneal bursitis is a pressure-induced (adventitious) bursa that produces diffuse pain and tenderness under the heel. Compression of the heel pad from the sides is painful, which distinguishes it from plantar fascia pain.

Whatever the cause, the pain is always worse in the morning as soon as weight is placed on the foot.

All of these lesions are treated with heel pads, and reduced walking; they are often self-limiting. A splint at night to hold the foot dorsiflexed and to stretch the plantar fascia is preferable to a local corticosteroid injection in plantar fasciitis. When an injection is necessary, a medial approach is used, rather than through the heel pad, often under ultrasound guidance.

Pain behind the heel and leg

Sever's disease is a traction apophysitis of the Achilles tendon in young people (cf. Osgood–Schlatter disease, p. 554).

Pain at the insertion of the Achilles tendon into the calcaneum is an enthesitis. This is traumatic or it can complicate seronegative spondyloarthropathy. Tendon damage or ruptive can occur with quinolone e.g. ciprofloxacin therapy. Raising the shoe heel reduces pain. Occasionally a low-pressure corticosteroid injection near the enthesis is necessary.

Table 10.10 Pain in the foot and heel – causes

Structural (flat (pronated) or high arched (supinated))	
Hallux valgus/rigidus (±OA)	
Metatarsalgia	
Morton's neuroma	
Stress fracture	
Inflammatory arthritis	
Acute, monoarticular – gout	
Chronic, polyarticular – RA	
Chronic, pauciarticular – seronegative spondyloarthropathy	
Tarsal tunnel syndrome	
Heel pain	
Plantar fasciitis	Below heel
Plantar spur	Below heel
Achilles tendonitis/bursitis	Behind heel
Sever's disease	Behind heel
Arthritis of ankle/subtaloid joints	

Achilles tendonosis causes a painful, tender swelling a few centimetres above the tendon's insertion. Advise against walking barefoot and jumping. Therapeutic ultrasound is helpful. (Caution – a local injection may cause the tendon to rupture.)

Achilles' bursitis lies clearly anterior to the tendon and can be safely injected with corticosteroid.

Compartment syndromes

The muscles of the lower leg are enclosed in fascial compartments, with little room for expansion to occur. Compartment syndromes can be acute and severe, such as following exercise.

In the *anterior tibial syndrome* there is severe pain in the front of the shin, occasionally with foot drop. Immediate surgical decompression to prevent muscle necrosis is sometimes required.

Chronic compartment syndrome produces pain in the lower leg that is aggravated by exercise and may therefore be mistaken for a vascular or neurological disorder.

PAIN IN THE CHEST

Musculoskeletal conditions are sometimes a cause of chest pain. An example is Tietze's disease. In this condition, pain arises from the costosternal junctions. It is usually unilateral and affects one, two or three ribs. There is local tenderness, which helps to make the diagnosis. The condition is benign and self-limiting. It often responds well to anti-inflammatory drugs. Other causes of chest wall pain include rib fractures due to trauma or osteoporosis or a malignant deposit. Costochondral pain occurs in ankylosing spondylitis (see p. 532). In patients with heart disease this may cause severe anxiety but this pain is not like angina and the patient should be reassured.

CHRONIC PAIN SYNDROMES

(see also p. 1193)

Chronic pain syndromes are difficult to manage. Psychological factors are at least as relevant as inflammation or damage in determining a patient's perception of pain. It is essential to be objective and non-judgmental when discussing physical, psychological and social factors without assuming which is primary. Chronic pain syndromes are difficult to explain scientifically and it is all too easy for a doctor to 'blame' the patient for this lack of explanation. Some chronic pain states may be exacerbated partly by the process of litigation that may follow an injury.

Any chronic painful condition can change the way a person copes. Some people with chronic diseases or chronic pain cope well, but others adopt coping strategies and patterns of behaviour which make things worse. They become anxious, depressed or socially isolated, and their quality of life is reduced. In chronic pain syndromes patients need help to lead a more normal life despite their pain, and are best referred to a specialist, multidisciplinary pain service.

Psychological states such as depression and anxiety produce physical symptoms, of which one is pain, while people with frank physical diseases are often understandably anxious and depressed. A biopsychosocial approach is best.

Chronic widespread pain (previously fibromyalgia)

Chronic widespread pain is defined as pain for more than three months both above and below the waist (p. 1193). It is a diagnosis of exclusion although it is still not universally accepted as a diagnosis. Patients value a name to explain symptoms previously dismissed or attributed simply to psychological or social problems. A feature for diagnosing fibromyalgia is tender trigger points although this is not specific. The patient is usually a middle-aged woman who struggles on with her work and/or housework despite the pain. Such individuals are difficult to live with and there is often family discord. Many patients have sleep disturbances, so they awake unrefreshed and have poor concentration. It can occur at any age and is increasingly recognized in teenagers.

The pain is a widespread, unremitting, aching discomfort. There are often other health problems, such as chronic fatigue syndrome (see below), irritable bowel syndrome, premenstrual syndrome, tension headache, anxiety and depression; doctors sometimes inappropriately label them 'heart sink' patients. The patient's frustration is compounded by the fact that most tests are normal, and they fear doctors believe it is 'all in their mind'. This is best regarded as a 'wind up' or pain amplification syndrome and is attributable to changes in the descending inhibitory pathways and in the spinal cord.

Treatment

A sympathetic approach is appropriate, with reassurance for the patient that their chronic widespread pain often improves and is not inevitably disabling. A graded aerobic exercise regimen over 3 months is safe and effective. When depression is present, it should be treated, but potentially addictive anxiolytic agents are best avoided. A behavioural psychologist may persuade the person to pace their life more effectively and to cope better, although patients often resist referral for psychological help.

Drugs

Analgesics or NSAIDs help in some cases but are best used intermittently. Gabapentin and pregabalin also help although drowsiness may be a problem.

Low doses of sedative antidepressant drugs, such as amitriptyline or dosulepin, help when taken a few hours before bedtime. They act by increasing the levels of serotonin (5HT) in the CNS and probably increasing descending sensory inhibition. It should be explained that these doses are analgesic and not antidepressant, and their side-effects should be outlined. Trigger-point injections with local anaesthetic, corticosteroids or acupuncture are sometimes helpful.

Oral corticosteroids are not helpful.

Chronic fatigue syndrome

Diffuse muscular pain and stiffness is common in this condition, which is described on page 1192.

Chronic (work-related) upper-limb pain syndrome

This name is preferred to 'repetitive strain injury' (RSI). The predominant symptoms are pain in all or part of one or both

arms. A specific lesion, such as tennis elbow or carpal tunnel syndrome, or muscular-pattern neck pain often develops first, and early recognition and treatment may prevent chronicity. After a variable period, the pain becomes more diffuse and no longer simply work-related, and there is often severe distress. It is seen in keyboard workers and others who perform the same task without breaks for prolonged periods, and also in musicians. When it arises at work, it is often at a time of changing work practices, shortage of staff or disharmony. Middle managers find it difficult to deal with and this compounds the stress.

It is seen throughout the developed world. It peaked in incidence in Australia in the 1970s and 1980s but has largely disappeared there, apparently because of changes in work practices, improvements in early medical management, changes in workers' compensation legislation, and reduced media discussion of the problem.

Treatment

If possible there should be a brief period off work and a gradual return to activity once the pain has settled. Use of analgesia and NSAIDs, with physiotherapy, is helpful during the initial phase to prevent a vicious circle developing. Amitriptyline or gabapentin is helpful for some patients.

A review of working practices and the positioning of screen, keyboard and chair are essential, as is support of the patient by their manager. Musicians are helped by expert advice on playing technique and should reduce playing times temporarily, but not stop completely.

Temporomandibular pain dysfunction syndrome

This is a disorder of the temporomandibular joint associated with nocturnal tooth grinding or abnormalities of bite. It particularly occurs in anxious people. It gives rise to pain in one or both temporomandibular joints.

Dental correction of the bite helps a few but when no dental cause is found, low-dose tricyclic antidepressant therapy is used. Many patients are exposed to much unnecessary dental treatment.

Chronic regional pain syndrome type 1 (previously called reflex sympathetic dystrophy or Sudek's atrophy)

This is defined as 'a complex disorder or group of disorders that may develop as a consequence of trauma affecting the limbs, with or without obvious nerve lesions'. It may also develop after central nervous system lesions (e.g. strokes) or without cause. It occurred in 1.5% of soldiers injured in Vietnam. Its features are pain and other sensory abnormalities, including hyperaesthesia, autonomic vasomotor dysfunction, leading to abnormal blood flow and sweating, and motor system abnormalities. This leads to structural changes of superficial and deep tissues (trophic changes). Not all components need be present. The sensory, motor and sympathetic nerve changes are not restricted to the distribution of a single nerve and may be remote from the site of injury. The early phase – with pain, swelling and increased skin temperature – is difficult to diagnose but potentially reversible.

After a period of weeks or months, a second, still painful, dystrophic phase develops, characterized by articular stiffness, cold skin and trophic changes, often with localized osteoporosis.

A late phase involves continued pain, skin and muscle atrophy, and muscle contractures, and is extremely disabling.

Diagnosis is initially clinical – a high index of suspicion and recognizing the unusual distribution of the pain. A three-phase bone scan shows diffuse or patchy increase in uptake in the affected limb in all three phases: early (a few seconds – arterial); middle (a few minutes – soft tissue); and late (several hours – mineral). The bone phase abnormalities appear early and well before demineralization is seen on X-ray. There is never loss of joint space, which distinguishes the appearances from the periarticular osteoporosis of inflammatory joint disease.

Treatment

Management is difficult and the problem often very disabling. The evidence base to treatment is poor, as in many rare disorders. Early diagnosis, effective pain relief and general care of the patient are essential. NSAIDs and corticosteroids are used in the early phase, together with active exercise of the limb encouraged by a physiotherapist. Calcitonin or intravenous disodium pamidronate may also help at this stage. If pain persists despite initial treatment, a phentolamine test is used to test for evidence of sympathetically maintained pain (i.v. infusion of up to 40 mg with careful cardiac monitoring). If this is positive, a stellate ganglion block is used for upper limb and a sympathetic chain block for lower limb involvement. Guanethidine (an alpha-blocking agent) or lidocaine administered to the limb under tourniquet is also useful. Referral to a pain management clinic is essential.

Chronic regional pain syndrome type II is discussed on page 1116.

ANALGESIC AND ANTI-INFLAMMATORY DRUGS FOR MUSCULOSKELETAL PROBLEMS

The key to using drugs, particularly in chronic disorders and the elderly, is to balance risk and benefit and constantly to review their appropriateness. Box 10.3 shows the main drugs available.

Simple and compound analgesic agents

Simple agents such as paracetamol, aspirin, or codeine compounds (or combination preparations), used when necessary or regularly, relieve pain and improve function. Paracetamol with dextropropoxyphene (co-proxamol) should not be prescribed and is being withdrawn. Sleep may also be improved. Side-effects are relatively infrequent, although drowsiness and constipation occur with codeine preparations, especially in the elderly.

Stronger analgesics, such as dihydrocodeine or morphine derivatives, should be used only with severe pain.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs have anti-inflammatory and centrally acting analgesic properties. They inhibit cyclo-oxygenase (COX), a key enzyme in the formation of prostaglandins, prostacyclins and thromboxanes (see Fig. 14.31). There are two specific cyclo-

Box 10.3 Analgesics and NSAIDs

Analgesics (in order of potency)

Advise that they be taken only if needed. Maximum doses are indicated here.

Paracetamol	500–1000 mg	6-hourly
Paracetamol with codeine	1–2 tablets	6-hourly
Paracetamol with dihydrocodeine	1–2 tablets	Every 6–8 hours
Dihydrocodeine	30–60 mg	Every 6–8 hours

Non-steroidal anti-inflammatory drugs (NSAIDs)

Always to be taken with food. Use slow-release preparations in inflammatory conditions or if more regular pain control is needed. Examples:

Ibuprofen	200–400 mg	Every 6–8 hours
Ibuprofen slow release	600–800 mg	12-hourly
Diclofenac	25–50 mg	8-hourly
Diclofenac slow release	75–100 mg	× 1–2 daily
Celecoxib*	100–200 mg	× 2 daily

*COX-2-specific NSAID (coxib).

FURTHER READING

Drenth JPH, Verheugt FWA. Do COX-2 inhibitors give enough gastrointestinal protection? *Lancet* 2007; **369:** 439–440.

oxygenase enzymes: COX-1, the constitutive form present in many normal tissues; and COX-2, the form mainly induced in response to pro-inflammatory cytokines and not found in most normal tissues. The latter is associated with oedema and the nociceptive and pyretic effects of inflammation. COX-2 appears to be constitutive in the kidney. Most of the older NSAIDs block both enzymes but with variable specificity; their therapeutic effect depends on blocking COX-2 and their side-effects mainly on blocking COX-1, for example, by the loss of gastric mucosal protection and a decrease in renal blood flow. COX-2 inhibitors (coxibs) were designed to reduce gastrointestinal toxicity by not blocking COX-1.

Uses

- *Short courses* of NSAIDs or coxibs are used occasionally in osteoarthritis and spondylosis, even when there is minimal inflammation. They are commonly used in musculoskeletal pain but simple analgesia is often more appropriate.
- *In crystal synovitis*, NSAIDs and coxibs have a true anti-inflammatory effect (see p. 538).
- *In chronic inflammatory synovitis*, NSAIDs and coxibs do not alter the chronic inflammatory process, or decrease the risk of joint damage, but they do reduce pain and stiffness.
- Slow-release preparations are useful for inflammatory arthritis and when more constant pain control is needed.
- Consider the patient's gastrointestinal and cardiac risks before prescribing NSAIDs or coxibs.
- NSAID gels have some value in chronic arthritis.

Side-effects

The most common with NSAIDs are indigestion or skin rashes. Gastric erosions and peptic ulceration with perforation and bleeding also occur. Ibuprofen should be avoided in combination with low dose aspirin as it significantly increases the risk of severe gastrointestinal bleeding. Proton pump inhibitors are probably the best drugs to protect those at high risk from serious gastrointestinal events and also reduce dyspepsia. H_2 blockers are less effective as gastroprotective agents. The value of prostaglandin E_2 analogues is limited by their tendency to cause nausea and diarrhoea. In the elderly, NSAIDs may cause gastric mucosal damage and gastrointestinal bleeding without warning symptoms, thereby causing significant morbidity and mortality. They may also reduce renal function, especially in the elderly (see Box 11.4). They should only be prescribed with a proton pump inhibitor in this group.

Coxibs produce fewer gastrointestinal side-effects but renal complications and fluid retention still occur. Rofecoxib was withdrawn because of an increase in cardiovascular events with prolonged use. It now appears that this may be a 'class' phenomenon of all NSAIDs and coxibs. Different agents may carry a lower risk in both groups but the studies remain unclear. Coxibs should be used in patients with a high risk of gastrointestinal disease and with no cardiovascular risk. Patients with a high risk of both may be better off taking an NSAID (diclofenac) and a proton pump inhibitor.

OSTEOARTHRITIS (OA)

Osteoarthritis is the most common type of arthritis. It occurs in synovial joints and is characterized by cartilage loss with an accompanying periarticular bone response. It is probably not a single disease entity but a multifactorial process in which mechanical factors have a central role. The whole joint structure including cartilage, subchondral bone, ligaments, menisci, synovium and capsule is involved. Pathologically, there is significant inflammation of articular and periarticular structures and alteration in cartilage structure. Enthesophytes and chrondrophytes seen on MRI precede radiologically apparent osteophytes and joint space narrowing. Clinically some patients complain of pain and disability. There are several patterns of involvement (p. 520).

Epidemiology

The prevalence of OA increases with age, and most people over 60 years will have some radiological evidence of it, although only a quarter of these will be symptomatic. It occurs world-wide, but with a variable distribution, e.g. in Asians, hip OA is less common and knee OA is more common than in Europeans. Women over 55 years are affected more commonly than are men of a similar age. There is a familial pattern of inheritance with distal interphalangeal joint involvement in nodal OA and also in primary generalized OA. OA has a variable distribution (Fig. 10.8). The resulting disabilities have major socio-economic resource implications, particularly in the developed world.

Aetiology (see Box 10.4)

Genes that encode collagen type II have been proposed as candidate genes for familial OA but the genes responsible have not yet been identified. Abnormal local mechanical factors play a role in most types of OA, possibly excluding the nodal form. Inflammation starting at periarticular entheses is seen during the inflammatory phase on MRI in nodal OA. Osteoarthritis is the result of active, sometimes inflammatory but potentially reparative processes rather than the inevitable result of trauma and ageing. Focal destruction of the articular cartilage is the common pathological feature. The spectrum of OA ranges from atrophic disease in which

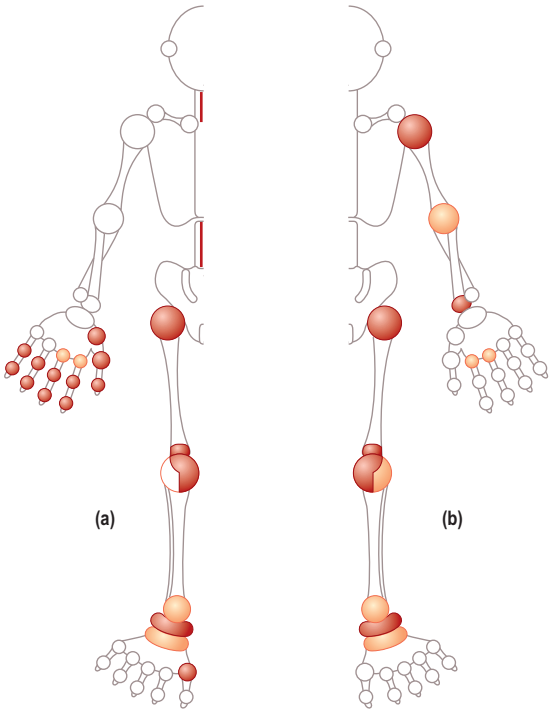

Fig. 10.8 **Typical distribution of affected joints in (a) primary generalized OA and (b) pyrophosphate arthropathy** (see p. 000). ●, more commonly affected; ●, less commonly affected.

Box 10.4 Factors predisposing to osteoarthritis

- *Obesity* – Predicts later risk of radiological and symptomatic OA in population studies.
- *Heredity* – Familial tendency to develop nodal and generalized OA.
- *Gender* – Polyarticular OA is more common in women; a higher prevalence after the menopause suggests a role for sex hormones.
- *Hypermobility* (see p. 554) – Increased range of joint motion and reduced stability lead to OA.
- *Osteoporosis* – There is reduced risk of OA.
- *Other diseases* – See Table 10.11.
- *Trauma* – A fracture through any joint. Meniscal and cruciate ligament tears cause OA of the knee.
- *Congenital joint dysplasia* – Alters joint biomechanics and leads to OA. Mild acetabular dysplasia is common and leads to earlier onset of hip OA.
- *Joint congruity* – Congenital dislocation of the hip or a slipped femoral epiphysis or Perthes' disease; osteonecrosis of the femoral head (see p. 565) in children and adolescents causes early-onset OA.
- *Occupation* – Miners develop OA of the hip, knee and shoulder, cotton workers OA of the hand, and farmers OA of the hip.
- *Sport* – Repetitive use and injury in some sports causes a high incidence of lower-limb OA.

cartilage destruction occurs without any subchondral bone response, to hypertrophic disease in which there is massive new bone formation at the joint margins.

Cartilage is a matrix of collagen fibres (mainly type II, see p. 568), which enclose a mixture of proteoglycans and water. Proteoglycans are present mainly as large molecular aggrecans, which consist of a protein core with polysaccharide side-chains of chondroitin sulphate and keratan sulphate.

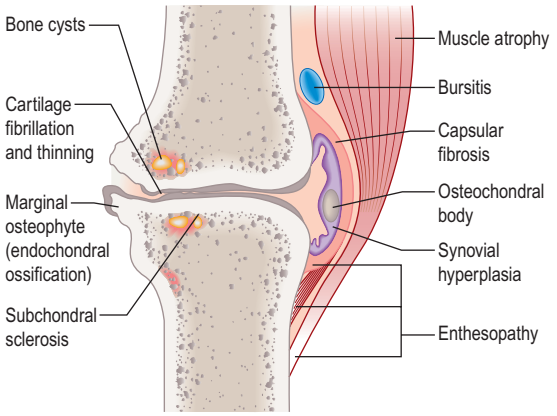

Fig. 10.9 **Early osteoarthritis of a knee** (diagram and X-ray). There is a medial compartment narrowing owing to cartilage thinning with subarticular sclerosis and marginal osteophyte formation (arrows).

The gene for human aggrecan has been cloned, and polymorphisms of the gene have been correlated with OA of the hand in older men.

Cartilage is smooth-surfaced and shock-absorbing. Under normal circumstances there is a dynamic balance between cartilage degradation by wear and its production by chondrocytes. Early in the development of OA this balance is lost and, despite increased synthesis of extracellular matrix, the cartilage becomes oedematous. Focal erosion of cartilage develops. Chondrocytes die and, although repair is attempted from adjacent cartilage, the process is disordered. Eventually the synthesis of extracellular matrix fails and the surface becomes fibrillated and fissured. Cartilage ulceration exposes underlying bone to increased stress, producing microfractures and cysts. The bone attempts repair but produces abnormal sclerotic subchondral bone and overgrowths at the joint margins, called osteophytes (Fig. 10.9). There is some secondary inflammation.

Pathogenesis

Several mechanisms have been suggested for the pathogenesis:

- Matrix loss is caused by the action of matrix metalloproteinases such as collagenase (MMP-1 and

MMP-13) which cleave collagen, and stromelysin (MMP-3) which is active against fibronectin and laminin in the extracellular matrix. MMPs are secreted by chrondrocytes in an inactive form. Extracellular activation then leads to the degradation of both collagen and proteoglycans.

- *Tissue inhibitors of metalloproteinases* (TIMPs) regulate the MMPs. Disturbance of this regulation may lead to increased cartilage degradation and contribute to the development of OA. TIMPs have not yet proven to be of therapeutic value.
- There is *synovial inflammation* in OA, and CRP may be raised. Interleukin-1 (IL-1) and tumour necrosis factor (TNF-α) release stimulates metalloproteinase production and IL-1 inhibits type II collagen production. IL-6 and IL-8 may also be involved. Anticytokine therapy has not yet been tested in OA. The production of cytokines by macrophages and of MMPs by chondrocytes in OA are dependent on the transcription factor NFκB. Inhibition of NFκB may have a therapeutic role in OA.
- *Growth factors*, including insulin-like growth factor (IGF-1) and transforming growth factor (TGF-β), are involved in collagen synthesis, and their deficiency may play a role in impairing matrix repair.
- *Vascular endothelial growth factor* (VEGF) from macrophages is a potent stimulator of angiogenesis and may contribute to inflammation and neovascularization in OA. Innervation can accompany vascularization of the articular cartilage where pressure and anoxia may stimulate these new nerves and lead to pain even when the inflammation has subsided.
- *Mutations* in the gene for type II collagen (*COL2A1*) have been associated with early polyarticular OA.
- *Twin studies* suggest a strong hereditary element underlying OA, and further studies may reveal genetic markers for the disease. The influence of genetic factors is estimated at 35–65%.
- In the *Caucasian* population there is an inverse relationship between the risk of developing OA and osteoporosis.
- A large population study has suggested that a high intake of *vitamin C* and other antioxidants may reduce the risk of OA. The lack of antioxidants is thought to contribute to many ageing processes.
- *Gender*. In *women*, weight-bearing sports produce a two- to threefold increase in risk of OA of the hip and knee. In *men*, there is an association between hip OA and certain occupations – farming and labouring.
- *Obesity* is a risk factor for developing OA in later life.

The term primary OA is sometimes used when there is no obvious known predisposing factor.

Box 10.4 shows some of the predisposing factors for the development of OA, whilst Table 10.11 shows other conditions that sometimes cause secondary arthritis.

Table 10.11 Causes of osteoarthritis

Primary OA	No known cause
Secondary OA	Pre-existing joint damage: Rheumatoid arthritis Gout Seronegative spondyloarthropathy Septic arthritis Paget's disease Avascular necrosis, e.g. corticosteroid therapy Metabolic disease: Chondrocalcinosis Hereditary haemochromatosis Acromegaly Systemic diseases: Haemophilia – recurrent haemarthrosis Haemoglobinopathies, e.g. sickle cell disease Neuropathies

Table 10.12 Features of nodal OA

Familial
Has a higher incidence in women
Typical pattern of polyarticular involvement of the hand joints
Develops in late middle age
Has a generally good long-term functional outcome
Associated with OA of the knee, hip and spine

Clinical features

Osteoarthritis affects many joints, with diverse clinical patterns. Hip and knee OA is the major cause of disability. Early OA is rarely symptomatic unless accompanied by a joint effusion, whilst advanced radiological and pathological OA is not always symptomatic.

Some flare-ups are due to inflammation and there may be a slight rise in ESR or CRP. Focal synovitis is caused by fragments of shed bone or cartilage. Radiological OA is usually, but not inevitably, progressive. This progression may be stepwise or continual. Radiological improvement is uncommon but has been observed, suggesting that repair is possible.

Symptoms

- Joint pain
- Joint gelling (stiffening and pain after immobility)
- Joint instability
- Loss of function.

Signs

- Joint tenderness
- Crepitus on movement
- Limitation of range of movement
- Joint instability
- Joint effusion and variable levels of inflammation
- Bony swelling
- Wasting of muscles.

Clinical subsets

Localized OA

Nodal OA (Table 10.12)

Joints of the hand are usually affected one at a time over several years, with the distal interphalangeal joints (DIPs) being more often involved than the proximal interphalangeal joints (PIPs). The onset may be painful and associated with tenderness, swelling and inflammation and impairment of hand function. At this stage enthesitis can be seen on MRI.

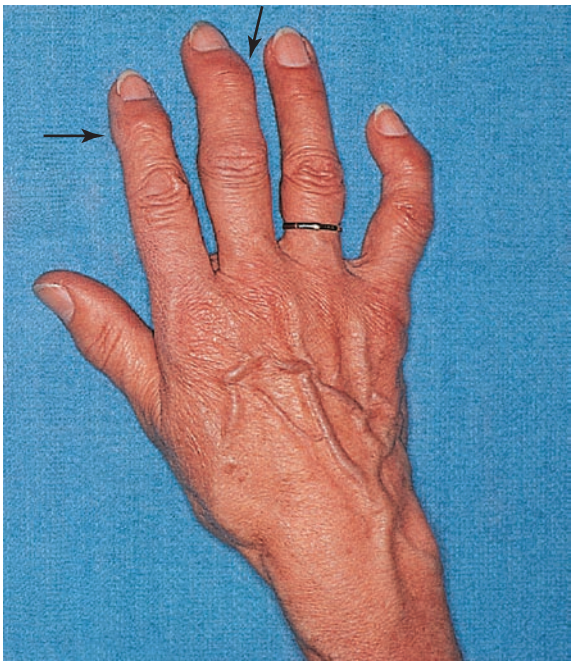

Fig. 10.10 **Severe nodal osteoarthritis.** The DIP joints demonstrate Heberden's nodes (arrows). The middle finger DIP joint is deformed and unstable. The thumb is adducted and the bony swelling of the first carpometacarpal joint is clearly shown – 'the squared hand of nodal OA'.

The inflammation often occurs around the female menopause. PIP-predominant nodal OA has a superficial similarity to early rheumatoid arthritis. Even if a weakly positive rheumatoid factor is found, it is of no significance. The inflammatory phase settles after some months or years, leaving painless bony swellings posterolaterally – Heberden's nodes (DIPs) and Bouchard's nodes (PIPs) – along with stiffness and deformity (Fig. 10.10). Functional impairment is slight for most, although PIP osteoarthritis restricts gripping more than DIP involvement. On X-ray, the nodes are marginal osteophytes and there is joint space loss.

Carpometacarpal and metacarpophalangeal OA of the thumb coexist with nodal OA and cause pain, which decreases as the joint stiffens. The 'squared' hand in OA is caused by bony swelling of the carpometacarpal joint and fixed adduction of the thumb. Function is rarely severely compromised.

Polyarticular hand OA is associated with a slightly increased frequency of OA at other sites.

Hip OA (see p. 512)

Hip OA affects 7–25% of white adult Caucasians but is significantly less common in black African and Asian populations. There are two major subgroups defined by the radiological appearance. The most common is *superior-pole hip OA*, where joint space narrowing and sclerosis predominantly affect the weight-bearing upper surface of the femoral head and adjacent acetabulum. This is most common in men and unilateral at presentation, although both hips may become involved because the disease is progressive. Early onset of hip OA is associated with acetabular dysplasia. Less commonly, *medial cartilage loss* occurs. This is most common in women and associated with hand involvement (nodal generalized OA – NGOA), and is usually bilateral. It is more rapidly disabling.

Knee OA

The prevalence of symptomatic knee OA is 40% in individuals aged over 75 years. It is commoner in women than in men. There is a strong relationship with obesity. The disease is generally bilateral and strongly associated with polyarticular OA of the hand in elderly women, sometimes alone, sometimes as part of generalized OA. The medial compartment is most commonly affected and leads to a varus (bow-legged) deformity. There is often also retropatellar OA. Previous trauma, meniscal and cruciate ligament tears are risk factors for developing knee OA.

Primary generalized OA

This is less common than nodal OA of the hands but is usually seen in combination. It is also called 'nodal generalized OA' (NGOA). The other joints affected are the knees, first MTP, hip, and intervertebral (spondylosis). There is a female preponderance and a strong familial tendency. NGOA is associated with immune complex deposition and may have an autoimmune cause. Its onset is often sudden and severe.

Erosive OA

This is rare. The DIPs and PIPs are inflamed and equally affected. In contrast to nodal OA, the functional outcome is poor. Radiologically, there are marked subchondral cysts. Erosive OA may develop into RA and may not be a true subset of OA.

Crystal-associated OA

This is most commonly seen with calcium pyrophosphate deposition in the cartilage (chondrocalcinosis). *Chondrocalcinosis* increases in frequency with age, but is usually asymptomatic. The joints most commonly affected are the knees (hyaline cartilage and fibrocartilage) and wrists (triangular fibrocartilage, see Fig. 10.8). There is patchy linear calcification on X-ray (Fig. 10.11).

A chronic arthropathy (pseudo-OA) occurs, predominantly in elderly women with severe chondrocalcinosis. There is a florid inflammatory component and marked osteophyte and cyst formation visible on X-rays. The joints affected differ from NGOA, being predominantly the knees, then wrists and shoulders, but also elbows, ankles and hips. Chondrocalcinosis is associated with pseudogout, an acute crystal-induced arthritis (see p. 539).

A rare, rapidly destructive arthritis in elderly women, affecting shoulders, hips and knees, is associated with finding crystals of calcium apatite in a bloody joint effusion. The outlook is poor and joints require early surgical replacement.

Investigations in OA

- **Blood tests**. There is no specific test; the ESR is normal although high sensitivity CRP may be slightly raised. Rheumatoid factor and antinuclear antibodies are negative.
- **X-rays** are abnormal only when the damage is advanced. They are useful to assess severity for operative intervention. For knees, a standing X-ray (stressed) is used to assess cartilage loss and 'skyline' views in flexion for patello-femoral OA.
- **MRI** demonstrates meniscal tears, early cartilage injury and subchondral bone changes.

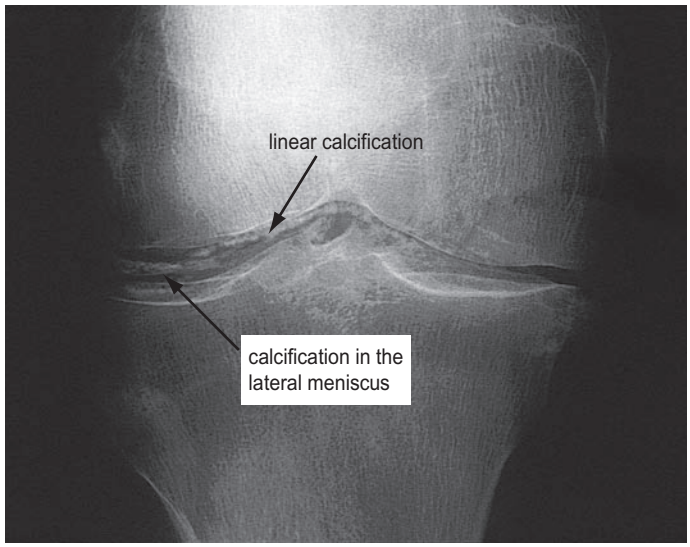

Fig. 10.11 **Chondrocalcinosis of the knee.** Note the linear calcification in the hyaline cartilage and calcification of the lateral meniscus (plus mild secondary OA).

- **Arthroscopy** reveals early fissuring and surface erosion of the cartilage.
- **Aspiration of synovial fluid** (if there is a painful effusion) shows a viscous fluid with few leucocytes and occasionally calcium pyrophosphate crystals (p. 536).

Management

The guiding principle is to treat the symptoms and disability, not the radiological appearances; depression and poor quadriceps strength are better predictors of pain than is radiological severity in OA of the knee. Education of the individual about the disease and its effects reduces pain, distress and disability and increases compliance with treatment. Psychological or social factors alter the impact of the disease.

Physical measures

Weight loss and exercises for strength and stability are useful. Hydrotherapy helps, especially in lower-limb OA. Local heat, ice packs, massage and rubifacients or local NSAID gels are all used. Insoles for shoes and a walking stick held on the contralateral side to the affected lower limb joint are useful.

There is increasing evidence that acupuncture helps knee OA. Other forms of complementary medicine are commonly used and, despite lack of scientific evidence, little is lost in trying it since a number of patients do seem to be helped.

Medication

Balance the potential benefit against potential side-effects. Patients should be prescribed short courses of simple analgesics before NSAIDs (see Box 10.3). NSAIDs or coxibs should be used intermittently.

Intra-articular corticosteroid injections produce short-term improvement when there is a painful joint effusion. Frequent injections into the same joint should be avoided. The role of intra-articular hyaluronan preparations is unproven.

The benefit of chondroitin sulphate and glucosamine compounds (sold as food supplements) is unproven. They appear to do no harm and some patients benefit.

There are no proven agents which halt or reverse OA although they are greatly needed. The role of bisphosphonates in reducing bone changes is unclear. The role of drugs which block tissue metalloproteinases or cytokines (see pathogenesis) is also unclear.

Surgery

Arthroscopic surgery for the knee is not beneficial. However, replacement arthroplasty has transformed the management of severe OA. The safety of hip and knee replacements is now equal, with a complication rate of about 1%; loosening, and late blood-borne infection are the most serious. Resurfacing hip surgery and unicompartmental knee replacement are less major procedures and appropriate for some patients. These slight but definite risks make it essential that the patient is certain that surgery is wanted, when all else has been tried. For the vast majority, a total hip or knee replacement reduces pain and stiffness and greatly increases function.

Other surgical procedures include realignment osteotomy of the knee or hip, excision arthroplasty of the first MTP and base of the thumb, and fusion of a first MTP joint.

INFLAMMATORY ARTHRITIS

Inflammatory arthritis includes a large number of arthritic conditions in which the predominant feature is synovial inflammation. This disparate group includes postviral arthritis, rheumatoid arthritis, seronegative spondyloarthropathy, crystal arthritis and Lyme arthritis. The diagnosis of these conditions is helped by the pattern of joint involvement (Table 10.13), along with any nonarticular disease; a past and family history is helpful. The distribution of the affected joints (symmetrical or asymmetrical; large or small) as well as the periodicity of the arthritis (single acute, relapsing, chronic and progressive) also help in the diagnosis.

Certain non-articular diseases – for example, psoriasis, iritis, inflammatory bowel disease, non-specific urethritis or recent dysentery – suggest a seronegative spondyloarthropathy. There may be evidence of recent viral illness (rubella, hepatitis B or erythro (parvo) virus), of rheumatic fever, or of a tick bite and skin rash (Lyme disease). In early arthritis it

Enteropathic arthritis
Arthritis associated with erythema nodosum

may not be possible to make a specific diagnosis until the disease has evolved.

There is a distinct genetic separation of rheumatoid-pattern synovitis and the seronegative group; RA (see below) is associated with a genetic marker in the class II major histocompatibility genes, whilst seronegative spondyloarthropathy shares certain alleles in the B locus of class I MHC genes, usually B27 (see p. 60).

In general the pain and stiffness of inflammatory arthritis are worse in the morning and after rest. This early-morning exacerbation may last several hours, in contrast to the much shorter post-rest gelling of OA. Inflammatory markers (ESR and CRP) are often raised in inflammatory arthritis, and there is often a normochromic, normocytic anaemia. Specific types of arthritis are discussed below.

RHEUMATOID ARTHRITIS (RA)

Rheumatoid arthritis is an autoimmune disease causing a chronic symmetrical polyarthritis with systemic involvement. Its course is extremely variable and it is associated with nonarticular features.

Epidemiology

RA has a world-wide distribution and affects 0.5–1% (with a female preponderance) of the population. The prevalence is high in the Pima Indian population and low in black Africans and Chinese people. The incidence, however, appears to be falling. RA is a significant cause of disability and mortality and carries a high socio-economic cost. It presents from early childhood (when it is rare) to late old age. The most common age of onset is between 30 and 50 years.

Aetiology and pathogenesis

The cause is multifactorial and genetic and environmental factors play a part.

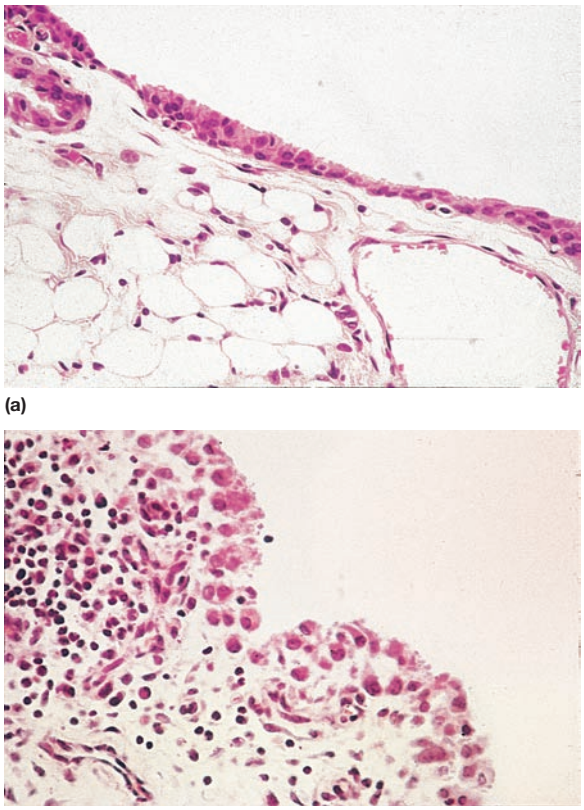
- *Gender*. Women before the menopause are affected three times more often than men. After the menopause the frequency of onset is similar between the sexes, suggesting an aetiological role for sex hormones. A meta-analysis of the use of the oral contraceptive pill has shown no affect on RA overall, as previously thought, but it may delay the onset of disease.
- *Familial*. The disease is familial with an increased incidence in first degree relatives and a high concordance amongst monozygotic twins (up to 15%) and dizygotic twins (3.5%). In occasional families it affects several generations.
- *Genetic* factors are estimated to account for up to 60% of disease susceptibility. There is a strong association between susceptibility to RA and certain HLA haplotypes. HLA-DR4, which occurs in 50–75% of patients, correlates with a poor prognosis, as does HLA-DRB1* 0404/0401. The possession of a specific pentapeptide (Q-K-RAA) in HLA-DRB1 increases susceptibility; combined with a positive rheumatoid factor it identifies individuals with a 13 times greater risk for developing bone erosions in early disease. In a genome-wide association study in anti-CCP positive RA, an association was found with loci near *HLA-DRBI* and *PTPN22* in people of European descent. A variant of *PAD14* has also been shown to be a risk factor in Asian populations. These genes affect the presentation of autoantigens (for *HLA-DRBI*), T cell receptor signal transduction (for *PTPN22*) and targets of anti-CCP antibodies (citrullination of proteins) for *PAD14*. Other variants have also been identified which modify changes at a molecular level, e.g. tumour necrosis factor receptor associated factor (*TRAF1*), variant C5, STAT4.

Immunology

Many factors have been implicated but the chronic synovial inflammation is caused by ongoing T cell activation.

- The presence of *activated T cells* and macrophages and local production of rheumatoid factor autoantibodies in the joint in RA suggests that immune dysregulation plays a fundamental role in pathogenesis.
- *Anti-CCP (anti-citrullinated cyclic peptide)* (p. 503) antibodies react with proteins where arginine has been replaced by citrulline. CCPs predate the clinical disease by several years. They help distinguish early RA from transient polyarthritis.
- Alternatively the inflammation may be maintained by the *local production of rheumatoid factors* and continuous stimulation of macrophages via IgG Fc receptors. Considering the extent of synovial inflammation and lymphocytic infiltration, there are only minimal amounts of factors normally produced by T cells (interferon and IL-2 and -4). Conversely, the cytokines (IL-1, IL-8, TNF-α, granulocyte–macrophage colony-stimulating factor) and chemokines produced by macrophages (macrophage inflammatory protein (MIP) and monocyte chemoattractant protein (MCP)) and fibroblasts (producing IL-6) are abundant.
- *Activated mast cells* which release histamine and TNF-α may also play a role.
- *CD4-specific antibodies*, when they were used therapeutically, produced a specific helper T cell lymphopenia but did not significantly alter the disease, raising the possibility that T cells play a lesser role. They are no longer used.

- *Temporary CD20 positive B cell ablation* (a technique used for treating B cell lymphomas) induces remission, reinforcing the central place of rheumatoid factor production in maintaining the chronic inflammation of RA. As the B cells return, the CRP rises and the disease flares again.
- The *TNF superfamily of cytokines* produced mainly by activated macrophages and T cells play a role in the development of joint inflammation. Antibodies to TNF-α, IL-1 or specific blocking agents produce marked short-term improvement in synovitis, indicating the pivotal role of these cytokines in the chronic synovitis (see p. 54). They also reduce the malaise and tiredness felt in active RA.
- *Synovial fibroblasts* have high levels of the adhesion molecule, vascular cell adhesion molecule (VCAM-1 – a molecule which supports B lymphocyte survival and differentiation), decay accelerating factor (DAF – a factor that prevents complement-induced cell lysis) and cadherin-II (which mediates cell to cell interactions). These molecules may facilitate the formation of ectopic lymphoid tissue in synovium. Recent studies have shown that mice deficient in cadherin-II are resistant to a form of inflammatory arthritis. High-affinity antibodies are not a feature of RA, unlike other autoimmune diseases.



The *triggering antigen* remains unclear, although it is suggested that the glycosylation pattern of immunoglobulins may be abnormal in RA and lead to their becoming potentially antigenic. There is little evidence that collagen type II is the triggering antigen, although it is a cause of arthritis in animal models of RA.

Bacterial or slow virus infections have been implicated but are unproven. It has been suggested that an immune response to any pathogen is to produce autoantibodies by B cell clonal expansion. In susceptible individuals such clones may persist.

Pathology

Rheumatoid arthritis is typified by widespread persisting synovitis (inflammation of the synovial lining of joints, tendon sheaths or bursae). The cause of this is unclear, but the production of rheumatoid factors (RFs, see below) by plasma cells in the synovium and the local formation of immune complexes play a part. The normal synovium is thin and comprises a lining layer a few cells thick containing fibroblast-like synoviocytes and macrophages overlying loose connective tissue. The synoviocytes play a central role in synovial inflammation. In RA the synovium becomes greatly thickened to the extent that it is palpable as a 'boggy' swelling around the joints and tendons. There is proliferation of the synovium into folds and fronds, and it is infiltrated by a variety of inflammatory cells, including polymorphs, which transit through the tissue into the joint fluid, and lymphocytes and plasma cells. There are disorganized lymphoid follicles that are responsive to exogenous antigens. The normally sparse surface layer of lining cells becomes hyperplastic and thickened (Fig. 10.12). There is marked vascular proliferation. Increased permeability of blood vessels and the synovial lining layer leads to joint effusions that contain lymphocytes and dying polymorphs.

The hyperplastic synovium spreads from the joint margins on to the cartilage surface. This 'pannus' of inflamed synovium damages the underlying cartilage by blocking its normal route for nutrition and by the direct effects of cytokines on the chondrocytes. The cartilage becomes thinned and the underlying bone exposed. Local cytokine production and joint disuse combine to cause juxta-articular osteoporosis during active synovitis.

(a)

(b)

Fig. 10.12 **Histological appearance of RA synovium.** **(a)** Normal synovium. **(b)** Synovial appearances in established RA, showing marked hypertrophy of the tissues with infiltration by lymphocytes and plasma cells. From Shipley M *Colour Atlas of Rheumatology*, 3rd edn. London: Mosby-Wolfe, 1993, with permission.

Fibroblasts from the proliferating synovium also grow along the course of blood vessels between the synovial margins and the epiphyseal bone cavity and damage the bone. This is shown by MRI to occur in the first 3–6 months following onset of the arthritis, and before the diagnostic, ill-defined juxta-articular bony 'erosions' appear on X-ray (Fig. 10.13). This early damage justifies the use of DMARDs (see p. 530) within 3–6 months of onset of the arthritis. Low-dose steroids delay and anti-TNF-α agents halt or even reverse erosion formation. Erosions lead to a variety of deformities and contribute to long-term disability.

Rheumatoid factors (RFs) and anti-CCP antibodies (see also p. 503)

RFs are circulating autoantibodies that have the Fc portion of IgG as their antigen. The nature of the antigen means that they self-aggregate into immune complexes and thus activate complement and stimulate inflammation, causing chronic synovitis. Transient production of RFs is an essential part of the body's normal mechanism for removing immune complexes, but in RA they show a much higher affinity and their production is persistent and occurs in the joints. They

Fig. 10.13 **X-ray of early RA**, showing typical erosions at the thumb (black and white arrows) and middle MCP joints (black arrow) and at the ulnar styloid (white arrow).

Box 10.5 Differential diagnosis of early rheumatoid arthritis

- Postviral arthritis – rubella, hepatitis B or parvovirus
- Seronegative spondyloarthropathies
- Polymyalgia rheumatica
- Acute nodal osteoarthritis (PIPs and DIPs involved)

Box 10.6 Presentations of rheumatoid arthritis

- **Palindromic** – Monoarticular attacks lasting 24–48 hours; 50% progress to other types of RA.
- **Transient** – A self-limiting disease, lasting less than 12 months and leaving no permanent joint damage. Usually seronegative for IgM rheumatoid factor and CCP. Some of these may be undetected postviral arthritis.
- **Remitting** – There is a period of several years during which the arthritis is active but then remits, leaving minimal damage.
- **Chronic, persistent** – The most typical form, it may be seropositive or seronegative for IgM rheumatoid factor. The disease follows a relapsing and remitting course over many years. Seropositive (plus anti-CCP) patients tend to develop greater joint damage and long-term disability. They warrant earlier and more aggressive treatment with disease-modifying agents.
- **Rapidly progressive** – The disease progresses remorselessly over a few years and leads rapidly to severe joint damage and disability. It is usually seropositive (plus anti-CCP), has a high incidence of systemic complications and is difficult to treat.

are of any immunoglobulin class (IgM, IgG or IgA), but the most common tests employed clinically detect IgM rheumatoid factor. Around 70% of patients with polyarticular RA have IgM rheumatoid factor in the serum. Positive titres can predate the onset of RA.

The term seronegative RA is used for patients in whom the standard tests for IgM rheumatoid factor are persistently negative. They tend to have a more limited pattern of synovitis.

IgM rheumatoid factor is not diagnostic of RA and its absence does not rule the disease out; however, it is a useful predictor of prognosis. A persistently high titre in early disease implies more persistently active synovitis, more joint damage and greater disability eventually, and justifies earlier use of DMARDs.

RF and the antibody to CCP (see p. 503) together are more specific. RF indicates persistence but anti-CCP predicts the development of erosions and a worse prognosis. Measurement of CCP may take over from RF in day to day management because of its greater predictive value of persistence in early inflammatory arthritis.

CLINICAL FEATURES OF RA

Typical presentation

The most typical presentation of rheumatoid arthritis (approximately 70% of cases) begins as a slowly progressive, symmetrical, peripheral polyarthritis, evolving over a period of a few weeks or months. The patient is usually in her thirties to fifties, but the disease can occur at any age. Less commonly (15%) a rapid onset can occur over a few days (or explosively overnight) with a severe symmetrical polyarticular involvement. These patients often have a better prognosis. A worse than average prognosis (with a predictive accuracy of about 80%) is indicated by being female, a gradual onset over a few months, and a positive IgM rheumatoid factor, and/or anaemia within 3 months of onset. The differential diagnosis of early RA is shown in Box 10.5.

Symptoms and signs

The majority of patients complain of pain and stiffness of the small joints of the hands (metacarpophalangeal, MCP; proximal and distal interphalangeal, PIP, DIP) and feet (metatarsophalangeal, MTP). The wrists, elbows, shoulders, knees and ankles are also affected. In most cases many joints are involved, but 10% present with a monoarthritis of the knee or shoulder or with a carpal tunnel syndrome.

The patient feels tired and unwell and the pain and stiffness are significantly worse in the morning and may improve with gentle activity. Sleep is disturbed.

The joints are usually warm and tender with some joint swelling. There is limitation of movement and muscle wasting. Deformities develop as the disease progresses. Non-articular features develop (see below).

Other presentations

The presentation and progression of RA is variable. Presentations are shown in Box 10.6. Relapses and remissions occur either spontaneously or in response to drug therapy. In some patients the disease remains active, producing progressive joint damage. Rarely the process may cease ('burnt-out RA').

A *seronegative, limited synovitis* initially affects the wrists more often than the fingers and has a less symmetrical joint involvement. It has a better long-term prognosis, but some cases progress to severe disability. This form can be confused with psoriatic arthropathy, which has a similar distribution (p. 1240).

Table 10.14 Complications of rheumatoid arthritis
Complications of the condition
Ruptured tendons
Ruptured joints (Baker's cysts)
Joint infection
Spinal cord compression (atlantoaxial or upper cervical spine)
Amyloidosis (rare)
Side-effects of therapy
See Table 10.15

Palindromic rheumatism is unusual (5%) and consists of short-lived (24–72 h) episodes of acute monoarthritis. The joint becomes acutely painful, swollen and red, but resolves completely. Further attacks occur in the same or other joints. About 50% go on to develop typical chronic rheumatoid synovitis after a delay of months or years. The rest remit or continue to have acute episodic arthritis. The detection of IgM rheumatoid factor/anti-CCP predicts conversion to chronic, destructive synovitis.

Complications (Table 10.14)

Septic arthritis

This is a serious complication with significant morbidity and mortality. Affected joints are hot and inflamed with accompanying fever and a neutrophil leucocytosis in the blood. However, these signs are often absent, and any effusion, particularly of sudden onset, should be aspirated. *Staphylococcus aureus* is the most common organism. Blood cultures are often positive. Treatment is with systemic antibiotics (see p. 539) and drainage.

Amyloidosis (see p. 1072)

Amyloidosis is found in a very small number of people with severe rheumatoid arthritis. RA is the most common cause of secondary AA amyloidosis. AL amyloidosis causes a polyarthritis that resembles RA in distribution and is also often associated with carpal tunnel syndrome and subcutaneous nodules.

Joint involvement in RA

Hands and wrists

The impact of RA on the hands is severe. In early disease the fingers are swollen, painful and stiff. Inflamed flexor tendon sheaths increase functional impairment and may cause a carpal tunnel syndrome. Joint damage causes a variety of typical deformities. Most typical is a combination of ulnar drift and palmar subluxation of the MCPs (Fig. 10.14). This leads to unsightly deformity, but function may be remarkably good once the patient has learned to adapt, and pain is controlled. Fixed flexion (buttonhole or boutonnière deformity) or fixed hyperextension (swan-neck deformity) of the PIP joints impairs hand function.

Swelling and dorsal subluxation of the ulnar styloid leads to wrist pain and may cause rupture of the finger extensor tendons, leading in turn to a sudden onset of finger drop of the little and ring fingers predominantly, which needs urgent surgical repair.

Shoulders

RA commonly affects the shoulders. Initially the symptoms mimic rotator cuff tendonosis (see p. 507) with a painful arc syndrome and pain in the upper arms at night. As the joints become more damaged, global stiffening occurs. Late in the disease rotator cuff tears are common (see p. 507) and interfere with dressing, feeding and personal toilet.

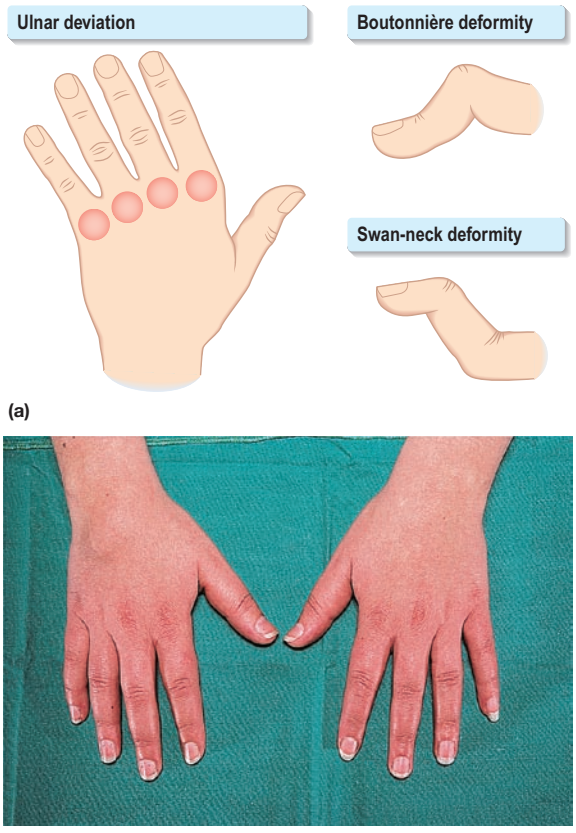


Fig. 10.14 Rheumatoid arthritis (a) Characteristic hand deformities in RA. (b) Early rheumatoid arthritis – dorsal tenosynovitis of the right wrist and small joints of both hands with spindling of the fingers.

Elbows

Synovitis of the elbows causes swelling and a painful fixed flexion deformity. In late disease flexion may be lost and severe difficulties with feeding result, especially combined with shoulder, hand and wrist deformities.

Feet

One of the earliest manifestations of RA is painful swelling of the MTP joints. The foot becomes broader and a hammer-toe deformity develops. Exposure of the metatarsal heads to pressure by the forward migration of the protective fibrofatty pad (Fig. 10.15) causes pain. Ulcers or callouses may develop under the metatarsal heads and the dorsum of the toes. Mid- and hindfoot RA causes a flat medial arch and loss of flexibility of the foot. The ankle often assumes a valgus position. Appropriate broad, deep, cushioned shoes are essential but rarely wholly adequate, and walking is often painful and limited. Podiatry helps and surgery may be required.

Knees

Massive synovitis and knee effusions occur, but respond well to aspiration and steroid injection (see p. 504). A persistent effusion increases the risk of popliteal cyst formation and

Ask the authors

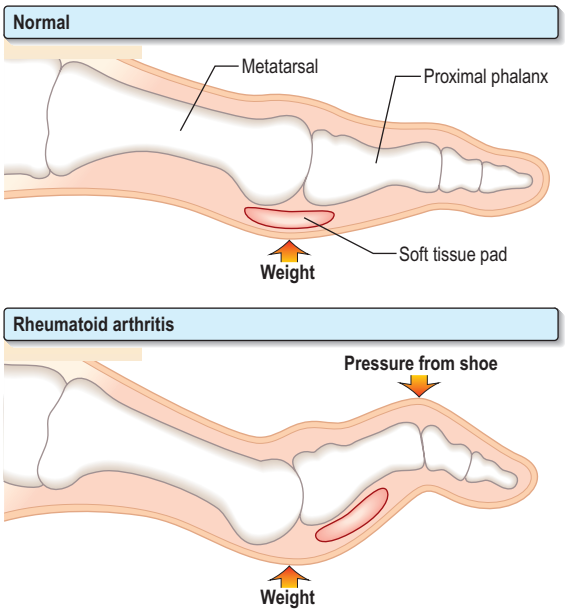

Fig. 10.15 **The toes in RA**, showing exposure of the metatarsal heads with forward migration of the soft tissue pad.

rupture (see p. 514). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary OA follows. Total knee replacement is often the only way to restore mobility and relieve pain.

Hips

The hips are rarely affected in early RA and are less commonly affected than the knees at all stages of the disease. Pain and stiffness are accompanied by radiological loss of joint space and juxta-articular osteoporosis. The latter may permit medial migration of the acetabulum (protrusio acetabulae). Later, secondary OA develops. Hip replacement is usually necessary.

Cervical spine

Painful stiffness of the neck in RA is often muscular, but it may be due to rheumatoid synovitis affecting the synovial joints of the upper cervical spine and the bursae which separate the odontoid peg from the anterior arch of the atlas and from its retaining ligaments. This synovitis leads to bone destruction, damages the ligaments and causes atlanto-axial or upper cervical instability. Subluxation and local synovial swelling may damage the spinal cord, producing pyramidal and sensory signs. MRI is the best way of visualizing this, but lateral flexed and extended neck X-rays can demonstrate instability. In late RA, difficulty walking which cannot be explained by articular disease, weakness of the legs or loss of control of bowel or bladder may be due to spinal cord compression and is a neurosurgical emergency. Image the cervical spine in flexion and extension in patients with RA before surgery or upper gastrointestinal endoscopy to check for instability and reduce the risk of cord injury during intubation. Severe neck involvement is less common than previously although the reason for this is not clear.

Other joints

The temporomandibular, acromioclavicular, sternoclavicular, cricoarytenoid and any other synovial joint can be affected.

Non-articular manifestations (Fig. 10.16)

Soft tissue surrounding joints

Subcutaneous nodules are firm, intradermal and generally occur over pressure points, typically the elbows, the finger joints and the Achilles tendon. Histologically there is a necrotic centre surrounded by rows of activated macrophages, which resembles synovitis without a synovial space.

The nodules may ulcerate and become infected, but usually resolve when the disease comes under control. The nodules can be removed surgically or injected with corticosteroids if causing a problem. They tend to recur.

The olecranon and other bursae may be swollen (bursitis).

Tenosynovitis of affected flexor tendons in the hand can cause stiffness and occasionally a trigger finger. Swelling of the extensor tendon sheath over the dorsum of the wrist is common.

Muscle wasting around joints is common. Muscle enzyme concentrations are normal; myositis is extremely rare. Corticosteroid-induced myopathy may occur.

Lungs (see also p. 871)

Peripheral, intrapulmonary nodules are usually asymptomatic but may cavitate. When pneumoconiosis is present (Caplan's syndrome), large cavitating lung nodules develop.

Other manifestations are:

- serositis causing pleural effusion
- pleural nodules
- fibrosing alveolitis (lung fibrosis)
- obstructive bronchiolitis
- infective lesions, e.g. TB in patients on biological DMARDs.

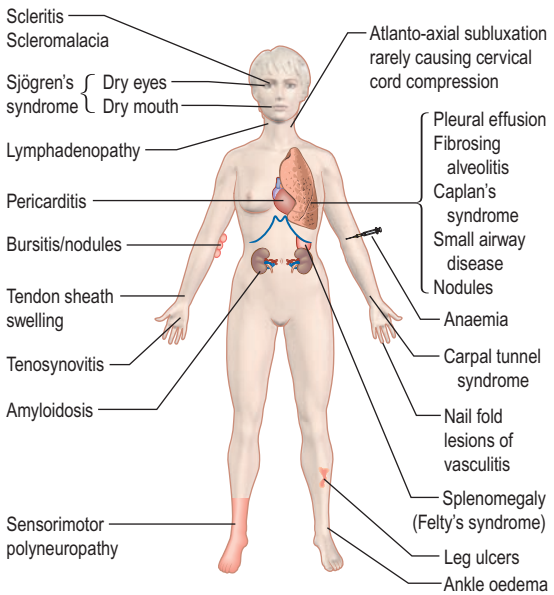

Fig. 10.16 **Non-articular manifestations of RA.**

Vasculitis

Vasculitis (see p. 548) is caused by immune complex deposition in arterial walls. It is uncommon. Smoking is a risk factor. Other manifestations are:

- nail fold infarcts due to cutaneous vasculitis
- widespread cutaneous vasculitis with necrosis of the skin (seen in patients with very active, strongly seropositive disease)
- mononeuritis multiplex (p. 1172)
- bowel infarction due to necrotizing arteritis of the mesenteric vessels (this may be indistinguishable from polyarteritis nodosa).

The heart and peripheral vessels

Poorly controlled RA with a persistently raised CRP is a risk factor for premature coronary artery and cerebrovascular atherosclerosis independent of traditional risk factors (i.e. raised lipids and hypertension). Clinical pericarditis is rare. In strongly seropositive RA, echocardiogram or post-mortem studies, however, show that 30–40% of patients have pericardial involvement.

Endocarditis and myocardial disease are rarely seen clinically, but are found at post-mortem in approximately 20% of cases. These are secondary to vasculitis.

Raynaud's syndrome occurs (see p. 809).

The nervous system

Neuropathies, either mononeuritis multiplex or a sensory loss in a glove and stocking pattern, are due to vasculitis of the vasa nervorum. Compression neuropathies such as carpal or tarsal tunnel syndrome are due to local synovial hypertrophy. Atlanto-axial subluxation can cause serious neurological abnormalities in advanced disease (see above).

The eyes

Scleritis and episcleritis occur in severe, seropositive disease and produce painful red lesions in the eye. Scleritis may lead to perforation of the eye (scleromalacia perforans) and requires active treatment with local and systemic corticosteroids.

Sicca syndrome causes dry mouth and eyes (see Sjögren's syndrome, p. 548).

The kidneys

Amyloidosis causes the nephrotic syndrome and renal failure. Presentation is with proteinuria. It occurs rarely in severe, long-standing rheumatoid disease and is due to the deposition of highly stable serum amyloid A protein (SAP) in the intercellular matrix of a variety of organs. SAP is an acute-phase reactant, produced normally in the liver. Amyloidosis is rare, and proteinuria in RA is more commonly due to DMARDs.

The spleen, lymph nodes and blood

Felty's syndrome is splenomegaly and neutropenia in a patient with RA. Leg ulcers or sepsis are complications. HLA-DR4 is found in 95% of patients, compared with 50–75% of patients with RA alone.

The lymph nodes may be palpable, usually in the distribution of affected joints. There may be peripheral lymphoedema of the arm or leg.

Anaemia is almost universal and is usually the normochromic, normocytic anaemia of chronic disease. It may be iron-deficient owing to gastrointestinal blood loss from NSAID ingestion, or rarely haemolytic (Coombs' positive). There may be a pancytopenia due to hypersplenism in Felty's syndrome or as a complication of DMARD treatment. A high platelet count occurs with active disease.

DIAGNOSIS AND INVESTIGATIONS

The diagnosis relies on the clinical features described above. The American College of Rheumatology (ACR) criteria are shown in Box 10.7 and are useful for epidemiological and investigative studies but unhelpful in early disease.

Initial investigations include:

- **Blood count**. Anaemia may be present. The ESR and/or CRP are raised in proportion to the activity of the inflammatory process and are useful in monitoring treatment.
- **Serology**. Anti-CCP (see p. 503) is positive earlier in the disease, and in early inflammatory arthritis indicates the likelihood of progressing to RA. Rheumatoid factor is present in approximately 70% of cases and ANA at low titre in 30%.
- **X-rays of the affected joint(s)** to establish a baseline. Only soft tissue swelling is seen in early disease. MRI demonstrates early erosions but is rarely warranted.
- **Aspiration of the joint** if an effusion is present. The aspirate looks cloudy owing to white cells. In a suddenly painful joint septic arthritis should be suspected (see p. 539).

Other investigations will depend on the clinical picture as outlined above. In severe disease extensive imaging of joints may be required. MRI is the technique of choice, especially for the knee and cervical spine.

MANAGEMENT OF RA (Box 10.8)

The diagnosis of RA inevitably causes concern and fear in the patient and requires a lot of explanation and reassurance. Early diagnosis with early referral to a rheumatologist is vital. The doctor and therapist should retain a positive approach and remind the patient that with the help of drugs most will continue to lead a more or less normal life despite their arthritis; 25% will recover completely. The earliest years are often the most difficult and people should be helped and encouraged to stay at work during this phase if possible. Uncertainty about when the disease will remit and flare, when

Box 10.7 Criteria for the diagnosis of rheumatoid arthritis (American College of Rheumatology, 1988 revision)

- Morning stiffness > 1 hour
- Arthritis of three or more joints
- Arthritis of hand joints and wrists

} For 6 weeks or more

- Symmetrical arthritis
- Subcutaneous nodules
- A positive serum rheumatoid factor
- Typical radiological changes (erosions and/or periarticular osteopenia)

Four or more criteria are necessary for diagnosis.

Box 10.8 Management of rheumatoid arthritis

- Establish the diagnosis clinically.
- Use NSAIDs and analgesics to control symptoms.
- Try to induce remission with i.m. depot methylprednisolone 80–120 mg if synovitis persists beyond 6 weeks.
- If synovitis recurs, refer to a rheumatologist to start sulfasalazine or methotrexate. Give a second dose of i.m. depot methylprednisolone.
- Refer for physiotherapy and general advice through a specialist team.
- If there is no significant improvement in 6–12 weeks as measured by less pain, less morning stiffness and reduced acute-phase response, use a combination of methotrexate and sulfasalazine.
- If no better, use an alternative agent, such as gold, D-penicillamine, leflunomide or anti-TNF-α therapy

Box 10.9 Problems associated with the use of corticosteroids

- Patients are increasingly anxious about the use of corticosteroids because of adverse publicity about their potential side-effects. This must be discussed frankly and the risks of not using corticosteroids in treatment should be described and balanced against the risks of the drugs themselves.
- Patients must be warned to avoid sugars and saturated fats and to eat less because of the risk of weight gain.
- The skin becomes thin and easily damaged.
- Monitor for diabetes and hypertension.
- Cataract formation may be accelerated.
- Osteoporosis develops within 6 months on doses above 7.5 mg daily. Monitor with DXA scan and treat with calcium and vitamin D and bisphosphonate (see p. 564).

and if drugs will work, and whether they produce side-effects, makes planning from day to day difficult. People learn to adjust remarkably but this takes time and support. A rheumatology unit will have a team, including doctors, specialist nurses and physiotherapists, to help the patient learn to cope. Leaflets and websites give helpful advice, as do local patient groups. Patients from socially deprived backgrounds and smokers have a worse prognosis. Statins have been shown to be of benefit in reducing cardiovascular risk and possibly inflammation whatever the cholesterol level; more studies are required.

Drug therapy

There is no curative agent available for RA but drugs are now available that prevent disease deterioration. Symptoms are controlled with analgesia and NSAIDs. Data now support the use of DMARDs early in the disease to prevent the long-term irreversible damaging effects of inflammation of the joints, and drugs that block TNF-α and IL-1 and the use of B cell ablation with rituximab are revolutionizing the management of RA.

Non-steroidal anti-inflammatory drugs (NSAIDs) and coxibs

Most patients with RA are unable to cope without an NSAID to relieve night pain and morning stiffness. NSAIDs do not reduce the underlying inflammatory process. They all act on the cyclo-oxygenase (COX) pathway (see Fig. 14.32). The individual response to NSAIDs varies greatly. It is desirable therefore to try several different drugs for a particular patient in order to find the best (see Box 10.8). Each compound should be given for at least a week. Start with an inexpensive NSAID with few side-effects and with which you are familiar. Regular doses are needed to be effective. The major side-effects of NSAIDs and the use of coxibs are discussed on page 517. If gastrointestinal side-effects are prominent, or the patient is over 65 years, add a proton pump inhibitor. Slow-release preparations (e.g. slow-release diclofenac, 75 mg, taken after supper), or a suppository at bedtime, usually work well and can be given in addition to daytime therapy if necessary. For additional relief a simple analgesic is taken as required (e.g. paracetamol or a combination of codeine or dihydrocodeine and paracetamol). Many patients need night sedation.

Corticosteroids

There is evidence to suggest that the early use of corticosteroids slows down the course of the disease.

Intra-articular injections with semicrystalline steroid preparations have a powerful but sometimes only short-lived effect.

Intramuscular depot injections (40–120 mg depot methylprednisolone) help to control severe disease flares, or can be used before a holiday or other life event, but should be used infrequently.

The use of oral corticosteroids has a number of problems (see Boxes 10.9 and 18.9). They are powerful disease-controlling drugs, but are avoided in the long term because side-effects are inevitable. Early intensive short-term regimens are used in some centres. Others use doses of 5–7.5 mg as maintenance therapy. There is some evidence that increased physical activity because of better symptom control reduces the risk of osteoporosis. Corticosteroids are also invaluable to patients with severe disease with extra-articular manifestations such as vasculitis.

Disease-modifying anti-rheumatic drugs

(Table 10.15)

- Traditional DMARDs, which mainly act through cytokine inhibition, reduce inflammation, with a reduction of joint swelling, a fall in the plasma acute-phase reactants and slowing of the development of joint erosions and irreversible damage. Their beneficial effect is not immediate (hence 'slow-acting agents') and may be partial or transient.
- DMARDs often only have a partial effect, achieving between 20 and 50% improvement by ACR criteria for disease remission (morning stiffness <15 min; no fatigue, joint pain, joint tenderness or soft tissue swelling; an ESR of <30 in women and <20 in men). TNF-α blocking agents and rituximab achieve almost 70% improvement in around 20% of patients and they also act more rapidly.
- Sulfasalazine, methotrexate, leflunomide, TNF-α blockers, ciclosporin and rituximab have all been shown to reduce the rate of progressive joint damage in early and late disease.

Generally DMARDs are used after symptomatic treatment. However, patients positive for RF and anti-CCP with persis-

Table 10.15 Disease-modifying anti-rheumatic drugs (DMARDs)

Drug	Dose	Side-effects	Monitoring to detect side-effects
Sulfasalazine (enteric coated)	500 mg daily after food, increasing to 2–3 g daily	Nausea Skin rashes and mouth ulcers	
		Neutropenia and/or thrombocytopenia	Initial, 2 weeks, then 4-monthly
		Abnormal liver biochemistry	Initial, 2 weeks, then 4-monthly
Methotrexate	2.5 mg increasing to 25 mg weekly, orally or s.c.	Nausea, mouth ulcers and diarrhoea	
		Abnormal liver biochemistry	Initial, 2 weeks, then monthly
		Neutropenia and/or thrombocytopenia	Initial, weekly, then monthly
		Renal impairment	Initial, then every 3–6 months
		Pulmonary fibrosis (rare)	Baseline chest X-ray
Leflunomide	100 mg daily for 1–3 days, then 20 (or 10) mg daily or 10–20 mg daily	Diarrhoea	
		Neutropenia and/or thrombocytopenia	Initial, then 2 weekly; monthly at 6 months
		Abnormal liver biochemistry Alopecia Hypertension	Initial, then 2 weekly; monthly at 6 months
TNF-α blockers		**For all**	
Etanercept (alone or with methotrexate)	s.c. 25 mg × 2 weekly or 50 mg weekly	Injection site reactions Infections, e.g. TB and septicaemia Hypersensitivity reactions Heart failure Rare – demyelination and autoimmune syndromes Reversible lupus-like syndrome	See British Society for Rheumatology Guidelines www.rheumatology.org.uk/guidelines/clinicalguidelines Stop if no response after 6 months
Adalimumab (with methotrexate)	s.c. 40 mg alternate weeks		
Infliximab (with methotrexate)	i.v. 3–10 mg/kg every 4–8 weeks		
Other biological agents (used with methotrexate)			
Anakinra	1 mg/kg s.c. daily	Injection site reaction Serious reactions – rare	Used after failure of anti-TNF agents
Rituximab	i.v. 500–1000 mg	Hypo/hypertension, skin rash, nausea, pruritis, back pain Rare – toxic epidermal necrolysis	
Abatacept	i.v. 10 mg/kg on days 1, 15, 30 and then monthly	Nausea, vomiting Headache Hypersensitivity – rare	
Tocilizumab	i.v. 8 mg/kg infusion	Headache, skin eruption, stomatitis, fever, anaphylactic reactions	Phase III studies

tent joint swelling have a poor prognosis and they should be treated early with DMARDs – preferably before the appearance of erosions on X-rays of hands and feet. Studies of early RA suggest that intervention with DMARDs at 6 weeks to 6 months improves the outcome. The use of combinations of three or four drugs (steroids, methotrexate, sulfasalazine and hydroxychloroquine) in early RA, reducing the number of agents once remission has been achieved, is more controversial and its long-term efficacy is yet to be proven. Toxicity appears to be reduced with such combinations, possibly because inflammation is controlled effectively. Effective treatment with DMARDs reduces the increased cardiovascular risk seen in patients with RA.

You must not, however, overtreat people who are not going to develop erosions. Most prognostic assessments in early disease are only 80% accurate for risk of erosions and subsequent disability, and clinical judgement retains a central place in managing RA. DMARDs are usually prescribed by a rheumatologist and early referral is essential.

Sulfasalazine

This is a combination of sulfapyridine and 5-amino-salicylic acid. Sulfapyridine is probably the active component. It is well tolerated and for many is the first-choice DMARD, especially in younger patients and women who are planning a family. It produces a response in about half the patients in the first 3–6 months. Serious side-effects are rare, being mainly leucopenia and thrombocytopenia.

Methotrexate

This is considered by many to be the drug of choice. It should not be used in pregnancy. Conception should be delayed for 3–6 months off the drug for either partner. It is given at an initial weekly dose of 2.5–7.5 mg orally, increased up to 15–25 mg if necessary. It is well tolerated and this therapy can be introduced early in the disease. Nausea or poor absorption may limit its efficacy. It can be self-administered by subcutaneous injection. Oral folic acid should be given in addition to reduce side-effects, although it may marginally

reduce efficacy. Full blood counts and liver biochemistry should be monitored. It usually works within 1–2 months. More patients remain on this agent than on most other DMARDs, indicating that it is effective and has relatively few side-effects.

Leflunomide

This DMARD exerts an immunomodulatory effect by preventing pyrimidine production in proliferating lymphocytes through blockade of the enzyme dihydroorotate dehydrogenase. Most cells are able to bypass this blockade but T cells cannot – thus it has a specific effect to block clonal expansion of T cells by slowing progression through the maturation phases G to S1. It is well absorbed when taken orally. It has a long half-life of 4–28 days. A loading dose of 100 mg daily is often used for 1–3 days (but is not essential), then 20 mg daily (10 mg if diarrhoea is a problem). The main side-effects are diarrhoea, nausea, alopecia and rash. Diarrhoea diminishes with time. Blood monitoring is obligatory. The onset of action is 4 weeks compared with 6 weeks for methotrexate. The initial response is similar to sulfasalazine but improvement continues and is better sustained at 2 years. Leflunomide works in some patients who have failed to respond to methotrexate, or it can be administered with methotrexate to enhance the response. It needs a 'washout' of 2 years before conception (3 months in men) so is best avoided in women planning a family.

Biological DMARDs

TNF-α blockers. The availability of agents that block TNF-α has significantly changed the traditional use of DMARDs. Because of their cost they are used after at least two DMARDs (usually sulfasalazine and methotrexate) have been tried. They represent a major therapeutic advance.

- *Etanercept* is a fully humanized p75 TNF-α receptor IgG_1 fusion protein given by self-administered subcutaneous injection. Around 65% of patients respond well. Some develop an injection reaction.
- *Adalimumab* is a fully human monoclonal antibody against TNF-α given along with methotrexate.
- *Infliximab* is a monoclonal antibody against TNF-α, given intravenously and co-prescribed with methotrexate to prevent loss of efficacy because of antibody formation.

These products slow or halt erosion formation in up to 70% of patients with RA and produce healing in a few. Patients often comment that their malaise and tiredness improve in a manner that is not seen with other DMARDs. There is a 50% incidence of secondary failure with infliximab in the first year, less with etanercept and adalimumab. Changing to another anti-TNF agent is justified and often regains control of the disease. Studies suggest that anti-TNF drugs given for 12 months in early disease may induce remission although this is not yet common practice. Cost effectiveness studies are underway.

Side-effects. The evidence to date of increased tumour development is controversial. A few people become ANA positive and develop a reversible lupus-like syndrome, leucocytoclastic vasculitis, some extracutaneous involvement or interstitial lung disease. Reactivation of old TB may occur (a pre-treatment chest X-ray is recommended, with or without skin testing) and any TB should be treated before using these agents. There is an increased risk of infections which requires close monitoring.

These agents are extremely expensive when compared with traditional DMARDs but they may save costs in the longer term by reducing disability and the need for hospitalization. Their use should be restricted to specialist centres. To date there is no evidence of an adverse effect on pregnancy outcome but care is essential.

Other biological agents

Anakinra is a human recombinant IL-1 receptor antagonist which is used in combination with methotrexate. It is used after other anti-TNF agents have been unsuccessful, mainly in clinical trials.

Rituximab is a genetically engineered chimeric monoclonal antibody (p. 76) that causes lysis of CD-20 positive B cells. CD20 is a pan-B cell surface antigenic phosphoprotein. Its expression is restricted to pre-B and mature B cells but it is not present on stem cells and is lost before differentiation into plasma cells. Rituximab produces significant improvement in RF-factor positive RA for 8 months to several years when used alone or in combination with corticosteroids and/or methotrexate. This is associated with a 6–9-month B cell lymphopenia with little change in circulating immunoglobulins. A re-flare is often accompanied by a return of peripheral lymphocytes and a rise in CRP. Rituximab can be reused as the disease flares. Repeated courses over up to 5 years are acceptable and well tolerated and around 80% of RF-positive patients respond with 50–60% showing persistent disease control. It is worth trying in patients who have failed to respond to anti-TNF agents. There may be an increased risk of chest infections, and immunoglobulin levels may fall progressively and need to be monitored.

Abatacept is a recombinant fusion protein of CTLA4 and the Fc portion of IgG_1, which selectively modulates T cell activation. It has FDA approval for use in the USA for RA.

Tocilizumab, a humanized anti-IL-6 receptor, is currently in clinical trials.

Drugs used less commonly

Gold (sodium aurothiomalate) is given by deep intramuscular injection. A test dose of 10 mg is followed by weekly doses of 50 mg until response occurs, usually in about 3 months. Occasionally remission is induced. If there is no improvement after a total dose of 1 g, treatment should be stopped. If a response is obtained, change to 4-weekly injections, continued for up to 5 years. Side-effects occur in a third of patients on i.m. gold. Rare side-effects include pulmonary fibrosis, colitis, polyneuropathy and cholestatic jaundice. Gold-induced glomerulonephritis can occur, particularly in patients who are HLA-DR3 positive, and routine urinalysis for proteinuria is performed.

Hydroxychloroquine, an antimalarial, 200–400 g daily, is well tolerated. It is used alone in mild disease or as an adjunct to other DMARDs. Retinopathy is the most serious side-effect, but this is rare before 6 years of treatment. Some rheumatologists arrange an initial check of macular function with an Amsler chart, and further reviews as retinopathy is irreversible.

Penicillamine, 125 g daily for 1 month, then 500–750 g daily, is given before food and for at least 3 months before improvement occurs. If proteinuria exceeds 2 g/24 h the drug must be stopped. Loss of taste is reversible. Other rare side-effects include a lupus erythematosus-like syndrome and a myasthenia gravis-like syndrome.

Azathioprine at a maximum dose of 2.5 mg/kg and *cyclophosphamide* 1–2 mg/kg have been used, usually when other DMARDs have been ineffective. They are often used when extra-articular features are severe, particularly with vasculitis. There is a high risk of neutropenia and possibly liver toxicity from azathioprine in patients who are genetically deficient for the enzyme thiopurine methyltransferase (TPMT) which metabolizes azathioprine into its active metabolites. Pretesting is not evidence based but a wise precaution.

Ciclosporin 2.5–4 mg/kg is used for active rheumatoid arthritis when conventional therapy has been ineffective. Side-effects include a rise in creatinine level and hypertension.

Physical measures

Patients with RA need constant advice and support from physiotherapists and nurse specialists, especially while they are learning to adjust. A combination of rest for active arthritis and exercises to maintain joint range and muscle power is essential. Exercise in a hydrotherapy pool is popular and effective. Advice about managing activities of daily living despite the arthritis, and about gadgets, seating or structural changes in the home or at work are helpful. Family and friends should be involved.

Surgery

Surgery has a useful role in the long-term approach to patient management. Its main objectives are prophylactic, to prevent joint destruction and deformity, and reconstructive, to restore function.

Single-joint disease can be treated by surgical synovectomy to reduce the bulk of inflamed tissue and prevent damage. Excision arthroplasty of the ulnar styloid reduces pain and the risk of extensor tendon damage. Excision arthroplasties of the metatarsal heads reduce metatarsal pain and relieve pressure points. The major surgical advance has been the development of total replacement arthroplasty of the hip, knee, finger joints, elbow and shoulder. Such procedures need careful planning and preparation, and the expected outcomes and risks should be explained to the patient.

PROGNOSIS

A poor prognosis is indicated by:

- A *clinical picture* of an insidious rather than an explosive onset of RA, female sex, increasing number of peripheral joints involved and the level of disability at the onset.
- *Blood tests* showing a high CRP/ESR, normochromic normocytic anaemia and high titres of anti-CCP antibodies and of rheumatoid factor.
- *X-rays* with early erosive damage (N.B. ultrasound and MRI can show cartilage and bone damage prior to conventional X-rays).

Prognosis can be altered dramatically with early DMARD therapy under expert supervision.

Table 10.16 Seronegative spondyloarthropathies

Ankylosing spondylitis (AS)
Psoriatic arthritis
Reactive arthritis (sexually acquired, Reiter's disease)
Post-dysenteric reactive arthritis
Enteropathic arthritis (ulcerative colitis/Crohn's disease)

SERONEGATIVE SPONDYLOARTHROPATHIES

This awkward title describes a group of conditions affecting the spine and peripheral joints which cluster in families and are linked to certain type 1 HLA antigens (Table 10.16).

The joint involvement is usually more limited than that seen in RA and its distribution is different. There are associated extra-articular and genetic features. These diseases occasionally present in childhood.

Histologically the synovitis itself is difficult to distinguish from that of RA, but there is no production of rheumatoid factors – hence 'seronegative'. Anti-CCP is usually negative. Inflammation of the enthesis (junction of ligament or tendon and bone) and joint ankylosis develop more commonly than in RA. All are associated with an increased frequency of sacroiliitis and an increased frequency of HLA-B27.

Aetiology

The common aetiological thread of these disorders is their striking association with HLA-B27, particularly ankylosing spondylitis (AS). HLA type B27 is present in >90% of Caucasians with AS but only 8% of controls. HLA-B27 exhibits a number of unusual characteristics including a high tendency to mis-fold but its aetiological relevance remains unclear. The role of class I HLA antigens in pathogenesis is supported by the fact that HLA-B27 transgenic mice spontaneously develop arthritis, skin, gut and genitourinary lesions.

There are clues that infections play a role, possibly by molecular mimicry, with parts of the organism which are structurally similar to the HLA molecule triggering cross-reactive antibody formation. This is unproven. AIDS is increasing the prevalence of reactive arthritis and spondylitis in sub-Saharan Africa even in the absence of HLA-B27. The explanation for this changing epidemiology is unclear.

The types of arthritis that follow a precipitating infection are called reactive arthritis (p. 535).

The specialized immune systems of the gut and genitourinary mucous membranes may also play a causal role, perhaps reacting to local infections or to antigens which cross the damaged mucosa.

ANKYLOSING SPONDYLITIS (AS)

This is an inflammatory disorder of the spine affecting mainly young adults. It occurs world-wide and affects 1% of men and 0.5% of women in Caucasian populations. The frequency of AS in different populations is roughly paralleled by the incidence of HLA-B27; Africans and Japanese have a low incidence of both HLA-B27 and ankylosing spondylitis, while the North American Haida Indians have a high incidence of both. There are at least 24 subtypes of HLA-B27 (B*2701–B*2724). Some appear to increase risk; others have a protec-

tive role. Twin studies indicate a much higher disease concordance in HLA-B27-positive monozygotic (up to 70%) twins than in dizygotic twins (about 20–25%). HLA-B60 and HLA-DR1 are also associated but are of less significance. There are also other genes lying within the major histocompatibility complex (interleukin-1 gene cluster and the gene *CYP2D6*) which also influence susceptibility to AS but the disease is polygenic with loci on other chromosomes likely to harbour additional susceptibility genes. The disease occurs in men and women (2.5:1). Spinal involvement is milder in women, so men are more likely to present with symptoms of the disease (in a ratio of 4:1). Spinal and sacroiliac disease have a high degree of heritability (>90%). Both sexes may develop iritis.

Epidemiology and pathogenesis

Environmental factors may also be involved but although Gram-negative organisms, e.g. Yersinia, Klebsiella, Salmonella, Shigella, can cause a reactive arthropathy, there is no conclusive evidence for their involvement in the pathogenesis of AS.

There is lymphocyte and plasma cell infiltration and local erosion of bone at the attachments of the intervertebral and other ligaments (enthesitis). This heals with new bone (syndesmophyte) formation.

Clinical features

Episodic inflammation of the sacroiliac joints in the late teenage years or early twenties is the first manifestation of AS. Pain in one or both buttocks and low back pain and stiffness are typically worse in the morning and relieved by exercise. Initially the diagnosis is often missed because the patient is asymptomatic between episodes and radiological abnormalities are absent. Retention of the lumbar lordosis during spinal flexion is an early sign. Later, paraspinal muscle wasting develops.

Classification criteria with a high sensitivity and specificity have been established. The presence of three of the four following indices in adults <50 years with chronic back pain indicates AS:

- morning stiffness >30 min
- improvement of back pain with exercise but not rest
- awakening because of back pain during second half of the night only
- alternating buttock pain.

Spinal stiffness can be measured by Schoeber's test – a tape measure is placed in the midline 10 cm above the dimples of Venus. Any movement of a marker at 15 cm during flexion is recorded. A reading of less than 5 cm implies spinal stiffness. Individuals may be able to touch the floor with a stiff back if they have good hip movements but serial measurement of the finger tip to floor distance highlights any change.

Non-spinal complications (uveitis or costochondritis) suggest the diagnosis of seronegative spondyloarthropathies (Box 10.10). Costochondral junction inflammation causes anterior chest pain. Measurable reduction of chest expansion is due to costovertebral joint involvement.

Peripheral joint involvement is asymmetrical and affects a few, predominantly large joints. Hip involvement leads to fixed flexion deformities of the hips and further deterioration of the posture. Young teenage boys occasionally present with a lower-limb monoarthritis (see p. 553) which later develops into AS.

Acute anterior uveitis is strongly associated with HLA-B27 in AS and related diseases and is occasionally the presenting complaint. Severe eye pain, photophobia and blurred vision are an emergency (see p. 1092). Overall clinical assessment is based on pain, tenderness, stiffness and fatigue using, for example, the Bath Ankylosing Spondylitis Disease Activity Index.

Box 10.10 Non-articular problems in seronegative spondyloarthropathies

- Uveitis, in all types
- Cutaneous lesions in reactive arthritis (keratoderma blenorrhagica), histologically identical to pustular psoriasis
- Nail dystrophy, in psoriasis and reactive arthritis
- Aortitis, occasionally in AS and reactive arthritis

Investigations

- **Blood**. The ESR and CRP are usually raised.
- **HLA testing** is rarely of value because of the high frequency of HLA-B27 in the population, but may give supporting evidence in a difficult case.
- **X-rays**. The medial and lateral cortical margins of both sacroiliac joints lose definition owing to erosions and eventually become sclerotic (Fig. 10.17). The earliest radiological appearances in the spine are blurring of the upper or lower vertebral rims at the thoracolumbar junction (best seen on a lateral X-ray) caused by an enthesitis at the insertion of the intervertebral ligaments. These changes may eventually affect the whole spine.

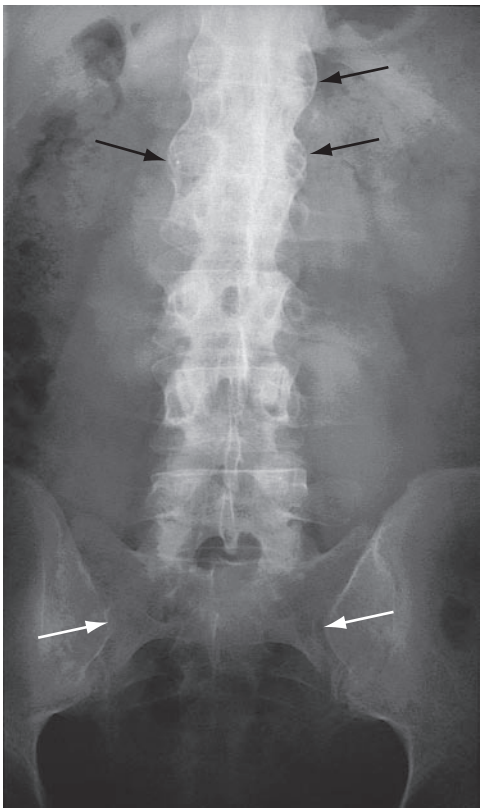

Fig. 10.17 **X-ray of ankylosing spondylitis.** The sacroiliac joints are eroded and show marginal sclerosis (white arrows). There is bridging syndesmophyte formation at the thoracolumbar junction (black arrows).

Persistent inflammatory enthesitis causes bony spurs (syndesmophytes). Syndesmophytes are more vertically oriented than the beak-like osteophytes of spondylosis and the disc is preserved, unlike in spondylosis (see p. 510). Syndesmophytes cause bony ankylosis and permanent stiffening. The sacroiliac joints eventually fuse, as may the costovertebral joints, reducing chest expansion. Calcification of the intervertebral ligaments and fusion of the spinal facet joints and syndesmophytes leads to what is often called a 'bamboo' spine (Fig. 10.18).

- **MRI** demonstrates sacroiliitis before it is seen on X-rays.

Braun J, Sieper J. Ankylosing spondylitis. *Lancet* 2007; **369**: 1379–1390.

Treatment

- The key to effective management of AS is early diagnosis so that a regimen of preventative exercises is started before syndesmophytes have formed. Morning exercises aim to maintain spinal mobility, posture and chest expansion.
- Failure to control pain and to encourage regular spinal and chest exercises leads to an irreversible dorsal kyphosis and wasted paraspinal muscles. This, along with stiffening of the cervical spine, makes forward vision difficult.
- When the inflammation is active, the morning pain and stiffness are too severe to permit effective exercise, an evening dose of a long-acting or slow-release NSAID or an NSAID suppository improves sleep, pain control and exercise compliance. Peripheral arthritis and enthesitis are managed with NSAIDs or local steroid injections.
- Methotrexate is effective for peripheral arthritis but not for spinal disease.
- In patients with persistent, active inflammation TNF-α blocking drugs (see Table 10.15) produce rapid, dramatic and sustained reduction of symptoms and of spinal and peripheral joint inflammation. Around half are able to stop NSAIDs. Relapse occurs on stopping therapy but may be delayed by several months making intermittent treatment feasible. Rituximab does not help seronegative arthritis.

Prognosis

With exercise and pain relief, the prognosis is excellent and over 80% of patients are fully employed. Anti-TNF therapies are likely to reduce the morbidity of severe disease, reducing the risk of permanent spinal stiffness and progressive peripheral joint disease.

Patients should be made aware that they risk passing the HLA-B27 gene to 50% of their children. HLA-B27 positive offspring then have a 30% risk of developing AS.

Fig. 10.18 **X-ray of bamboo spine in ankylosing spondylitis.** In advanced disease there is calcification of the interspinous ligaments and fusion of the facet joints as well as syndesmophytes at all levels. The sacroiliac joints fuse.

PSORIATIC ARTHRITIS (see also p. 1240)

The term 'psoriatic arthritis' describes a variety of different patterns of arthritis and enthesitis seen in people with psoriasis or with a family history of psoriasis. Five to eight per cent of individuals with psoriasis develop one of several different patterns of arthritis for which there is no serological marker. The aetiology and pathogenesis is described on page 1240.

Clinical features

The arthritis is typically more limited in distribution and less severe than in RA. The skin disease can be mild and may develop after the arthritis.

- A **distal interphalangeal arthritis** is the most typical pattern of joint involvement in psoriasis. It is unsightly, but rarely disabling, and there is often adjacent nail dystrophy (see p. 1266) reflecting inflammation in the enthesis extending into the nail root. Cutaneous lesions, interphalangeal joint synovitis and tenosynovitis causing a 'sausage' finger or toe (dactylitis) are seen in pauciarticular psoriatic arthritis (and in reactive arthritis).
- A **seronegative symmetrical polyarthritis** similar to rheumatoid arthritis also occurs.
- **Arthritis mutilans** affects about 5% of patients with psoriatic arthritis and causes marked periarticular osteolysis and bone shortening ('telescopic' fingers) (Fig. 10.19), in which, despite the deformity, pain may be mild and function often surprisingly good.

Fig. 10.19 **Hand showing psoriatic arthritis mutilans.** All the fingers are shortened and the joints unstable, owing to underlying osteolysis.

- Radiologically, **psoriatic arthritis** is erosive but the erosions are central in the joint, not juxta-articular, and produce a 'pencil in cup' appearance (Fig. 10.20).
- A **unilateral or bilateral sacroiliitis** and spondylitis develops in 15% of patients with early involvement of the cervical spine; only 50% are HLA-B27 positive.

Treatment and prognosis

NSAIDs and/or analgesics help the pain but they can occasionally worsen the skin lesions. Local synovitis responds to intra-articular corticosteroid injections.

In milder, polyarticular cases, sulfasalazine or methotrexate slows the development of joint damage.

When the disease is severe, methotrexate or ciclosporin is given because they control both the skin lesions and the arthritis. Anti-TNF-α agents, e.g. etanercept (see p. 530), are highly effective and safe for severe skin and joint disease. Corticosteroids orally may destabilize the skin disease and are best avoided but are valuable when injected into a single inflamed joint. Rituximab has no role in treating psoriatic arthritis.

The prognosis for the joint involvement is generally better than in RA.

REACTIVE ARTHRITIS

Reactive arthritis is a sterile synovitis, which occurs following an infection (see also post-streptococcal arthritis, p. 554).

Seronegative spondyloarthropathy develops in 1–2% of patients after an acute attack of dysentery, or a sexually acquired infection – non-specific urethritis (NSU) in the male, non-specific cervicitis in the female. In male patients who are HLA-B27 positive the relative risk is 30–50. Being HLA-B27 positive is not obligatory, however. Women are less commonly affected.

Aetiology

A variety of organisms can be the trigger, including some strains of *Salmonella* or *Shigella* spp. in bacillary dysentery. *Yersinia enterocolitica* causes diarrhoea and a reactive arthritis. In NSU the organisms are *Chlamydia trachomatis* or *Ureaplasma urealyticum*.

Patients with reactive arthritis are not more susceptible to infection but appear to respond differently with bacterial persistence and altered intracellular replication when HLA-B27 is present. Bacterial antigens or bacterial DNA have been found in the inflamed synovium of affected joints, suggesting that this persistent antigenic material is driving the inflammatory process. Other environmental factors may explain why, even in susceptible individuals, repeated infections do not necessarily produce a reactive arthritis. The methods by which HLA-B27 increases susceptibility to reactive arthritis may include:

- T cell receptor repertoire selection
- molecular mimicry causing autoimmunity against HLA-B27 and/or other self antigens
- mode of presentation of bacteria-derived peptides to T lymphocytes.

These are not mutually exclusive.

There are other organisms that also trigger reactive arthritis but have a different genetic basis; see post-streptococcal arthritis (p. 554), gonococcal arthritis (p. 540) and brucellosis (p. 540). In these, the borderline between reactive arthritis and septic arthritis is more indistinct and they can cause both.

Clinical features (Fig. 10.21)

The arthritis is typically an acute, asymmetrical, lower-limb arthritis, occurring a few days to a couple of weeks after the infection. The arthritis may be the presenting complaint if the infection is mild or asymptomatic. Enthesitis is common, causing plantar fasciitis or Achilles tendon enthesitis (see p. 515). Seventy per cent recover fully within 6 months but many have a relapse.

In susceptible individuals with reactive arthritis, sacroiliitis and spondylitis may also develop. Sterile conjunctivitis is common. Acute anterior uveitis may complicate more severe

Fig. 10.20 **X-ray of psoriatic arthritis.** There is osteolysis of the metatarsal heads and central erosion of the proximal phalanges to produce the 'pencil in cup' appearance (circle). All the lesser toes are subluxed.

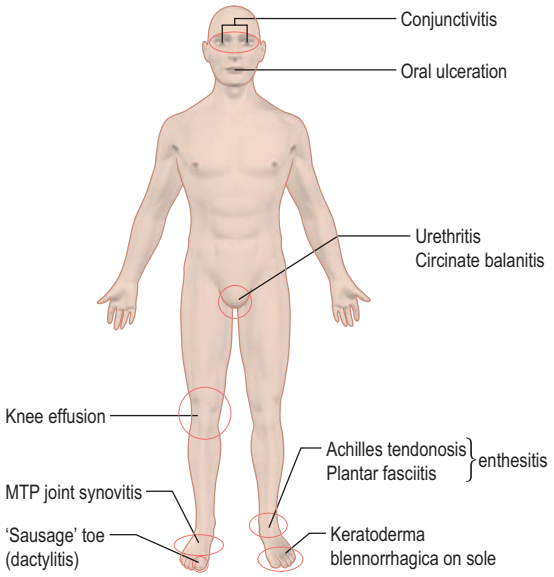

Fig. 10.21 **Clinical features of reactive arthritis.**

or relapsing disease but is not synchronous with the arthritis.

The skin lesions resemble psoriasis:

- Circinate balanitis in the uncircumcised male causes painless superficial ulceration of the glans penis. In the circumcised male the lesion is raised, red and scaly. Both heal without scarring.
- Keratoderma blenorrhagica – the skin of the feet and hands develops painless, red and often confluent raised plaques and pustules histologically similar to pustular psoriasis.
- Nail dystrophy may occur.

Other features

These include:

- bilateral conjunctivitis in 30%
- the classically described triad of *Reiter's disease* – urethritis, arthritis and conjunctivitis.

Treatment

There is some evidence that treating persisting infection with antibiotics will alter the course of the arthritis, once it has developed. Cultures should be taken and any infection treated. Sexual partners may require specialist advice about, and treatment for, sexually acquired infections.

Pain responds well to NSAIDs and local corticosteroid injections. The majority of individuals with reactive arthritis have a single attack which settles, but a few develop a disabling relapsing and remitting arthritis. Relapsing cases are sometimes treated with sulfasalazine or methotrexate (see Table 10.15). TNF-α blocking agents are being increasingly used in severe and persistent disease.

ENTEROPATHIC ARTHRITIS ASSOCIATED WITH INFLAMMATORY BOWEL DISEASE

Enteropathic synovitis occurs in approximately 10–15% of patients with ulcerative colitis and Crohn's disease see p. 288. The link between the bowel disease and the inflammatory arthritis is not clear. Selective mucosal leakiness may expose the individual to antigens that trigger synovitis.

The arthritis is asymmetrical and predominantly affects lower-limb joints. An HLA-B27-associated sacroiliitis or spondylitis is seen in 5% of patients with inflammatory bowel disease and is independent of disease activity. The joint symptoms may predate the development of bowel disease and lead to its diagnosis.

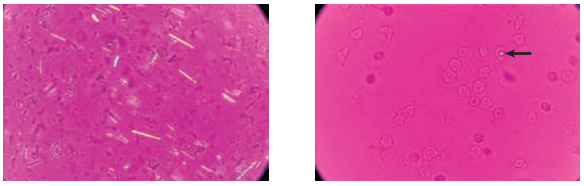
Remission of ulcerative colitis or total colectomy usually leads to remission of the joint disease, but arthritis may persist even in well-controlled Crohn's disease.

Treatment

The inflammatory bowel disease should be treated (see p. 285). In all cases of enteropathic arthritis, the joint disease should be managed symptomatically with NSAIDs, although they may make diarrhoea worse. A monoarthritis is best treated by intra-articular corticosteroids. Sulfasalazine is more frequently prescribed than mesalazine as it may help both bowel and joint disease. The TNF-α blocking drug infliximab is used in inflammatory bowel disease (p. 289) and can help the arthritis.

CRYSTAL ARTHRITIS

Aetiology



Two main types of crystal account for the majority of crystal-induced arthritis. They are sodium urate and calcium pyrophosphate and are distinguished by their different shapes and refringence properties under polarized light with a red filter (Fig. 10.22). Rarely, crystals of calcium apatite (see p. 521) or cholesterol cause acute synovitis.

GOUT AND HYPERURICAEMIA

Gout is an inflammatory arthritis associated with hyperuricaemia and intra-articular sodium urate crystals.

Epidemiology

The prevalence of gout is increasing mainly in developed countries, and in Europe and the USA it is approximately 0.2%, although hyperuricaemia in this population occurs in about 5%. Gout develops in men more than women (10:1) and rarely occurs before young adulthood (when it suggests a specific enzyme defect), and seldom in premenopausal females. The prevalence in older females is increasing with increased diuretic use. Hyperuricaemia is common in certain ethnic groups (e.g. Maoris).

(a) (b)

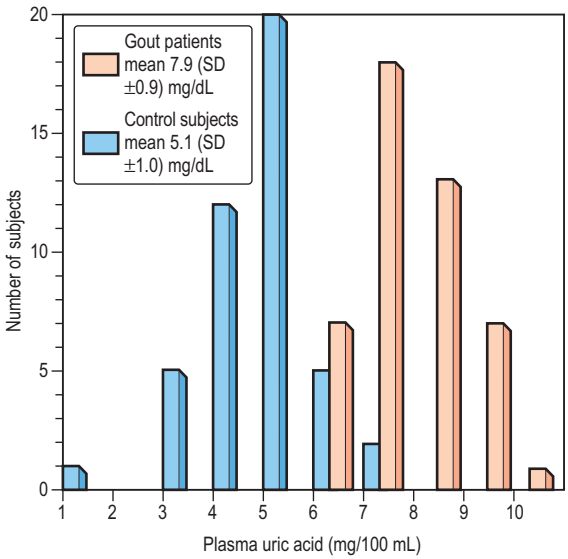

Fig. 10.23 **Serum uric acid levels in normals and in patients with gout.** 7.9 mg/dL is equivalent to 474 µmol/L, 5.1 mg/dL is equivalent to 306 µmol/L. From Snaith ML, Scott JT Uric acid clearance in patients with gout and normal subjects. (1971) *Annals of Rheumatic Disease*, with permission from the BMJ Publishing Group.

Table 10.17 Causes of hyperuricaemia

Impaired excretion of uric acid
Chronic renal disease (clinical gout unusual)
Drug therapy, e.g. thiazide diuretics, low-dose aspirin
Hypertension
Lead toxicity
Primary hyperparathyroidism
Hypothyroidism
Increased lactic acid production from alcohol, exercise, starvation
Glucose-6-phosphatase deficiency (interferes with renal excretion)
Increased production of uric acid
Increased purine synthesis de novo due to:
- Hypoxanthine-guanine-phosphoribosyl transferase (HGPRT) reduction (an X-linked inborn error causing the Lesch–Nyhan syndrome)
- Phosphoribosyl-pyrophosphate synthase overactivity
- Glucose-6-phosphatase deficiency with glycogen storage disease type 1 (patients who survive develop hyperuricaemia due to increased production as well as decreased excretion)

Increased turnover of purines due to:
- Myeloproliferative disorders, e.g. polycythaemia vera
- Lymphoproliferative disorders, e.g. leukaemia
- Others, e.g. carcinoma, severe psoriasis

Uric acid levels start to rise after puberty and are higher in men than in women until the female menopause. There is a normal distribution of serum uric acid in the population with a skewed distribution at the upper end of the range. Hyperuricaemia is defined as a serum uric acid level greater than two standard deviations from the mean (420 µmol/L in males, 360 µmol/L in females). This is close to the limit of solubility.

Most people with hyperuricaemia are asymptomatic even though sodium urate crystals are found in the joints. However, osteoarthritic joints are more prone to gouty attacks. The range for gouty individuals is higher than for normals, but the curves overlap (Fig. 10.23). Serum uric acid levels increase with age, obesity, a high-protein diet, a high alcohol consumption (particularly beer drinkers), a high fructose intake from sweetened drinks, combined hyperlipidaemia, diabetes mellitus, ischaemic heart disease and hypertension (metabolic syndrome, p. 799). There is often a family history of gout.

Pathogenesis

Causes of hyperuricaemia are shown in Table 10.17. In many patients with gout there is no obvious cause. Hyperuricaemia results from inadequate renal excretion of uric acid relative to its production and is the major determinant for developing gout. Only around 30% is derived from the diet.

Uric acid is the final product of purine metabolism in humans and levels in the blood depend on the balance between purine synthesis and the ingestion of dietary purines, and the elimination of urate by the kidney (66%) and intestine (33%). The body pool is about 1000 mg and 60% is turned over daily.

Acute gout is precipitated by the ingestion by polymorpholeucocytes of sodium urate crystals causing the release of proinflammatory cytokines from phagosomes and complement activation. Colchicine works by inhibition of microtubule formation necessary for this to occur.

Uric acid synthesis. The last two steps of purine metabolism in humans are the conversion of hypoxanthine to xanthine and of xanthine to uric acid, catalysed by the enzyme xanthine oxidase. Humans lack the enzyme uricase.

Uric acid excretion (Fig. 10.24). Uric acid excretion by the kidney is complex. It is completely filtered by the glomerulus; 98–100% is then reabsorbed in the proximal tubule via the urate transporter-1 (URAT1) expressed at the apical membrane and 50% is secreted by the distal tubule. Some postsecretory reabsorption also takes place. Low-dose aspirin blocks uric acid secretion. High-dose aspirin also blocks its reabsorption, leading to increased net excretion. Insulin resistance enhances uric acid resorption.

Ninety per cent of patients with gout have impaired excretion of uric acid, 10% have increased production also and in less than 1% an inborn error of metabolism leads to purine overproduction. One-third of uric acid is eliminated in the faeces.

Clinical features

Hyperuricaemia, whether in the context of the metabolic syndrome (see p. 799) or not, causes four clinical syndromes:

- acute sodium urate synovitis – gout
- chronic polyarticular gout
- chronic tophaceous gout
- urate renal stone formation (p. 610).

Acute gout presents typically in a middle-aged male with sudden onset of agonizing pain, swelling and redness of the

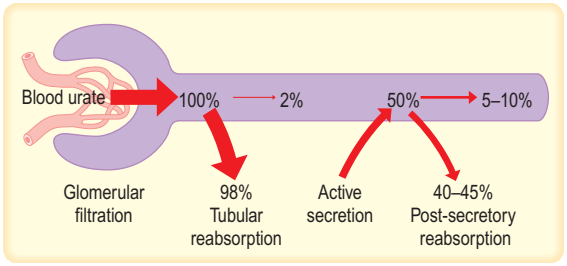

Fig. 10.24 **Urate renal transport.** The net result is that about 5–10% of the glomerular load is excreted in the urine under normal circumstances.

first MTP joint. The attack occurs at any time, but may be precipitated by too much food or alcohol, by dehydration or by starting a diuretic. Untreated attacks last about 7 days. Recovery is typically associated with desquamation of the overlying skin. In 25% of attacks, a joint other than the great toe is affected.

In severe attacks, overlying crystal cellulitis makes gout difficult to distinguish clinically from infective cellulitis. A family or personal history of gout and the finding of a raised serum urate suggest the diagnosis but, if in doubt, blood and joint fluid cultures should be taken.

Chronic polyarticular gout is unusual, except in elderly people on long-standing diuretic treatment, in renal failure, or occasionally in men who have been started on treatment with allopurinol too soon after an acute attack.

Chronic tophaceous gout (see below).

Investigations

The clinical picture is often diagnostic, as is the rapid response to NSAIDs or colchicine.

- **Joint fluid microscopy** is the most specific and diagnostic test but is technically difficult.
- **Serum uric acid** is usually raised (>600 µmol/L). If it is not, recheck it several weeks after the attack, as the level falls immediately after an acute attack. Acute gout never occurs with a serum uric acid in the lower half of the normal range below the saturation point of 360 µmol/L.
- **Serum urea and creatinine** are monitored for signs of renal impairment.

Treatment

The use of NSAIDs or coxibs in high doses rapidly reduces the pain and swelling. Initial doses, taken with food, are:

- naproxen: 750 mg immediately, then 500 mg every 8–12 hours
- diclofenac: 75–100 mg immediately, then 50 mg every 6–8 hours
- lumiracoxib: 100 mg once daily
- indometacin: 75 mg immediately, then 50 mg every 6–8 hours. Although regarded as the 'gold standard' treatment by some, the frequency of side-effects is unacceptably high with indometacin.

After 24–48 hours, reduced doses are given for a further week. *Caution*: NSAIDs may cause renal impairment. In individuals with renal impairment or a history of peptic ulceration, alternative treatments include:

- colchicine: 1000 µg immediately, then 500 µg every 6–12 hours, but this causes diarrhoea
- corticosteroids: intramuscular or intra-articular depot methylprednisolone.

Dietary advice

The first attacks may be separated by many months or years and are managed symptomatically. Individuals should be advised to reduce their alcohol intake, especially beer, which is high in purines and fructose. A diet which reduces total calorie and cholesterol intake and avoids such foods as offal, some fish and shellfish and spinach, all of which are rich sources of purines, is advised. This can reduce serum urate by 15% and delay the need for drugs that reduce serum urate levels. Dietary advice is readily available on the internet.

Treatment with agents that reduce serum uric acid levels

Allopurinol should only be used when the attacks are frequent and severe (despite dietary changes) or associated with renal impairment or tophi, or when the patient finds NSAIDs or colchicine difficult to tolerate. It should never be started within a month of an acute attack and always be started under cover of a course of NSAID or colchicine for the first 2–4 weeks before and 4 weeks after starting allopurinol, as it may induce acute gout.

Allopurinol (300–600 mg) blocks the enzyme xanthine oxidase, which converts xanthine into uric acid (see Fig. 15.11). It reduces serum uric acid levels rapidly and is relatively non-toxic but should be used at low doses (50–100 mg) in renal impairment. Alternatively the dose can be increased gradually from 100 mg every few weeks until the uric acid level is below the 360 µmol/L level. Skin rashes and gastrointestinal intolerance are the most common side-effects. A hypersensitivity reaction is the most serious adverse event, with rash, fever, eosinophilia, hepatitis and progressive renal failure. This is rare, as is bone marrow suppression.

Febuxostat (80–120 mg) is a new non-purine analogue inhibitor of xanthine oxidase and available in some countries. It appears to be well tolerated but longer term studies are needed. Uricosuric agents lower the serum uric acid. Benzbromarone is available in some European countries and probenecid in the USA. The angiotensin I-receptor antagonist, losartan, is uricosuric in hypertensive patients on diuretics.

Chronic tophaceous gout

Individuals with very high levels of uric acid can present with different clinical pictures. In chronic tophaceous gout, sodium urate forms smooth white deposits (tophi) in skin and around joints. They occur on the ear, the fingers (Fig. 10.25) or the

Fig. 10.25 **Gout with tophi.** Courtesy of Dr Varkey Alexander, Al-Sabah Hospital, Kuwait.

Achilles tendon. Large deposits are unsightly and ulcerate. There is chronic joint pain and sometimes superimposed acute gouty attacks.

Periarticular deposits lead to a halo of radio-opacity and clearly defined ('punched out') bone cysts on X-ray.

Tophaceous gout is often associated with renal impairment and/or the long-term use of diuretics. There may be acute or chronic urate nephropathy or renal stone formation. Whenever possible, stop the diuretics or change to less urate-retaining ones, such as bumetamide. Treat with allopurinol and/or uricosuric agents (see above).

PSEUDOGOUT (PYROPHOSPHATE ARTHROPATHY)

Calcium pyrophosphate deposits in hyaline and fibrocartilage produce the radiological appearance of chondrocalcinosis (see p. 522). Shedding of crystals into a joint precipitates acute synovitis which resembles gout, except that it is more common in elderly women and usually affects the knee or wrist. The attacks are often very painful. In young people it may be associated with haemochromatosis, hyperparathyroidism, Wilson's disease or alkaptonuria.

Diagnosis

The diagnosis is made by detecting rhomboidal, weakly positively birefringent crystals in joint fluid, or deduced from the presence of chondrocalcinosis on X-ray. The joint fluid looks purulent. Septic arthritis must be excluded and joint fluid should be sent for culture.

The attacks may be associated with fever and a raised white blood cell count.

Treatment

Aspiration of the joint reduces the pain dramatically but it is usually necessary to use an NSAID or colchicine, as for gout. If infection can be excluded, an intra-articular injection of a corticosteroid helps.

INFECTIONS OF JOINTS AND BONES

Joints become infected by direct injury or by blood-borne infection from an infected skin lesion or other site.

Chronically inflamed joints (e.g. in rheumatoid arthritis) are more prone to infection than are normal joints. Individuals who are immunosuppressed, by AIDS or by immunosuppressive agents, are particularly at risk, as are infants, the elderly and those who abuse alcohol. Artificial joints are also potential sites for infection.

SEPTIC ARTHRITIS

The organism that most commonly causes septic arthritis is *Staphylococcus aureus*. Other organisms include streptococci, other species of staphylococcus, *Neisseria gonorrhoeae, Haemophilus influenzae* in children, and these and other Gram-negative organisms in the elderly or complicating RA.

Clinical features

Suspected septic arthritis is a medical emergency. In young and previously fit people, the joint is hot, red, swollen, and agonizingly painful and held immobile by muscle spasm. In the elderly and immunosuppressed and in RA the clinical picture is less dramatic, so a high index of suspicion is needed to avoid missing treatable but potentially severely destructive and occasionally fatal septic arthritis. In 20% the sepsis affects more than one joint. Chronic destructive arthritis due to tuberculosis is rare.

Investigations

- **Aspirate** the joint and send the fluid for urgent Gram staining and culture. The fluid is usually frankly purulent. The culture techniques should include those for gonococci and anaerobes.
- **Blood cultures** are often positive.
- **Leucocytosis** is usual, unless the person is severely immunosuppressed.
- **X-rays** are of no value in diagnosis in acute septic arthritis.
- **Skin wound swabs, sputum and throat swab or urine** may be positive and indicate the source of infection.

Treatment

This should be started immediately on diagnosis because joint destruction occurs in days. The joint should be immobilized initially and then physiotherapy started early to prevent stiffness and muscle wasting. Intravenous antibiotics should be given for 1–2 weeks. It is usual to give two antibiotics to which the organism is sensitive for 6 weeks, then one for a further 6 weeks orally. Monitor clinically and with the ESR and CRP.

Empirical treatment in septic arthritis

This is started before the results of culture are obtained. Discuss the case with a microbiologist. Intravenous flucloxacillin 1–2 g is given 6-hourly, plus fusidic acid 500 mg orally 8-hourly. If the patient is allergic to penicillin, replace flucloxacillin with erythromycin 1 g i.v. 6-hourly or clindamycin 600 mg i.v. 8-hourly. In immunosuppressed patients, flucloxacillin 1–2 g i.v. 6-hourly plus gentamicin (to cover Gram-negative organisms) should be used. Change the antibiotics if the organism is not sensitive. Drainage of the joint and arthroscopic joint washouts are helpful in relieving pain.

Management of infected prostheses

If chronically infected, the prosthesis is removed and the joint space filled with an antibiotic-impregnated spacer for 3–6 weeks before a new prosthesis is inserted. The whole process is covered by antibiotics.

Prognosis

Surgical drainage may be required if there is joint destruction and osteomyelitis. Patients can start weight-bearing as soon as the inflammation subsides. Resolution of the septic arthritis with complete recovery can occur in a few days or weeks. It may lead to secondary osteoarthritis (see p. 520).

FURTHER READING

Moreland LW. Treatment for hyperuricaemia and gout. *New England Journal of Medicine* 2005; **353**: 2505–2506.

SPECIFIC TYPES OF BACTERIAL ARTHRITIS

Gonococcal arthritis

This is the most common cause of a septic arthritis in previously fit young adults, more commonly affecting women and homosexual men.

Initially the patient becomes febrile and develops characteristic pustules on the distal limbs. Polyarthralgia and tenosynovitis are common at this stage and about 40% have a gonococcaemia. This phase settles and blood cultures usually become negative. Later, large-joint mono- or pauciarticular arthritis may follow. Culture is usually positive from the genital tract, although the joint fluid may be sterile. It is not clear whether this is simply a septic arthritis – although it responds rapidly to antibiotics – or whether there is also a reactive element to bacterial lipopolysaccharide.

Treatment consists of oral penicillin, ciprofloxacin or doxycycline for 2 weeks, and joint rest.

Tuberculous arthritis

Around 1% of patients with tuberculosis develop joint and/or bone involvement. It occurs as the primary disease in children. In adults, it is usually due to haematogenous spread from secondary pulmonary or renal lesions. The onset is insidious and diagnosis often delayed.

The organism invades the synovium or intervertebral disc. There are caseating granulomas and rapid destruction of cartilage and adjacent bone. Some patients develop a reactive polyarthritis (Poncet's disease).

The hip or knee (30%) is quite commonly affected, but around 50% develop spinal disease. The patient is febrile, has night sweats, is anorexic and loses weight. The usual risk factors for tuberculosis apply – debility, alcohol abuse or immunosuppression. HIV-positive/AIDS patients are at particular risk.

Investigations should include culture of fluid, and culture and biopsy of the synovium. *M. tuberculosis* is the usual organism, but atypical mycobacteria are occasionally implicated. A chest X-ray should be performed. Initially joint or spinal X-rays may be normal but joint-space reduction and bone destruction develop rapidly if treatment is delayed. MRI shows the abnormality earlier in the spine and CT-guided biopsy from the affected disc is necessary to obtain cultures.

Treatment is as for tuberculosis with therapy for 9 months (see p. 866). The joint should be rested and the spine immobilized in the acute phase.

Meningococcal arthritis

This may complicate a meningococcal septicaemia and presents as a migratory polyarthritis. Organisms can only rarely be cultured from the joint and most cases are due to immune complex deposition. Treatment is with penicillin.

Infective endocarditis

This may present with arthralgia, polymyalgia rheumatica-like symptoms or an infective arthritis. It is discussed on page 769.

Lyme arthritis

A person with Lyme disease (see p. 139) develops a fever and headache, and an expanding, erythematous rash called erythema chronicum migrans. About 25% of cases develop an acute pauciarticular arthritis. This usually resolves but 10% of untreated cases go on to develop a chronic arthritis. There are no positive markers in these patients of an ongoing infection (p. 139).

Diagnosis is by the detection of IgM antibodies against the spirochaete *Borrelia burgdorferi*.

Treatment with antibiotics (amoxicillin or doxycycline) is highly effective in early disease. The response of chronic arthritis to antibiotic treatment may be delayed for months.

Brucellosis

Brucellosis (see p. 138) has a world-wide distribution. The most common cause of chronic brucellosis and of arthritis is *Brucella melitensis*. There is usually a peripheral mono- or oligoarticular arthritis, which may be septic or reactive. Arthritis is more common in chronic infections of more than 6 months.

Syphilitic arthritis

Congenital syphilis (see p. 178) can cause an acute painful epiphysitis or osteochondritis sometimes associated with para-articular swelling in the first few weeks of life. Later, at age 8–16 years, painless effusion of the knees may occur (Clutton's joints).

In acquired syphilis, arthralgia and arthritis occur in the secondary stage. Charcot's (neuropathic) joints usually involve the knees in tabes dorsalis (see p. 555).

Leprosy (p. 140)

Symmetrical polyarthritis, tenosynovitis and thickened nerves with or without cutaneous manifestations are seen in leprosy.

Actinomycetes infection

Actinomycetes (see p. 149) can affect the mandible or vertebrae.

ARTHRITIS IN VIRAL DISEASE

A transient polyarthritis or arthralgia can occur before, during or after many viral illnesses. These include infectious mononucleosis, chickenpox, mumps, adenovirus, rubella, erythro(parvo)virus B19, hepatitis B and C, arboviral infections and HIV. In most of these it is due to a direct toxic effect or immune complex deposition.

In *rubella* (see p. 113) the virus can occasionally be isolated from the joint. This arthritis is uncommon in countries where rubella vaccination is routine. It occurs most commonly in up to 50% of young adult females a few days after rubella infection (6% of men). It is a symmetrical polyarthritis involving the MCP or PIP joints most commonly, but many joints can be affected. It closely resembles rheumatoid arthritis. IgM rubella antibodies are present. It resolves within a few weeks in most cases. A mild arthritis occurs rarely 2–4 weeks after rubella vaccination.

Erythro(parvo)virus B19 (p. 109) causes an acute, self-limiting arthritis and is associated with erythema infectiosum ('slapped cheek disease').

In *hepatitis B* infection (see p. 336) a sudden symmetrical polyarticular arthritis of the small joints of the hands occurs in approximately one-third of patients, often in the prodromal

Systemic lupus erythematosus (SLE)

phase and mostly resolving before the onset of jaundice. Hepatitis C causes type II mixed cryoglobulinaemia (see p. 340).

Arbovirus infections (see p. 113) which are endemic in many parts of the world give rise to an arthralgia and/or arthritis. For example, the Ross River virus has caused an epidemic polyarthritis in Australia and the South Pacific; it involves the small joints of the hands and clears in 2–4 weeks. Other viral infections causing epidemic arthritis include chikungunya (p. 114) and O'nyong-nyong (p. 113).

Musculoskeletal aspects of infection with human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS)

The clinical features seen in these patients are due to a number of causes such as opportunistic infections and drug therapy and are not usually caused directly by HIV. Infective arthritis seen in these immunosuppressed patients often has minimal symptoms and signs. Some of the antiviral agents cause an acute arthritis, possibly because of crystallization in the joint.

Arthralgia is common in AIDS. There is a *seronegative, predominantly lower-limb arthritis*, similar to psoriasis or Reiter's disease. *Spondylitis* also occurs but is not HLA-B27 associated. *Avascular necrosis*, possibly associated with corticosteroids or alcohol, is seen.

Non-articular diseases such as Sjögren's- and lupus-like syndromes, systemic vasculitis of the necrotizing and hypersensitivity types and myositis also occur.

FUNGAL INFECTION

Fungal infections of joints occur rarely. Bone abscesses may be seen. Destructive joint lesions can also occur with blastomycosis. A benign polyarthritis accompanied by erythema nodosum occasionally occurs in coccidioidomycosis and histoplasmosis. Culture of purulent synovial fluid and skin tests for fungi may help the diagnosis.

BONE INFECTIONS

Acute and chronic osteomyelitis

Osteomyelitis can be due either to metastatic haematogenous spread (e.g. from a boil) or to local infection. Malnutrition, debilitating disease and decreased immunity may play a part in the pathogenesis.

Staphylococcus is the organism responsible for 90% of cases of acute osteomyelitis. Other organisms include *Haemophilus influenzae* and salmonella; infection with the latter may occur as a complication of sickle cell anaemia. The classic presentation is with fever and localized pain with overlying erythema. Diagnosis and treatment within a few days carries a good prognosis. Delayed treatment leads to chronic osteomyelitis. In chronic osteomyelitis sinus formation is usual. Subacute osteomyelitis is associated with a chronic abscess within the bone (Brodie's abscess). Symptoms may be limited to local pain.

Treatment of osteomyelitis is with immobilization and antibiotic therapy with flucloxacillin and fusidic acid. Surgical drainage and removal of dead bone (sequestrum) may be possible but recurrence is common.

Tuberculous osteomyelitis

This is usually due to haematogenous spread from a reactivated primary focus in the lungs or gastrointestinal tract. The disease starts in intra-articular bone. The spine is commonly involved (Pott's disease), with damage to the bodies of two neighbouring vertebrae leading to vertebral collapse and acute angulation of the spine (gibbus). Later an abscess forms ('cold abscess'). Pus can track along tissue planes and discharge at a point far from the affected vertebrae. Symptoms consist of local pain and later swelling if pus has collected. Systemic symptoms of malaise, fever and night sweats occur.

Treatment is as for pulmonary tuberculosis but extended to 9 months (see p. 866) together with initial immobilization.

AUTOIMMUNE RHEUMATIC DISEASES

AUTOIMMUNITY AND AUTOANTIBODIES

Autoimmune diseases are conditions in which the immune system attacks tissues of the body. The antigens can be present in multiple organs so the clinical manifestations are systemic and diverse. In some diseases, such as Graves' disease, Hashimoto's thyroiditis, and insulin-dependent diabetes mellitus only a single organ is affected. The term 'autoimmune rheumatic disease' (ARD) is preferable to the older term 'connective tissue disease' because the clinical effects of ARD are not limited to connective tissues. Each individual ARD has a characteristic pattern of symptoms and signs, which are used to make the diagnosis. In some ARD there are also characteristic autoantibodies (i.e. antibodies that recognize antigens which are normal constituents of the body, such as DNA and phospholipids). Positive blood tests for autoantibodies are useful but not essential in the diagnosis of ARD (see Table 10.2 and p. 504).

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

SLE is an inflammatory, multisystem disorder with arthralgia and rashes as the most common clinical features, and cerebral and renal disease as the most serious problems.

Epidemiology

SLE occurs world-wide but the prevalence varies from country to country, with the most common prevalence of 1:250 being in African American women. In other populations the prevalence varies between 1:1000 and 1:10 000. It is about nine times as common in women as in men, with a peak age of onset between 20 and 40 years.

Aetiology

The cause is unknown but there are several predisposing factors:

- *Heredity*. There is a higher concordance rate in monozygotic twins (up to 25%) compared to dizygotic twins (3%). First-degree relatives have a 3% chance of developing the disease, but approximately 20% have autoantibodies.

Ask the authors
www.studentconsult.com

- *Genetics*. Eight different chromosomal areas have been identified containing genes linked to development of SLE. These include some HLA genes, especially A1, B8 and DR3. Homozygous deficiencies of the complement genes C1q, C2 or C4 convey a high risk of developing SLE.
- *Sex hormone status*. Premenopausal women are most frequently affected. In addition, SLE has been seen in males with Klinefelter's syndrome (XXY) (see p. 40). Treatment with hormone replacement therapy increases the risk of a flare of SLE.
- *Drugs* such as hydralazine, isoniazid, procainamide and penicillamine can induce a form of SLE which is usually mild in that kidneys and the CNS are not affected.
- *Ultraviolet light* can trigger flares of SLE, especially in the skin.
- *Exposure to Epstein–Barr virus* has been suggested as a trigger for SLE.

Pathogenesis

When cells die by apoptosis the cellular remnants appear on the cell surface as small blebs which carry self-antigens. These antigens include nuclear constituents (e.g. DNA and histones) which are normally hidden from the immune system. In patients with SLE, removal of these blebs by phagocytes is inefficient so that they are transferred to lymphoid tissues where they can be taken up by antigen-presenting cells. The self-antigens from these blebs can then be presented to T cells which in turn stimulate B cells to produce autoantibodies directed against these antigens (p. 74). It has been shown that in some patients the autoantibodies are present in stored blood samples that were taken years before the patient developed clinical features of SLE. The combination of availability of self-antigens and failure of the immune system to inactivate B cells and T cells which recognize these self-antigens (i.e. a breakdown of *tolerance* – see Ch. 3, p. 74) leads to the following immunological consequences.

- Development of autoantibodies that either form circulating complexes or deposits by binding directly to tissues.
- This leads to activation of complement and influx of neutrophils causing inflammation in those tissues.
- Abnormal cytokine production – increased blood levels of IL-10 and alpha-interferon are particularly closely linked to high activity of inflammation in SLE.

Pathology

SLE of the skin and kidneys is characterized by deposition of complement and IgG antibodies and influx of neutrophils and lymphocytes. Biopsies of other tissues are carried out less frequently but can show vasculitis affecting capillaries, arterioles and venules. The synovium of joints can be oedematous and may contain immune complexes. Haematoxylin bodies (rounded blue homogeneous haematoxylin-stained deposits) are seen in inflammatory infiltrates and are thought to result from the interaction of antinuclear antibodies and cell nuclei.

The pathology of lesions in other organs is described in the appropriate chapters.

Clinical features

The manifestations of SLE vary greatly between patients. Most patients suffer fatigue, arthralgia and/or skin problems. Involvement of major organs is less common but more serious (Fig. 10.26).

General features

Fever is common in exacerbations. Patients complain of marked malaise and tiredness and these symptoms do not correlate with disease activity or severity of organ-based complications.

The joints and muscles

Joint involvement is the most common clinical feature (≥90%). Patients often present with symptoms resembling RA with symmetrical small joint arthralgia. Joints are painful but characteristically appear clinically normal, although sometimes there is slight soft-tissue swelling surrounding the joint. Deformity because of joint capsule and tendon contraction is rare, as are bony erosions. Rarely, major joint deformity resembling RA (known as Jaccoud's arthropathy) is seen. Aseptic necrosis affecting the hip or knee is a rare complication of the disease or of treatment with corticosteroids.

Myalgia is present in up to 50% of patients but a true myositis is seen only in <5%. If myositis is prominent, the patient may well have an overlap ARD with both polymyositis and SLE (see section on 'Overlap syndromes', p. 548).

The skin (see p. 1252)

This is affected in 85% of cases. Erythema, in a 'butterfly' distribution on the cheeks of the face and across the bridge of the nose (see Fig. 23.26), is characteristic. Vasculitic

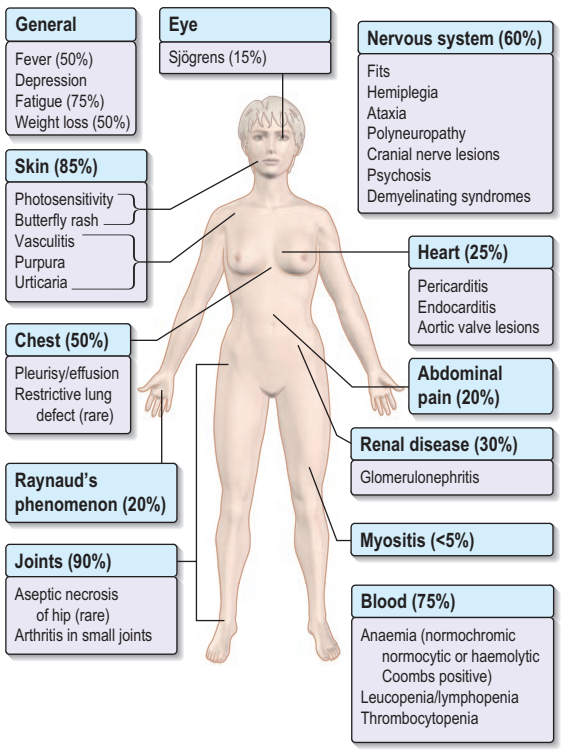

Fig. 10.26 Clinical features of systemic lupus erythematosus (SLE).

lesions on the finger tips and around the nail folds, purpura and urticaria occur. In 40–50% of cases there is photosensitivity (especially in patients positive for anti-Ro antibodies). Prolonged exposure to sunlight can lead to exacerbations of the disease. Livedo reticularis, palmar and plantar rashes, pigmentation and alopecia are seen. Scarring alopecia can lead to irreversible bald patches which are especially upsetting for women – who form the majority of patients with SLE. Raynaud's phenomenon (see p. 809) is common and may precede the development of other clinical problems by years.

Discoid lupus is a benign variant of lupus in which only the skin is involved. The rash is characteristic and appears on the face as well-defined erythematous plaques that progress to scarring and pigmentation (see p. 1252). Subacute cutaneous lupus erythematosus, a rare variant, is described on page 1252.

The lungs (see p. 871)

Up to 50% of patients will have lung involvement sometime during the course of the disease. Recurrent pleurisy and pleural effusions (exudates) are the most common manifestations and are often bilateral. Pneumonitis and atelectasis may be seen; eventually a restrictive lung defect develops with loss of lung volumes and raised hemidiaphragms. This 'shrinking lung syndrome' is poorly understood but may have a neuromuscular basis. Rarely, pulmonary fibrosis occurs, more commonly in overlap syndromes. Intrapulmonary haemorrhage associated with vasculitis is a rare but potentially life-threatening complication.

The heart and cardiovascular system

The heart is involved in 25% of cases. Pericarditis, with small pericardial effusions detected by echocardiography, is common. A mild myocarditis also occurs, giving rise to arrhythmias. Aortic valve lesions and a cardiomyopathy can rarely be present. A non-infective endocarditis involving the mitral valve (Libman–Sacks syndrome) is very rare. Raynaud's, vasculitis, arterial and venous thromboses can occur, especially in association with the antiphospholipid syndrome (see below). There is an increased frequency of ischaemic heart disease and stroke in patients with SLE. This is partly due to altered levels of common risk factors such as hypertension and lipid levels but the presence of chronic inflammation over many years may also play a role. It is not known whether intensive treatment of cardiovascular risk factors in SLE will alter the risk of developing coronary disease or stroke. The benefit of statin therapy in the absence of significant hypercholesterolaemia remains to be proved.

The kidneys

A classification of types of nephritis is on page 590. Autopsy studies suggest that histological changes are very frequent, but clinical renal involvement occurs in only approximately 30% of cases. All patients should have regular screening of urine for blood and protein. An asymptomatic patient with proteinuria may be in the early stages of lupus nephritis, and treatment may prevent progression to renal impairment. Proteinuria should be quantified and haematuria should prompt examination for urinary casts or fragmented red cells that suggest glomerulonephritis. Renal vein thrombosis can occur in nephrotic syndrome or associated with antiphospholipid antibodies.

The nervous system

Involvement of the nervous system occurs in up to 60% of cases and symptoms often fluctuate. There may be a mild depression but occasionally more severe psychiatric disturbances occur. Epilepsy, migraines, cerebellar ataxia, aseptic meningitis, cranial nerve lesions, cerebrovascular disease or a polyneuropathy may be seen. The pathogenic mechanism for cerebral lupus is complex. Lesions may be due to vasculitis or immune-complex deposition, thrombosis or non-inflammatory microvasculopathy. The commonest finding on MRI scan is of increased white matter signal abnormality. In patients with cerebral lupus, infection should be excluded or treated in parallel with administration of corticosteroids and immunosuppression.

The eyes

Retinal vasculitis can cause infarcts (cytoid bodies) which appear as hard exudates, and haemorrhages. There may be episcleritis, conjunctivitis or optic neuritis, but blindness is uncommon. Secondary Sjögren's syndrome is seen in about 15% of cases.

The gastrointestinal system

Mouth ulcers are common and may be a presenting feature. These may be painless or become secondarily infected and painful. Mesenteric vasculitis can produce inflammatory lesions involving the small bowel (infarction or perforation). Liver involvement and pancreatitis are uncommon.

Investigations

- Blood:
  - *A full blood count* may show a leucopenia, lymphopenia and/or thrombocytopenia. Anaemia of chronic disease or autoimmune haemolytic anaemia also occurs. The ESR is raised in proportion to the disease activity. In contrast, the CRP is usually normal but may be high when the patient has lupus pleuritis or arthritis or a coexistent infection.
  - *Urea and creatinine* only rise when renal disease is advanced. Low serum albumin or high urine protein/creatinine ratio are earlier indicators of lupus nephritis.
  - *Autoantibodies* – many different autoantibodies may be present in SLE but the most significant are ANA, anti-dsDNA, anti-Ro, anti-Sm and anti-La (see Box 10.11). Antiphospholipid antibodies are present in 25–40% of cases but not all of these patients develop antiphospholipid syndrome (see below).
  - *Serum complement* C3 and C4 levels are often reduced during active disease. The combination of high ESR, high anti-dsDNA and low C3 may herald a flare of disease. All these markers tend to return towards normal as the flare improves but in some patients anti-dsDNA levels remain high even during clinical remission.
- **Histology**. Characteristic histological and immunofluorescent abnormalities (deposition of IgG and complement) are seen in biopsies from the kidney and skin.
- **Diagnostic imaging**. CT scans of the brain sometimes show infarcts or haemorrhage with evidence of cerebral atrophy. MR can detect lesions in white matter which are not seen on CT. However, it can be very difficult to distinguish true vasculitis from small thrombi.

Box 10.11 Autoantibodies and disease associations

Antibody	Disease	Prevalence
ds DNA	SLE	70%
Anti-histone	Drug induced lupus	–
Anti-centromeric	Limited SS	70%
Anti-Ro (SS-A)	SLE	40–60%
	Primary Sjögren's	60–90%
Anti-La (SS-B)	SLE	15%
	Primary Sjögren's	35–85%
Anti-Sm	SLE	10–25% (Caucasian)
		30–50% (Black African)
Anti-UI-RNP	SLE	30%
	Overlap syndrome	
Anti-JO (anti-synthetase)	Polymyositis	30%
	Dermatomyositis	
Anti-topoisomerase 1 (Scl-70)	Diffuse cutaneous SSc	30%

SS-A, SS-B, Sjögren's syndrome -A and –B; -Ro, -La -, first two letters of name of patients; -Sm, Smith – patient name; RNP, ribonucleoprotein; SSc, systemic scleroderma.

Management

General measures

The disease and its management should be discussed with the patient, particularly the effect upon the patient's lifestyle, e.g. appearance and debility due to fatigue. Patients are advised to avoid excessive exposure to sunlight and it is also necessary to reduce cardiovascular risk factors (p. 755).

Symptomatic treatment

Many patients do not need treatment with corticosteroid tablets or immunosuppressive agents. Arthralgia, arthritis, fever and serositis all respond well to standard doses of NSAIDs (p. 517). Topical corticosteroids are effective and widely used in cutaneous lupus. Antimalarial drugs (chloroquine or hydroxychloroquine) help mild skin disease, fatigue and arthralgias that cannot be controlled with NSAIDs but patients require regular eye checks because of rare retinal toxicity (1 in 2000).

Corticosteroids and immunosuppressive drugs

Single intramuscular injections of long-acting corticosteroids or short courses of oral corticosteroids are useful in treating severe flares of arthritis, pleuritis or pericarditis. In some cases, these symptoms can only be kept under control using long-term oral corticosteroids.

Renal (p. 590) or cerebral disease and severe haemolytic anaemia or thrombocytopenia must be treated with high-dose oral corticosteroids and the first two of these require immunosuppressive drugs in addition. Cyclophosphamide was most commonly used to achieve remission in these severe forms of lupus but is being replaced by mycophenolate mofetil, which has fewer side-effects. Azathioprine is also used to maintain remission. Newer agents such as rituximab (anti-CD20) are used in refractory cases. Rituximab depletes CD20 positive B lymphocytes and thus reduces levels of autoantibodies.

Course and prognosis

An episodic course is characteristic, with exacerbations and complete remissions that may last for long periods. However, SLE can also be a chronic persistent condition. The mortality rate in SLE has fallen dramatically over the last 50 years; the 10-year survival rate is about 90%, but this is lower if major organ-based complications are present. Deaths early in the course of disease are mainly due to renal or cerebral disease or infection. Later coronary artery disease and stroke become more prevalent. Chronic progressive destruction of joints as seen in RA and OA occurs rarely, but a few patients develop deformities such as ulnar deviation. Patients with SLE have an increased long-term risk of developing some cancers, especially lymphoma.

Pregnancy and SLE

Fertility is usually normal except in severe disease and there is no major contraindication to pregnancy. Recurrent miscarriages can occur, especially in patients with antiphospholipid antibodies. Exacerbations can occur during pregnancy with frequent exacerbations of the disease postpartum. The patient's usual treatment should be continued during pregnancy. Hypertension must be controlled. Patients with anti-Ro or anti-La antibodies have a 2% risk of giving birth to babies with neonatal lupus syndrome (rash, hepatitis and fetal heart block).

ANTIPHOSPHOLIPID SYNDROME

Patients who have thrombosis (arterial or venous) and/or recurrent miscarriages and who also have persistently positive blood tests for antiphospholipid antibodies (aPL) have the antiphospholipid syndrome (APS). aPL can be detected by several different tests:

- The *anticardiolipin test*, which detects antibodies (IgG or IgM) that bind the negatively charged phospholipid, cardiolipin.
- The *lupus anticoagulant test* which detects changes in the ability of blood to clot in a test tube. Despite the name, this is not a test for lupus. It is a test for APS. The *anticoagulant* effect caused by aPL in the test tube causes an opposite *procoagulant* effect inside the body, because the factors stimulating thrombosis are different (see below).
- The *anti-β_2-glycoprotein I* test, which detects antibodies that bind β_2-glycoprotein I, a molecule that interacts closely with phospholipids.

A persistently positive test (i.e. positive on at least two occasions, 6 weeks or more apart) in one or more of these assays is needed to diagnose APS. However, some people who test positive for aPL will never get APS, i.e. not all aPLs are harmful. APS can present in patients who already have another ARD, especially SLE. APS can also occur on its own (primary APS).

Pathogenesis

Negatively charged phospholipids and β_2-glycoprotein I are present on the outer surface of apoptotic blebs and so aPL are believed to arise by a similar mechanism to the lupus autoantibodies described above. Pathogenic aPL bind to the N-terminal domain of β_2-glycoprotein I and this interaction is facilitated when the protein is bound to

phospholipid on the surface of cells such as endothelial cells, platelets, monocytes and trophoblasts. This alters the functioning of those cells leading to thrombosis and/or miscarriage.

Clinical features

Since APS is defined by the presence of thrombosis and/or pregnancy loss it is not surprising that these are the most common features. Ischaemic strokes occur in about 20% of patients and deep vein thrombosis in about 40%. Unlike most causes of thrombophilia, APS can cause either arterial or venous thrombosis (though rarely both in the same patient). Twenty-seven per cent of women who have had two or more spontaneous miscarriages have APS.

However, large studies show that patients with APS can also have many other features including:

- thrombocytopenia
- chorea, migraine and epilepsy
- valvular heart disease
- cutaneous manifestations (e.g. livedo reticularis)
- positive Coombs' test
- renal impairment due to ischaemia in the small renal vessels.

Rarely it can be catastrophic. The syndrome may also be involved in the development of accelerated atheroma.

Treatment

In patients with APS who have had one or more thrombosis, the recommended treatment to prevent further thrombosis is long-term anticoagulation with warfarin. Although it was previously thought that high-intensity anticoagulation (INR >3) was essential, this is now disputed and many patients are managed with lower target INR. Pregnant patients with APS are given oral aspirin and subcutaneous heparin from early in gestation. This reduces the chance of a miscarriage but pre-eclampsia and poor fetal growth remain common. There are no definite guidelines for managing patients with aPL who have never had thrombosis. Aspirin or clopidogrel are sometimes given prophylactically especially in those with high IgG aPL. Warfarin is given much more rarely in these circumstances.

SYSTEMIC SCLEROSIS (SCLERODERMA)

(see p. 1252)

Systemic sclerosis (SSc) is a multisystem disease. This distinguishes it from localized scleroderma syndromes, such as morphoea, that do not involve internal organ disease and are rarely associated with vasospasm (Raynaud's phenomenon). SSc has the highest case-specific mortality of any of the autoimmune rheumatic diseases. SSc occurs world-wide but there may be racial or ethnic differences in clinical features. For example, renal involvement is less frequent in Japanese cases.

The incidence of SSc is 10/million population per year with a 3:1 female to male ratio. The peak incidence is between 30 and 50 years of age. It is rare in children.

Environmental risk factors for scleroderma-like disorders include exposure to vinyl chloride, silica dust, adulterated rapeseed oil and trichlorethylene. Drugs such as bleomycin also produce a similar picture. Although unusual, familial cases are reported and twin cohorts suggest higher concordance in monozygotic pairs, consistent with genetic determinants of aetiology.

Pathology and pathogenesis

Figure 10.27 shows the pathogenic interaction and mechanisms in systemic sclerosis.

Vascular features

An early lesion is widespread vascular damage involving small arteries, arterioles and capillaries. There is initial endothelial cell damage with release of cytokines including endothelin-1, which causes vasoconstriction. There is continued intimal damage with increasing vascular permeability, leading to cellular activation, activation of adhesion molecules (E-selectin, VCAM, ICAM-1), with migration of cells into the extracellular matrix. Migrating lymphocytes are IL-2-producing cells, expressing surface antigens such as CD3, CD4 and CD5. All these factors cause release of other mediators (e.g. interleukin-1, -4, -6 and -8, TGF-β and PDGF) with activation of fibroblasts.

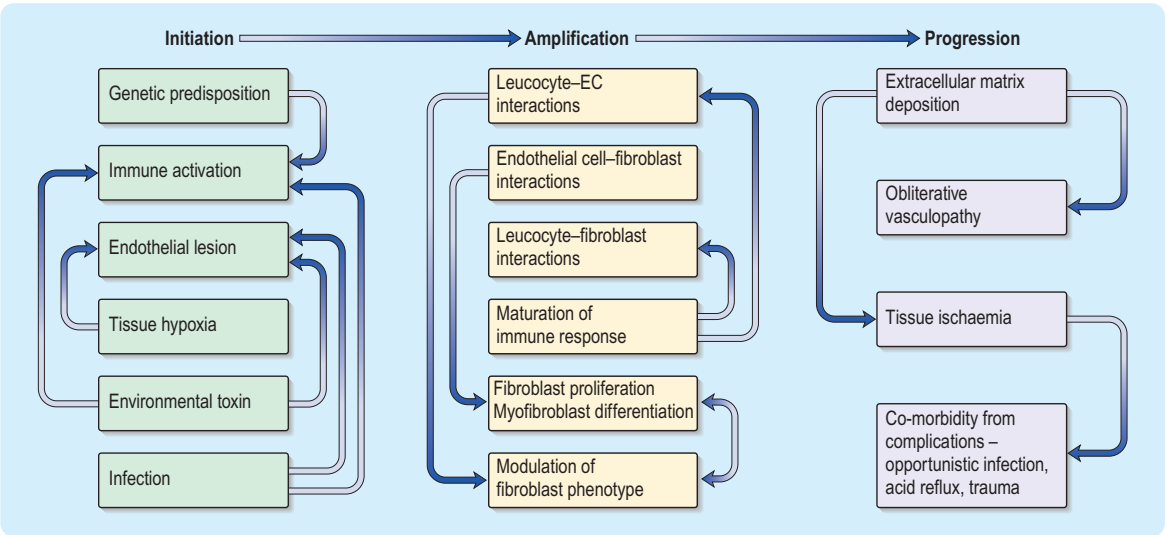

Fig. 10.27 **Pathogenic mechanisms in systemic sclerosis.** EC, endothelial cell.

The damage to small blood vessels also produces widespread obliterative arterial lesions and subsequent chronic ischaemia.

Fibrotic features

Fibroblasts synthesize increased quantities of collagen types I and III, as well as fibronectin and glycosaminoglycans, producing fibrosis in the lower dermis of the skin as well as the internal organs. It is possible that antibodies to platelet derived growth factor receptor, which have been found in blood of patients with SSc, stimulate fibroblasts to cause fibrosis.

Clinical features

Raynaud's phenomenon

Raynaud's phenomenon is seen in almost 100% of cases and can precede the onset of the full-blown disease by many years.

Limited cutaneous scleroderma (LcSSc) – 70% of cases

This usually starts with Raynaud's phenomenon many years (up to 15) before any skin changes. The skin involvement is limited to the hands, face, feet and forearms. The skin is tight over the fingers and often produces flexion deformities of the fingers. Involvement of the skin of the face produces a characteristic 'beak'-like nose and a small mouth (microstomia). Painful digital ulcers and telangiectasia with dilated nail-fold capillary loops are seen. Digital ischaemia may lead to gangrene. Gastrointestinal tract involvement is common in this group. Pulmonary hypertension (PHT) develops in 10–15% of this group and pulmonary interstitial disease may occur.

The CREST syndrome (Calcinosis, Raynaud's phenomenon, Esophageal involvement, Sclerodactyly and skin changes in the fingers, Telangiectasia) was the term previously used to describe this syndrome.

Diffuse cutaneous scleroderma (DcSSc) – 30% of cases

Initially oedematous in onset, skin sclerosis rapidly follows. Raynaud's phenomenon usually starts just before or concomitant with the oedema.

Diffuse swelling and stiffness of the fingers is rapidly followed by more extensive skin thickening which can involve most of the body in the severest cases. Later the skin becomes atrophic. Early involvement of other organs occurs with general symptoms of lethargy, anorexia and weight loss.

- Heartburn, reflux or dysphagia due to oesophageal involvement is almost invariable and anal incontinence occurs in many patients. Malabsorption from bacterial overgrowth due to dilatation and atony of the small bowel is not infrequent, and more rarely dilatation and atony of the colon occurs. Pseudo-obstruction is a known complication.
- Renal involvement is acute or chronic. Acute hypertensive renal crisis used to be the most common cause of death in systemic sclerosis. ACE inhibitors and better care along with dialysis and renal transplantation have changed this.
- Lung disease, both fibrosis and pulmonary hypertension, contributes significantly to mortality in SSc. PHT can be isolated or secondary to fibrosis, and high plasma levels of endothelin-1 are seen.
- Myocardial fibrosis leads to arrhythmias and conduction defects. Pericarditis is found occasionally.

Sometimes these systemic features occur without skin involvement (SSc sine scleroderma). Overlap syndromes with additional features of SLE, RA or inflammatory muscle disorder occur.

Investigations

- **Full blood count**. A normochromic, normocytic anaemia occurs and a microangiopathic haemolytic anaemia is seen in some patients with renal disease.
- **Urea and electrolytes**. Urea and creatinine rise with acute renal disease
- **Autoantibodies** (see Box 10.11):
  - **(a)** *In LcSSc*: speckled, nucleolar or anti-centromere antibodies (ACAs) occur in 70% of cases.
  - **(b)** *In DcSSc*: there are anti-topoisomerase-1 antibodies (called anti-ScL-70) in 30% of cases, and anti-RNA polymerase (I, II and III) antibodies in 20–25%.
  - **(c)** *Rheumatoid factor* is positive in 30%.
  - **(d)** *ANA* is positive in 95%.
- **Urine** microscopy and, if there is proteinuria, urine protein/creatinine ratio should be measured.
- **Imaging**:
  - **(a)** CXR – to exclude other pathology, for changes in cardiac size and established lung disease.
  - **(b)** Hands – deposits of calcium around fingers (in severe cases, erosion and absorption of the tufts of the distal phalanges – termed acrosteolysis).
  - **(c)** Barium swallow generally confirms impaired oesophageal motility. Scintigraphy, manometry impedance, and upper GI endoscopy are also valuable.
  - **(d)** High-resolution CT – to demonstrate fibrotic lung involvement.
- **Other investigations** of gastrointestinal tract (e.g. see Fig. 6.5, p. 250), lung, renal and cardiac as appropriate.

Management

Treatment should be organ-based in order to try to control the disease. Currently there is no cure. In contrast to many other ARD, corticosteroids and immunosuppressants are rarely used in SSc, with the exception of SSc-related pulmonary fibrosis.

- Education, counselling and family support are essential.
- Regular exercises and skin lubricants may limit contractures but no treatment has proven efficacy in reducing skin fibrosis.
- Raynaud's may be improved by hand warmers and oral vasodilators (calcium-channel blockers, ACE inhibitors). In severe cases, parenteral vasodilators (prostacyclin analogues and calcitonin gene-related peptide) are used. Lumbar sympathectomy can help foot symptoms. Radical micro-arteriolysis (digital sympathectomy) can be used where individual fingers or toes are severely ischaemic and thoracic sympathectomy under video assisted thoracic surgery is now performed.
- Oesophageal symptoms can almost always be improved by proton-pump inhibitors, and prokinetic drugs are also helpful.
- Symptomatic malabsorption requires nutritional supplements and rotational antibiotics (see p. 280) to treat small intestinal bacterial overgrowth.

- Renal involvement requires intensive control of hypertension. First drug of choice is an ACE inhibitor. Vigilance for hypertensive scleroderma renal crisis (SRC) is critical, especially in early-stage dcSSc with rapidly progressive skin and tendon friction rubs. High-dose corticosteroids (above 10 mg prednisolone daily) may increase the risk of SRC.
- Pulmonary hypertension is treated with oral vasodilators, oxygen and warfarin. Advanced cases should receive prostacyclin therapy (inhaled, subcutaneous or intravenous) or the oral endothelin-receptor antagonists (bosentan and sitaxentan). Right heart failure is treated conventionally and transplantation (heart–lung or single lung) should be considered in eligible cases.
- Pulmonary fibrosis is currently treated with immunosuppression, most often with cyclophosphamide or azathioprine combined with low-dose oral prednisolone.

Prognosis

In limited cutaneous scleroderma the disease is often milder, with much less severe internal organ involvement and a 70% 10-year survival. Pulmonary hypertension is a significant later cause of death. Lung fibrosis and severe gut involvement also determine mortality. In diffuse disease, where organ involvement is often severe at an earlier stage, many patients die of pulmonary, cardiac or renal involvement. Overall, pulmonary involvement (vascular or interstitial) accounts for around 50% of scleroderma-related deaths.

Localized forms of scleroderma occur either in patches (morphoea, p. 1252) or linear forms. These are more commonly seen in children and adolescents and do not convert into systemic forms, although ANA may occur in localized scleroderma and very occasionally there is coexistence of localized and systemic forms.

POLYMYOSITIS (PM) AND DERMATOMYOSITIS (DM)

Polymyositis is a rare disorder of unknown cause, in which the clinical picture is dominated by inflammation of striated muscle, causing proximal muscle weakness. When the skin is involved it is called 'dermatomyositis'. The incidence is about 2–10/million population per annum and it occurs in all races and at all ages. The aetiology is unknown, although viruses (e.g. Coxsackie, rubella, influenza) have been implicated and persons with HLA-B8/DR3 appear to be genetically predisposed.

Clinical features

Adult polymyositis

Women are affected three times more commonly than men.

The onset can be insidious, over months, or acute. General malaise, weight loss and fever can develop during the acute phase, but the cardinal symptom is proximal muscle weakness. The shoulder and pelvic girdle muscles may become wasted but are not usually tender. Face and distal limb muscles are not usually affected. Movements such as squatting and climbing stairs become difficult. As the disease progresses, involvement of pharyngeal, laryngeal and respiratory muscles can lead to dysphonia and respiratory failure. These severe complications are rare if the disease is treated early.

Adult dermatomyositis

This is also more common in women. Apart from muscle weakness these patients often suffer from myalgia, polyarthritis and Raynaud's phenomenon but DM is primarily distinguished from PM by the characteristic rash. This typically affects the eyelids, where heliotrope (purple) discoloration is accompanied by periorbital oedema, and the fingers where one sees purple-red raised vasculitic patches. These patches occur over the knuckles (Gottron's papules) in 70% of patients, and this appearance is highly specific for DM. Ulcerative vasculitis and calcinosis of the subcutaneous tissue occurs in 25% of cases. In the long term, muscle fibrosis and contractures of joints occur.

Other organ involvement (antisynthetase syndrome)

Twenty to thirty per cent of patients with PM or DM have antibodies to tRNA synthetase enzymes. These patients are more likely to develop pulmonary interstitial fibrosis, Raynaud's phenomenon, arthritis and hardening and fissuring of skin over the pulp surface of the fingers (mechanic's hands). This variant of PM/DM is sometimes called antisynthetase syndrome and often has a poor outcome. Respiratory muscles are affected in PM/DM and this compounds the effects of interstitial fibrosis. Dysphagia is seen in about 50% of patients owing to oesophageal muscle involvement.

Association with other ARD

There is an association with other ARD (e.g. SLE, RA and SSc) with their associated clinical features such as deforming arthritis, malar rash and skin sclerosis.

Association with malignancies

The relative risk of cancer is 2.4 for male and 3.4 for female patients, and a wide variety of cancers have been reported. The onset and clinical picture does not differ from that of typical DM/PM. The associated cancer may not become apparent for 2–3 years, and recurrent or refractory DM should prompt a search for occult malignancy.

Malignancy (e.g. lung, ovary, breast, stomach) can also predate the onset of myositis, particularly in males with DM.

Childhood dermatomyositis

This most commonly affects children between the ages of 4 and 10 years. The typical rash of DM is usually accompanied by muscle weakness. Muscle atrophy, subcutaneous calcification and contractures may be widespread and severe. Ulcerative skin vasculitis is common and recurrent abdominal pain due to vasculitis is also a feature.

Investigations

- **Serum creatine kinase (CK),** aminotransferases, lactate dehydrogenase (LDH) and aldolase are usually raised and are useful guides to muscle damage but may not reflect activity.
- The **ESR** is usually not raised.
- **Serum autoantibody studies**. Anti-nuclear antibody testing is commonly positive in patients with DM. Rheumatoid factor is present in up to 50% and many *myositis-specific* antibodies (MSAs) have been recognized and correlate with certain subsets. Anti-synthetase antibodies have been described above.

- **Electromyography (EMG)** shows a typical triad of changes with myositis: spontaneous fibrillation potentials at rest; polyphasic or short-duration potentials on voluntary contraction; and salvos of repetitive potentials on mechanical stimulation of the nerve.
- **MRI** can be used to detect abnormally inflamed muscle.
- **Needle muscle biopsy** shows fibre necrosis and regeneration in association with an inflammatory cell infiltrate with lymphocytes around the blood vessels and between muscle fibres. Open biopsy allows more thorough assessment.
- **Screening for malignancy** is usually limited to relatively non-invasive investigations such as CXR, mammography, pelvic/abdominal ultrasound, urine microscopy and a search for circulating tumour markers.
- **PET** scan.

Treatment

Bed rest may be helpful but must be combined with an exercise programme. Prednisolone is the mainstay of treatment; 0.5–1.0 mg/kg bodyweight as initial therapy continued until at least one month after myositis has become clinically and enzymatically inactive. Tapering of steroids must be slow. Early intervention with steroid-sparing agents such as methotrexate, azathioprine, ciclosporin, cyclophosphamide and mycophenolate mofetil is common, especially where there is clinical relapse or rise in CK as the dose of steroids is reduced. Intravenous immunoglobulin therapy (IVIG) is helpful in some recalcitrant cases. Treatment of childhood DM tends to be more intensive with earlier use of immunosuppressive agents.

Inclusion body myositis

Inclusion body myositis is an idiopathic inflammatory myopathy occurring usually in men over 50 years. Weakness of the pharyngeal muscles causes difficulty in swallowing in over 50%. It is a slowly progressive weakness of mainly distal muscles. In contrast to polymyositis, the creatine kinase is only slightly elevated; the EMG shows both myopathic and neuropathic changes. On MRI, the changes are often more distal but can be similar to polymyositis. A muscle biopsy shows inflammation and basophilic rimmed vacuoles with diagnostic filamentous inclusions and vacuoles on electron microscopy. A trial of corticosteroids is worthwhile but generally the response is poor.

SJÖGREN'S SYNDROME

The syndrome of dry eyes (keratoconjunctivitis sicca) in the absence of rheumatoid arthritis or any of the autoimmune diseases is known as 'primary Sjögren's syndrome'. There is an association with HLA-B8/DR3. Dryness of the mouth, skin or vagina may also be a problem. Salivary and parotid gland enlargement is seen.

Associated systemic features include:

- arthralgia and occasional non-progressive polyarthritis, like that seen in SLE (but much less common)
- Raynaud's phenomenon
- dysphagia and abnormal oesophageal motility as seen in systemic sclerosis (but less common)
- other organ-specific autoimmune disease, including thyroid disease, myasthenia gravis, primary biliary cirrhosis and autoimmune hepatitis
- renal tubular defects (uncommon) causing nephrogenic diabetes insipidus and renal tubular acidosis
- pulmonary diffusion defects and fibrosis
- polyneuropathy, fits and depression
- vasculitis
- increased incidence of non-Hodgkin's B cell lymphoma.

Pathology and investigations

Biopsies of the salivary gland or of the lip show a focal infiltration of lymphocytes and plasma cells.

- **Schirmer tear test**. A standard strip of filter paper is placed on the inside of the lower eyelid; wetting of <10 mm in 5 minutes indicates defective tear production.
- **Rose Bengal staining** of the eyes shows punctate or filamentary keratitis.
- **Laboratory abnormalities**. These include raised immunoglobulin levels, circulating immune complexes and autoantibodies. Rheumatoid factor is usually positive. Anti-nuclear antibodies are found in 80% of cases and anti-mitochondrial antibodies in 10%. Anti-Ro (SSA) antibodies are found in 60–90%, compared with 10% of cases of RA and secondary Sjögren's syndrome. This antibody is of particular interest because it can cross the placenta and cause congenital heart block.

Management

Symptomatic treatment is with artificial tears and saliva-replacement solutions. Hydroxychloroquine may help fatigue and arthralgia. Corticosteroids are rarely needed but are used to treat persistent salivary gland swelling or neuropathy.

'OVERLAP' SYNDROMES AND UNDIFFERENTIATED AUTOIMMUNE RHEUMATIC DISEASE

An *overlap syndrome* is one where the patient shows the characteristic clinical features of more than one ARD. Treatment of each ARD is usually the same as if they occurred separately.

Undifferentiated ARD is a term used for patients who have evidence of autoimmunity (e.g. positive autoantibody test) and some clinical features of such diseases (commonly Raynaud's phenomenon and/or arthralgia) but not enough to make a clear diagnosis of any individual ARD. These patients sometimes develop a clearer ARD over time, but some always remain undifferentiated and tend to have relatively mild disease without major organ problems.

SYSTEMIC INFLAMMATORY VASCULITIS

Vasculitis is a histological term describing inflammation of the vessel wall. Vasculitis can be seen in many diseases (see Table 10.18 and 10.19). The group of diseases described in this section (systemic inflammatory vasculitides) are characterized by widespread vasculitis leading to systemic symptoms and signs, generally requiring treatment with corticosteroids and/or immunosuppressive drugs. The classification remains controversial, but is usually based on the type of artery affected (Fig. 10.28 and Table 10.18).

- Large vessel vasculitis refers to the aorta and its major tributaries.
- Medium vessel vasculitis refers to medium and small-sized arteries and arterioles.
- Small vessel vasculitis refers to small arteries, arterioles, venules and capillaries.

Table 10.18 Types of systemic vasculitis

Large	Giant cell arteritis/ polymyalgia rheumatica	
	Takayasu's arteritis	
Medium	Classical polyarteritis nodosa (PAN)	
	Kawasaki's disease	
Small	Microscopic polyangiitis	ANCA associated
	Wegener's granulomatosis	ANCA associated
	Churg–Strauss syndrome	ANCA associated
	Henoch–Schönlein purpura	
	Cutaneous leucocytoclastic vasculitis	
	Essential cryoglobulinaemia	

Table 10.19 Other conditions associated with vasculitis (see also Table 10.18)

Infective	e.g. Subacute infective endocarditis
Non-infective	Vasculitis with rheumatoid arthritis
	Systemic lupus erythematosus
	Scleroderma
	Polymyositis/dermatomyositis
	Drug-induced Behçet's disease
	Goodpasture's syndrome
	Hypocomplementaemia
	Serum sickness
	Paraneoplastic syndromes
	Inflammatory bowel disease

Within this classification based on size, different types of vasculitis can be distinguished in terms of histological appearance or autoantibody status. In particular, only some vasculitides are associated with giant cells or granulomata in the vessel wall, and the presence or absence of anti-neutrophil cytoplasmic antibody (ANCA, see p. 504) is also a useful distinguishing feature.

LARGE VESSEL VASCULITIS

Polymyalgia rheumatica (PMR) and giant cell (temporal) arteritis are systemic illnesses of the elderly. Both are associated with the finding of a giant cell arteritis on temporal artery biopsy.

Polymyalgia rheumatica (PMR)

PMR causes a sudden onset of severe pain and stiffness of the shoulders and neck, and of the hips and lumbar spine; a limb girdle pattern. These symptoms are worse in the morning, lasting from 30 minutes to several hours. The clinical history is usually diagnostic and the patient is always over 50 years old.

Patients develop systemic features of tiredness, fever, weight loss, depression and occasionally nocturnal sweats if PMR is not diagnosed and treated early. A differential diagnosis is shown in Box 10.12.

Box 10.12 Symptom patterns in some muscle disorders

- **Polymyositis** – proximal muscle ache and weakness
- **Polymyalgia rheumatica** – proximal morning stiffness and pain
- **Myopathy** – weakness, but no pain or stiffness

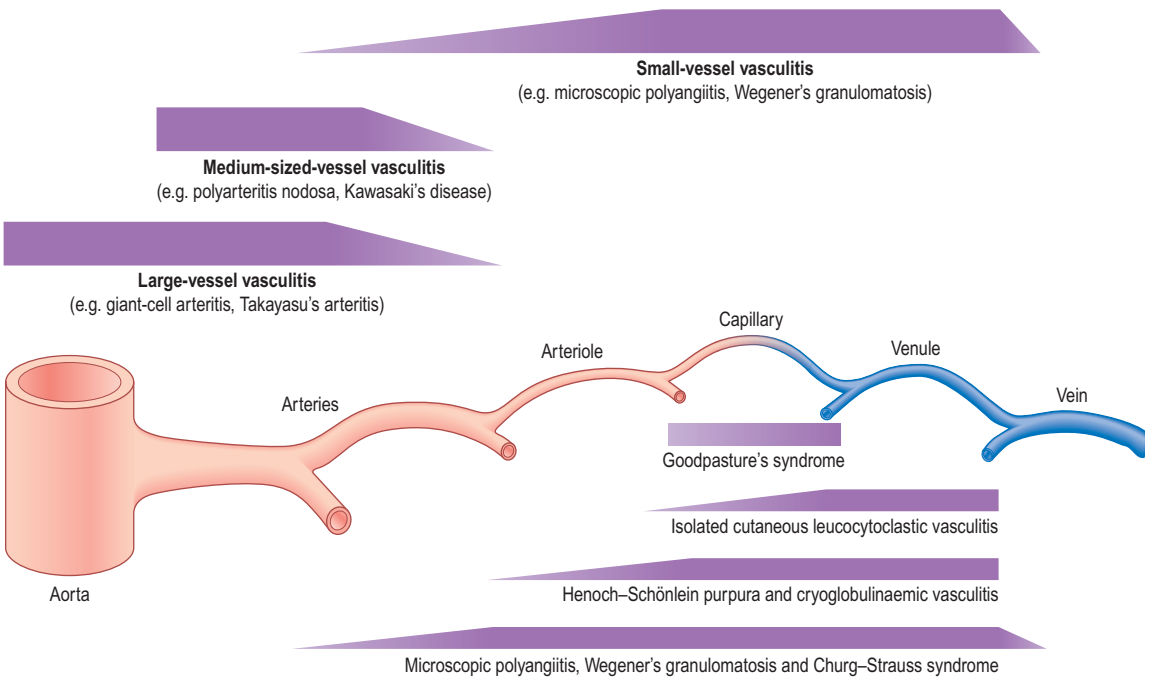

Fig. 10.28 **Sites of vascular involvement by vasculitides.** From Jeanette JC and Falk RJ. *New England Journal of Medicine* 1997; **337:** 1512–1523. Copyright © 1997 Massachusetts Medical Society. All rights reserved.

Investigation of PMR

- **A raised ESR and/or CRP** is a hallmark of this condition. It is rare to see PMR without an acute-phase response. If it is absent, the diagnosis should be questioned and the tests repeated a few weeks later before treatment is started.
- **Serum alkaline phosphatase and γ-glutamyl-transpeptidase** may be raised as markers of the acute inflammation.
- **Anaemia** (mild normochromic, normocytic) is often present.
- **Temporal artery biopsy** shows giant cell arteritis in 10–30% of cases, but is not usually performed.

Giant cell arteritis (GCA)

GCA is inflammatory granulomatous arteritis of large cerebral arteries which occurs in association with PMR. The patient may have current PMR, a history of recent PMR, or be on treatment for PMR. It is extremely rare under 50 years of age. Presenting symptoms of GCA include severe headaches, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness and swelling of one or more temporal or occipital arteries. The most feared manifestation is sudden painless temporary or permanent loss of vision in one eye due to involvement of the ophthalmic artery (see p. 1138). Systemic manifestations of severe malaise, tiredness and fever occur.

Investigation of GCA

- **Normochromic, normocytic anaemia.**
- **ESR** is usually raised (in the region of 50–120 mm/h) and the CRP very high.
- **Liver biochemistry.** Abnormalities occur, as in PMR. The albumin may be low.
- **A temporal artery biopsy** from the affected side is the definitive diagnostic test. This should be taken before, or within 7 days of starting, high doses of corticosteroids. The lesions are patchy and the whole length of the biopsy (>1 cm long) must be examined; even so, negative biopsies occur.

The histological features of GCA are:

- intimal hypertrophy
- inflammation of the intima and sub-intima
- breaking up of the internal elastic lamina
- giant cells, lymphocytes and plasma cells in the internal elastic lamina.

Treatment of PMR or GCA

Corticosteroids produce a dramatic reduction of symptoms of PMR within 24–48 hours of starting treatment, provided the dose is adequate. If this improvement does not occur, the diagnosis should be questioned. This treatment should reduce the risk of patients with PMR developing GCA. NSAIDs are less effective and should not be used.

In GCA, corticosteroids are obligatory because they significantly reduce the risk of irreversible visual loss and other focal ischaemic lesions, but much higher doses are needed than in PMR. If GCA is suspected, it may not be possible to arrange a temporal artery biopsy rapidly. In these circumstances, treatment should not be delayed, especially if there have already been episodes of visual loss or stroke.

Starting doses of prednisolone are:

- **PMR**: 10–15 mg prednisolone as a single dose in the morning
- **GCA**: 60–100 mg prednisolone, usually in divided doses.

The dose should then be reduced gradually in weekly or monthly steps. While the dose is above 20 mg, the step reductions are 5 mg, reducing the evening doses first. Between 20 mg and 10 mg the reduction can be in 2.5 mg steps, but below 10 mg the rate should be slower and the steps each of 1 mg. Most patents will eventually be able to stop corticosteroids after 12–18 months but up to 25% may need low doses long-term. Steroid-sparing immunosuppressive agents are used in refractory cases where it is hard to reduce the corticosteroid dose without causing a flare of disease or a rise in ESR or CRP.

Calcium and vitamin D supplements and sometimes bisphosphonates are necessary to prevent osteoporosis while high-dose steroids are being used (p. 563).

Takayasu's arteritis

This is a granulomatous inflammation of the aorta and its major branches and is discussed on page 809.

MEDIUM-SIZED VESSEL VASCULITIS

Polyarteritis nodosa (PAN)

Classical PAN is a rare condition which, unlike other vasculitic diseases, usually occurs in middle-aged men. It is accompanied by severe systemic manifestations, and its occasional association with hepatitis B antigenaemia suggests a vasculitis secondary to the deposition of immune complexes. Pathologically, there is fibrinoid necrosis of vessel walls with microaneurysm formation, thrombosis and infarction.

Clinical features

These include fever, malaise, weight loss and myalgia. These initial symptoms are followed by dramatic acute features that are due to organ infarction.

- *Neurological* – mononeuritis multiplex is due to arteritis of the vasa nervorum.
- *Abdominal* – pain due to arterial involvement of the abdominal viscera, mimicking acute cholecystitis, pancreatitis or appendicitis. Gastrointestinal haemorrhage occurs because of mucosal ulceration.
- *Renal* – presents with haematuria and proteinuria. Hypertension and acute/chronic renal failure occur.
- *Cardiac* – coronary arteritis causes myocardial infarction and heart failure. Pericarditis also occurs.
- *Skin* – subcutaneous haemorrhage and gangrene occur. A persistent livedo reticularis is seen in chronic cases. Cutaneous and subcutaneous palpable nodules occur, but are uncommon.
- *Lung* – involvement is rare.

Investigations and treatment

- **Blood count**. Anaemia, leucocytosis and a raised ESR occur.
- **Biopsy** material from an affected organ shows features listed above.

- **Angiography**. Demonstration of microaneurysms in hepatic, intestinal or renal vessels if necessary.
- **Other investigations** as appropriate (e.g. ECG and abdominal ultrasound), depending on the clinical problem. ANCA is positive only rarely in classic PAN.

Treatment is with corticosteroids, usually in combination with immunosuppressive drugs such as azathioprine.

Kawasaki's disease

This is an acute systemic vasculitis involving medium-sized vessels, affecting mainly children under 5 years of age. It is very frequent in Japan, and an infective trigger is suspected. It occurs world-wide and is also seen in adults.

Clinical features and treatment

The clinical features are:

- fever lasting 5 days or more
- bilateral conjunctival congestion 2–4 days after onset
- dryness and redness of the lips and oral cavity 3 days after onset
- acute cervical lymphadenopathy accompanying the fever
- polymorphic rash involving any part of the body
- redness and oedema of the palms and soles 2–5 days after onset.

Five of these six features should be present to make the diagnosis, or four of six if coronary aneurysms can be seen on two-dimensional echocardiography, MRI or angiography.

Cardiovascular changes in the acute stage include pancarditis and coronary arteritis leading to aneurysms or dilatation. Other features include diarrhoea, albuminuria, aseptic meningitis and arthralgia and, in most, there is a leucocytosis, thrombocytosis and a raised CRP. Anti-endothelial cell autoantibodies are often detectable.

Treatment is with high-dose intravenous immunoglobulin, which prevents the coronary artery disease, followed after the acute phase by aspirin 200–300 mg daily. There is no evidence that steroid treatment improves the outcome.

SMALL VESSEL VASCULITIS

This can be separated into those that are positive or negative for anti-neutrophilic cytoplasmic antibody (ANCA) (see p. 504).

The clinical features and diagnosis of small vessel vasculitis are shown in Table 10.20.

ANCA-positive small vessel vasculitis

- Wegener's granulomatosis – see page 870.
- Churg–Strauss granulomatosis – see page 870.
- Microscopic polyangiitis – see page 871.

ANCA-negative small vessel vasculitis

Henoch–Schönlein purpura – see pages 554 and 592

Cryoglobulinaemic vasculitis – see page 591

Cutaneous leucocytoclastic vasculitis (p. 1263)

This is the characteristic acute purpuric lesion which histologically involves the dermal post-capillary venules. This lesion affects only the skin and should be differentiated from similar lesions produced in systemic vasculitis. The purpura may be accompanied by arthralgia and glomerulonephritis. Hepatitis C infection is common and may be an aetiological agent. The condition can also be caused by drugs such as sulphonamides and penicillin.

Treatment of small cell vasculitis

The treatment depends on the organs involved. Vasculitis confined to the skin may not require systemic treatment

Table 10.20 Diagnosis and clinical features of small vessel vasculitis

	Wegener's granulomatosis	Churg–Strauss syndrome	Microscopic polyangiitis	Henoch–Schönlein purpura	Cryoglobulinaemic vasculitis
Features					
ANCA (in blood)	90%	+	+	–	–
PR3					
MPO	–	60%	60%		
Necrotizing granulomas	+	+	–	–	–
Cryoglobulins (in blood and vessels)	–	–	–	–	–
IgA immune deposits (mainly)	–	–	–	+	–
Asthma and eosinophilia	–	+	–	–	–
Organs involved					
Skin	40	60	40	90	90
Kidneys	80	45	90	50	55
Lungs	90	70	50	<5	<5
ENT	90	50	35	<5	<5
Musculoskeletal	60	50	60	75	70
Neurological	50	70	30	10	40
Gastrointestinal	50	50	50	60	30

Modified from Jeanette JC, Falk RJ. Small vessel vasculitis. *New England Journal of Medicine* 1997; **337:** 1512–1523. Copyright © 1997 Massachusetts Medical Society. All rights reserved.

whereas involvement of major organs (e.g. lungs or kidneys in Wegener's granulomatosis) requires high-dose corticosteroids, immunosuppression and sometimes plasma exchange.

BEHÇET'S DISEASE

Behçet's disease is an inflammatory disorder of unknown cause. There is a striking geographical distribution, it being most common in Turkey, Iran and Japan. The prevalence per 100 000 is 10–15 in Japan and 80–300 in Turkey. There is a link to the HLA-B51 allele (a split antigen of B5), with a relative risk of 5–10; this association is not seen in patients in the USA and Europe.

Clinical features

The cardinal clinical feature is recurrent oral ulceration. The international criteria for diagnosis require oral ulceration and any two of the following: genital ulcers, defined eye lesions, defined skin lesions, or a positive skin pathergy test (see below). Oral ulcers can be aphthous or herpetiform. The eye lesions include an anterior or posterior uveitis or retinal vascular lesions. Cutaneous lesions consist of erythema nodosum, pseudofolliculitis and papulopustular lesions.

Other manifestations include a self-limiting peripheral mono- or oligoarthritis affecting knees, ankles, wrists and elbows; gastrointestinal symptoms of diarrhoea, abdominal pain and anorexia; pulmonary and renal lesions; a brainstem syndrome, organic confusional states and a meningoencephalitis. All the common manifestations are self-limiting except for the ocular attacks. Repeated attacks of uveitis can cause blindness.

The pathergy reaction is highly specific to Behçet's disease. Skin injury, by a needle prick for example, leads to papule or pustule formation within 24–48 hours. Blood tests usually show raised ESR and CRP but not autoantibodies.

Treatment

Corticosteroids, immunosuppressive agents and ciclosporin are used for chronic uveitis and the rare neurological complications. Colchicine helps erythema nodosum and joint pain. Thalidomide may be useful in some cases although side-effects of drowsiness and peripheral neuropathy are common. It should not be used in pregnant women because of phocomelia (limb abnormalities).

DIFFERENTIAL DIAGNOSIS OF RHEUMATIC COMPLAINTS IN THE ELDERLY (Fig.10.29)

Musculoskeletal problems

These are common at all ages. In the elderly, pain arises from a combination of age-related changes and injury.

Back and neck pain (see pp. 509 and 505)

These are commonly associated with spondylosis on X-ray. Complications include spinal stenosis or nerve root claudication. Look for locally tender areas, which might be injected. Mechanical back pain may be worse in the morning, especially when spondylosis is severe or there is marked deformity; there is a normal ESR and CRP, which distinguishes this from polymyalgia rheumatica. Rarely, elderly women present with previously undiagnosed ankylosing spondylitis.

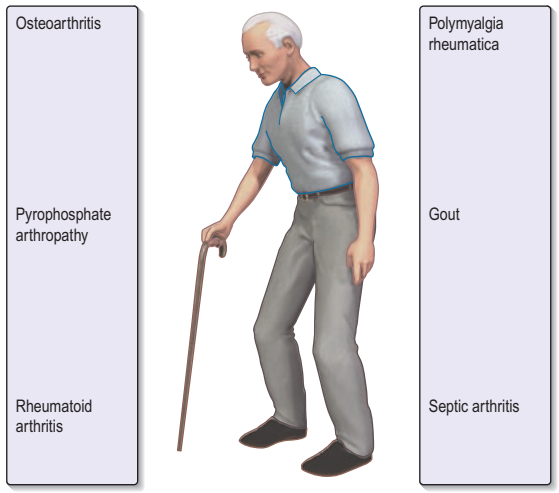

Fig. 10.29 **The differential diagnosis of arthritis in the elderly.**

Osteoporotic fractures

Osteoporotic fractures of the spine cause acute pain or deformity and subsequent postural back pain. The acute pain may warrant a period of bed rest (see p. 561). Intravenous pamidronate helps severe pain. The role of cement vertebroplasty is under investigation. The management of such problems in the elderly is the same as for younger people but a response to treatment is less predictable. Advice about posture, exercise, general fitness and about medication for osteoporosis to reduce the risk of further fractures is necessary but must be tempered by the patient's general health.

Symptomatic osteoarthritis (see p. 518)

This increases with increasing age and is uncommon below the age of 50 years. It is necessary to look for possible reversible causes of pain and disability, such as periarticular lesions or a joint effusion. Caution about drug treatment is necessary because of the increased risk of side-effects in older patients. Joint replacement surgery has transformed the outlook for many older people with OA by offering pain control and increased mobility and independence.

Rheumatoid arthritis (see p. 523)

RA may present in the elderly as a dramatic onset of symmetrical polyarthritis. This has a reasonable prognosis and responds well to low doses of prednisolone and other drug therapy. RA in the older patient may mimic polymyalgia rheumatica; the synovitis becomes apparent as the corticosteroid dose is reduced. Treat with DMARDs as for RA in order to reduce the corticosteroid dose.

Polymyalgia rheumatica and giant cell arteritis (see p. 549)

These must be recognized and treated. Failure to respond to adequate doses of prednisolone should trigger a search for an alternative disease, such as RA, vasculitis, infection or malignancy.

Systemic inflammatory vasculitis
Behçet's disease
Differential diagnosis of rheumatic complaints in the elderly
Arthritis in children
Juvenile idiopathic arthritis (JIA)

Chondrocalcinosis

This increases with increasing age and is seen on over 40% of knee X-rays in the over-80s. It may produce a variety of arthritic conditions (see p. 522).

Pseudogout (see p. 539)

This causes acute monoarthritis of the wrist or knee in older people. It responds well to aspiration and intra-articular corticosteroids or oral NSAIDs.

Gout

Gout causes acute monoarthritis in the elderly but may also present as a polyarticular inflammatory arthritis, especially in elderly women on long-term diuretic treatment, or as tophaceous gout (p. 538).

Septic arthritis (see p. 339)

Septic arthritis in the elderly and frail produces articular symptoms, and signs that may be muted. The patient usually has septicaemia and the best way to ensure the recognition of septic arthritis is to retain it in the differential diagnosis of all musculoskeletal presentations in unwell, elderly people.

Treatment

In all cases the management is similar to that described in the main part of the chapter, but special care should be taken to reduce doses of medication where possible and to think about possible adverse drug effects or interactions.

ARTHRITIS IN CHILDREN

Joint and limb pains are common in children but arthritis is fortunately rare. Babies and young children may present with immobility of a joint or a limp, but the diagnosis can be extremely difficult. Figure 10.30 summarizes the differential diagnosis.

For chronic conditions, the child and family often need a great deal of support from physiotherapists, occupational therapists, psychologists, teachers, social workers and orthopaedic surgeons. These are best obtained in specialist paediatric centres.

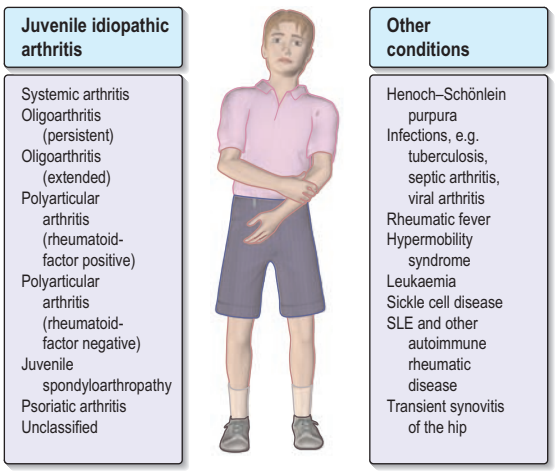

Fig. 10.30 **The differential diagnosis of arthritis in children.**

JUVENILE IDIOPATHIC ARTHRITIS (JIA)

Systemic onset JIA

Still's disease (which accounts for 10% of cases of JIA) affects boys and girls equally up to 5 years of age; then girls are more commonly affected. Adult-onset Still's disease is extremely rare.

Clinical features include a high (>39°) fever and evanescent pink maculopapular rash at the same time, with arthralgia and arthritis, myalgia and generalized lymphadenopathy. Hepatosplenomegaly, pericarditis and pleurisy occur. The differential diagnoses include malignancy, in particular leukaemia and neuroblastoma, and infection. Laboratory tests show a high ESR and CRP, neutrophilia and thrombocytosis. Autoantibodies are negative. Macrophage activation syndrome (an excessive proliferation of T cells and macrophages) is a rare but potentially fatal complication.

Oligoarthritis (persistent)

This is the most common form of JIA (50–60%) but is still a relatively uncommon condition. It affects, by definition, four or fewer joints – especially knees, ankles and wrists – often in an asymmetrical pattern. It affects mainly girls, with a peak age of 3 years. The prognosis is generally good with most going into remission. Uveitis (often with a positive ANA) occurs and requires regular screening by slit-lamp examination. Blindness can occur if it is untreated. Prognosis is generally good, with remission occurring eventually in most patients.

Oligoarthritis (extended)

In approximately 25% of patients, oligoarthritis extends to affect many more joints after around 6 months. This form of arthritis can be very destructive.

Polyarticular JIA

The rheumatoid factor-positive form (usually also anti-CCP positive) occurs in older girls, usually over 8 years. It is a systemic disease; the arthritis commonly involves the small joints of the hands, wrists, ankles and feet initially, and eventually larger joints. It can be a very destructive arthritis and needs aggressive treatment.

The rheumatoid factor-negative form is commoner. It usually affects girls under 12 years but can occur at any age. The arthritis is often asymmetrical, with a distribution similar to that seen in the RF-positive form. It may also affect the cervical spine, temporomandibular joints and elbows. Patients may be ANA positive, with a risk of chronic uveitis.

Enthesitis-related arthritis (formerly juvenile spondyloarthropathy)

This affects teenage and younger boys mainly, producing an asymmetrical arthritis of lower-limb joints and enthesitis. It is associated with HLA-B27 and a risk of iritis. It is the childhood equivalent of adult ankylosing spondylitis but spinal involvement is rare in childhood. Approximately one in three develops spinal disease in adulthood.

Psoriatic arthritis

This occurs in children and is similar in pattern to the adult form. The arthritis can be very destructive. Psoriasis may develop long after the arthritis but is found commonly in a first-degree relative.

Treatment of JIA

JIA should always be referred to a specialist paediatric rheumatology unit with facilities to assess and design treatment plans which aim to prevent long-term disability. These units also need facilities for rehabilitation, education and surgical intervention. NSAIDs reduce pain and stiffness but disease-modifying agents such as methotrexate are used to control moderate and severe disease. Corticosteroids are often required in systemic disease: intravenous pulsed methylprednisolone is used, followed by methotrexate (10–15 mg/m^2) weekly to control disease and prevent growth suppression. Anti-TNF agents (see Table 10.15) are used if methotrexate fails, and are highly effective in all types except systemic-onset disease where the results are variable. In the UK etanercept was approved by the National Institute for Health and Clinical Excellence for the treatment of JIA in 2002. Sulfasalazine is used only in enthesitis-related JIA. Aspirin may be a cause of Reye's syndrome and should not be used under the age of 12 years.

Prognosis

Before biological therapy, up to 50% of children developed long-term disability; 25% continued to have active arthritis into adult years. Death was due to infection or systemic disease with pericarditis or amyloidosis. The prognosis has now improved but long-term studies are awaited.

OTHER TYPES

Henoch–Schönlein purpura (see also p. 592)

This is the commonest systemic vasculitis seen in children. IgA immune complexes deposit in the small vessels. It often occurs after upper respiratory tract infections. Other manifestations include lower limb purpura, a transient non-migratory polyarthritis, and abdominal pain. Fifty per cent of these patients will have haematuria and proteinuria, due to a glomerulonephritis; treatment of this is discussed on page 592. The prognosis is excellent, although 1% develop chronic renal damage.

Rheumatic fever

Rheumatic fever still occurs occasionally in developed countries but is more common in developing countries. It is described on page 136.

The arthritis affects large joints and migrates between joints, each being affected for a few days at a time. This is unlike systemic onset JIA, where arthritis is usually much more persistent in each affected joint. The fever is persistent but rarely as high as in systemic onset JIA, and the temperature often remains above normal. A child may not volunteer a history of sore throat and the carditis may be silent. Isolated arthritis is the presenting symptom in 14–42%. The disease is easily missed if not included in the differential diagnosis of acute childhood arthritis.

Treatment is described on page 137.

Hypermobility syndrome

Five to ten per cent of children are hypermobile. A proportion of them will develop various musculoskeletal complaints in early childhood, such as late walking, flat feet, or nocturnal leg pains, probably due to hypermobile ankles and knees suffering recurrent sprains and strains after exercise. Joint effusions, subluxation, dislocation and ligamentous injuries may occur throughout childhood. Low back pain may develop in affected adolescents. There may be some risk of the early development of osteoarthritis in adulthood. More severe hypermobility is also seen in Ehlers–Danlos and Marfan's syndromes (see pp. 568 and 780).

Treatment is with exercise directed at improving the strength of muscles that cross affected joints, as well as overall fitness and endurance. It may be necessary to reduce or change sporting and other activities.

Miscellaneous conditions

Idiopathic musculoskeletal pain can become chronic in children. Management requires exclusion of the causes shown in Figure 10.30, but without performing unnecessary laboratory investigations. Nocturnal musculoskeletal pains are episodic and may be associated with hypermobility. They are called 'growing pains'. They often last 15–30 minutes and awaken the child from sleep, and may require physiotherapy and analgesics, together with advice and support to the parents.

Low back pain in children may reflect psychosocial problems at home or school as much as any obvious musculoskeletal pathology.

Osteochondritis can affect the ossification centre of the ends of bones. A typical condition is *Osgood–Schlatter disease*, which is characterized by localized pain and swelling over the tibial tubercle or at the patellar tendon insertion. It is usually seen in athletic teenagers and responds to local treatment and changes of sporting activities. Sever's disease is an osteochondritis of the insertion of the Achilles tendon into the calcaneum.

Perthes' disease is an idiopathic, possibly avascular, necrosis of the proximal femoral epiphysis, of unknown aetiology. It presents as a painless limp, usually in boys aged 3–12 years, and is occasionally bilateral. If severe it may require surgical correction.

Transient synovitis of the hip (irritable hip) causes painful limitation of movement, usually of one hip, after an upper respiratory infection in young children (usually boys). Symptoms usually resolve within a few weeks (2–3% develop Perthes' disease) but other more serious causes of hip pain should be excluded. Treatment is with rest and analgesia until the pain resolves.

RHEUMATOLOGICAL PROBLEMS SEEN IN OTHER DISEASES

Gastrointestinal and liver disease

- *Enteropathic synovitis* – see page 536.
- *Autoimmune hepatitis* (see p. 344) may be accompanied by an arthralgia similar to that seen in systemic lupus erythematosus. Joint pain occurs in a bilateral, symmetrical distribution, with the small joints of the hands being predominantly affected. Joints usually look

normal but sometimes there is a slight soft-tissue swelling. These patients often have positive tests for anti-nuclear antibodies.
- *Primary biliary cirrhosis* patients occasionally have a symmetrical arthropathy.
- *Hereditary haemochromatosis* is associated with arthritis in 50% of cases; this is often the first sign of the disease and chondrocalcinosis is common.
- *Whipple's disease* (see p. 281) is accompanied by fever and arthralgia.

Malignant disease

It is not uncommon for malignant diseases to present with musculoskeletal symptoms. Bone pain may be due to multiple myeloma, lymphoma, a primary tumour of bone or secondary deposits. The pain is typically unremitting, worse at night and there are other clinical clues such as weight loss or ill-health. Secondary gout occurs in conditions such as chronic myeloid leukaemia.

Neoplastic disease of bone

Malignant tumours of bone are shown in Table 10.21. The most common tumours are metastases from the bronchus, breast and prostate. Metastases from kidney and thyroid are less common. Primary bone tumours are rare and usually seen only in children and young adults.

Symptoms are usually related to the anatomical position of the tumour, with local bone pain. Systemic symptoms (e.g. malaise and pyrexia) and aches and pains occur and are occasionally related to hypercalcaemia (see p. 1020). The diagnosis of metastases can often be made from the history and examination, particularly if the primary tumour has already been diagnosed. Symptoms from bony metastases may, however, be the first presenting feature.

Investigations

- **Skeletal isotope scans** show bony metastases as 'hot' areas before radiological changes occur.
- **X-rays** may show metastases as osteolytic areas with bony destruction. Osteosclerotic metastases are characteristic of prostatic carcinoma.
- **Serum alkaline phosphatase** (from bone) is usually raised.
- **Hypercalcaemia** is seen in 10–20% of patients with malignancies. It is associated chiefly with metastases, but can also result from ectopic parathormone or parathyroid hormone-related protein secretion.
- **Prostate-specific antigen** (PSA) and serum acid phosphate are raised in the presence of prostatic metastases.

Table 10.21 Malignant neoplasms of bone

Metastases (osteolytic)
Bronchus
Breast
Prostate (often osteosclerotic as well)
Thyroid
Kidney
Multiple myeloma
Primary bone tumours (rare; seen in the young) e.g.
Osteosarcomas
Fibrosarcomas
Chondromas
Ewing's tumour

Treatment

Treatment is usually with analgesics and anti-inflammatory drugs. Local radiotherapy to bone metastases relieves pain and reduces the risk of pathological fracture. Some tumours respond to chemotherapy; others are hormone-dependent and respond to hormonal therapy. Biphosphonates (p. 564) can help symptomatically. Occasionally pathological fractures require internal fixation.

Hypertrophic pulmonary osteoarthropathy

Hypertrophic osteoarthropathy is most often associated with carcinoma of the bronchus. It is a paraneoplastic, non-metastatic complication and may be the presenting feature of the disease. It occurs only rarely with other conditions that also cause clubbing. It is seen most often in middle-aged men, who present with pain and swelling of the wrists and ankles. Other joints are involved occasionally.

The diagnosis is made on the presence of clubbing of the fingers, which is usually gross, and periosteal new bone formation along the shafts of the distal ends of the radius, ulna, tibia and fibula on X-ray. A chest X-ray usually shows the malignancy.

Treatment should be directed at the underlying carcinoma; if this can be removed, the arthropathy disappears. NSAIDs relieve the symptoms.

Paraneoplastic polyarthritis

This is seen with carcinoma of the breast in women and of the lung in men, and also with renal cell carcinoma. The neoplasm may be occult at onset and the diagnosis is then difficult to make.

Skin disease

Psoriatic arthritis

This is discussed on page 1242.

Erythema nodosum (p. 1250)

This is accompanied by arthritis in over 50% of cases. The knees and ankles are particularly affected, being swollen, red and tender. The arthritis subsides, along with the skin lesions, within a few months. Treatment is with NSAIDs or occasionally steroids.

Neurological disease

Neuropathic joints (Charcot's joints) are joints damaged by trauma as a result of the loss of the protective pain sensation. They were first described by Charcot in relation to tabes dorsalis. They are also seen in syringomyelia, diabetes mellitus and leprosy. The site of the neuropathic joint depends upon the localization of the pain loss:

- In tabes dorsalis, the knees and ankles are most often affected.
- In diabetes mellitus, the joints of the tarsus are involved.
- In syringomyelia, the shoulder is involved.

Ask the authors
www.studentconsult.com

Neuropathic joints are not painful, although there may be painful episodes associated with crystal deposition. Presentation is usually with swelling and instability. Eventually severe deformities develop.

The characteristic finding is a swollen joint with abnormal but painless movement. This is associated with neurological findings that depend upon the underlying disease (e.g. dissociated sensory loss in syringomyelia or polyneuropathy in diabetes). X-ray changes are characteristic, with gross joint disorganization and bony distortion.

Treatment is symptomatic. Surgery may be required in advanced cases.

Blood disease

Arthritis due to haemarthrosis is a common presenting feature of *haemophilia* (see p. 438). Attacks begin in early childhood in most cases and are recurrent. The knee is the most commonly affected joint but the elbows and ankles are sometimes involved. The arthritis can lead to bone destruction and disorganization of joints. Apart from replacement of factor VIII, affected joints require initial immobilization followed by physiotherapy to restore movement and measures to prevent and correct deformities.

Sickle cell crises (p. 411) are often accompanied by joint pain that particularly affects the hands and feet in a bilateral, symmetrical distribution. Affected joints usually look normal but are occasionally swollen. This condition may also be complicated by avascular necrosis (see p. 410) and by osteomyelitis.

Arthritis can also occur in *acute leukaemia*; it may be the presenting feature in childhood. The knee is particularly affected and is very painful, warm and swollen. Treatment is directed at the underlying leukaemia. Arthritis may also occur in chronic leukaemia, with leukaemic deposits in and around the joints.

Individuals with *thalassaemia major* (see p. 408) are living longer and are presenting with back pain due to premature disc degeneration, secondary spondylosis and crush fractures due to osteoporosis. There is marked discal calcification.

Endocrine and metabolic disorders

Hypothyroid patients may complain of pain and stiffness of proximal muscles, resembling polymyalgia rheumatica. They may also have carpal tunnel syndrome. Less often, there is an arthritis accompanied by joint effusions, particularly in the knees, wrist and small joints of the hands and feet. These problems respond rapidly to thyroxine.

Hyperparathyroidism may be complicated by chondrocalcinosis and acute pseudogout.

In *acromegaly*, arthralgia occurs in about 50% of patients. It particularly affects the small joints of the hands and knees. There may be carpal tunnel syndrome.

In *Cushing's disease*, back pain is common.

Joint disorders related to *diabetes mellitus* are described on page 1057.

Familial hypercholesterolaemia is associated with oligo- or polyarthritis usually with tendon xanthomata. Arthritis also occurs in combined hyperlipidaemia.

MISCELLANEOUS ARTHROPATHIES

Familial Mediterranean Fever (FMF)

FMF is inherited as an autosomal recessive condition and occurs in certain ethnic groups, particularly Arabs, Turks, Armenians and Sephardic Jews. The gene, called *MEFV*, has been localized to chromosome 16. It encodes for pyrin or marenostrin, which activate the biosynthesis of a chemotactic-factor inactivator in neutrophils. Failure to produce this leads to FMF attacks.

These are characterized by recurrent attacks of fever, arthritis and serositis. Abdominal or chest pain due to peritonitis or pleurisy occurs. The arthritis is usually monoarticular and attacks last up to 1 week. The condition may be mistaken for palindromic rheumatism (p. 525), but such attacks are not usually accompanied by fever.

The diagnosis can be made by PCR, if available, but usually it is based on the clinical picture and exclusion of other conditions.

Treatment. Regular colchicine 1000–1500 μg daily can usually prevent the attacks. In resistant patients, thalidomide (p. 552) and anakinra (p. 530) can be tried. In general the disorder is benign but in 25% of cases renal amyloidosis develops.

Sarcoidosis (see also p. 868)

The most common type of arthritis is that associated with erythema nodosum, which occurs in 20% of cases of sarcoidosis at or soon after the onset of the disease. The most useful diagnostic test is a chest X-ray, which shows hilar lymphadenopathy in 80% of cases.

Other patterns of arthritis occur later in the disease. These include a transient rheumatoid-like polyarthritis and an acute monoarthritis that can be mistaken for gout.

Treatment is with NSAIDs, but if these fail to control the symptoms, corticosteroids are usually very effective.

Osteochondromatosis

In this condition, foci of cartilage form within the synovial membrane. These foci become calcified and then ossified (osteochondromas). They may give rise to loose bodies within the joint. The condition occurs in a single joint of a young adult and X-rays are usually diagnostic.

Treatment involves removal of loose bodies and synovectomy.

Pigmented villonodular synovitis

This is characterized by exuberant synovial proliferation that occurs either in joints or in tendon sheaths. The main manifestation in joints is recurrent haemarthrosis. It may produce progressive local bone destruction. A malignant form is seen occasionally.

Treatment is synovectomy or radiotherapy. In tendon sheaths, the condition gives rise to a nodular mass that requires excision.

Relapsing polychondritis

Relapsing polychondritis is a rare inflammatory condition of cartilage. It occurs equally in males and

females, usually the elderly. Tenderness, inflammation and eventual destruction of cartilage occur, mainly in the ear, nose, larynx or trachea. A seronegative polyarthritis occurs, as well as episcleritis and evidence of a vasculitis (e.g. glomerulonephritis). The diagnosis is clinical with laboratory evidence of acute inflammation.

Treatment involves corticosteroids and immunosuppressive agents.

DISEASES OF BONE

Bone is a specialized connective tissue serving three major functions:

- *mechanical* – structure and muscle attachment for movement
- *metabolic* – providing the body's primary store of calcium and phosphate
- *protective* – enclosing the marrow and other vital organs.

STRUCTURE AND PHYSIOLOGY

(Fig. 10.31)

Bone structure

Bone is comprised of cells and a matrix of organic protein and inorganic mineral. Long bones (femur, tibia, humerus) and flat bones (skull, scapula) have different embryological templates, with varying proportions of cortical and trabecular bone.

- *Cortical (compact) bone* forms the shaft of long bones and the outer shell of flat bones. Formed of concentric rings of bone, it is particularly adapted to withstand bending strain.

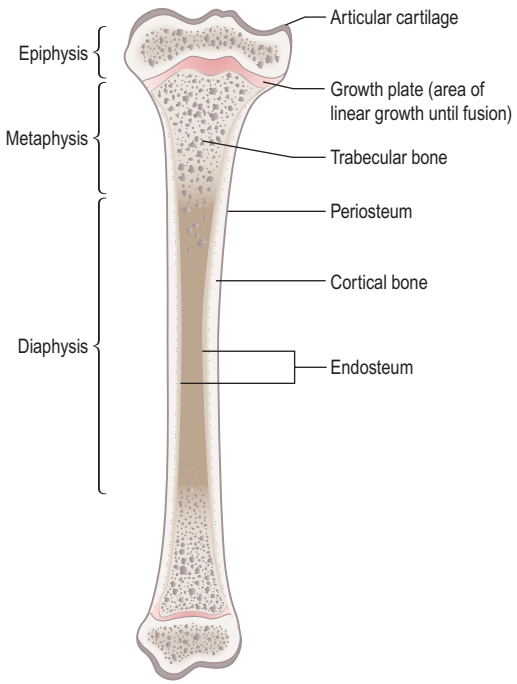

Fig. 10.31 **Diagram of a longitudinal section of a growing long bone.**

- *Trabecular (cancellous) bone* is found at the ends of long bones and inside flat bones. Comprised of a network of interconnecting rods and plates of bone, it offers resistance to compressive loads. It is also the main site of bone remodelling for mineral homeostasis.
- *Woven bone* lacks an organized structure. It appears in the first few years of life, at sites of fracture repair and in high-turnover bone disorders such as Paget's disease.
- *Lamellar bone*, in which the collagen fibres are arranged in parallel bundles, forms the bone in adult life.

Matrix components

Type I collagen is the main protein, forming parallel lamellae of differing density (which impairs spreading of cracks). In cortical bone, concentric lamellae form around a central blood supply (Haversian system) which communicates via transverse (Volkmann's) canals. Non-collagen proteins include osteopontin, osteocalcin and fibronectin. Bone mineral largely consists of calcium and phosphate in the form of hydroxyapatite.

Bone cells

Osteocytes

These are small cells, derived from osteoblasts, embedded in bone and interconnected with each other and with bone lining cells through cytoplasmic processes. They respond to mechanical strain by undergoing apoptosis or through altered cell signalling.

Osteoblasts

Derived from local mesenchymal stem cells, these cells synthesize matrix (osteoid) and regulate its mineralization. After bone formation, the majority of osteoblasts are removed by apoptosis, others remaining at the bone/marrow interface as lining cells or within the bone as osteocytes. Osteoblasts critically regulate bone resorption through the balance in expression of the stimulatory RANKL (the *l*igand for *r*eceptor *a*ctivator of *n*uclear factor *k*appaB) and its antagonist, osteoprotegerin (OPG). Osteoblasts are rich in alkaline phosphatase and express receptors for PTH, oestrogen, glucocorticoids, vitamin D, inflammatory cytokines and the transforming growth factor-β family, all of which may therefore influence bone remodelling.

Osteoclasts

These are cells with the unique capacity to resorb bone and are derived from haematopoietic precursors of the macrophage lineage. In response to RANKL and macrophage colony stimulating factor (M-CSF), they attach to bone, creating a ruffled border which forms a number of extracellular lysosomal compartments. Hydrogen ions are actively

secreted into these spaces and the acid environment removes the mineral phase before specialized cysteine proteases (e.g. cathepsin K) resorb the collagen matrix.

Bone growth and remodelling

Longitudinal growth occurs at the epiphyseal growth plate, a cartilage structure between the epiphysis and metaphysis (Fig. 10.31). Cartilage production is tightly regulated, with subsequent mineralization and growth finally arrested at between 18 and 21 years when the epiphysis and metaphysis fuse.

In adults, bone is regularly remodelled to ensure repair of microdamage and turnover of calcium and phosphate for homeostasis. This is carried out by the *basic multicellular unit* (BMU) (Fig. 10.32). Retraction of bone lining cells and altered expression of RANKL and OPG and other regulators of bone remodelling lead to induction of osteoclast formation and bone resorption. Unknown factors limit the amount of bone resorbed, after which osteoblasts fill in the resorption cavity. Bone remodelling is said to be coupled as formation normally follows resorption. New bone formation without resorption may, however, occur in the adult skeleton in response to anabolic therapy such as parathyroid hormone peptides. The cellular regulation of remodelling is incompletely defined. Recognized signals include changes in osteocytes (apoptosis or altered signalling of sclerostin, prostaglandins and other molecules), regulation of bone formation (reciprocal effects of *wnt* and of *dickkopf (Dkk)* and sclerostin on the LRP5/6–β-catenin pathway), and altered balance of RANKL and OPG. Additional influences include systemic hormones of which oestrogen (in both sexes) is particularly involved, promoting survival of osteocytes and inhibiting osteoclastogenesis.

CALCIUM HOMEOSTASIS AND ITS REGULATION

Calcium homeostasis is regulated by the effects of parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (1,25$(OH)_2D_3$) on gut, kidney and bone. Calcium-sensing receptors are present in the parathyroid glands, kidney, brain and other organs.

CALCIUM ABSORPTION AND DISTRIBUTION (Fig. 10.33)

Daily calcium consumption, primarily from dairy foods, should ideally be around 20–25 mmol (800–1000 mg). The combined effect of calcium and vitamin D deficiency contributes to bone fragility in some older persons. Intestinal

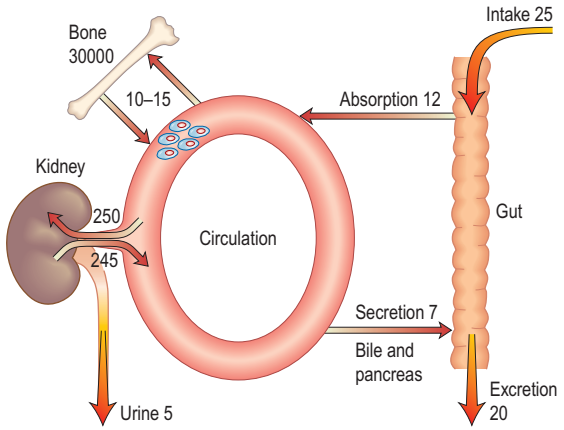

Fig. 10.33 **Calcium exchange in the normal human.** The amounts are shown in mmol per day.

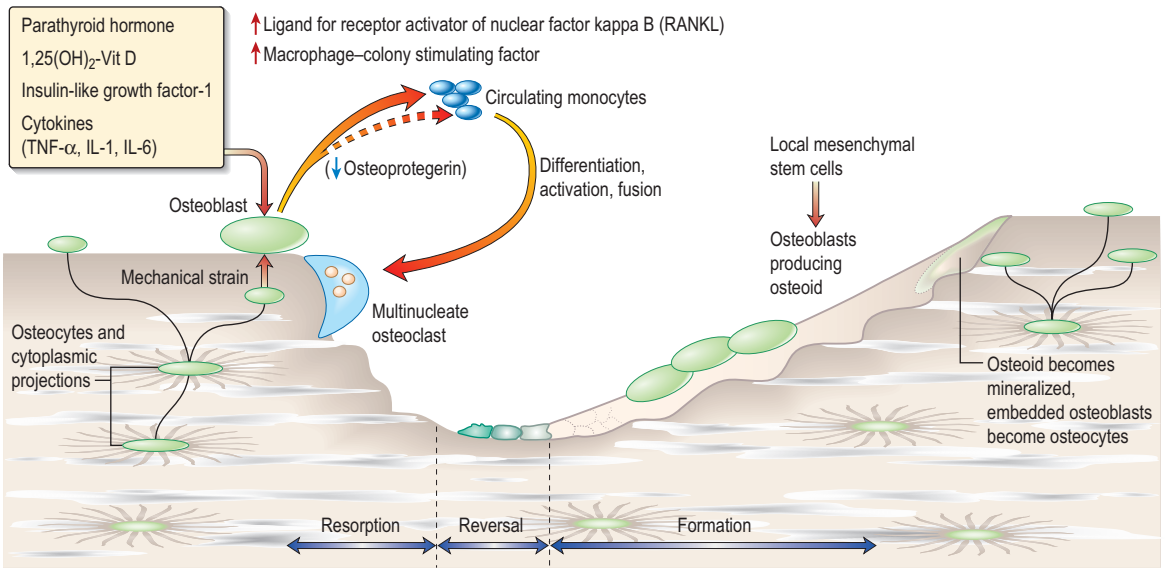

Fig. 10.32 **A diagram of a basic multicellular unit on a trabecular bone surface.** *Resorption*, reversal and bone formation are occurring simultaneously at different locations within the remodelling space. The sequence of events over time is shown, from left to right. A multinucleate osteoclast has formed in response to stimuli including increased RANKL and M-CSF and reduced osteoprotegerin (OPG) expression by osteoblasts lining the bone surface. The osteoclast removes an area of bone, with unknown signals limiting the depth of resorption. During the *reversal phase* (centre) macrophages appear in the osteoclasts' wake, removing apoptotic cells and preparing the bone surface to receive newly formed osteoid from osteoblasts (right) which form some time after the osteoclasts, possibly in response to the microenvironment of healthy bone exposed by resorption. This osteoid will gradually be fully mineralized, completing the cycle over approximately 120 days.

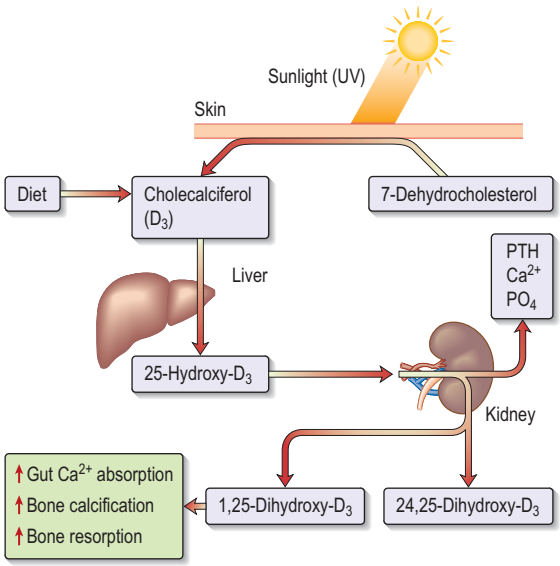

Fig. 10.34 **The metabolism and actions of vitamin D.**

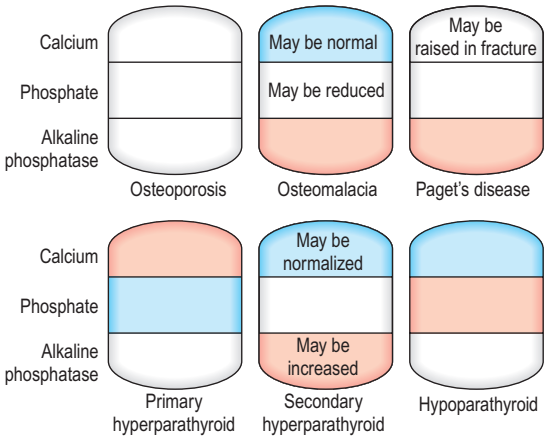

Fig. 10.35 **Changes in serum calcium, phosphate and alkaline phosphatase in main bone disorders.** Shading represents increased (red), reduced (blue) or normal (white) levels.

absorption of calcium is reduced by vitamin D deficiency, and in malabsorption states.

Vitamin D metabolism (Fig. 10.34)

The primary source of vitamin D in humans is photoactivation in the skin of 7-dehydrocholesterol to cholecalciferol, which is then converted first in the liver to 25-hydroxyvitamin D ($25(OH)D_3$) and subsequently in the kidney (by the enzyme 1α hydroxylase) to $1,25(OH)_2D_3$. Regulation of the latter step is by PTH, phosphate and feedback inhibition by $1,25(OH)_2D_3$.

Parathyroid hormone (PTH)

PTH, an 84 amino-acid hormone, is secreted from the chief cells of the parathyroid gland, which bear calcium-sensing and vitamin D receptors. PTH increases renal phosphate excretion and increases plasma calcium by:

- increasing osteoclastic activity (a rapid response)
- increasing intestinal absorption of calcium (a slower response)
- increasing 1α-hydroxylation of vitamin D (the rate-limiting step)
- increasing renal tubular reabsorption of calcium.

Hypomagnesaemia can suppress the normal PTH response to hypocalcaemia.

Calcitonin

Calcitonin is produced by thyroid C cells. Although calcitonin inhibits osteoclastic bone resorption and increases the renal excretion of calcium and phosphate, neither excess calcitonin (in medullary carcinoma of the thyroid) nor its deficiency following thyroidectomy has significant skeletal effects in humans.

INVESTIGATION OF BONE AND CALCIUM DISORDERS (Fig. 10.35)

Total plasma calcium (2.2–2.6 mmol/L)

About 40% is ionized and physiologically active: the remainder is complexed or protein bound. As ionized calcium is difficult to measure, normal practice is to measure total calcium, correcting the value to allow for protein binding according to the following formula: add or subtract 0.02 mmol/L for each gram per litre of a simultaneous albumin level below or above 40 g/L. For critical measurements, samples should be taken in the fasting state and without a tourniquet (the latter may increase local plasma calcium concentration).

Plasma phosphate (0.8–1.4 mmol/L)

Phosphate is essential to most biological systems. High levels are found in renal failure and hypoparathyroidism, while low levels are associated with primary hyperparathyroidism, hypophosphataemic rickets and osteomalacia and other disorders associated with reduced renal tubular phosphate reabsorption.

Plasma PTH (reference range 10–65 ng/mL, need to check with your local laboratory)

The PTH assay measures the intact hormone. In hypercalcaemia due to causes other than hyperparathyroidism, serum PTH levels are suppressed. Lithium toxicity may be associated with raised PTH levels, and in familial hypocalciuric hypercalcaemia (FHH) serum PTH may be normal or marginally elevated.

Serum 25-hydroxyvitamin D (reference ranges are seasonal; generally >20 ng/mL or 50 nmol/L are considered normal)

Serum $25-(OH)D_3$ provides an assessment of vitamin D status, provided there is no reason to suspect defective 1α-hydroxylation in the kidney. Very low levels (e.g. ≤7.5 ng/mL) indicate the presence of severe vitamin D deficiency whereas reductions of a lesser magnitude are referred to as vitamin D *insufficiency*, in which the main functional consequence is secondary hyperparathyroidism and increased bone turnover, particularly in cortical bone.

24-hour urinary calcium (normal range 2.5 up to 6.25 (female) and 7.5 (male) mmol/24 h)

This is increased where renal tubular reabsorption of calcium is decreased, and in hypercalcaemia. One exception

is familial hypocalciuric hypercalcaemia where the genetic defect leads to inappropriately reduced calcium excretion. Measurement of 24-hour urinary calcium excretion should be routinely performed in the assessment of hypercalcaemic patients.

Biochemical markers of bone formation and resorption

While these are available in many laboratories, their use is limited by large biovariability and measurement variance. Serial measurements at the same time of day in individual patients are useful in assessing response to treatment of metabolic bone diseases. In addition, measurements of bone turnover markers may have a role in the assessment of fracture risk.

- *Bone-specific alkaline phosphatase.* Circulating alkaline phosphatase is derived from bone, liver and placenta. The bone-specific isoenzyme can be measured as a marker of formation, although there is some overlap with the liver isoenzyme. Elevated serum levels occur during bone growth, fracture repair, and in high bone turnover states (Fig. 10.35).
- *Type 1 collagen propeptides* are by-products of collagen synthesis. Serum levels of both the carboxyterminal (P1CP) and aminoterminal (P1NP) propeptides reflect bone formation.
- *Serum osteocalcin* is another bone formation marker.
- *Serum or urine levels of N-terminal (NTX) and C-terminal (CTX) cross-linked telopeptides* reflect bone resorption. They may change rapidly in response to anti-resorptive drugs or in disease states.

Diagnostic imaging

- *Plain radiographs* identify fractures, tumours and infections. Other specific features may be seen (see following sections).
- *Radionucleotide imaging*. Technetium-99m-labelled methylene bisphosphonate uptake in bone reflects bone turnover and blood flow. Increased uptake is therefore seen in fracture, tumour and metastatic deposits, infection and Paget's disease of bone.
- *Magnetic resonance imaging* is rarely used specifically to image bone. However, variation in technique to suppress the high signal associated with bone marrow (such as STIR sequences, see p. 505) allows highly sensitive recognition of 'bone marrow oedema', a non-specific feature of a number of bone disorders including avascular necrosis. High-resolution MRI provides information about bone microarchitecture, but this is not yet applied in the clinical setting.
- *Bone biopsy* (Fig. 10.36). A core of bone is removed, including both cortices of the iliac crest, using a trephine. The non-decalcified specimen is examined for static and dynamic (bone turnover) indices. An oral tetracycline is given to the patient prior to the biopsy, for 2 days on two occasions 10 days apart, allowing assessment of the rate of bone turnover and mineralization. Biopsy is most commonly used in assessment of suspected renal bone disease and osteomalacia.
- *Bone densitometry measurements* (p. 562).

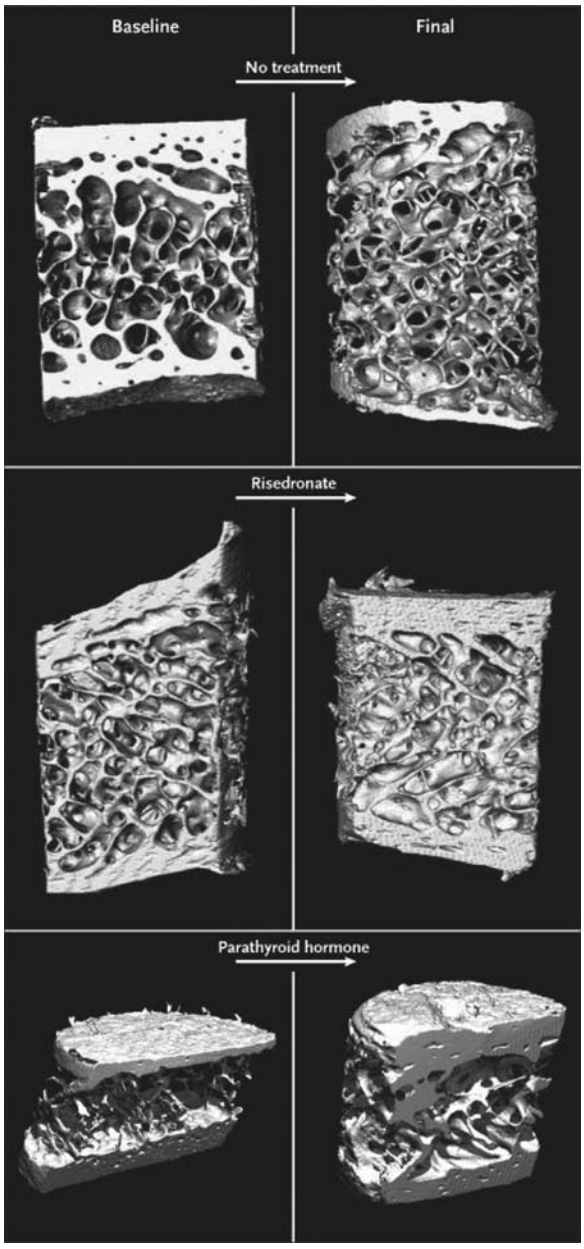

Fig. 10.36 **Computerized images of bone biopsies in osteoporosis demonstrate changes in bone architecture over time.** *Upper pair*: without treatment, the bone cortex becomes thinner, and numerous trabecular rods and plates are lost. *Centre pair*: in response to bisphosphonate treatment, resorption is reduced, with preservation of bone mineral and structure. *Lower pair*: in response to anabolic therapy, bone is increased at both trabecular and cortical sites. Reproduced from *Journal of Bone and Mineral Research* 2003; **18**: 1932–1941 with permission of the American Society for Bone and Mineral Research.

OSTEOPOROSIS

Definition and incidence

Osteoporosis is defined as 'a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and an increase in fracture risk'.

The World Health Organization (WHO) defines osteoporosis as a bone density of 2.5 standard deviations (SDs)

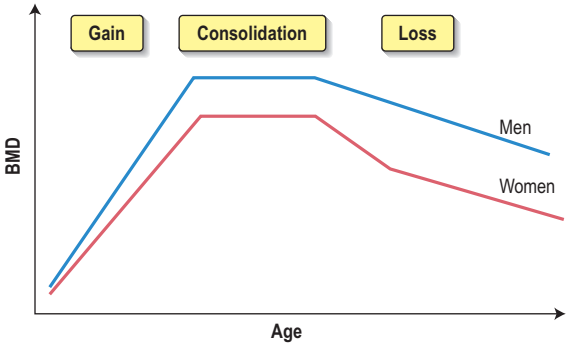

Fig. 10.37 **Lifetime changes in bone mineral density (BMD).** Peak bone mass is achieved between 20 and 30 years of age (gain), and consolidated up to around the age of 40 years. Then, age-related bone loss occurs in both men and women, with an accelerated loss in women starting around the time of menopause which lasts between 5 and 10 years.

below the young healthy adult mean value (T-score ≤ –2.5) or lower. Values between –1 and –2.5 SDs below the young adult mean are termed 'osteopenia'. The rationale for this definition is the inverse relationship between bone mineral density and fracture risk in postmenopausal women and also older men. However, this definition should not be applied to younger women, men or children.

Fractures due to osteoporosis are a major cause of morbidity and mortality in elderly populations. One in two women and one in five men aged 50 years will have an osteoporotic fracture during their remaining lifetime. Caucasian and Asian races are particularly at risk. The annual cost to the health services in the UK is estimated at around £1.8 billion. As the risk of fracture increases exponentially with age, changing population demographics will increase the burden of disease.

Pathogenesis

Osteoporosis results from increased bone breakdown by osteoclasts and decreased bone formation by osteoblasts leading to loss of bone mass.

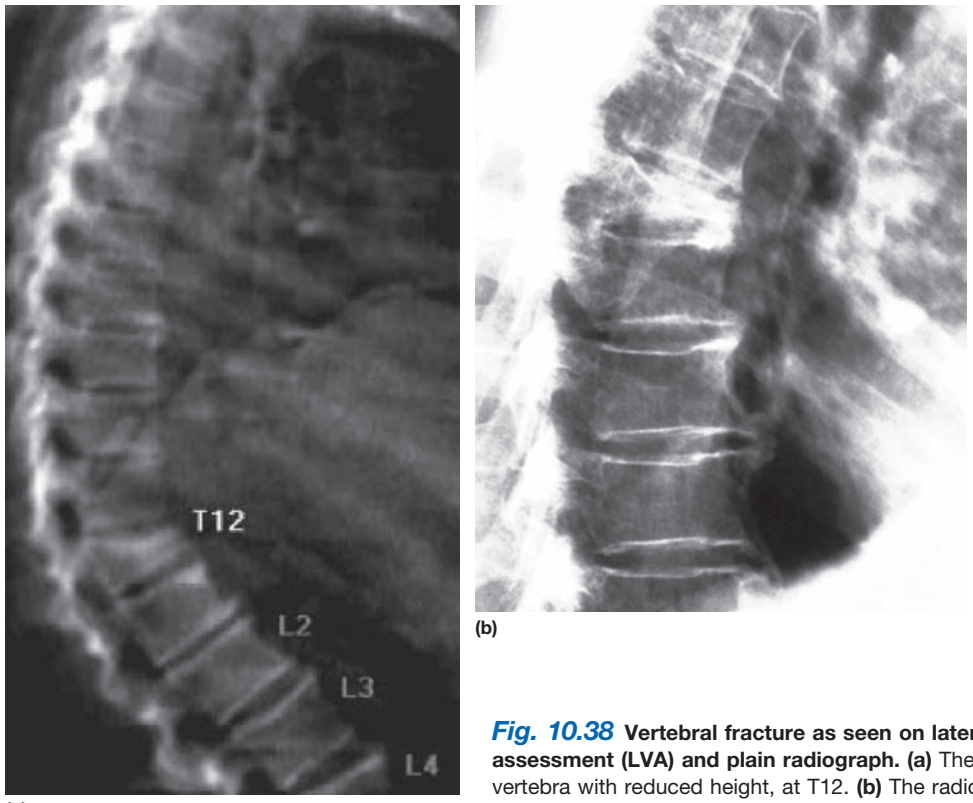
Bone mass decreases with age (Fig. 10.37) but will depend on the 'peak' mass attained in adult life and on the rate of loss in later life. Genetic factors are the single most significant influence on peak bone mass, but multiple genes are involved, including collagen type1A1 (p. 568), vitamin D receptor and oestrogen receptor genes. Nutritional factors, sex hormone status and physical activity also affect peak mass.

Risk factors

Oestrogen deficiency is a major factor in the pathogenesis of accelerated bone loss. In the elderly, vitamin D insufficiency and consequent hyperparathyroidism are pathogenetic factors.

Additional risk factors are associated with increased bone loss, or with increased bone fragility but are independent of effects on the bone mineral density (Table 10.22). For example, hyperparathyroidism, hyperthyroidism and malabsorption each increase the risk of the person having a low bone mass and are BMD dependent. However, other risk factors such as previous fracture, increasing age, glucocorticoid therapy, smoking and falls increase the risk of fracture, on top of the risk associated with their particular low bone mass. The effect of many of these risk factors is particularly notable in terms of hip fracture risk.

Table 10.22 Risk factors for osteoporosis



BMD-dependent	BMD-independent
Female sex	Increasing age
Caucasian/Asian	Previous fragility fracture
Gastrointestinal disease	Family history of hip fracture
Hypogonadism	Low body mass index
Immobilization	Smoking
Chronic liver disease	Alcohol abuse
Chronic renal disease	Glucocorticoid therapy
Low dietary calcium intake	High bone turnover
Vitamin D insufficiency	Increased risk of falling
Chronic obstructive pulmonary disease	Rheumatoid arthritis
Drugs	
Heparin	
Calcineurin inhibitors e.g. ciclosporin	
Anticonvulsants	
Thiazolidinediones	
Aromatase inhibitors	
Anti-androgens	
GnRH analogues	
Proton pump inhibitors	
?Selective serotonin reuptake inhibitors	
Endocrine disease	
Cushing's syndrome	
Hyperthyroidism	
Hyperparathyroidism	
Other diseases	
Diabetes mellitus	
Mastocytosis	
Multiple myeloma	
Osteogenesis imperfecta	

Treatment also can depend on the type of risk factors, for if they are recognized as 'skeletal', they respond to bone-directed treatment and if as 'non-skeletal', they require other intervention (e.g. reduction of falls risk).

Not all causes of osteoporosis affect bone remodelling and architecture in the same way. For example, oestrogen deficiency results in increased numbers of remodelling units, and increased resorption depth exceeding osteoblast synthethic capacity, with a loss of resistance to fracture that is not fully reflected in the bone density measurement. Glucocorticoids induce a high turnover state initially, with increased fracture risk evident within three months of starting therapy. More prolonged use leads to a reduced turnover state but with a net loss due to reduced synthesis (through increased inhibition of the *wnt*–LRP5/6 axis).

Clinical features

Fracture is the only cause of symptoms in osteoporosis. Sudden onset of severe pain in the spine, often radiating around to the front, suggests *vertebral crush fracture*. However, only about one in three vertebral fractures is symptomatic. Pain from mechanical derangement, increasing kyphosis, height loss and abdominal protuberance follow crushed vertebrae. *Colles' fractures* typically follow a fall on an outstretched arm. *Fractures of the proximal femur* usually

(a) (b)

Fig. 10.38 **Vertebral fracture as seen on lateral vertebral assessment (LVA) and plain radiograph. (a)** The LVA image shows a vertebra with reduced height, at T12. **(b)** The radiograph shows a typical wedge compression fracture.

occur in older individuals falling on their side or back. Other causes of low-trauma fractures must not be overlooked, including metastatic disease and myeloma.

Investigations

Plain radiographs usually show a fracture and may reveal previously asymptomatic vertebral deformities. Such clinically silent fractures may also be detected during the DXA scan with an additional analysis (called *lateral vertebral assessment,* Fig. 10.38) carried out with a much lower radiation dose than conventional imaging.

Bone density

- *Dual energy X-ray absorptiometry* (DXA) measures areal bone density (mineral per surface area rather than a true volumetric density), usually of the lumbar spine and proximal femur. It is precise, accurate, uses low doses of radiation and is the gold standard in osteoporosis diagnosis (Fig. 10.39). Because of osteophytes, spinal deformity and vertebral fractures, spinal values may be artefactually elevated and should be interpreted with caution in the elderly.
- *Quantitative ultrasound* of the calcaneum. This does not require ionizing radiation and is cheaper than other methods. It cannot be used for diagnostic purposes but is useful as a screening procedure prior to DXA assessment. The WHO T-score definition of osteoporosis should only be applied to DXA carried out at the hip and spine, and not to ultrasound, where a term such as 'low bone mass' is preferable.
- *Quantitative CT scanning* allows true volumetric assessment, and distinction between trabecular and cortical bone. However, it is more expensive, requires higher radiation than other techniques, and to date offers no clinical advantage.

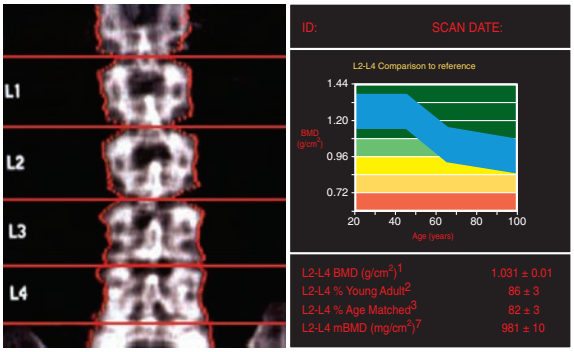


Fig. 10.39 **Dual energy X-ray absorptiometry of the lumbar spine.** The AP image of the lumbar spine is shown on the left and on the right, the patient's value is expressed in relation to the reference range.

Associated disease and risk factors

Investigations to exclude other diseases or identify contributory factors associated with osteoporosis should be per-

formed and are particularly necessary in men, in whom secondary causes are more common (see Table 10.22).

Selection of individuals for treatment: risk assessment

The purpose of treatment is to reduce the risk of fractures. Thus, assessment of absolute fracture risk should be made in every case. Although bone mineral density measurements in the spine and proximal femur provide useful information about fracture risk, they have a relatively low sensitivity and the majority of fragility fractures occur in women with a T-score ≥–2.5. Prediction of fracture risk can be improved by the addition of risk factors that are at least partially independent of bone mineral density (see Table 10.22). This forms the basis of a 'fracture risk tool' for clinical practice that has been developed under the auspices of the WHO, which provides an algorithm for calculation of 10-year fracture probabilities, based on independent clinical risk factors with and without bone mineral density values. The intervention threshold can then be determined by the cost-effectiveness of treatment and by clinical judgement.

All postmenopausal women and older men with a history of fragility fracture should be reviewed for treatment. In those aged ≥75 years, DXA is often not necessary prior to treatment but in those ≤75 years, DXA is useful in guiding treatment decisions (see Table 10.23) . However, other risk factors should also be taken into account when deciding whether to treat, particularly age and a history of previous fracture. Thus individuals with higher BMD values but with other clinical risk factors have a greater fracture probability than those with low BMD values in the absence of risk factors (Fig. 10.40).

Prevention and treatment

- *Symptomatic management.* New vertebral fractures require bed rest for 1–2 weeks with strong analgesia (e.g. meptazinol 200 mg every 3–6 hours i.m. or i.v. – 100 mg) and transcutaneous electrical nerve stimulation (TENS) may be helpful. Muscle relaxants (e.g. diazepam 2 mg three times daily), subcutaneous calcitonin (50 IU daily) or a single intravenous infusion of pamidronate (60–90 mg) may be useful for pain relief, and physiotherapy helps restore confident mobilization. Non-spinal fractures should be treated by conventional orthopaedic means.
- *Calcium and vitamin D.* Daily intakes of 700–1000 mg of calcium (ideally 1500 mg postmenopausally) and 400–800 IU of vitamin D are recommended. In those with low dietary calcium intake and at risk from vitamin D insufficiency, calcium and vitamin D supplements should be advised. Vitamin D and calcium supplements should also be given to patients receiving bone protective medication.
- *Exercise.* Thirty minutes of weight-bearing exercise three times a week may increase BMD, though this has not been a universal finding in all studies. Gentle exercise in the elderly may reduce the risk of falls and improve the protective responses to falling.
- *Smoking cessation.* Smoking is associated with lower BMD and increased fracture risk. Alcohol abuse (>3 units/day) should be avoided.
- *Reduce falls.* Physiotherapy and assessment of home safety are helpful. Hip protectors do reduce fractures in the elderly in residential care when worn correctly, but compliance is poor.

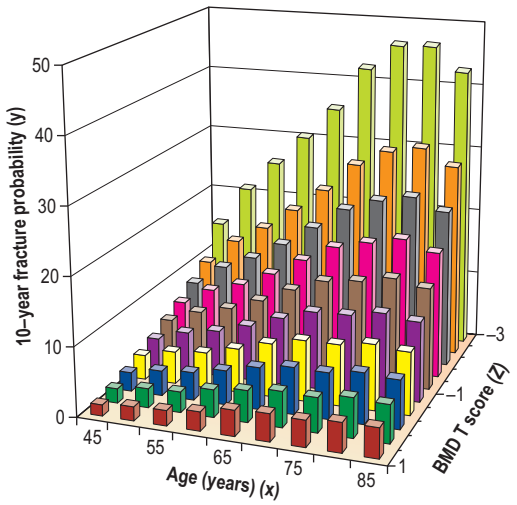

Fig. 10.40 **A graph illustrating the combined effects of age (x-axis) and reduced bone mass (expressed as T-scores on the z-axis) on the 10-year probability of fracture (y-axis) in a population of women.** Reduced bone mass osteopenia, T-scores between –1 and –2.5. Osteoporotic bone (T-scores less than –2.5) is shown in pale green. Note that the risk of fracture may be greater in an older woman with osteopenia than in a young woman with osteoporosis. Data from Kanis JA. Diagnosis of osteoporosis and assessment of fracture risk. *Lancet* 2002; **359**: 1929–1936 with permission.

Table 10.23 Indications for DXA scanning

Radiographic osteopenia
Previous fragility fracture (in those aged less than 75 years)
Glucocorticoid therapy (in those aged less than 65 years)
Body mass index below 19 (kg/m^2)
Maternal history of hip fracture
BMD-dependent risk factors in Table 10.22

In patients presenting with height loss and/or kyphosis, lateral thoracic spine X-ray should be the initial investigation.

Pharmacological intervention (see Fig. 10.36)

Most interventions used act by inhibiting bone resorption (anti-resorptives) although parathyroid hormone peptides stimulate bone formation. The mechanism of action of strontium ranelate remains incompletely defined.

The evidence base for *anti-fracture efficacy* of interventions varies. Adequately powered randomized controlled trials, with fracture as the primary endpoint, exist for alendronate, risedronate, ibandronate, zoledronate, raloxifene, hormone replacement therapy, strontium ranelate, teriparatide (recombinant human PTH peptide 1-34), human recombinant parathyroid hormone 1-84 and combined calcium/vitamin D (the latter in frail older individuals only).

Some interventions have been shown to reduce fracture at vertebral and non-vertebral sites, including the hip, whereas others have not been demonstrated to be effective at all sites (Table 10.24). Since a fracture at one site increases the risk of subsequent fracture at any site, treatments with efficacy at all major fracture sites (particularly spine and hip) are preferable. Hence the bisphosphonates and strontium ranelate are generally regarded as first-line options in the majority of postmenopausal women with osteoporosis.

Table 10.24 Medications to reduce fracture risk in postmenopausal women

Intervention	Vertebral fracture	Non-vertebral fracture	Hip fracture
Alendronate	+	+	+
Etidronate	+	ND	ND
Ibandronate	+	+*	ND
Raloxifene	+	ND	ND
Risedronate	+	+	+
Strontium ranelate	+	+	+*
Zoledronate	+	+	+
Teriparatide	+	+	ND
PTH (1–84)	+	ND	ND

*Demonstrated only in high-risk subgroup.
ND, not demonstrated.

- *Bisphosphonates*, synthetic analogues of bone pyrophosphate, adhere to hydroxyapatite and inhibit osteoclasts. *Alendronate, risedronate and zoledronate* increase bone mineral density at the hip and spine, and reduce the incidence of fractures at vertebral, hip and other sites, particularly in women who have already sustained a vertebral fracture. Alendronate and risedronate are given as once daily or, most commonly, once weekly doses (70 mg and 35 mg, respectively) and zoledronate is given as a once yearly infusion of 5 mg. *Ibandronate* is a recent addition, available as a once monthly oral therapy (150 mg per month) or as a three-monthly intravenous injection (3 mg per 3 months). However, anti-fracture efficacy at non-vertebral sites has only been shown in high-risk subgroups.
  - Oral bisphosphonates should be taken in the fasting state with a large drink of water, while the patient is standing or sitting upright. The patient should subsequently remain upright and avoid food and drink for at least 30 minutes.
  - Bisphosphonates are generally well tolerated but may be associated with upper gastrointestinal side-effects such as oesophagitis, particularly if the dosing instructions are not closely followed. Bisphosphonates should be used with caution in patients with chronic kidney disease. Osteonecrosis of the jaw is seen following high dose i.v. (rarely oral) nitrogen-containing bisphosphonate in patients with malignant disease. It is associated with poor dental hygiene. An association with bisphonate use in osteoporosis has not been clearly eatablished.
  - The optimal duration of bisphosphonate therapy is unknown; prolonged suppression of bone turnover may have adverse effects, and it is currently advised to reassess treatment after 5–10 years.
- *Strontium ranelate* consists of two stable strontium atoms linked to an organic acid, ranelic acid. Its mechanism of action remains uncertain although it has weak anti-resorptive activity whilst maintaining bone formation. It reduces the risk of vertebral, hip and other non-vertebral fractures in postmenopausal women with osteoporosis. The dose is 2 g daily, given as granules dissolved in water at night. It is a useful alternative option to the bisphosphonates particularly in the frail elderly population, in whom oral bisphosphonates are often contraindicated because of difficulty in complying with the dosing regimen. Nausea, diarrhoea and headaches are infrequent side-effects, and there is a small increase in the risk of venous thromboembolism.
- *Raloxifene* 60 mg daily is a selective oestrogen-receptor modulator (SERM). It has no stimulatory effect on the endometrium but activates oestrogen receptors in bone. It prevents BMD loss at the spine and hip in postmenopausal women, though fracture rates were only reduced in the spine. It also reduces the incidence of oestrogen-receptor-positive breast carcinoma in women treated for up to 4 years. Leg cramps and flushing may occur and the risk of thromboembolic complications is also increased to a degree similar to that seen with HRT. Its use is associated with a small increase in the risk of stroke.
- *Recombinant human parathyroid hormone peptide 1–34 (teriparatide)* and *recombinant human parathyroid hormone 1–84* (anabolic agents that stimulate bone formation). *Teriparatide* has been shown to reduce vertebral and non-vertebral fractures in postmenopausal women with established osteoporosis, although data on hip fracture are not available. It is given by daily subcutaneous injection in a dose of 20 μg for 18 months. *Recombinant human parathyroid hormone* 1–84 is also administered by once daily subcutaneous injection at a dose of 100 μg and has been shown to reduce vertebral, but not non-vertebral fractures. An anti-resorptive drug may be given after parathyroid hormone peptide therapy to maintain the increase in bone mineral density. Parathyroid hormone peptide therapy is mainly indicated in severe cases of vertebral osteoporosis or in women who fail to respond to other therapies. Teriparatide causes only mild transient hypercalcaemia and routine monitoring is not required. Nausea and headache may occur. Recombinant human parathyroid hormone 1–84 is associated with a higher incidence of hypercalcaemia and hypercalciuria and routine monitoring is advised.
- *Calcium given with vitamin D* has been shown to reduce non-vertebral fractures, including hip fractures, in elderly women living in residential care (but not in free-living older community dwellers). The recommended dose is 800 IU of vitamin D and 1–1.2 g calcium daily.
- *Hormone replacement therapy* (HRT). Because of adverse effects on breast cancer and cardiovascular disease risk, HRT is a second-line option for osteoporosis except in early postmenopausal women at high fracture risk who also have perimenopausal symptoms.
- *Calcitriol* ($1,25\text{-}(OH)_2D_3$) may reduce vertebral fracture rate, although the data are inconsistent. Hypercalcaemia and hypercalciuria may occur and monitoring is necessary.
- *Calcitonin*. Nasal or subcutaneous calcitonin may be used; vertebral fracture rates may be reduced, although this has not been a universal finding.
- *Combination therapies*, either with two anti-resorptive agents or an anti-resorptive and an anabolic agent, often produce larger increases in BMD than monotherapy but have not been shown to result in greater fracture reduction than with monotherapy.

Glucocorticoid-induced osteoporosis

Individuals requiring continuous oral glucocorticoid therapy for 3 months or more (at any dose) should be assessed for coexisting risk factors (age, previous fracture, hormone status). Men and women aged over 65 years and individuals who have sustained a fragility fracture aged 40 years or more should receive treatment without delay for DXA scanning. DXA results guide treatment for other patients. Bisphosphonates (etidronate, alendronate and risedronate) and teriparatide are the approved agents for this indication. Calcium and vitamin D supplementation should also be given (see Table 10.23).

Osteoporosis in men

Alendronate (10 mg daily) and risedronate (5 mg daily) have been shown to increase BMD and to reduce vertebral fractures in men with osteoporosis. Teriparatide is also used with osteoporosis and increased risk of fracture. In men with osteoporosis who have clinical and biochemical evidence of hypogonadism, testosterone replacement is used.

OSTEONECROSIS

This is also known as aseptic avascular or ischaemic necrosis of the bone. It is due to a multitude of factors including haemoglobinopathies (e.g. sickle cell disease), deep sea diving (Caisson's disease), medication (e.g. corticosteroids, bisphosphonates), endocrine or metabolic disorders (e.g. Cushing's, diabetic mellitus), trauma, HIV infection, irradiation and alcohol abuse. Osteonecrosis of the jaw is rarely seen in patients on nitrogen-containing bisphosphonates, e.g. alendronic acid for malignant disease.

It causes symptoms similar to arthritis with pain and arthropathy, although it can be asymptomatic. If undiagnosed, it can lead to bone collapse.

MRI best confirms the diagnosis by showing bone marrow oedema. If advanced, it can be seen on plain X-rays. *Treatment* depends on the cause and preventative measures should always be taken.

PAGET'S DISEASE

Osteitis deformans or Paget's disease is a focal disorder of bone remodelling. The initial event of excessive resorption is followed by a compensatory increase in new bone formation, increased local bone blood flow and fibrous tissue in adjacent bone marrow. Ultimately, formation exceeds resorption but the new bone is structurally abnormal.

Epidemiological studies are difficult because most affected individuals are asymptomatic. Paget's disease is most often seen in Europe and particularly in northern England. It affects men and women (2:3) over the age of 40 years. The incidence approximately doubles per decade thereafter, with up to 10% of individuals radiologically affected by the age of 90. A positive family history is noted in about 14%.

Aetiology and pathogenesis

A number of genes have been implicated in Paget's disease, including nuclear factor kappa B (NFκB), sequestosome p62 (which results in activation of NFκB), osteoprotegerin and *6Cl2* (an anti-apoptotic gene). Intracellular inclusions in the osteoclasts in pagetic lesions are believed to be paramyxovirus nucleocapsid (e.g. canine distemper virus, measles or respiratory syncytial virus). However, similar microfilaments are seen in other bone disorders, and theories of a viral aetiology in Paget's remain contentious. Altered expression of *c-fos* (an oncogene) is one suggested mechanism linking viral infection with the pathogenic changes in osteoclasts, which are more numerous and contain an increased number of nuclei (up to 100). Increased osteoclastic bone resorption is followed by formation of woven bone, which is weaker than normal bone, which leads to deformity and increased fracture risk. Unaffected bone remains normal throughout life (i.e. Paget's disease does not spread, but can become symptomatic at previously silent sites).

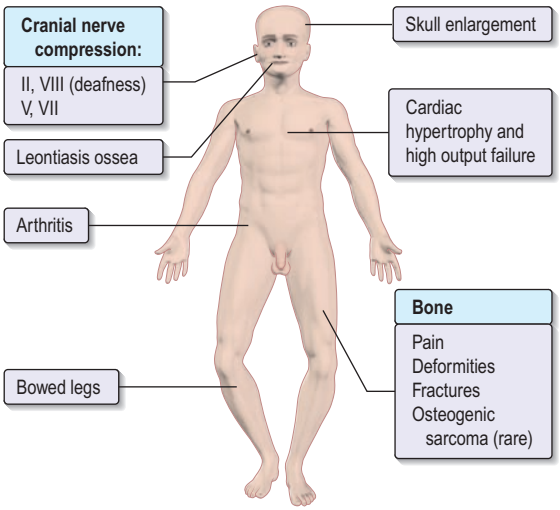
Clinical features (Fig. 10.41)

Most (60–80%) patients with radiologically identified Paget's disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, or a plain X-ray performed for other indications. The disease may involve one bone (monostotic, in 15%) or many (polyostotic). The most common sites in order of frequency are pelvis, lumbar spine, femur, thoracic spine, sacrum, skull and tibia. Small bones of the feet and hands are rarely involved.

Symptoms include the following:

- bone pain, most often in the spine or the pelvis
- joint pain when an involved bone is close to a joint, leading to cartilage damage and osteoarthritis
- deformities, in particular bowed tibia and skull changes
- complications from:
  - **(a)** nerve compression (deafness from VIIIth cranial nerve involvement; also cranial nerves II, V, VII may be involved; spinal stenosis, hydrocephalus)
  - **(b)** increased bone blood flow (myocardial hypertrophy and high-output cardiac failure)
  - **(c)** pathological fractures
- osteogenic sarcoma in pagetic bone (fewer than 1% of cases, but a 30-fold increased risk compared with non-pagetic patients).

Investigations



- *X-ray* features (Fig. 10.41b) vary from predominantly lytic lesions (osteoporosis circumscripta in the skull is characteristic), through a mixed phase, to a mainly sclerotic phase of bone expansion, thickening of trabeculae and loss of distinction between cortex and trabeculae (dedifferentiation).
- *Isotope bone scans* show the extent of skeletal involvement, but are unable to distinguish between Paget's disease and sclerotic metastatic carcinoma (especially breast and prostate).
- *Increased serum alkaline phosphatase* with normal serum calcium and phosphate reflects increased bone turnover. Levels may be normal with limited or monostotic Paget's. Levels are reduced with treatment and increase during relapse. Mild hypercalcaemia follows immobilization only when there is very extensive disease. *Urinary hydroxyproline* excretion is increased and may also be used as a marker of disease activity.

Treatment

Bisphosphonates are the mainstay of treatment. New bone formed after treatment is lamellar, not woven (reflecting normalization of bone turnover rather than a direct effect on osteoblasts). In addition to treating symptomatic patients (i.e. bone pain or pain in joints adjacent to pagetic bone), treatment of asymptomatic lesions is appropriate if there is a significant risk of potential complications, e.g. fracture in weight-bearing long bones or the spine, nerve entrapment or deafness with skull involvement, and before orthopaedic procedures in involved bone (to reduce vascularity).

Intravenous bisphosphonates

Intravenous pamidronate has been largely replaced by the more potent zoledronate. Repeat courses of treatment are guided by symptoms and by recurrence in elevation of alkaline phosphatase or urinary hydroxyproline. Both drugs are amino-bisphosphonates and can be associated with a first-dose reaction characterized by 'flu-like' symptoms including transient pyrexia over 24–48 hours.

Oral bisphosphonates

Oral bisphosphonates are typically used at doses higher than those for osteoporosis. Options include:

- tiludronate (400 mg daily for 12 weeks, repeated as necessary after 6 weeks or longer)
- ibandronate (30 mg daily for 2 months repeated if necessary after at least 2 months)
- risedronate (30 mg/day for 2 months, repeated as necessary after at least 2 months)
- etidronate is also approved but is less often used because of its lower potency.

Surgery

Joint replacement or osteotomy is sometimes necessary to correct deformity or pain due to associated degenerative joint disease (osteoarthrosis). Intra-articular injection of lidocaine can be useful to differentiate joint or bone disease. Neurosurgery may be required where there is spinal disease. Osteosarcoma usually requires amputation, though wide excision and limb-salvage can be successful at distal sites.

RICKETS AND OSTEOMALACIA

Rickets (in children) and osteomalacia (in adults) result from inadequate mineralization of bone matrix (osteoid). They are usually caused by a defect in vitamin D availability or metabolism.

Pathology

In children the growth plate is elongated with distortion of the arrangement of chondrocytes. Calcification is delayed and vascularization impaired. In adults, osteomalacia is characterized on bone biopsy by increased osteoid width (>15 μm), increased mineralization lag time, and lack of uptake of double tetracycline labelling in osteoid seams. Changes of secondary hyperparathyroidism are often present, except in hypophosphataemic osteomalacia.

Aetiology (Table 10.25)

Vitamin D deficiency is usually due to inadequate sunlight exposure and/or dietary insufficiency (Fig. 10.34). Asian women and elderly individuals, particularly those who are housebound, are particularly at risk. Anticonvulsant therapy (especially phenytoin and phenobarbitone) affects vitamin D metabolism and predisposes to vitamin D deficiency. Malabsorption of vitamin D occurs in some gastrointestinal diseases, particularly coeliac disease and small intestinal Crohn's disease.

Chronic kidney disease results in reduced 1α-hydroxylation of 25OHD. Mutations in the *p*450c1 α gene (chromosome 12) cause 1α-hydroxylase deficiency, also known as *vitamin D-dependent rickets type I (VDDR type 1)*, an autosomal recessive disease. In *type II vitamin D-dependent rickets* there is a defect in the intracellular $1,25(OH)_2D_3$ receptor.

X-linked hypophosphataemic rickets, results in lower-limb deformities and stunted growth rate in affected males, (see p. 670). In the Fanconi syndrome and in renal tubular acidosis, osteomalacia can also develop. Phosphaturia is the common pathway underlying these conditions, caused by mutations in the *PEX* gene or excess FGF-23 production by tumours in hypophosphataemic osteomalacia. In the latter, treatment of the underlying (usually mesenchymal type) tumour results in remineralization of bone. However, location of the tumour is often difficult, and treatment with phosphate and high-dose vitamin D may be necessary.

Table 10.25 Causes of rickets/osteomalacia

Deficient intake or absorption of vitamin D
Inadequate synthesis in skin
Low dietary intake
Malabsorption:
Coeliac disease
Intestinal resection
Defective 25-hydroxylation
Chronic cholestasis (e.g. primary biliary cirrhosis)
Anticonvulsant therapy e.g. phenytoin
Defective 1-alpha hydroxylation
Chronic kidney disease
Tubular disorders (renal tubular acidosis, Fanconi's syndrome)
Vitamin D-dependent rickets types I and II
Inhibitors of mineralization
Fluoride, aluminium, bisphosphonates
Miscellaneous
X-linked hypophosphataemia (vitamin D-resistant rickets or Dent's disease)
Tumour-induced hypophosphataemic osteomalacia and rickets)
Enzyme deficiency e.g. hypophosphatasia from mutations in alkaline phosphatase gene

Clinical features

Adult osteomalacia produces vague symptoms of bone or muscle pain and tenderness. Pathological fractures occur. Occasionally a marked proximal myopathy leads to a characteristic 'waddling' gait. Deformity is uncommon. In modern practice many cases are detected biochemically in high-risk patients, especially the elderly and those with gastrointestinal disease or surgery, before clear symptoms are present. Occasionally, tetany or other hypocalcaemic features may occur.

At birth, neonatal rickets may present as craniotabes (thin deformed skull). In the first few years of life there may be widened epiphyses at the wrists and beading at the costochondral junctions, producing the 'rickety rosary', or a groove in the rib cage (Harrison's sulcus). In older children, lower limb deformities are seen. A myopathy may also occur. Hypocalcaemic tetany may occur in severe cases.

Investigations

- **Increased serum alkaline phosphatase**, indicating increased osteoblast activity, is the most common abnormality (note: alkaline phosphatase is elevated during pubertal skeletal growth).
- **Plasma calcium** is usually normal, in association with secondary hyperparathyroidism and a raised PTH, but may be low in severe cases.
- **Serum phosphate** may be low, owing to increased PTH-dependent phosphaturia, though this is variable.
- **Serum 25OHD** is usually low (the exception being vitamin D-resistant rickets). Serum $1,25(OH)_2D$ levels are also usually low, especially in VDDR type 1.
- **X-rays** are often normal in adults, but may show defective mineralization, especially in the pelvis, long bones and ribs, with pseudofractures or 'Looser's zones' – linear areas of low density surrounded by sclerotic borders.
- **Iliac crest biopsy** with double tetracycline labelling (see above) is occasionally necessary if biochemical tests are equivocal.
- **Serum fibroblast FGF-23** is sometimes elevated in tumour-associated osteomalacia.

Treatment

Treatment should be directed towards correction of the cause where possible, with increase in vitamin D intake and sunlight exposure.

Multiple formulations of vitamin D and its metabolites are available. When deficiency is nutritional, 'replacement' doses of the native vitamin are needed (400–800 IU daily). Higher 'pharmacological' doses, sometimes administered parenterally, may be needed in some patients with gastrectomy, malabsorption or liver disease, although many respond to more conventional doses. Treatment with calcitriol or alfacalcidol (see p. 633) is indicated where there is defective

FURTHER READING

Wharton B, Bishop N. Rickets. *Lancet* 2003; **362:** 1389–1400.

1α-hydroxylation, e.g. chronic kidney disease, vitamin D dependency and hypophosphataemic rickets with osteomalacia.

Monitoring of serum calcium, alkaline phosphatase and renal function should be undertaken regularly to screen for hypercalcaemia. Normalization of alkaline phosphatase is a good measure of healing.

SKELETAL DYSPLASIAS

These include a large group of heterogeneous disorders of bone and connective tissue.

Collagen defects

Collagen is responsible for many of the structural, tensile and load-bearing properties in the various tissues where it is found. The structure of collagen is discussed on page 500. Thirty or more dispersed genes encode for more than 19 different types of collagen:

- The fibrillar collagens, e.g. types I, II, III, V and XI, are encoded by *COL1A1–2, COL2A1, COL3, COL5, COL11*. Mutations of these genes produce osteogenesis imperfecta and Ehlers–Danlos syndrome.
- Basement membrane collagen, type IV, is encoded by *COL4A1–5*. Mutations lead to Alport's disease (see p. 594).
- Fibril-associated collagens with interrupted triple helices (FACIT), e.g. types IX, XII and XIV, are encoded by *COL9, COL12*.
- Filament-producing collagen type VI is encoded by *COL6A1, 2, 3*.
- Network-forming collagens types VIII and X are encoded by *COL8A1, COL10A1*.
- Anchoring fibril collagen, e.g. type VII, is encoded by *COL7A1*. Mutations of this gene produce epidermolysis bullosa (p. 1257).

Ehlers–Danlos syndrome

This is a heterogeneous group of disorders of collagen. Ten different types have been recognized with varying degrees of skin fragility, skin hyperextensibility and joint hypermobility.

Types I, II and III are inherited in an autosomal dominant fashion; the biochemical basis is unknown. No abnormalities in *COL1A1, COL1A2* and *COL2A1* genes have been found.

Type IV (vascular type) is also autosomal dominant and involves arteries, the bowel and uterus, as well as the skin. Mutations in *COL3A1* gene produce abnormalities in structure, synthesis or secretion of type III collagen.

Type VI is a recessively inherited disorder and results from a mutation in the gene that encodes lysyl hydroxylase.

Type VII is an autosomal dominant disorder where there is a defect in the conversion of procollagen to collagen; *COL1A1* and *COL1A2* mutations delete the N-proteinase cleavage sites.

Other forms of Ehlers–Danlos are very rare and their defects have not been elucidated. The clinical features are described on page 1263.

Osteogenesis imperfecta (fragilitas ossium, brittle bone syndrome)

This is a heterogeneous group of mainly autosomally dominant inherited disorders. In the majority there are mutations in the genes encoding the chains in type I collagen, i.e. *COL1A1, COL1A2*. There are four main types with very variable clinical pictures ranging from death in the perinatal period (type II), severe bone deformity (type III), to a normal lifespan (types I and IV). Recently three separate clinical subtypes have been identified (V, VI and VII).

The major clinical feature is very fragile and brittle bones but other collagen-containing tissues are also involved, such as tendons, the skin and the eyes. Osteogenesis imperfecta tarda (type I) has mild bony deformities, blue sclerae, defective dentine, early-onset deafness, hypermobility of joints, and heart valve disorders. More severe forms present with multiple fractures and gross deformities.

Treatment is with bisphosphonates, which enhances bone cortical thickness. Prognosis is variable, depending on the severity of the disease. Stem cell therapy is being used.

Miscellaneous defects

Osteopetrosis (marble bone disease)

This condition may be inherited in either an autosomal dominant or an autosomal recessive manner; the recessive type is severe and the dominant type is mild. In addition, another recessive form associated with renal tubular acidosis is due to carbonic anhydrase II deficiency.

In the severe form, which is due to a mutation in the gene, encoding for a chloride channel is necessary for osteoclast activity. Bone density is increased throughout the skeleton but bones tend to fracture easily. Involvement of the bone marrow leads to a leucoerythroblastic anaemia. There is mental retardation and early death.

In the mild form there may be only X-ray changes, but fractures and infection can occur. The acid phosphate level is raised. Stem cell transplantation has been successful.

Marfan's syndrome

This is described on page 780.

Fibroblast growth factor receptor defect

Achondroplasia ('dwarfism') is diagnosed in the first years of life. The disease is inherited in an autosomal dominant manner and is caused by a defect in the fibroblast growth factor receptor-3 gene. The trunk is of normal length but the limbs are very short and broad due to abnormal endochondrial ossification. The vault of the skull is enlarged, the face is small and the nose bridge is flat. Intelligence is normal.

FUNCTIONAL ANATOMY

The kidneys are paired organs, 11–14 cm in length in adults, 5–6 cm in width and 3–4 cm in depth. The kidneys lie retroperitoneally on either side of the vertebral column at the level of T12 to L3. The renal parenchyma comprises an outer cortex and an inner medulla. The functional unit of the kidney is the nephron, of which each contains approximately one million. Each *nephron* is made up of a glomerulus, proximal tubule, loop of Henle, distal tubule and collecting duct. The renal capsule and ureters are innervated via T10–12 and L1 nerve roots, and renal pain is felt over the corresponding dermatomes.

Arterial blood is supplied to the kidneys via the renal arteries, which branch off the abdominal aorta, and venous blood is conveyed to the inferior vena cava via the renal veins. Approximately 25% of humans possess dual or multiple renal arteries on one or both sides. The left renal vein is longer than the right and for this reason the left kidney, where possible, is usually chosen for live donor transplant nephrectomy.

The *renal artery* undergoes a series of divisions within the kidney (Fig. 11.1) forming successively the *interlobar arteries*, which run radially to the corticomedullary junction, *arcuate arteries*, which run circumferentially along the corticomedullary junction, and interlobular arteries which run radially through the renal cortex towards the surface of the kidney. Afferent glomerular arterioles arise from the interlobular arteries to supply the glomerular capillary bed, which drains into *efferent glomerular arterioles*. Efferent arterioles from the outer cortical glomeruli drain into a peritubular capillary network within the renal cortex and then into increasingly large and more proximal branches of the renal vein. By contrast, blood from the juxtamedullary glomeruli passes via the vasa recta in the medulla and then turns back towards the area of the cortex from which the vasa recta originated.

Vasa recta possess fenestrated walls, which facilitates movement of diffusible substances. The collecting ducts merge in the inner medulla to form the ducts of Bellini, which empty at the apices of the papillae into the calyces. The calyces, in common with the renal pelvis, ureter and bladder, are lined with transitional cell epithelium.

The *glomerulus* comprises four main cell types: (1) endothelial cells which are fenestrated with 500–1000 Å pores; (2) visceral epithelial cells (podocytes) which support the delicate glomerular basement membrane by means of an extensive trabecular network (foot processes); (3) parietal epithelial

cells which cover the Bowman's capsule; (4) mesangial cells (see Fig. 11.11). Mesangial cells are believed to be related to macrophages of the reticuloendothelial system and have a phagocytic function and contractile capabilities that can control blood flow and filtration surface area along the glomerular capillaries in response to a host of mediators. They also secrete the mesangial matrix, which provides a skeletal framework for the glomerular capillaries. The glomerular capillary basement membrane lies between the endothelial and the visceral epithelial cells. The latter put out multiple long foot processes which interdigitate with those of adjacent epithelial cells. Together the endothelial cells, basement membrane and epithelial cells form the filtration barrier or sieve (see Fig. 11.12a).

The *renal tubules* are lined by epithelial cells, which are cuboidal except in the thin limb of the loop of Henle where they are flat. Proximal tubular cells differ from other cells of the system as they have a luminal brush border. The cortical portion of the collecting ducts contains two cell types with different functions, namely principal cells and intercalated cells (see p. 653). Fibroblast-like cells in the renal cortical interstitium have been shown to produce erythropoietin in response to hypoxia (p. 576).

The *juxtaglomerular apparatus* comprises the macula densa, the extraglomerular mesangium and the terminal portion of the afferent glomerular arteriole (which contains renin-producing granular cells) together with the proximal portion of the efferent arteriole. The macula densa is a plaque of cells containing large, tightly packed cell nuclei (hence the name macula densa) within the thick ascending limb of the loop of Henle. This anatomical arrangement is such as to allow changes in the renal tubule to influence behaviour of the adjacent glomerulus (tubulo-glomerular feedback).

RENAL FUNCTION

PHYSIOLOGY

A conventional diagrammatic representation of the nephron is shown in Figure 11.2a and a physiological version in Figure 11.2b.

An essential feature of renal function is that a large volume of blood – 25% of cardiac output or approximately 1300 mL per minute – passes through the two million glomeruli.

A hydrostatic pressure gradient of approximately 10 mmHg (a capillary pressure of 45 mmHg minus 10 mmHg of pressure within Bowman's space and 25 mmHg of plasma oncotic pressure) provides the driving force for ultrafiltration of virtually protein-free and fat-free fluid across the glomerular capillary wall into Bowman's space and so into the renal tubule (Fig. 11.3).

The *ultrafiltration rate* (glomerular filtration rate; GFR) varies with age and sex but is approximately 120–130 mL/min per 1.73 m^2 surface area in adults. This means that, each day, ultrafiltration of 170–180 L of water and unbound small-molecular-weight constituents of blood occurs. If these large volumes of ultrafiltrate were excreted unchanged as urine, it would be necessary to ingest huge amounts of water and electrolytes to stay in balance. This is avoided by the selective reabsorption of water, essential electrolytes and other blood constituents, such as glucose and amino acids, from the filtrate in transit along the nephron. Thus, 60–80% of filtered water and sodium are reabsorbed in the proximal tubule along with virtually all the potassium, bicarbonate, glucose and amino acids (Fig. 11.2b). Additional water and sodium chloride are reabsorbed more distally, and fine tuning of salt and water balance is achieved in the distal tubules

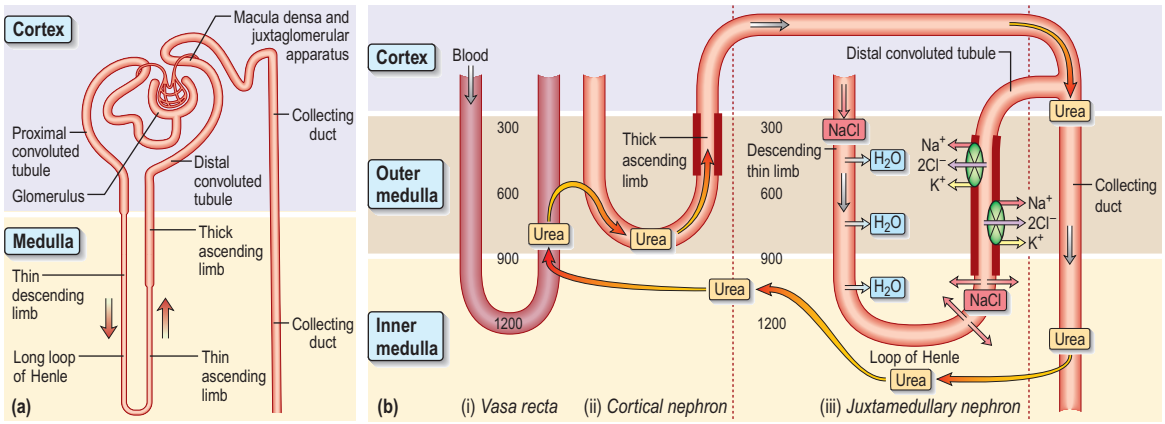

Fig. 11.2 **(a) Principal parts of the nephron.** The point where the distal tubule is in close proximity to its own glomerulus is called the juxtaglomerular apparatus. This contains the macula densa.
(b) Diagrammatic representation of the countercurrent system. (i) *Vasa recta:* these vessels descend from the cortex into the medulla and then turn back towards the cortex. (ii) *Cortical nephron:* these have short descending limbs extending into the outer medulla. (iii) *Juxtamedullary nephron:* the descending limb dips deeply into the hypertonic inner medulla. Numbers indicate approximate osmolalities.

and collecting ducts under the influence of aldosterone and antidiuretic hormone (ADH). The final urine volume is thus 1–2 L daily. Calcium, phosphate and magnesium are also selectively reabsorbed in proportion to the need to maintain a normal electrolyte composition of body fluids.

The urinary excretion of some compounds is more complicated. For example, potassium is freely filtered at the glomerulus, almost completely reabsorbed in the proximal tubule, and secreted in the distal tubule and collecting ducts. A clinical consequence of this is that the ability to eliminate unwanted potassium is less dependent on GFR than is the elimination of urea or creatinine. Other compounds filtered and reabsorbed or secreted to a variable extent include urate, many organic acids and many drugs or their metabolic breakdown products. The more tubular secretion of a compound that occurs, the less dependent elimination is on the GFR; penicillin and cefradine are examples of drugs secreted by the tubules.

Urine concentration and the countercurrent system

Urine is concentrated by a complex interaction between the loops of Henle, the medullary interstitium, medullary blood vessels (vasa recta) and the collecting ducts (see p. 651). The proposed mechanism of urine concentration is termed 'the countercurrent mechanism'. The countercurrent hypothesis states that: 'a small difference in osmotic concentration at any point between fluid flowing in opposite directions in two parallel tubes connected in a hairpin manner is multiplied many times along the length of the tubes'. Tubular fluid moves from the renal cortex towards the papillary tip of the medulla via the proximal straight tubule and the thin descending limb of the loop of Henle, which is permeable to water and impermeable to sodium. The tubule then loops back towards the cortex so that the direction of the fluid movement is reversed in the ascending limb, which is impermeable to water but permeable to sodium. This results in a large osmolar concentration difference between the corticomedullary junction and the hairpin loop at the tip of the papilla, and hence countercurrent multiplication. There is an analogy with heat exchangers.

Since the urine that emerges from the proximal tubule is iso-osmotic, the first nephron segment actually involved in urinary concentration is the descending limb of Henle's loop. There are two types of descending limbs (Fig. 11.2b). The short loops originate in superficial and midcortical glomeruli, and turn in the outer medulla. The long loops, which originate in the deep cortical and juxtamedullary glomeruli, penetrate the outer medulla up to the tip of the papilla. Approximately 15% of nephrons have long loops and the remaining 85% have short loops. Both the ascending limb in the outer and inner medulla and the first part of the distal tubule are impermeable to water and urea. Through the $Na^+/K^+/2Cl^-$ cotransporter, the thick ascending limb actively transports sodium chloride, increasing the interstitial tonicity, resulting in tubular dilution with no net movement of water and urea on account of low permeability. The hypotonic fluid under ADH action undergoes osmotic equilibration with the interstitium in the late distal and the cortical and outer medullary collecting duct, resulting in water removal. Urea concentration in the

tubular fluid rises on account of low urea permeability. At the inner medullary collecting duct, which is highly permeable to urea and water, especially in response to ADH, the urea enters the interstitium down its concentration gradient, preserving interstitial hypertonicity and generating high urea concentration in the interstitium.

The hypertonic interstitium pulls water from the descending limb of the loop of Henle, which is relatively impermeable to NaCl and urea. This makes the tubular fluid hypertonic with high NaCl concentration as it arrives at the bend of the loop of Henle. Urea plays a key role in the generation of medullary interstitial hypertonicity. The urea that is reabsorbed into the inner medullary stripe from the terminal inner medullary collecting duct is carried out of this region by ascending vasa recta, which deposit urea into the adjacent descending limb of both short and long loops of Henle, thus recycling the urea to the inner medullary collecting tubule. This process is facilitated by the close anatomical relationship that the hairpin loop of Henle and the vasa recta share.

GLOMERULAR FILTRATION RATE (GFR)

In health, the GFR remains remarkably constant owing to intrarenal regulatory mechanisms. In disease, (e.g. a reduction in intrarenal blood flow, damage to or loss of glomeruli, or obstruction to the free flow of ultrafiltrate along the tubule), the GFR will fall. The ability to eliminate waste material and to regulate the volume and composition of body fluid will decline. This will be manifest as a rise in the plasma urea or creatinine and as a reduction in measured GFR.

The concentration of urea or creatinine in plasma represents the dynamic equilibrium between production and elimination. In healthy subjects there is an enormous reserve of renal excretory function, and serum urea and creatinine do not rise above the normal range until there is a reduction of 50–60% in the GFR. Thereafter, the level of urea depends both on the GFR and its production rate (Table 11.1). The latter is heavily influenced by protein intake and tissue catabolism. The level of creatinine is much less dependent on diet but is more related to age, sex and muscle mass. Once it is elevated, serum creatinine is a better guide to GFR than urea and, in general, measurement of serum creatinine is a good way to monitor further deterioration in the GFR.

It must be re-emphasized that a normal serum urea or creatinine is not synonymous with a normal GFR.

Table 11.1 Factors influencing serum urea levels

Production	Elimination
Increased by	**Increased by**
High-protein diet	Elevated GFR, e.g. pregnancy
Increased catabolism	
Surgery	**Decreased by**
Infection	Glomerular disease
Trauma	Reduced renal blood flow
Corticosteroid therapy	Hypotension
Tetracyclines	Dehydration
Gastrointestinal bleeding	Urinary obstruction
Cancer	Tubulointerstitial nephritis
Decreased by	
Low-protein diet	
Reduced catabolism, e.g. old age	
Liver failure	

GFR, glomerular filtration rate

Measurement of the glomerular filtration rate

Measurement of the GFR is necessary to define the exact level of renal function. It is essential when the serum (plasma) urea or creatinine is within the normal range. The most widely used measurement is the creatinine clearance (Fig. 11.4).

Creatinine clearance is dependent on the fact that daily production of creatinine (principally from muscle cells) is remarkably constant and little affected by protein intake. Serum creatinine and urinary output thus vary very little throughout the day.

Creatinine excretion is, however, by both glomerular filtration and tubular secretion, although at normal serum levels the latter is relatively small. As most laboratory methods for measurement of serum creatinine give slight overestimates, the calculation of clearance fortuitously gives a value close to that of inulin.

With progressive renal failure, creatinine clearance may overestimate GFR but, in clinical practice, this is seldom significant. Certain drugs – for example cimetidine, trimethoprim, spironolactone and amiloride – reduce tubular secretion of creatinine, leading to a rise in serum creatinine and a fall in measured clearance.

Given these observations, creatinine clearance, nevertheless, is a reasonably accurate measure of GFR in those situations in which it is most required – **normal or near normal renal function.** Urine is collected over 24 hours for measurement of urinary creatinine. A single plasma level of creatinine is measured some time during the 24-hour period.

$$\text{Creatinine clearance} = U \times V/P$$

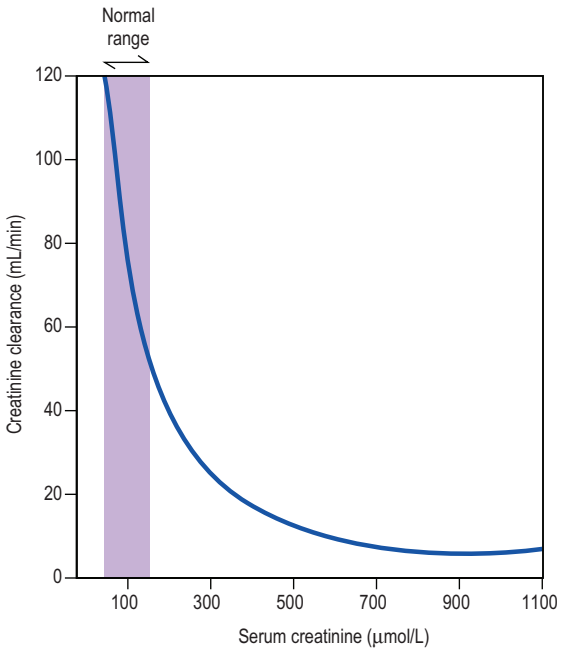

Fig. 11.4 **Creatinine clearance versus serum creatinine.** Note that the serum creatinine does not rise above the normal range until there is a reduction of 50–60% in the glomerular filtration rate (creatinine clearance).

where U = urine concentration of creatinine; V = rate of urine flow in mL/min; P = plasma concentration of creatinine. Normal ranges: men 90–140 mL/min; women 80–125 mL/min.

Where urine collections are difficult (e.g. with ileal conduits) or deemed inaccurate, the GFR may be measured by the single injection of compounds such as [^{51}Cr]EDTA (ethylenediaminetetraacetic acid), [^{99m}Tc]DTPA (diethylenetriaminepentaacetic acid) or [^{125}I]iothalamate, their excretion being primarily by glomerular filtration. Following intravenous injection of the compound, three blood samples are obtained at 2, 3 and 4 hours (or rather longer intervals if the patient is oedematous or if renal failure is suspected). The GFR may then be calculated from the slope of the exponential fall in blood level of the compound. *Iohexol* (a low-osmolality, non-ionic contrast medium) is also used as it is non-radioactive and can be measured reliably by a routine biochemical HPLC (high-pressure liquid chromatography) technique. Iohexol clearance correlates with radioisotopic techniques and can be assessed from finger-prick blood samples.

Cystatin C is an endogenous cysteine protease inhibitor. It is a low-molecular-weight protein filtered freely by the glomerulus and is produced at a constant rate. It is not secreted by tubules and therefore correlates with GFR. The cystatin C level is unaffected by gender, and correction for surface area is not needed. Studies suggest that cystatin C levels correlate better with radioisotope estimation of GFR than do creatinine levels and are more sensitive to mild renal impairment, particularly when the creatinine level is still normal.

Calculated GFR. Measurement of true GFR is cumbersome, time consuming and may be inaccurate if 24-hour urine collections are incomplete. Therefore, several formulae have been developed that allow a prediction of creatinine clearance or GFR from serum creatinine and demographics. The Cockroft–Gault formula is used mostly to adjust the dose of drugs by physicians and pharmacists and takes into account the patient's age, gender, weight and plasma creatinine (Box 11.1). A prediction equation has been developed based on the data derived from the Modification of Diet in Renal Disease (MDRD) study in patients with chronic renal failure (Box 11.1). This equation is based on age, sex, creatinine and ethnicity which makes it more reliable than the Cockroft–Gault equation in ethnically diverse groups of individuals. It is very popular in large population-based epidemiological studies where weight of the patient is usually not available. A modification of MDRD equation is used by most chemical pathology laboratories to calculate eGFR but it is less reliable if actual GFR is ≤60 mL/min and can result in inappropriate referral to renal physicians. Another clinical practice guideline formula is produced by the National Kidney Foundation. All these equations have not, however, been validated across all ranges of renal impairment, weights or body mass index (BMI), or ethnic groups; this makes them unreliable in the monitoring of patients with acute or chronic kidney renal disease whilst being treated and many clinicians still rely on measured creatinine clearance.

Box 11.1 Estimation of creatinine clearance

Cockroft–Gault equation

$$\text{Creatinine clearance} = \frac{(140 - \text{age}) \times \text{weight (kg)} \times (\text{constant})}{\text{Serum creatinine } [\mu\text{mol/L}]}$$

Constant = 1.23 for males and 1.04 for women.

Modification of diet in renal disease (MDRD) equation

Calculation of Estimated GFR by 4 variables:

$$\text{Estimated GFR } (\text{mL/min/1.73 m}^2) = 186 \times (S_{Cr})^{-1.154} \times (\text{age})^{-0.203} \times \text{constant } (0.742 \text{ if female}) \times (1.210 \text{ if Black African})$$

To convert creatinine values in μmol/L to mg/dL multiply by 0.0113.

TUBULAR FUNCTION

The major function of the tubule is the selective reabsorption or excretion of water and various cations and anions to keep the volume and electrolyte composition of body fluid normal (see Ch. 12).

The active reabsorption from the glomerular filtrate of compounds such as glucose and amino acids also takes place. Within the normal range of blood concentrations these substances are completely reabsorbed by the proximal tubule. However, if blood levels are elevated above the normal range, the amount filtered (filtered load = GFR × plasma concentration) may exceed the maximal absorptive capacity of the tubule and the compound 'spills over' into the urine. Examples of this occur with hyperglycaemia in diabetes mellitus or elevated plasma phenylalanine in phenylketonuria.

Conversely, inherited or acquired defects in tubular function may lead to incomplete absorption of a normal filtered load, with loss of the compound in the urine (a lowered 'renal threshold'). This is seen in renal glycosuria, in which there is a genetically determined defect in tubular reabsorption of glucose. It is diagnosed by demonstrating glycosuria in the presence of normal blood glucose levels. Inherited or acquired defects in the tubular reabsorption of amino acids, phosphate, sodium, potassium and calcium also occur, either singly or in combination. Examples include cystinuria and the Fanconi syndrome (see p. 1069 and Ch. 12). Tubular defects in the reabsorption of water result in nephrogenic diabetes insipidus (p. 1018). Under normal circumstances, antidiuretic hormone induces an increase in the permeability of water in the collecting ducts by attachment to receptors with subsequent activation of adenyl cyclase. This then activates a protein kinase, which induces preformed cytoplasmic vesicles containing water channels (termed 'aquaporins') to move to and insert into the tubular luminal membrane. This allows water entry into tubular cells down a favourable osmotic gradient. Water then crosses the basolateral membrane and enters the bloodstream. When the effect of ADH wears off, water channels return to the cell cytoplasm (Fig. 12.5).

Acid–base balance

Tubular function is also critical to the control of acid–base balance. Thus, filtered bicarbonate is largely reabsorbed and

hydrogen ions are excreted mainly buffered by phosphate (see p. 714).

Investigation of tubular function in clinical practice

Various tubular mechanisms could theoretically be investigated, but, in clinical practice, tests of tubular function are required less often than glomerular function.

Twenty-four-hour sodium output may be helpful in determining whether a patient is complying with a low-salt diet and in the management of salt-losing nephropathy. Tests of proximal tubular function may be required in the diagnosis of Fanconi's syndrome or isolated proximal tubular defects (e.g. urate clearance). Bicarbonate, glucose, phosphate and amino acid are all reabsorbed in the proximal tubule. Their presence in the urine is abnormal, and though formal methods of measuring maximal reabsorption are available, they are seldom necessary. *Retinol-binding protein and β_2-microglobulin* are normally reabsorbed by the proximal tubule, and their urinary excretion is non-specifically increased by diseases of the proximal tubule.

Two tests of distal tubular function are commonly applied in clinical practice: measurement of urinary concentrating capacity in response to water deprivation, and measurement of urinary acidification. These tests are dealt with on pages 1017 and 676.

Protein and polypeptide metabolism

The kidney is a major site for the catabolism of many small-molecular-weight proteins and polypeptides, including many hormones such as insulin, parathyroid hormone (PTH) and calcitonin, by endocytosis carried out by the megalin–cubilin complex in the brush border of proximal tubular cells. In renal failure the metabolic clearance of these substances is reduced and their half-life is prolonged. This accounts, for example, for the reduced insulin requirements of diabetic patients as their renal function declines.

Drug and toxicant elimination

A substantial fraction of prescription drugs are handled and eliminated by the kidney. Many of these medications (e.g. penicillins, cephalosporins, diuretics, NSAIDs, antivirals and methotrexate) circulate in the plasma as small organic anions. These organic anions, which are often bound to albumin, are actively eliminated by the proximal tubule of the nephron by an organic anion transporter (OAT) system. The OAT system translocates drugs as well as endogenous substances and toxins.

ENDOCRINE FUNCTION

Renin–angiotensin system (see also p. 1023)

The juxtaglomerular apparatus is made up of specialized arteriolar smooth muscle cells that are sited on the afferent glomerular arteriole as it enters the glomerulus. These cells synthesize prorenin, which is cleaved into the active proteolytic enzyme renin. Active renin is then stored in and released from secretory granules. Prorenin is also released in the circulation and comprises 50–90% of circulating renin, but its physiological role remains unclear as it cannot be converted into active renin in the systemic circulation. Renin converts angiotensinogen in blood to angiotensin I. Angiotensin-converting enzyme (ACE), which is located in the lung, luminal border of endothelial cells, glomeruli and other organs, converts angiotensin I (decapeptide) to angiotensin II (octapeptide). Renin release is controlled by:

- pressure changes in the afferent arteriole
- sympathetic tone
- chloride and osmotic concentration in the distal tubule via the macula densa (Fig. 11.2a)
- local prostaglandin and nitric oxide release.

Angiotensin II has two major systemic effects; systemic vasoconstriction and sodium and water retention. Both of these actions will tend to reverse the hypovolaemia or hypotension that is usually responsible for the stimulation of renin release. Angiotensin II promotes renal NaCl and water absorption by direct stimulation of Na^+ reabsorption in the early proximal tubule and by increased adrenal aldosterone secretion which enhances Na^+ transport in the collecting duct. In addition to influencing systemic haemodynamics, angiotensin II also regulates GFR. Although it constricts both afferent and efferent arterioles, vasoconstriction of efferent arterioles is three times greater than that of afferent, resulting in increase of glomerular capillary pressure and maintenance of GFR. In addition, angiotensin II constricts mesangial cells, reducing the filtration surface area, and sensitizes the afferent arteriole to the constricting signal of tubuloglomerular feedback (see p. 572). The net result is that angiotensin II has opposing effects on the regulation of GFR: (a) an increase in glomerular pressure and consequent rise in GFR; (b) reduction in renal blood flow and mesangial cell contraction, reducing filtration (see Fig. 11.49). In renal artery stenosis with resultant low perfusion pressure, angiotensin II maintains GFR. However, in cardiac failure and hypertension, GFR may be reduced by angiotensin II.

Erythropoietin (see also p. 390)

Erythropoietin is the major stimulus for erythropoiesis. It is a glycoprotein produced principally by fibroblast-like cells in the renal interstitium.

- Under hypoxic conditions both the alpha and beta subunits of hypoxia inducible factor 1 (HIF-1) are expressed forming a heterodimer, causing erythropoietin gene transcription via the combined effects of hepatic nuclear factor 4 (HNF-4) and coactivator p300. Erythropoietin, once formed, binds to its receptors on erythroid precursor cells.
- Under *normal oxygen* conditions, only the HIF-1-beta subunit is constitutively expressed. The alpha subunit undergoes proline hydroxylation in the presence of iron and oxygen by prolyl hydroxylase.
- The hydroxylated HIF-1-alpha subunit binds to von Hippel–Lindau protein and a ubiquitin ligase E3 complex is activated. This leads to ubiquitination (p. 20) and subsequent degradation of HIF-1-alpha via proteosomes so that no erythropoietin is transcribed. In normoxic conditions HIF-1-alpha also undergoes asparaginyl hydroxylation which prevents HIF complex from recruiting coactivators. These hydroxylation steps have absolute requirement for molecular oxygen which forms the basis of oxygen sensing.

Loss of renal substance, with decreased erythropoietin production, results in a normochromic, normocytic anaemia.

Conversely, erythropoietin secretion may be increased, with resultant polycythaemia, in patients with polycystic renal disease, benign renal cysts or renal cell carcinoma. Recombinant human erythropoietin has been biosynthesized and is available for clinical use, particularly in patients with chronic renal disease (see p. 633).

Vitamin D metabolism (see also p. 559)

Naturally occurring vitamin D (cholecalciferol) requires hydroxylation in the liver at position 25 and again by a 1α-hydroxylase enzyme (mitochondrial cytochrome P450) mainly in the distal convoluted tubule, the cortical and inner medullary part of the collecting ducts and the papillary epithelia of the kidney to produce the metabolically active 1,25-dihydroxycholecalciferol (1,25-$(OH)_2D_3$). The 1α-hydroxylase activity is increased by high plasma levels of parathyroid hormone (PTH), low phosphate and low 1,25-$(OH)_2D_3$. 1,25-dihydroxycholecalciferol and 25-hydroxycholecalciferol are degraded in part by being hydroxylated at position 24 by 24-hydroxylase. The activity of this enzyme is reduced by PTH and increased by 1,25-$(OH)_2D_3$ (which therefore promotes its own inactivation).

Reduced 1α-hydroxylase activity in diseased kidneys results in relative deficiency of 1,25-$(OH)_2D_3$. As a result, gastrointestinal calcium and to a lesser extent phosphate absorption is reduced and bone mineralization impaired. Receptors for 1,25-$(OH)_2D_3$ exist in the parathyroid glands, and reduced occupancy of the receptors by the vitamin alters the set-point for release of PTH in response to a given decrement in plasma calcium concentration. Gut calcium malabsorption, which induces hypocalcaemia, and relative lack of 1,25-$(OH)_2D_3$, contribute therefore to the hyperparathyroidism seen regularly in patients with renal impairment, even of modest degree.

Autocrine function

Endothelins

The endothelins ET-1, ET-2 and ET-3 are a family of similar potent vasoactive peptides that also influence cell proliferation and epithelial solute transport. They do not circulate but act locally. ETs are produced by most types of cells in the kidney. The vascular actions are mediated by two receptors, with ETA (specific for ET-1) mediating vasoconstriction and ETB (responsive to all ETs) causing vasodilatation. Endothelins inhibit sodium and water absorption by suppressing Na^+/K^+-ATPase and Na^+/H^+ antiporter activity in the proximal tubule and antagonizing the action of ADH and aldosterone in the collecting duct. Tubular transport actions are mediated by ETB. Endothelins, through vasoconstriction by ETA and salt and water retention via ETB receptors, cause hypertension. Endothelins, mainly through ETA receptors, can also alter cell proliferation and matrix accumulation by increasing tissue inhibitor of metalloproteinase (TIMP), cytokines, fibronectin and collagen. These peptides also stimulate the proliferation of a variety of renal cell types.

Prostaglandins

Prostaglandins are unsaturated, oxygenated fatty acids, derived from the enzymatic metabolism of arachidonic acid, mainly by constitutively expressed cyclo-oxygenase-1 (COX-1) or inducible COX-2 (see Fig. 14.32). COX-1 is highly expressed in the collecting duct, while COX-2 expression is restricted to the macula densa. Both COX isoforms convert arachidonic acid to the same product, the bioactive but unstable prostanoid precursor, prostaglandin H_2 (PGH_2). PGH_2 is converted to:

- PGE_2 (formed by PDE_2 synthase in the collecting duct, responsible for natriuretic and diuretic effects)
- PGD_2 (undetermined significance, produced in proximal tubule)
- prostacyclin (PGI_2) (mainly synthesized in the interstitial and vascular compartment)
- thromboxane A_2 (vasoconstrictor, mainly synthesized in glomerulus).

They all act through G-coupled transmembrane receptors, maintaining renal blood flow and glomerular filtration rate in the face of reductions induced by vasoconstrictor stimuli such as angiotensin II, catecholamines and α-adrenergic stimulation. In the presence of renal underperfusion, inhibition of prostaglandin synthesis by non-steroidal anti-inflammatory drugs results in a further reduction in GFR, which is sometimes sufficiently severe as to cause acute renal failure (acute kidney injury). Renal prostaglandins also have a natriuretic renal tubular effect and antagonize the action of antidiuretic hormone. Renal prostaglandins do not regulate salt and water excretion in normal subjects, but in some circumstances, such as chronic renal failure (chronic kidney disease), prostaglandin-induced vasodilatation is involved in maintaining renal blood flow. Patients with chronic kidney disease are thus vulnerable to further deterioration in renal function on exposure to non-steroidal anti-inflammatory drugs, as are elderly patients in many of whom renal function is compromised by renal vascular disease and/or the effects of ageing upon the kidney. Moreover, in conditions such as volume depletion, which are associated with high renin release (facilitated by prostaglandins), inhibition of prostaglandin synthesis may lead to hyperkalaemia due to hyporeninaemic hypoaldosteronism (since angiotensin II is the main stimulus for aldosterone).

Urodilatin: renal natriuretic peptide

(see also p. 1023)

A 32-amino-acid atrial natriuretic-like peptide (ANP-like peptide), synthesized by different post-translational processing of pro-ANP in the connecting and collecting ducts in the kidney, has been isolated from human urine. Its natriuretic potency exceeds that of atrial ANP by increasing cGMP production in the collecting duct. It is postulated that cardiac ANP is primarily a regulator of the cardiovascular system through its vascular effects and that renal natriuretic peptide participates in the intrarenal regulation of sodium and chloride transport. These potent natriuretic properties are being utilized by the use of synthetic urodilatin infusion in patients with cirrhosis to enhance sodium and water excretion.

Nitric oxide and the kidney

Nitric oxide (Fig. 15.10), a molecular gas, is formed by the action of three isoforms of nitric oxide synthase (NOS). All three enzymes, neuronal (nNOS or NOS1), inducible (iNOS or NOS2) and endothelial (eNOS or NOS3), which are cytochrome P450-like proteins, facilitate the addition of the guanidine nitrogen of the amino acid arginine to molecular oxygen, producing nitric oxide and water. In general nNOS and eNOS are constitutively active, producing low levels of nitric oxide dependent upon intracellular calcium elevation. In contrast, the transcriptional regulation of iNOS can be

markedly induced, particularly by inflammatory cytokines, resulting in extremely large amounts of nitric oxide. The most recognized cellular target of nitric oxide is soluble guanylate cyclase. The stimulation of this enzyme enhances the synthesis of cyclic GMP from GTP. All three isoforms are expressed in the kidney with eNOS in the vascular compartment, nNOS mainly in the macula densa and inner medullary collecting duct, and iNOS in several tubule segments. Nitric oxide mediates the following physiological actions in the kidney:

- regulation of renal haemodynamics
- natriuresis by inhibiting Na^+/K^+-ATPase and Na^+/H^+ antiporter and antagonizing ADH
- modulation of tubuloglomerular feedback so that the composition of tubular fluid delivered to the macula densa changes the filtration rate of the associated glomerulus.

INVESTIGATIONS

EXAMINATION OF THE URINE

Appearance

This is of little value in the differential diagnosis of renal disease except in the diagnosis of haematuria. Overt 'bloody' urine is usually unmistakable but should be checked using dipsticks (Stix testing). Very concentrated urine may also appear dark or smoky. Other causes of discoloration of urine include cholestatic jaundice, haemoglobinuria, drugs such as rifampicin, use of fluorescein or methylthioninium chloride (methylene blue), and ingestion of beetroot. Discoloration of urine after standing for some time occurs in porphyria, alkaptonuria and in patients ingesting the drug L-dopa.

Volume

In health, the volume of urine passed is primarily determined by diet and fluid intake. In temperate climates it lies within the range 800–2500 mL per 24 hours. The minimum amount passed to stay in fluid balance is determined by the amount of solute – mainly urea and electrolytes – being excreted and the maximum concentrating power of the kidneys would be approximately 650 mL.

In diseases such as chronic kidney disease (CKD) or diabetes insipidus, impairment of concentrating ability requires increased volumes of urine to be passed, given the same daily solute output. An increased solute output, such as in glycosuria or increased protein catabolism following surgery, also demands increased urine volumes.

Specific gravity and osmolality

Urine specific gravity is a measure of the weight of dissolved particles in urine, whereas urine osmolality reflects the number of such particles. Usually the relationship between the two is close. Measurement of urine specific gravity or osmolality is required only in the differential diagnosis of oliguric renal failure or the investigation of polyuria or inappropriate ADH secretion. Specific gravity is usually fixed at 1.010 in CKD or acute tubular necrosis as compared to prerenal acute kidney injury and inappropriate ADH secretion where specific gravity is very high – close to 1.025.

Urinary pH

Measurement of urinary pH is unnecessary except in the investigation and treatment of renal tubular acidosis (see p. 676).

Chemical (Stix) testing

Routine Stix testing of urine for blood, protein and sugar is obligatory in all patients suspected of having renal disease.

Blood

Haematuria may be overt, with bloody urine, or microscopic and found only on chemical testing. A positive Stix test must always be followed by microscopy of fresh urine (with the exception of menstruating women) to confirm the presence of red cells and so exclude the relatively rare conditions of haemoglobinuria or myoglobinuria. Bleeding may come from any site within the urinary tract (Fig. 11.5):

- *Overt bleeding from the urethra* is suggested when blood is seen at the start of voiding and then the urine becomes clear.
- *Blood diffusely present* throughout the urine comes from the bladder or above.
- *Blood only at the end of micturition* suggests bleeding from the prostate or bladder base.

Urine microscopy is used to detect red-cell casts, which are diagnostic of glomerulonephritis. In the absence of red-cell casts, further investigations, such as urine cytology, renal imaging and cystoscopy, are required to define the site of bleeding. Renal biopsy may be required (see p. 582).

Protein

Proteinuria is one of the most common signs of renal disease. Detection is primarily by Stix testing. Most reagent strips can detect protein if albuminuria exceeds 300 mg/d. They react primarily with albumin and are relatively insensitive to globulin and Bence Jones proteins.

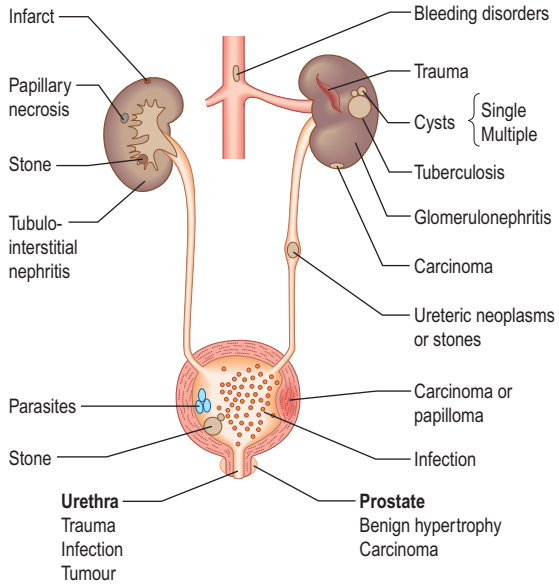

Fig. 11.5 **Sites and causes of bleeding from the urinary tract.**

If proteinuria is confirmed on repeated Stix testing, protein excretion in 24-hour urine collections should be measured (but see below). Healthy adults excrete up to 30 mg daily of albumin. Pyrexia, exercise and adoption of the upright posture (*postural proteinuria*) all increase urinary protein output but are benign.

Microalbuminuria

Normal individuals excrete less than 20 µg of albumin per minute (30 mg in 24 hours). Dipsticks, however, detect albumin only in a concentration above 200 µg (300 mg per 24 hours if urine volume is normal). An albumin excretion between these two levels – so-called 'microalbuminuria' – is now known to be an early indicator of diabetic glomerular disease and systemic endothelial dysfunction and is a useful prognostic marker for future cardiovascular events.

Timed 24-hour urinary excretion rates provide the most precise measure of microalbuminuria. However, in clinical practice it is more convenient to test for microalbuminuria using random urine samples in which albumin concentration is related to urinary creatinine concentration. Generally an albumin : creatinine ratio of 2.5 to 20 corresponds to albuminuria of 30–300 mg daily respectively. Kits are available to test for microalbuminuria.

Glucose

Renal glycosuria is uncommon, so that a positive test for glucose always requires exclusion of diabetes mellitus.

Bacteriuria

Dipstick tests for bacteriuria are based on the detection of *nitrite* produced from the reduction of urinary nitrate by bacteria and also for the detection of leucocyte esterase, an enzyme specific for neutrophils. Although each test on its own has limitations, a positive reaction with both tests has a high predictive value for urinary tract infection (p. 602).

Microscopy

Urine microscopy should be carried out in all patients suspected of having renal disease, on a 'clean' sample of mid-stream urine. The presence of numerous skin squames suggests a contaminated, poorly collected sample that cannot be properly interpreted.

If a clean sample of urine cannot be obtained, suprapubic aspiration is required in suspected urinary tract infections, particularly in children.

- *White blood cells*. The presence of 10 or more WBCs per cubic millimetre in fresh unspun mid-stream urine samples is abnormal and indicates an inflammatory reaction within the urinary tract such as urinary tract infection (UTI), stones, tubulointerstitial nephritis, papillary necrosis, tuberculosis and interstitial cystitis.
- *Red cells*. The presence of one or more red cells per cubic millimetre in unspun urine samples results in a positive Stix test for blood and is abnormal.
- *Casts* (see Fig. 11.6) are cylindrical bodies, moulded in the shape of the distal tubular lumen, and may be hyaline, granular or cellular. Coarse granular casts occur with pathological proteinuria in glomerular and tubular disease. Red-cell casts – even if only single – always indicate renal disease. White cell casts may be seen in acute pyelonephritis. They may be confused with the tubular cell casts that occur in patients with acute tubular necrosis.

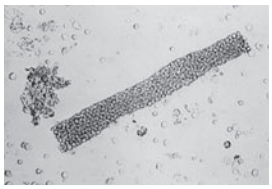

Fig. 11.6 **Red-cell cast.** Note aggregation of red cells as a 'cast' of the tubule.

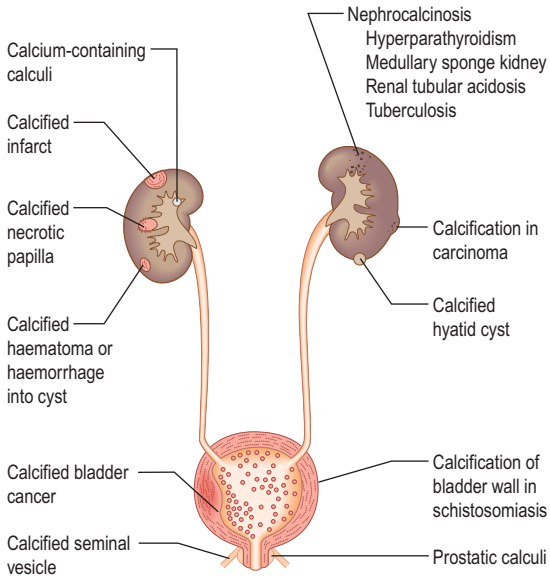

Fig. 11.7 **Calcification in the renal tract.** Calculi can occur at any site.

- *Bacteria* – see p. 602. Always culture urine prior to starting antibiotic therapy for sensitivities. Stix testing for blood or protein is of no value in the diagnosis of a UTI as both can be absent in the urine of many patients with bacteriuria.

BLOOD AND QUANTITATIVE TESTS

The use of serum urea, creatinine and GFR as measures of renal function is discussed on page 574. Other quantitative tests of disturbed renal function are described under the relevant disorders, as are diagnostic tests, e.g. ANCA, immunofluorescence, and complement.

IMAGING TECHNIQUES

Plain X-ray

A plain radiograph of the abdomen is valuable to identify renal calcification or radiodense calculi in the kidney, renal pelvis, line of the ureters or bladder (Fig. 11.7).

Ultrasonography

Ultrasonography of the kidneys and bladder has the advantage over X-ray techniques of avoiding ionizing radiation and intravascular contrast medium. In renal diagnosis it is the method of choice for:

- Renal measurement and for renal biopsy or other interventional procedures.
- Checking for pelvicalyceal dilatation as an indication of renal obstruction when chronic renal obstruction is suspected. (In suspected acute ureteric obstruction, unenhanced spiral CT is the method of choice.)
- Characterizing renal masses as cystic or solid.
- Diagnosing polycystic kidney disease.
- Detecting intrarenal and/or perinephric fluid (e.g. pus, blood).
- Demonstrating renal arterial perfusion or detecting renal vein thrombosis using Doppler. *Doppler ultrasonography* is based on the principle that, when incident sound waves are reflected from a moving structure, their frequency is shifted by an amount proportional to the velocity of the reflector (e.g. an RBC); this shift can be quantified and displayed as a spectral Doppler scan or colour overlay (colour Doppler).
- Measurement of bladder wall thickness in a distended bladder and to check for bladder tumours and stones. A scan obtained after voiding allows bladder emptying to be assessed.

The disadvantages of using ultrasonography to assess the urinary tract are:

- It does not show detailed pelvicalyceal anatomy.
- It does not fully visualize the normal adult ureter.
- It may miss small renal calculi and does not detect the majority of ureteric calculi.
- It is operator-dependent.

In patients with suspected benign prostatic hypertrophy, examination of the bladder before and after voiding, with measurement of the prostate, and examination of the kidneys to check for pelvicalyceal dilatation suffice. If prostate cancer is suspected, more detailed ultrasound examination of the prostate with a transrectal transducer, usually with transrectal prostate biopsy, is necessary.

Computed tomography (CT)

Computed tomography is used as a first-line investigation in cases of *suspected ureteric colic*. Spiral CT has both improved image resolution and allows reconstruction of the imaging data in a variety of planes. CT is also used:

- to characterize renal masses which are indeterminate at ultrasonography
- to stage renal tumours
- to detect 'lucent' calculi; low-density calculi which are lucent on plain films (e.g. uric acid stones) are well seen on CT
- to evaluate the retroperitoneum for tumours, retroperitoneal fibrosis (periaortitis) and other causes of ureteric obstruction
- to assess severe renal trauma
- to visualize the renal arteries and veins by CT angiography
- to stage bladder and prostate tumours; MRI is, however, increasingly used to stage prostate cancer
- *Disadvantages* include radiation and contrast nephrotoxicity (p. 624).

The use of spiral unenhanced CT in suspected ureteric colic permits diagnosis of causes of pain other than calculi more readily than does urography.

Magnetic resonance imaging (MRI)

MRI is used:

- to characterize renal masses as an alternative to CT
- to stage renal, prostate and bladder cancer
- to demonstrate the renal arteries by magnetic resonance *angiography* with gadolinium as contrast medium. In experienced hands its sensitivity and specificity approaches renal angiography.

Magnetic resonance urography is preferred over intravenous urography (IVU) in patients with chronic urolithiasis or intrinsic or extrinsic ureteric tumour, and in paediatric uroradiology. It is analogous to IVU. Gadolinium is used as contrast medium and is less nephrotoxic than iodine-containing agents used in IVU. However, the Federal Drug Administration (FDA) advises not using gadolinium in patients with renal insufficiency because of development of nephrogenic systemic fibrosis (p. 1254).

Excretion urography

Excretion urography (also known as IVU or intravenous pyelography (IVP)) has largely been replaced by ultrasonography and CT scanning.

Antegrade pyelography (Fig. 11.8)

Antegrade pyelography involves percutaneous puncture of a pelvicalyceal system with a needle and the injection of contrast medium to outline the pelvicalyceal system and

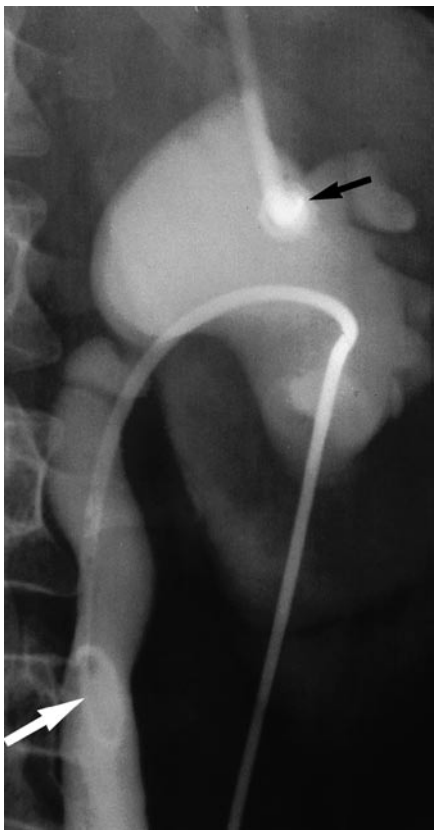

Fig. 11.8 **Antegrade pyelography via percutaneous catheter (small arrow) of obstructed system.** Percutaneous drainage catheter (large arrow) has been inserted.

ureter to the level of obstruction. It is used when ultrasonography has shown a dilated pelvicalyceal system in a patient with suspected obstruction. Antegrade pyelography is the preliminary to percutaneous placing of a drainage catheter or ureteric stent in the obstructed pelvicalyceal system (percutaneous nephrostomy).

Retrograde pyelography

Following cystoscopy, preferably under screening control, a catheter is either impacted in the ureteral orifice or passed a short distance up the ureter, and contrast medium is injected. Retrograde pyelography is mainly used to investigate lesions of the ureter and to define the lower level of ureteral obstruction shown on excretion urography or ultrasound plus antegrade studies. It is invasive, commonly requires a general anaesthetic, and may result in the introduction of infection.

Micturating cystourethrography (MCU)

This involves catheterization and the instillation of contrast medium into the bladder. The catheter is then removed and the patient screened during voiding to check for vesicoureteric reflux and to study the urethra and bladder emptying. It is used in children with recurrent infection (see p. 601).

MCU is not an appropriate investigation in adults because vesicoureteric reflux tends to disappear by the time adulthood is reached. The presence or absence of vesicoureteric reflux may also be investigated by scintigraphy (see below).

Aortography or renal arteriography

Conventional or digital subtraction angiography (DSA) is used. The latter allows the use of smaller doses of contrast medium which can be injected via a central venous catheter (venous DSA) or via a fine transfemoral arterial catheter (arterial DSA). Angiography is mainly used to define extrarenal or intrarenal arterial disease. Arteriography is still the 'gold standard' method of renal artery imaging but magnetic resonance angiography and spiral CT angiography are being used increasingly (Fig. 11.9). Complications include cholesterol embolizations (p. 609) and contrast-induced kidney damage (contrast nephropathy).

Venography is only used occasionally to exclude renal vein thrombosis. In most instances this can be done less invasively with Doppler ultrasonography, CT or MRI.

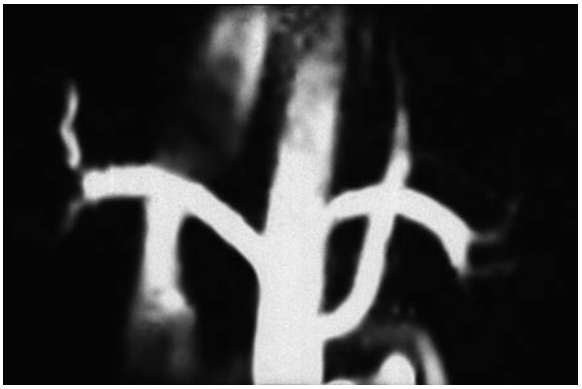

Fig. 11.9 **Magnetic resonance angiogram of normal renal arteries.**

Renal scintigraphy

Renal scintigraphy using a gamma camera is divided into:

- dynamic studies in which the function of the kidney is examined serially over a period of time, most often using a radiopharmaceutical excreted by glomerular filtration
- static studies involving imaging of tracer that is taken up and retained by the renal tubule.

Dynamic scintigraphy

The radiopharmaceutical technetium-labelled diethylenetriaminepentaacetic acid, [^{99m}Tc]DTPA, is excreted by glomerular filtration. ^{123}I-labelled ortho-iodohippuric acid (Hippuran) is both filtered and secreted by the tubules, and mercaptoacetyltriglycine (MAG3) labelled with technetium (^{99m}Tc) is excreted by renal tubular secretion. Following venous injection of a bolus of tracer, emissions from the kidney can be recorded by gamma camera. This information allows examination of blood perfusion of the kidney, uptake of tracer as a result of glomerular filtration, transit of tracer through the kidney, and the outflow of tracer-containing urine from the collecting system.

Renal blood flow. Dynamic studies can be used to investigate patients in whom renal artery stenosis is suspected as a cause for hypertension and patients with severe oliguria (post-traumatic, post-aortic surgery, or after a kidney transplant) to establish whether, and to what extent, there is renal perfusion. In patients with unilateral renal artery stenosis there is, typically, a slowed and reduced uptake of tracer with delay in reaching a peak. Studies carried out before and after administration of an ACE inhibitor may demonstrate a fall in uptake that is suggestive of functional arterial stenosis. Both false-positive and false-negative results occur, particularly in patients with renal impairment, and renal arteriography remains the 'gold standard' in the diagnosis of renal artery stenosis. In patients with total renal artery occlusion, no kidney uptake of tracers is observed.

Investigation of obstruction. Renal scintigraphy provides functional evidence of obstruction. After injection usually of (^{99m}Tc)MAG3 a rise in resistance to flow in the pelvis or ureter prolongs the parenchymal transit of tracer and there is usually a delay in emptying the pelvis. On whole-kidney renograms, the time–activity curve fails to fall after an initial peak, or continues to rise (Fig. 11.10).

When the possibility of obstruction is suspected, a dynamic renal scintigram is performed with diuresis. Furosemide (0.5 mg/kg, adult dose 40 mg) is given intravenously about 18–20 minutes into the study. Time–activity curves show an immediate fall after furosemide in the absence of obstruction but the retention of activity in the pelvis persists in the presence of obstruction. A decision as to whether conservative surgery or nephrectomy should be carried out in unilateral obstruction is facilitated by renographic assessment of the contribution of each kidney.

At the end of dynamic studies, bladder emptying may be investigated and any postmicturition residual urine measured.

Glomerular filtration rate. This is discussed on page 574.

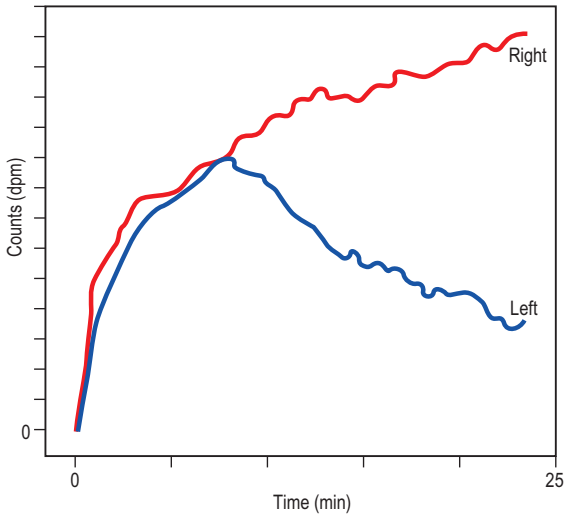

Fig. 11.10 **Dynamic scintigram.** Note the progressive rise of the right kidney curve to a plateau (in contrast to the normal left kidney curve) owing to urinary tract obstruction on the right side.

Static scintigraphy

This is usually performed using [^{99m}Tc]DMSA (dimercaptosuccinic acid), which is taken up by tubular cells. Uptake is proportional to renal function.

Relative renal function. Function is normally evenly divided between the kidneys, with a range of 45–55%. Static studies are particularly useful in unilateral renal disease, where the relative uptake of the two kidneys can be calculated.

Kidney visualization. Normal kidneys show a uniform uptake with a smooth renal outline. Scars can be identified as photon-deficient 'bites'. Static scintigraphy is of considerable value in identifying ectopic kidneys or 'pseudotumours' of the kidneys (i.e. normally functioning renal tissue abnormally placed within the kidney).

Localization of infection. The use of citrate labelled with gallium-67 or isotopically labelled leucocytes that are taken up by inflammatory tissue may be of value in defining localized infection, such as renal abscesses or infection within a renal cyst.

TRANSCUTANEOUS RENAL BIOPSY

(Practical box 11.1)

Renal biopsy is carried out under ultrasound control in specialized centres and requires interpretation by an experienced pathologist. Renal biopsy is helpful in the investigation of the nephritic and nephrotic syndromes, acute and chronic renal failure, haematuria after urological investigations and renal graft dysfunction. Native renal biopsy material must be examined by conventional histochemical staining, by electron microscopy, and by immunoperoxidase or immunofluorescence. Techniques like in situ hybridization and polymerase chain reaction analysis are also widely used in renal biopsy specimens.

The complications of transcutaneous renal biopsy are shown in Table 11.2.

Practical Box 11.1 Transcutaneous renal biopsy

Before biopsy

1. A coagulation screen is performed. It must be normal.
2. The serum is grouped and saved for crossmatching.
3. The patient is given a full explanation of what is involved and consent obtained.

During biopsy

1. The patient lies prone with a hard pillow under the abdomen.
2. The kidney is localized by ultrasound.
3. Local anaesthetic is injected along the biopsy track.
4. The patient holds a breath when the biopsy is performed.

After biopsy

1. A pressure dressing is applied to the biopsy site and the patient rests in bed for 24 hours.
2. The fluid intake is maximized to prevent clot colic.
3. The pulse and blood pressure are checked regularly.
4. The patient is advised to avoid heavy lifting or gardening for 2 weeks.

Table 11.2 Complications of transcutaneous renal biopsy

Macroscopic haematuria – about 20%
Pain in the flank, sometimes referred to shoulder tip
Perirenal haematoma
Arteriovenous aneurysm formation – about 20%, almost always of no clinical significance
Profuse haematuria demanding blood transfusion – 1–3%
Profuse haematuria demanding occlusion of bleeding vessel at angiography or nephrectomy – approximately 1 in 400
Introduction of infection
The mortality rate is about 0.1%

GLOMERULAR DISEASES

A glomerulus consists of a collection of capillaries which come from the afferent arteriole and are confined within the urinary space (Bowman's capsule); this is continuous with the proximal tubule. The capillaries are partially attached to mesangium, a continuation of the arteriolar wall consisting of mesangial cells and the matrix. The free wall of glomerular capillaries (across which filtration takes place) consists of basement membrane covered by visceral epithelial cells with individual foot processes and lined by endothelial cells (Fig. 11.11). The normal thickness of the basement membrane equals about 250–300 nm. The spaces between foot processes, with diameters of 20–60 nm, are called filtration pores, by which filtered fluid reaches the urinary space. The endothelial cells on the luminal aspect of the basement membrane are fenestrated (diameter 70–100 nm). The basement membrane is arranged in three zones – lamina rara externa, lamina rara densa and lamina rara interna – and is composed of type IV collagen and negatively charged proteoglycans (heparan sulphate).

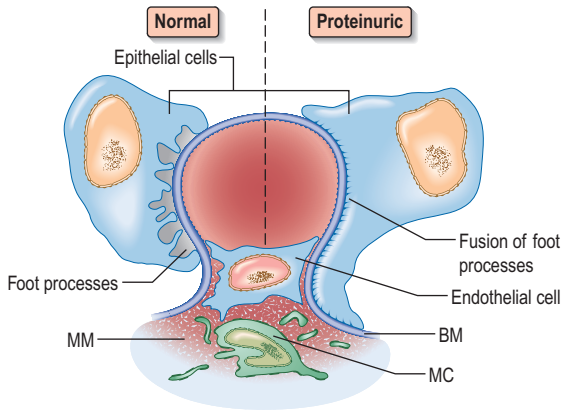
Filtration barrier (slit diaphragm)

(Figure 11.12)

The glomerular filtration barrier consists of the fenestrated endothelium, the glomerular basement membrane and the

terminally differentiated visceral epithelial cells known as podocytes. Podocytes dictate the size-selective nature of the filtration barrier. Foot processes extend from the cell body to adhere to the glomerular basement membrane and establish a zipper-like molecular diaphragm (slit diaphragm) with a foot process from a neigbouring cell. Discovery of nephrin as the key protein of the slit diaphragm led to the identification of other proteins, such as CD2AP (CD2-associated protein), canonical TRPC6 (transient receptor potential channel 6), podocin, P-cadherin, α- and β-catenin, ZO-1 (zonula occludens-1) which co-localize within the subcellular domain to function as a molecular sieve. These proteins, in addition to providing structural support to the cytoskeletal proteins like filamentous actin, also have signalling functions in order to maintain the normal function of podocytes. Abnormalities in any of these proteins result in the breakdown of the filtration barrier with consequent torrential leak of macromolecules.

Glomerular disease includes glomerulonephritis, i.e. inflammation of the glomeruli, and glomerulopathies when there is no evidence of inflammation. There is an overlap between these terms.



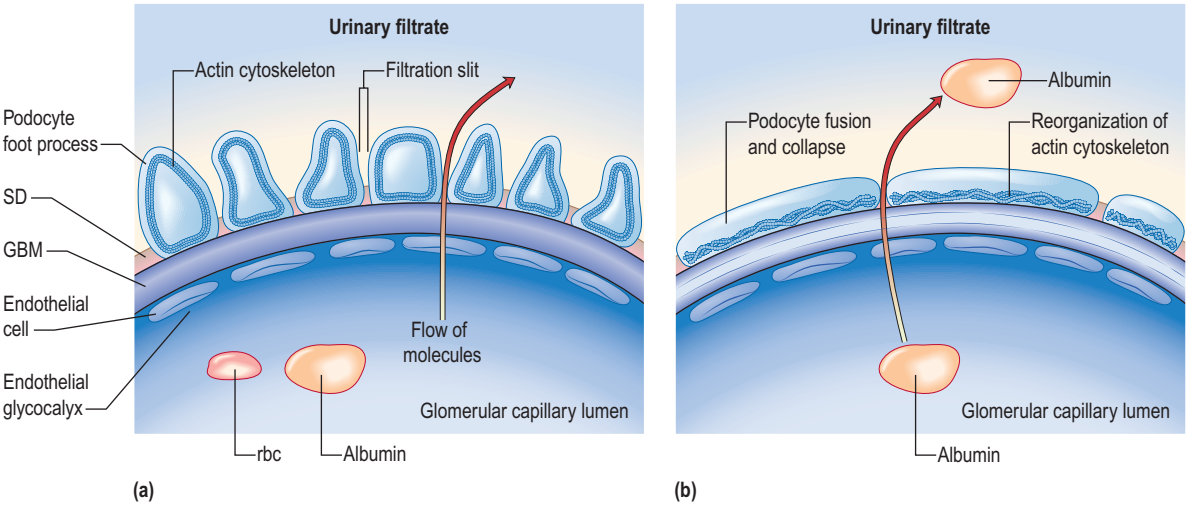


Fig. 11.11 **Diagram showing a normal (left) and proteinuric (right) glomerulus.** A capillary loop showing normal glomerular morphology on the left with an epithelial cell with pseudopodia (foot processes). In the proteinuric diagram (right) there is fusion of the foot processes characteristic of many diseases. BM, basement membrane; MC, mesangial cell; MM, mesangial matrix. After Marsh FP *Postgraduate Nephrology*. Butterworth Heinemann 1985.

GLOMERULOPATHIES

Glomerulopathies are the third most common cause of end-stage renal disease (after diabetes and hypertension) in Europe and the USA, accounting for some 10–15% of such patients.

Glomerulopathy (GN) is a general term for a group of disorders in which:

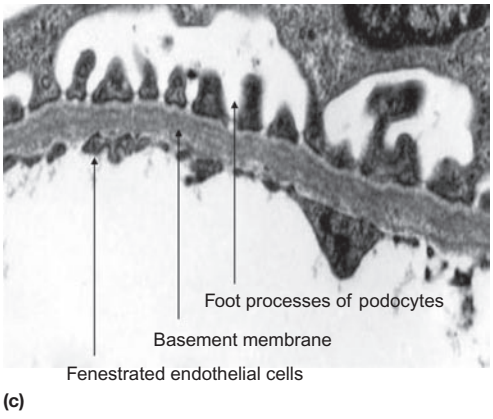

Fig. 11.12 **The glomerular filtration barrier.**
(a) Blood enters the glomerular capillaries and is filtered across the endothelium and the glomerular basement membrane and through the filtration slits between podocyte foot processes to produce the primary urine filtrate. In healthy glomeruli, this barrier restricts the passage of macromolecules. The proteins which form the slit diaphragm are essential for the normal functioning of the filtration barrier.
(b) Loss of these proteins, either genetically or acquired, leads to foot process effacement and breakdown of the barrier and leakage of albumin. **(a, b)** Adapted from Quaggin S. Sizing up sialic acid in glomerular disease. *Journal of Clinical Investigation* **117**: 1480–1483.
(c) Electron micrograph of normal filtration barrier. SD, slit diaphragm.

- There is primarily an immunologically mediated injury to glomeruli, although renal interstitial damage is a regular accompaniment.
- The kidneys are involved symmetrically.
- Secondary mechanisms of glomerular injury come into play following an initial immune insult such as fibrin deposition, platelet aggregation, neutrophil infiltration and free radical-induced damage.
- Renal lesions may be part of a generalized disease (e.g. systemic lupus erythematosus, SLE).

Pathogenesis

GN is considered to be an immunologically mediated disorder with involvement of cellular immunity (T lymphocytes, macrophages/dendritic cells), humoral immunity (antibodies, immune complexes, complement), and other inflammatory mediators (including cytokines, chemokines and the coagulation cascade). The immune response can be directed against known target antigens, particularly when GN complicates infections, neoplasia or drugs. More frequently the underlying antigenic target is unknown. Primary GN may occur in genetically susceptible individuals following an environmental insult. The genetic susceptibility is usually determined by major histocompatibility complex (HLA) genes (e.g. HLA-A1, B8, DR2, DR3). The environmental factors may be drugs (e.g. hydralazine), chemicals (e.g. gold, silica, hydrocarbons) or infectious agents. The known predisposing factors are discussed in more detail below. The physical evidence of immune reactions is indicated by the presence of circulating autoantibodies and/or abnormalities in serum complement and glomerular deposition of antibodies, immune complexes, complement and fibrin.

Pathological terms in glomerular disease

The most commonly used terms are:

- *Focal*: some but not all the glomeruli contain the lesion.
- *Diffuse* (global): most of the glomeruli (>75%) contain the lesion.
- *Segmental*: only a part of the glomerulus is affected (most focal lesions are also segmental, e.g. focal segmental glomerulosclerosis).
- *Proliferative*: an increase in cell numbers due to hyperplasia of one or more of the resident glomerular cells with or without inflammation.
- *Membrane alterations*: capillary wall thickening due to deposition of immune deposits or alterations in basement membrane.
- *Crescent formation*: epithelial cell proliferation with mononuclear cell infiltration in Bowman's space.

Classification of glomerulopathies

There is no complete correlation between the histopathological types of GN and the clinical features of disease. Glomerular diseases have been classified in numerous ways. Here they are organized and discussed as they relate to four major glomerular syndromes:

- *Nephrotic syndrome* – massive proteinuria (>3.5 g/day), hypoalbuminaemia, oedema, lipiduria and hyperlipidaemia.
- *Acute glomerulonephritis (acute nephritic syndrome)* – abrupt onset of glomerular haematuria (RBC casts or dysmorphic RBC), non-nephrotic range proteinuria, oedema, hypertension and transient renal impairment.
- *Rapidly progressive glomerulonephritis* – features of acute nephritis, focal necrosis with or without crescents and rapidly progressive renal failure over weeks.
- *Asymptomatic haematuria, proteinuria* or both.

Table 11.3 Investigation of glomerular diseases

Investigations	Positive findings
Urine microscopy	Red cells, red-cell casts
Urinary protein	Nephrotic or sub-nephrotic range proteinuria
Serum urea	May be elevated
Serum creatinine	May be elevated
Culture (throat swab, discharge from ear, swab from inflamed skin)	Nephritogenic organism (not always)
Antistreptolysin-O titre	Elevated in post-streptococcal nephritis
C3 and C4 levels	May be reduced
Antinuclear antibody	Present in significant titre in systemic lupus erythematosus
ANCA	Positive in vasculitis
Anti-GBM	Positive in Goodpasture's syndrome
Cryoglobulins	Increased in cryoglobulinaemia
Creatinine clearance	Normal or reduced
Chest X-ray	Cardiomegaly, pulmonary oedema (not always)
Renal imaging	Usually normal
Renal biopsy	Any glomerulopathy

Certain types of GN, particularly those that are a part of a systemic disease, can present as more than one syndrome, e.g. lupus nephritis, cryoglobulinaemia, and Henoch–Schönlein purpura, but more typically they are associated with the nephrotic syndrome and will be discussed below. Investigation of glomerular diseases is shown in Table 11.3.

NEPHROTIC SYNDROME

Pathophysiology

Hypoalbuminaemia. Urinary protein loss of the order 3.5 g daily or more in an adult is required to cause hypoalbuminaemia. In children, proportionately less proteinuria results in hypoalbuminaemia. The normal dietary protein intake in the UK is of the order 70 g daily and the normal liver can synthesize albumin at a rate of 10–12 g daily. How then does a urinary protein loss of the order of 3.5 g daily result in hypoalbuminaemia? This can be partly explained by increased catabolism of reabsorbed albumin in the proximal tubules during the nephrotic syndrome even though actual albumin synthesis rate is increased. However, in addition, dietary intake of protein increases albuminuria, so that the plasma albumin concentration tends to decrease during consumption of a high-protein diet. If the increase in urinary albumin excretion that follows dietary augmentation is prevented by

administration of ACE inhibitors (ACEI), a high-protein diet causes an increase in plasma albumin concentration in the nephrotic syndrome. Therefore, to maximize serum albumin concentration in nephrotic patients, a reduction in urinary albumin excretion with an ACEI is always necessary.

Proteinuria. The mechanism of the proteinuria is complex. It occurs partly because structural damage to the glomerular basement membrane leads to an increase in the size and number of pores, allowing passage of more and larger molecules. Electrical charge is also involved in glomerular permeability. Fixed negatively charged components are present in the glomerular capillary wall, which repel negatively charged protein molecules. Reduction of this fixed charge occurs in glomerular disease and appears to be a key factor in the genesis of heavy proteinuria.

Hyperlipidaemia. The characteristic disorder is an increase in the low-density lipoprotein (LDL), very-low-density lipoprotein (VLDL), and/or intermediate-density lipoprotein (IDL) fractions, but no change or decrease in HDL. This results in an increase in the LDL/HDL cholesterol ratio. Hyperlipidaemia is the consequence of increased synthesis of lipoproteins (such as apolipoprotein B, C-III lipoprotein (a)), as a direct consequence of a low plasma albumin. There is also a reduced clearance of the principal triglycerides bearing lipoprotein (chylomicrons and VLDL) in direct response to albuminuria.

Oedema in hypoalbuminaemia. See Chapter 12 (p. 655).

Management

General measures

- *Initial treatment* should be with dietary sodium restriction and a thiazide diuretic (e.g. bendroflumethiazide 5 mg daily). Unresponsive patients require furosemide 40–120 mg daily with the addition of amiloride (5 mg daily), with the serum potassium concentration monitored regularly. Nephrotic patients may malabsorb diuretics (as well as other drugs) owing to gut mucosal oedema, and parenteral administration is then required initially. Patients are sometimes hypovolaemic, and moderate oedema may have to be accepted in order to avoid postural hypotension.
- *Normal protein intake* is advisable. A high-protein diet (80–90 g protein daily) increases proteinuria and can be harmful in the long term. Infusion of albumin produces only a transient effect. It is only given to diuretic-resistant patients and those with oliguria and uraemia in the absence of severe glomerular damage, e.g. in minimal-change nephropathy. Albumin infusion is combined with diuretic therapy and diuresis often continues with diuretic treatment alone.
- *Hypercoagulable states* predispose to venous thrombosis. The hypercoagulable state is due to loss of clotting factors (e.g. antithrombin) in the urine and an increase in hepatic production of fibrinogen. Prolonged bed rest should therefore be avoided as thromboembolism is very common in the nephrotic syndrome. In the absence of any contraindication, long-term prophylactic anticoagulation is desirable. If renal vein thrombosis occurs, permanent anticoagulation is required.
- *Sepsis* is a major cause of death in nephrotic patients. The increased susceptibility to infection is partly due to loss of immunoglobulin in the urine. Pneumococcal infections are particularly common and pneumococcal vaccine should be given. Early detection and aggressive treatment of infections, rather than long-term antibiotic prophylaxis, is the best approach.
- *Lipid abnormalities* are responsible for an increase in the risk of cardiovascular disease in patients with proteinuria. Treatment of hypercholesterolaemia starts with an HMG-CoA reductase inhibitor.
- *ACE inhibitors and/or angiotensin II receptor antagonists* (AIIRA) are used for their antiproteinuric properties in all types of GN. These groups of drugs reduce proteinuria by lowering glomerular capillary filtration pressure; the blood pressure and renal function should be monitored regularly.

Specific measures

The aim is to reverse the abnormal urinary protein leak. These measures are discussed in detail below.

Table 11.4 shows the glomerular lesions commonly associated with the nephrotic syndrome. These are divided into diseases with or without RBC casts (active or bland urine sediments). Each of these entities occurs as a primary renal lesion or as a secondary component of a systemic disease.

Nephrotic syndrome with 'bland' urine sediments

Minimal-change glomerular lesion (minimal-change nephropathy)

In this condition the glomeruli appear normal on light microscopy (Fig. 11.13). The only abnormality seen on electron

microscopy is fusion of the foot processes of epithelial cells (podocytes) (Fig. 11.12b). This is a non-specific finding and is seen in many conditions associated with proteinuria. Neither immune complexes nor anti-GBM antibody can be demonstrated by immunofluorescence. However, the immunological pathogenesis of this condition is suggested by three factors:

- its response to steroids and immunosuppressive drugs
- its occurrence in Hodgkin's lymphoma, with remission following successful treatment
- patients with the condition and their family members have a high incidence of asthma and eczema; remission of the nephrotic syndrome following desensitization or antigen avoidance has been described.

A suggested explanation for the proteinuria is that immature differentiating CD34 stem cells rather than mature T lymphocytes are responsible for the pathogenesis of minimal change nephropathy.

Clinical features

Minimal-change nephropathy is most common in children, particularly males, accounting for the large majority of cases of nephrotic syndrome (proteinuria is usually highly selective) in childhood. Oedema is present and in children this may be facial. The condition accounts for 20–25% of cases of adult nephrotic syndrome. It is often regarded as a condition that does not lead to chronic kidney disease (but see 'Focal segmental glomerulosclerosis' below).

Management

High-dose corticosteroid therapy with prednisolone 60 mg/m^2 daily (up to a maximum of 80 mg/day) for a maximum of 4–6 weeks followed by 40 mg/m^2 every other day for a further 4–6 weeks corrects the urinary protein leak in more than 95% of children. Response rates in adults are significantly lower and response may occur only after many months (12 weeks with daily steroid therapy and 12 weeks of maintenance with alternate-day therapy). Spontaneous remission also occurs and steroid therapy should, in general, be withheld if urinary protein loss is insufficient to cause hypoalbuminaemia or oedema.

In children, two-thirds subsequently relapse and further courses of corticosteroids are required. One-third of these children regularly relapse on steroid withdrawal, so that cyclophosphamide should be added after repeat induction with steroids. A course of cyclophosphamide 1.5–2.0 mg/kg daily is given for 8–12 weeks with concomitant prednisolone 7.5–15 mg/day. This increases the likelihood of long-term remission. Steroid unresponsive patients may also respond to cyclophosphamide. No more than two courses of cyclophosphamide should be prescribed in children because of the risk of side-effects, which include azoospermia.

In both children and adults, if remission lasts for 4 years after steroid therapy, further relapse is very rare.

An alternative to cyclophosphamide is ciclosporin 3–5 mg/kg/day, which is effective but must be continued long term to prevent relapse on stopping treatment. Excretory function and ciclosporin blood levels (recommended trough levels 80–150 ng/mL) must be monitored regularly, as ciclosporin is potentially nephrotoxic. In corticosteroid-dependent children, the anthelminthic agent levamisole 2.5 mg/kg to a maximum of 150 mg on alternate days is useful in maintenance of remission but its mode of action is unexplained. Most of the controlled studies have been conducted in the paediatric age group, making recommendations on treatment in adults difficult.

Congenital nephrotic syndrome

Congenital nephrotic syndrome (Finnish type) is an autosomal recessively inherited disorder due to mutations in the gene coding for a transmembrane protein, nephrin, that occurs with a frequency of 1 per 8200 live births in Finland. Its loss of function results in massive proteinuria shortly after birth; these patients usually have an enlarged placenta. This disorder can be diagnosed *in utero*; increased α-fetoprotein in amniotic fluid is a common feature. The microscopic features of the kidney are varied. Some glomeruli are small and infantile, whereas others are enlarged, more mature and have diffuse mesangial hypercellularity. Because of the massive proteinuria, some tubules develop microcysts and are dilated. On electron microscopy, complete effacement of the foot processes of visceral epithelial cells is observed. This condition is characterized by relentless progression to end-stage renal failure.

Other inherited nephrotic syndromes involve mutations in other genes that encode podocyte proteins such as podocin, α-actinin-4 and Wilms' tumour suppressor gene.

Focal segmental glomerulosclerosis (FSGS)

Clinical features

This disease of unknown aetiology usually presents as massive proteinuria (usually non-selective), haematuria, hypertension and renal impairment. Patients with nephrotic syndrome are often resistant to steroid therapy. All age groups are affected. It usually recurs in transplanted kidneys, sometimes within days of transplantation, particularly in patients with aggressive native renal disease.

Aetiology

A circulating permeability factor (with serine protease activity) causes the increased protein leak; plasma from patients increases membrane permeability in isolated glomeruli. Kidneys transplanted into murine models of FSGS develop the lesion, but kidneys from FSGS-prone mice transplanted to a normal strain are protected. Removal of this factor by plasmapheresis results in transient amelioration of proteinuria. Upregulation of CD80 in podocytes has a major role in the co-stimulatory immune response pathway. Anti-CD80 antibodies, used in renal transplantation, are likely to be used in FSGS in the future.

Pathology

This glomerulopathy is defined primarily by its appearance on light microscopy. Segmental glomerulosclerosis is seen,

www.studentconsult.com
Ask the authors

which later progresses to global sclerosis. The deep glomeruli at the corticomedullary junction are affected first. These may be missed on transcutaneous biopsy, leading to a mistaken diagnosis of a minimal-change glomerular lesion. A pathogenetic link may exist between minimal-change nephropathy and focal glomerulosclerosis, as a proportion of cases classified as having the former condition develop progressive renal impairment, which is unusual. Immunofluorescence shows deposits of C3 and IgM in affected portions of the glomerulus. The other glomeruli are usually enlarged but may be of normal size. In some patients mesangial hypercellularity is a feature. Focal tubular atrophy and interstitial fibrosis are invariably present. Electron microscopic findings mirror light microscopic features with capillary obliteration by hyaline deposits (mesangial matrix and basement membrane material) and lipids. The other glomeruli exhibit primarily foot process effacement, occasionally in a patchy distribution.

Five histological variants of FSGS exist:

- In *classic FSGS* (Fig. 11.14a) the involved glomeruli show sclerotic segments in any location of the glomerulus.
- The *glomerular tip lesion* is characterized by segmental sclerosis, at the tubular pole of all the affected glomeruli at a very early stage (tip FSGS) (Fig. 11.14b). Capillaries contain foam cells, and overlying visceral epithelial cells are enlarged and adherent to the most proximal portion of proximal tubules. These patients have a more favourable response to steroids and run a more benign course.
- In *collapsing FSGS* (Fig. 11.14c) the visceral cells are usually enlarged and coarsely vacuolated with wrinkled and collapsed capillary walls. These features indicate a severe lesion, with a corresponding progressive clinical course of the disease. Collapsing FSGS is commonly seen in young blacks with human immunodeficiency virus (HIV) infection or disease and is known as HIV-associated nephropathy (HIVAN) (see p. 189).
- The *perihilar variant* (Fig 11.14d) consists of perihilar sclerosis and hyalinosis in more than 50% of segmentally sclerotic glomeruli. It is frequently observed with secondary FGS due to processes associated with increased glomerular capillary pressure and declining renal mass.
- The *cellular variant* (Fig 11.14e) is characterized by at least one glomerulus with segmental endocapillary hypercellularity that occludes the capillary lumen. Other glomeruli may exhibit findings consistent with classic FGS.

The tip and collapsing variants have to be excluded histologically to make a diagnosis of the cellular variant. Patients with this variant can have severe proteinuria.

Similar glomerular changes are seen as a secondary phenomenon when the number of functioning nephrons is reduced for any reasons (e.g. nephrectomy, hypertension, gross obesity, ischaemia, sickle nephropathy, reflux nephropathy, heroin abuse, chronic allograft nephropathy, IgA nephropathy and scarring following renal vasculitis), leading to the hypothesis that FSGS results from overloading (glomerular hyperfiltration) of the remaining nephrons.

Treatment

Prednisolone 0.5–2 mg/kg/day is used in most patients and continued for 6 months before the patient is considered resistant to therapy, which is common. The use of ciclosporin at doses to maintain serum trough levels at 150–300 ng/mL may be effective in reducing or stopping urinary protein excretion. Relapse after reducing or stopping ciclosporin is very common so that long-term use is required. Cyclophosphamide, chlorambucil or azathioprine are used for second-line therapy in adults. In FSGS patients with mesangial hypercellularity and tip lesion, cyclophosphamide 1–1.5 mg/kg/day with 60 mg of prednisolone for 3–6 months followed by prednisolone and azathioprine can be used as maintenance therapy. About 50% of patients progress to end-stage renal failure within 10 years of diagnosis, particularly those who are resistant to therapy.

Membranous glomerulopathy

Clinical features

This condition occurs mainly in adults, predominantly in males. Patients present with asymptomatic proteinuria or frank nephrotic syndrome. Microscopic haematuria, hypertension and/or renal impairment may accompany the nephrotic syndrome. As in all nephritides, hypertension and a greater degree of renal impairment are poor prognostic signs. In membranous GN almost half of the patients undergo

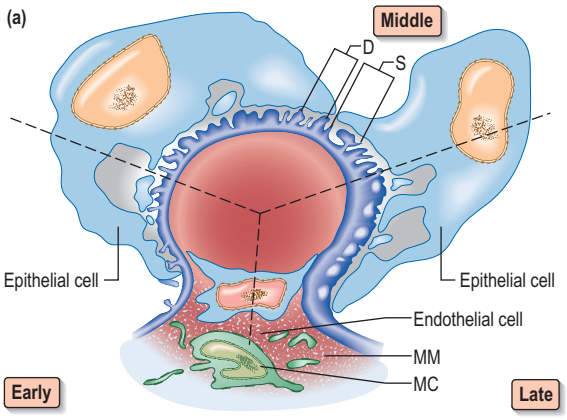
(e) FSGS cellular variant.

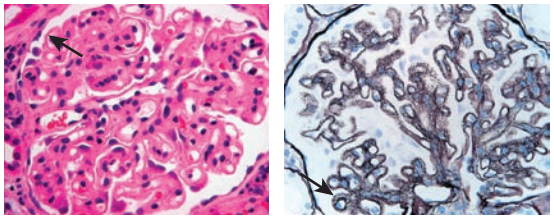
spontaneous or therapy-related remission. However, eventually about 40% develop chronic kidney disease, usually in association with persistent nephrotic range proteinuria. Younger patients, females and those with asymptomatic proteinuria of modest degree at the time of presentation do best.

Aetiopathogenesis



An identical glomerular histological picture is seen in the primary or idiopathic form (which comprises 75% of the cases) and also when membranous GN is secondary to drugs (e.g. penicillamine, gold, NSAIDs, probenecid, mercury, captopril), autoimmune disease (e.g. SLE, thyroiditis), infectious disease (e.g. hepatitis B, hepatitis C, schistosomiasis, *Plasmodium malariae*), neoplasia (e.g. carcinoma of lung, colon, stomach, breast and lymphoma) and other causes (e.g. sarcoidosis, kidney transplantation, sickle cell disease). At all stages, immunofluorescence shows the presence of uniform granular capillary wall deposits of IgG and complement C3. In the early stage the deposits are small and can be missed on light microscopy. Electron microscopy reveals small electron-dense deposits in the subepithelial aspects of the capillary walls. In the intermediate stage the deposits are encircled by basement membrane, which gives an appearance of spikes of basement membrane perpendicular to the basement membrane on silver staining. Late in the disease the deposits are completely surrounded by basement membrane and are undergoing resorption, which appears as uniform thickening of the capillary basement membrane on light microscopy (Fig. 11.15a, b and c).

An animal model (Heymann nephritis) in which the morphological appearances closely resemble the human condition can be induced in susceptible rats by immunization with renal autoantigens such as the brush border component of proximal tubular cells, megalin (gp330). However, the target autoantigen is unknown in humans, as megalin is absent from human podocytes. Several neutral endopeptidases located in the brush border and glomeruli are potential target autoantigens. Immune complexes are formed in situ after reacting with autoantibodies directed against these renal autoantigens.



Treatment

There is no consensus on therapies for all cases but, in general, patients with moderate to heavy proteinurea are treated:

- Oral high-dose corticosteroids and azathioprine are not associated with any significant benefits.
- The alkylating agents, cyclophosphamide and chlorambucil, are both effective in the management of membranous GN but are reserved for patients with severe or prolonged nephrosis (i.e. proteinuria >6 g/day for >6 months), renal insufficiency and hypertension. There is a high likelihood of progression to end-stage renal failure.
- Chlorambucil (0.2 mg/kg/day in months 2, 4 and 6 alternating with oral prednisolone 0.4 mg/kg/day in months 1, 3 and 5) or cyclophosphamide (1.5–2.5 mg/kg/day for 6–12 months with 1 mg/kg/day of oral prednisolone on alternate days for the first 2 months) are equally effective.
- Ciclosporin and mycophenolate with oral steroids may become the agents of choice.

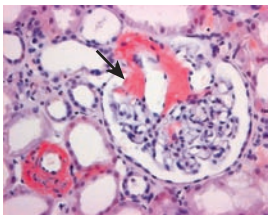
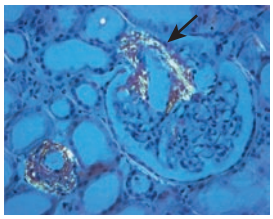
Fig. 11.15 **Membranous glomerulopathy.**



- Anti-CD20 antibodies (rituximab, which ablates B lymphocytes) have been shown to improve renal function, reduce proteinuria and increase the serum albumin; no significant adverse affects have been shown in the short term.

Amyloidosis (see p. 1072)



Amyloidosis is an acquired or inherited disorder of protein folding, in which normally soluble proteins or fragments are deposited extracellularly as abnormal insoluble fibrils causing progressive organ dysfunction and death.

Pathology

On light microscopy, eosinophilic deposits are seen in the mesangium, capillary loops and arteriolar walls. Staining with Congo red renders these deposits pink and they show green birefringence under polarized light (Fig. 11.16). Immunofluorescence is unhelpful, but on electron microscopy the characteristic fibrils of amyloid can be seen. Amyloid consisting of immunoglobulin light chains (AL amyloid) can be identified by immunohistochemistry in only 40% of the cases as compared to almost 100% of patients with protein found in secondary amyloid (AA amyloid). Amyloid A (AA) amyloidosis, also referred to as secondary amyloidosis, is a rare but serious complication of chronic inflammatory diseases and chronic infections.

(a)

(b)

Fig. 11.16 **Amyloid.**
(a) Light microscopy of eosinophilic amyloid deposits (arrow). **(b)** Congo red stain under polarized light showing apple green refringence.

Diagnosis and treatment (see p. 1073)

The *diagnosis* can often be made clinically when features of amyloidosis are present elsewhere. On imaging, the kidneys are often large. Scintigraphy with radiolabelled serum amyloid P (SAP), a technique for quantitatively imaging amyloid deposits in vivo, is used to detect the rate of regression or progression of amyloidosis over a period of time (p. 1073). Renal biopsy is necessary in all suspected cases of renal involvement.

Treatment. Treatments that reduce production of the amyloidogenic protein can improve organ function and survival in immunoglobulin-light-chain-related (AL) amyloidosis and hereditary transthyretin-associated (ATTR) amyloidosis (see p. 1073).

In AA amyloidosis, production of serum amyloid A can sometimes be decreased by treatment of the underlying inflammatory condition but cannot be completely suppressed. A new class of drug, eprodisate (see p. 1073), has shown modest success in patients with renal amyloidosis.

Renoprotective measures should be started (p. 632). The success of dialysis and kidney transplantation is dependent upon the extent of amyloid deposition in extrarenal sites, especially the heart.

Diabetic nephropathy

Diabetic renal disease is the leading cause of end-stage renal failure in the western world. Type 1 and type 2 diabetic patients (see p. 1053) have equivalent rates of proteinuria, azotaemia, and ultimately end-stage renal failure. Both types of diabetes show strong similarities in their rate of renal functional deterioration, and onset of co-morbid complications.

Pathology

The kidneys enlarge initially and there is glomerular hyperfiltration (GFR >150 mL/min). The major early histological lesions seen are glomerular basement membrane thickening and mesangial expansion. Moreover, progressive depletion of podocytes from the filtration barrier due to either apoptosis or detachment and resulting podocyturia appears to be a very early ultrastructural change. Later, glomerulosclerosis develops with nodules (Kimmelstiel–Wilson lesion) and hyaline deposits in the glomerular arterioles (see Fig. 11.17). It has recently been shown that the mesangial expansion and the hyalinosis are partly due to amylin (beta islet specific amyloid protein) deposits. These later changes are associated with heavy proteinuria. The lesions seen in type 1 are also seen in type 2. The pathophysiology is discussed on page 1053.

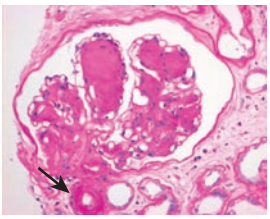


Fig. 11.17 **Diabetes mellitus**. Advanced diabetic glomerulopathy and arteriolar sclerosis (arrow).

Treatment

Lifestyle changes (cessation of smoking and increase in exercise), hypertension, poor metabolic regulation and hyperlidaemia should be addressed in every diabetic. Microalbuminuria is a reason to start treatment with ACE inhibitors or an angiotensin II receptor antagonist (AIIRA) in either type of diabetes, regardless of blood pressure elevation. Like other kidney diseases, however, nearly the entire course of renal injury in diabetes is clinically silent. The timing of medical intervention during this silent phase (see Box 11.6, p. 632) is renoprotective, as judged by slowed loss of glomerular filtration. Despite intensified metabolic control and antihypertension treatment in diabetic patients, a substantial number still go on to develop end-stage renal failure.

Nephrotic syndrome with 'active' urine sediments (mixed nephrotic/nephritic)

Mesangiocapillary (membranoproliferative) glomerulonephritis (MCGN)

This uncommon lesion has three subtypes with similar clinical presentations: the nephrotic syndrome, haematuria, hypertension and renal impairment. They also have similar microscopic findings although the pathogenesis may be different. Electron microscopy defines:

- *Type 1 MCGN*. There is mesangial cell proliferation, with mainly subendothelial immune deposition and apparent splitting of the capillary basement membrane, giving a 'tram-line' effect. It can be associated with persistently reduced plasma levels of C3 and normal levels of C4 due to activation of the complement cascade by the classical pathway. It is often idiopathic but occurs with chronic infection (abscesses, infective endocarditis, infected ventriculoperitoneal shunt) or cryoglobulinaemia secondary to hepatitis C infections (Fig. 11.18a).
- *Type 2 MCGN*. There is mesangial cell proliferation with electron-dense, linear intramembranous deposits that usually stain for C3 only (Fig. 11.18b). This type may be idiopathic or be associated with partial lipodystrophy (loss of subcutaneous fat on face and upper trunk). MCGN affects young adults. These patients have low C3 levels as in type 1 but this is due to the activation of the alternative pathway of the complement cascade; they also have autoantibodies to C3 convertase enzyme.
- *Type 3 MCGN* has features of both types 1 and 2. Complement activation appears to be via the final common pathway of the cascade.

Most patients eventually go on to develop renal failure over several years. Type 2 MCGN recurs in virtually 100% of renal transplant patients but recurrence is less common in type 1

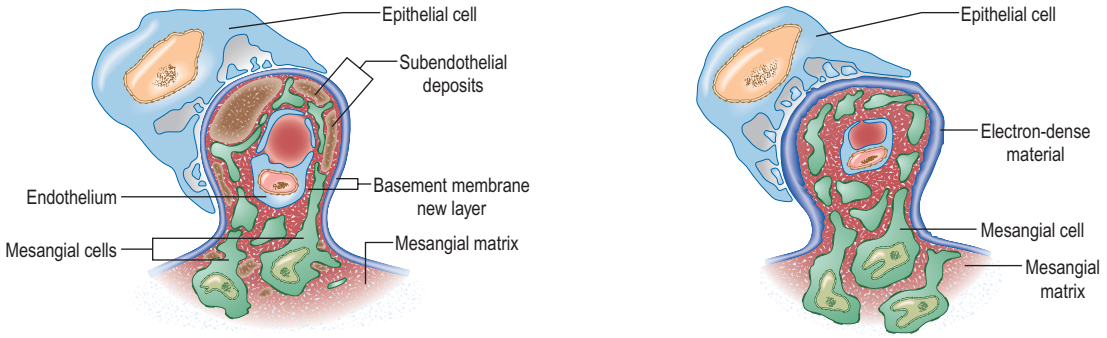

Fig. 11.18 **Mesangiocapillary glomerulonephritis (MCGN). (a)** Type 1 MCGN showing expanded mesangial matrix and mesangial cells, thickened capillary wall, large subendothelial deposits and formation of a new layer of basement membrane (tram-line effect). **(b)** Type 2 MCGN. This shows a variable glomerular appearance; very electron-dense material has replaced Bowman's capsule, tubular basement membrane and part of the capillary. There is some proliferation of mesangial cells. (After Marsh FP *Postgraduate Nephrology.* Oxford: Butterworth Heinemann 1985.)

(25%). However, recurrence does not interfere with long-term graft function.

Management

In idiopathic MCGN (*all age groups*) with normal renal function, non-nephrotic range proteinuria, no specific therapy is required. Follow-up every four months, with specific attention to blood pressure control, is required.

In *children* with the nephritic syndrome and/or impaired renal function, a trial of steroids is warranted (alternate-day prednisolone 40 mg/m^2 for a period of 6–12 months). If no benefit is seen, this treatment is discontinued. Regular follow-up with control of blood pressure, use of agents to reduce proteinuria and correction of lipid abnormalities is necessary.

In *adults* with the nephritic syndrome and/or renal impairment, aspirin (325 mg) or dipyridamole (75–100 mg) daily or a combination of the two, should be given for 6–12 months. Again, if no benefits are seen, the treatment should be stopped. Treatment to slow the rate of progression of renal failure is instituted (p. 632).

Mesangial proliferative GN (IgM nephropathy, C1q nephropathy)

In addition to minimal-change disease, there are two other disorders that usually present with heavy proteinuria with only minor changes on light microscopy.

IgM nephropathy is characterized by increased mesangial cellularity in most of the glomeruli, associated with granular immune deposits (IgM and complement) in the mesangial regions. Patients present with episodic or persistent haematuria with the nephrotic syndrome. Unlike minimal-change disease, the prognosis is not uniformly good, as steroid response is only 50% compared to 90% in minimal-change disease. Between 10% and 30% develop progressive renal insufficiency with signs of secondary FSGS (p. 587) on repeat biopsy. A trial of cyclophosphamide with prednisolone is used with persistent nephrotic syndrome, particularly with a rising plasma creatinine concentration.

C1q nephropathy is very similar to IgM nephropathy in presenting features and microscopic appearance with the exception of C1q deposits in the mesangium. Sometimes it is misdiagnosed as lupus nephritis, particularly in patients with negative serology (so-called 'seronegative lupus'). The distinguishing features are intense C1q staining and absence of tubuloreticular inclusions (attributable to high circulating alpha-interferon) on electron microscopy. Only some patients are steroid dependent. Progression to renal failure is, as in most glomerular diseases, most likely to occur in patients with heavy proteinuria and renal insufficiency.

Systemic lupus erythematosus (lupus glomerulonephritis) (see also p. 541)

Overt renal disease occurs in at least one-third of SLE patients and, of these, 25% reach end-stage renal failure within 10 years. Histologically almost all patients will have changes which were classified by the World Health Organization (1982) and have recently been reviewed by the International Society of Nephrology/Renal Pathological Society (2003). There is a progression of histological findings and clinical picture from I to VI shown in Box 11.2 with modification to include clinical details.

Box 11.2 Classification of lupus nephritis

Class I – Minimal mesangial lupus nephritis (LN), with immune deposits but normal on light microscopy. Asymptomatic.
Class II – Mesangial proliferative LN with mesangial hypercellularity and matrix expansion. Clinically, mild renal disease.
Class III – Focal LN (involving <50% of glomeruli) with subdivisions for active or chronic lesions. Subepithelial deposits seen. Clinically have haematuria and proteinuria. 10–20% of all LN.
Class IV – Diffuse LN (involving ≥50% of glomeruli) (Fig. 11.19) classified by the presence of segmental and global lesions as well as active and chronic lesions. Subendothelial deposits are present. Clinically there is progression to the nephrotic syndrome, hypertension and renal insufficiency. Most common and most severe form of LN.
Class V – Membranous LN affects 10–20% of patients. Can occur in combination with III or IV. Good prognosis.
Class VI – Advanced sclerosing LN (≥90% globally sclerosed glomeruli without residual activity). This represents the advanced stages of the above, as well as healing. Immunosuppressive therapy is unlikely to help as it is 'inactive'. Progressive renal failure.

Modified from International Society of Nephrology/Renal Pathological Society (2004)

Serial renal biopsies show that in approximately 25% of patients, histological appearances alter from one class to another during the interbiopsy interval. The prognosis is better in patients with types I, II and V. Immune deposits in the glomeruli and mesangium are characteristic of SLE (tubuloreticular structure in glomerular endothelial cells) and stain positive for IgG, IgM, IgA and the complement components C3, C1q and C4 on immunofluorescence.

Pathophysiology

SLE is now known to be an autoantigen-driven, T-cell-dependent and B-cell-mediated autoimmune disease (p. 542). Lupus nephritis typically has circulating autoantibodies to cellular antigens (particularly anti-dsDNA, anti-Ro) and complement activation which leads to reduced serum levels of C3, C4, and particularly C1q. C1q is the first component of the classical pathway of the complement cascade (see p. 56) and is involved in the activation of complement and clearance of self-antigens generated during apoptosis. Anti-C1q antibodies may help in distinguishing a renal from a non-renal relapse. However, not all autoantibodies are pathogenic to the kidney. These nephritogenic antibodies have specific physicochemical characteristics and correlate well with the pattern of renal injury. DNA was thought to be the inciting autoantigen, but now nucleosomes (structures comprising DNA and histone, generated during apoptosis) are the most likely autoantigen. Nucleosome-specific T cells, antinucleosome antibodies and nephritogenic immune complexes are generated. Positively charged histone components of the nucleosome bind to the negatively charged heparan sulphate (within the glomerular basement membrane) inciting an inflammatory reaction and resulting in mesangial cell proliferation, mesangial matrix expansion and inflammatory leucocytes. Other pathogenic mechanisms include infarction of glomerular segments, thrombotic microangiopathy, vasculitis and glomerular sclerosis.

The extraglomerular features of lupus nephritis include tubulointerstitial nephritis (75% of patients), renal vein thrombosis and renal artery stenosis. Thrombotic manifestations are associated with autoantibodies to phospholipids (anticardiolipin or lupus anticoagulant) (p. 544).

Management

Initial treatment depends on the clinical presentation but hypertension and oedema should be treated. A definite histopathological diagnosis is required. *Type I* requires no treatment. *Type II* usually runs a benign course but some patients are treated with steroids.

There have been a number of clinical trials with immunosuppressive agents in *types III, IV and V.* At present, steroids and cyclophosphamide or mycophenolate mofetil are usually used for induction, with azathioprine and mycophenolate mofetil for maintenance therapy.

B cell depletion with rituximab (anti-CD20) has been used in some patients with favourable results over the short term; controlled trials are awaited.

Prognosis

Treatment leading to the normalization of proteinuria, hypertension and renal dysfunction indicates a good prognosis. Glomerulosclerosis (type VI) usually predicts end-stage renal disease (p. 625).

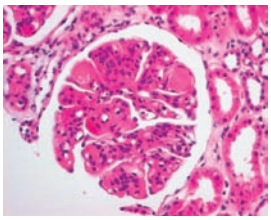

Fig. 11.19 **Lupus nephritis type IV – a diffuse proliferative nephritis.** There is proliferation of endothelial and mesangial cells.

Cryoglobulinaemic renal disease

Cryoglobulins (CG) are immunoglobulins and complement components, which precipitate reversibly in the cold. Three types are recognized:

Type I: the cryoprecipitable immunoglobulin is a single monoclonal type, as is found in multiple myeloma and lymphoproliferative disorders.

Types II and III cryoglobulinaemias are mixed types. In each, a polyclonal IgG antigen is bound to an antiglobulin. In type II, the antiglobulin component, which is usually of the IgM or IgA class with rheumatoid factor activity, is monoclonal, while in type III it is polyclonal. Type II CGs account for 40–60% cases, whilst 40–50% of all CG cases are of type III.

Glomerular disease is more common in type II than in type III cryoglobulinaemia. In approximately 30% of these 'mixed' cryoglobulinaemias, no underlying or associated disease is found (essential cryoglobulinaemia). Recognized associations include viral infections (hepatitis B and C, HIV, cytomegalovirus, Epstein–Barr infection), fungal and spirochaetal infections, malaria and infective endocarditis and autoimmune diseases (SLE, rheumatoid arthritis and Sjögren's syndrome). Glomerular pathological changes resemble MCGN (Fig. 11.18).

Presentation is usually in the fourth or fifth decades of life, and women are more frequently affected than men. Systemic features include purpura, arthralgia, leg ulcers, Raynaud's phenomenon, evidence of systemic vasculitis, a polyneuropathy and hepatic involvement. The glomerular disease presents typically as asymptomatic proteinuria, microscopic haematuria or both, but presentation with an acute nephritic and nephrotic syndrome (commonest presentation) or features of renal impairment also occurs.

A reduction in concentration of early complement components with an elevation of later components, detection of CGs, monoclonal gammopathy, rheumatoid factor, autoantibodies and antiviral antibodies or mRNA of hepatitis C, depending on the associated disorder, is seen.

Spontaneous remission occurs in about one-third of cases and approximately one-third pursue an indolent course. Corticosteroid and/or immunosuppressive therapy with cyclophosphamide may be of benefit, but evaluation of treatment is difficult owing to the rarity of the disease and the occurrence of spontaneous remissions. Intensive plasma exchange or cryofiltration has been used in selected cases. Interferon reduces the viraemia in hepatitis C but does not influence the cryoglobulinaemia. Uncontrolled studies of the anti-CD20 chimeric monoclonal antibody rituximab, which depletes B cells, appear promising, reporting improvement in general manifestations as well as glomerulonephritis.

Henoch–Schönlein syndrome (purpura)

This clinical syndrome comprises a characteristic skin rash, abdominal colic, joint pain and glomerulonephritis. Approximately 30–70% have clinical evidence of renal disease with haematuria and/or proteinuria. The renal disease is usually mild but the nephrotic syndrome and acute kidney injury can occur. The renal lesion is a focal segmental proliferative glomerulonephritis, sometimes with mesangial hypercellularity. In the more severe cases, epithelial crescents may be present. Immunoglobulin deposition is mainly IgA in the glomerular mesangium distribution, similar to IgA nephropathy. There is no treatment of proven benefit. Recently in a placebo-controlled study steroid therapy was found to be ineffective. Treatment is usually supportive but with crescentic GN aggressive immunosuppression has been tried with variable outcome.

Idiopathic fibrillary glomerulopathy

In this rare condition, characteristic microfibrillary structures are seen in the mesangium and glomerular capillary wall on electron microscopy that are clearly different from those seen in amyloidosis; the fibrils are larger than those in amyloidosis (20–30 versus 10 nm diameter) and do not stain with Congo red. The median age at presentation is approximately 45 years (range 10–80 years). Patients present with proteinuria, mostly in the nephrotic range (60%), and microscopic haematuria (70%), hypertension and renal impairment (50%) that may progress rapidly: 40–50% of patients develop end-stage renal failure within 2–6 years.

No treatment is known to be of benefit, although isolated instances of an apparent response to corticosteroid and immunosuppressive therapy have been reported.

Immunotactoid glomerulopathy

In this disorder, microtubules which are much larger (30–40 nm diameter) than the fibrils in fibrillary glomerulopathy are seen on electron microscopy. The majority of patients have circulating paraproteins, or monoclonal immunoglobulin deposition is seen in the glomeruli on immunofluorescence microscopy. A lymphoproliferative disease is the underlying cause in over 50% of cases. The clinical presentation and course are similar to fibrillary glomerulopathy, although therapy can be effective in patients with lymphoproliferative disease and/or paraproteinaemia. Complete or partial remission of the nephrotic syndrome can be achieved by various chemotherapeutic agents in over 80% of patients.

Fibronectin glomerulopathy

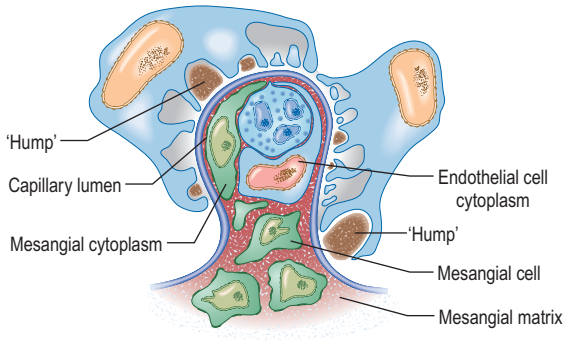
This is also a form of glomerulonephritis due to fibrillar deposits which, unlike amyloidosis but like fibrillary glomerulonephritis and immunotactoid glomerulopathy, is Congo red staining negative. It is inherited as an autosomal dominant disorder and is associated with the massive deposition of fibronectin, a large dimeric glycoprotein consisting of two similar subunits (approximately 250 kDa in weight). The possible genetic abnormality in this disorder is a loss of function mutation in uteroglobin.

Fibronectin glomerulopathy is extremely rare and was described only in Caucasians of European descent. An Asian family with this disease has since been reported. There are as yet no known cases in blacks or Hispanic patients. It presents with varying degrees of proteinuria seen first between the ages of 20 and 40. This is followed by hypertension, microscopic haematuria, and slow progression to end-stage renal disease in most patients. Diagnosis is confirmed by renal biopsy which demonstrates enlarged glomeruli with minimal proliferation and massive Congo red negative fibrillary deposits in the capillary walls. Treatment includes non-specific measures such as adequate blood pressure control by blockade of the renin angiotensin system. End stage renal disease (ESRD or chronic kidney disease) patients are treated with dialysis, and recurrence of disease following renal transplant has been noted.

ACUTE GLOMERULONEPHRITIS (ACUTE NEPHRITIC SYNDROME) (Table 11.5)

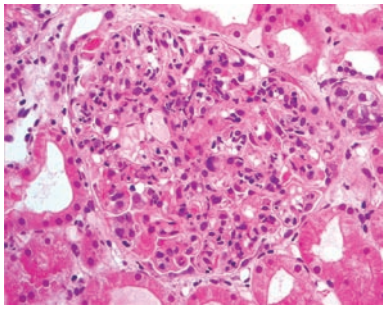
This comprises:

- haematuria (macroscopic or microscopic) – red-cell casts are typically seen on urine microscopy
- proteinuria
- hypertension
- oedema (periorbital, leg or sacral)
- temporarily oliguria and uraemia.



The histological pattern is characterized by cellular proliferation (mesangial and endothelial) and inflammatory cell infiltration (neutrophils, macrophages).

Post-streptococcal glomerulonephritis (PSGN)



The patient, usually a child, suffers a streptococcal infection 1–3 weeks before the onset of the acute nephritic syndrome. Streptococcal throat infection, otitis media or cellulitis can all be responsible. The infecting organism is a Lancefield group A β-haemolytic streptococcus of a nephritogenic type. The latent interval between the infection and development of symptoms and signs of renal involvement reflects the time taken for immune complex formation and deposition and glomerular injury to occur. PSGN is now rare in developed countries. Renal biopsy shows diffuse, florid, acute inflammation in the glomerulus (without necrosis but occasionally cellular crescents), with neutrophils and deposition of immunoglobulin (IgG) and complement (Fig. 11.20a, b). Ultrastructural findings are those of electron-dense deposits, characteristically but not solely in the subepithelial aspects of the capillary walls. Endothelial cells often are swollen. Similar biopsy findings may be seen in *non-streptococcal post-infectious glomerulonephritis* (Table 11.5).

Table 11.5 Diseases commonly associated with the acute nephritic syndrome

Post-streptococcal glomerulonephritis
Non-streptococcal post-infectious glomerulonephritis, e.g. *Staphylococcus*, pneumococcus, *Legionella*, syphilis, mumps, varicella, hepatitis B and C, echovirus, Epstein–Barr virus, toxoplasmosis, malaria, schistosomiasis, trichinosis
Infective endocarditis
Shunt nephritis
Visceral abscess
Systemic lupus erythematosus (see p. 541)
Henoch–Schönlein syndrome (see p. 592)
Cryoglobulinaemia (see p. 591)

After Marsh FP *Postgraduate Nephrology.* Oxford: Butterworth Heinemann 1985.

Management

The acute phase should be treated with antihypertensives, diuretics, salt restriction and dialysis as necessary. If recovery is slow, corticosteroids may be helpful. The prognosis is usually good in children. A small number of adults develop hypertension and/or renal impairment later in life. Therefore in older patients, an annual blood pressure check and measurement of serum creatinine are required. Evidence in support of long-term penicillin prophylaxis after the development of glomerulonephritis is lacking. In non-streptococcal post-infectious glomerulonephritis, prognosis is equally good if the underlying infection is eradicated.

Glomerulonephritis with infective endocarditis

GN occurs rarely in patients with infective endocarditis (usually i.v. drug abusers). It usually manifests itself as the acute nephritic syndrome. A similar presentation is in patients with infected ventriculoperitoneal shunt (*shunt nephritis*). Microscopic appearances resemble post-infectious GN, but lesions are usually focal and segmental. Crescentic GN with acute renal failure has been described, particularly with *Staphylococcus aureus* infection. Appropriate antibiotic therapy or surgical eradication of infection in fulminant cases (embolic infarct of the kidney) usually results in a return of normal renal function.

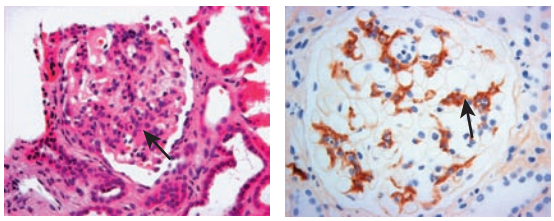
Glomerulonephritis associated with visceral abscesses (mainly pulmonary)

Clinical and microscopic features are indistinguishable from post-infectious GN, but usually complement levels are normal and immune deposits are absent on biopsy. Antibiotic therapy and surgical drainage of the abscess result in complete recovery of renal function in approximately 50% of patients.

ASYMPTOMATIC URINARY ABNORMALITIES

A variety of renal lesions may present as either isolated proteinuria or haematuria, alone or with proteinuria.

Isolated proteinuria without haematuria in asymptomatic patients is usually an incidental finding. It is usually in the sub-nephrotic range without an active urine sediment and there is normal renal function. Over 50% of these patients have postural proteinuria. The outcome of isolated proteinuria (postural or non-postural) is excellent in the majority of patients, with a gradual decline in proteinuria. Occasionally, it may be an early sign of a serious glomerular lesion such as membranous GN, IgA nephropathy, FSGS, diabetic nephropathy or amyloidosis. Moreover, mild proteinuria may accompany a febrile illness, congestive heart failure or infectious diseases with no clinical renal significance.



Haematuria with or without sub-nephrotic range proteinuria in an asymptomatic patient may lead to early discovery of potentially serious glomerular disease such as SLE, Henoch–Schönlein purpura, post-infectious GN or idiopathic hypercalciuria in children. Asymptomatic haematuria is also the primary presenting manifestation of a number of specific glomerular diseases discussed below.

IgA nephropathy (Fig. 11.21a, b)

This disease has replaced post-streptococcal glomerulonephritis as the commonest form of glomerulonephritis world-wide.

Pathogenesis

There is a focal and segmental proliferative glomerulonephritis with mesangial deposits of polymeric IgA_1. In some cases IgG, IgM and C3 are also seen in the glomerular mesangium. The disease may be a result of an exaggerated bone marrow and tonsillar IgA_1 immune response to viral or other antigens and is associated with an abnormality in O-linked galactosylation in the hinge region of the IgA_1 molecule. Functional abnormalities of two IgA receptors – CD89 expressed on blood myeloid cells and the transferring receptor (CD71) on mesangial cells – are seen. Abnormal IgA_1 induces the release

www.studentconsult.com

of soluble CD89, which is responsible for the formation of circulating IgA complexes. These complexes are then trapped by CD71, which is overexpressed on mesangial cells in IgA nephropathy patients, allowing IgA complex formation in the mesangium. Up to 50% of patients exhibit elevated serum IgA (polyclonal) concentration. Superimposed crescent formation is frequent, particularly following macroscopic haematuria due to upper respiratory tract infection.

Several diseases are associated with IgA deposits, including Henoch–Schönlein purpura, chronic liver disease, malignancies (especially carcinoma of bronchus), seronegative spondyloarthritides, coeliac disease, mycosis fungoides and psoriasis.

Clinical presentation

IgA nephropathy tends to occur in children and young males. They present with asymptomatic microscopic haematuria or recurrent macroscopic haematuria sometimes following an upper respiratory or gastrointestinal viral infection. Proteinuria occurs and 5% can be nephrotic. The prognosis is usually good, especially in those with normal blood pressure, normal renal function and absence of proteinuria at presentation. Surprisingly, recurrent macroscopic haematuria is a good prognostic sign, although this may be due to 'lead-time bias' (p. 454), as patients with overt haematuria come to medical attention at an earlier stage of their illness. The risk of eventual development of end-stage renal failure is about 25% in those with proteinuria of more than 1 g per day, elevated serum creatinine, hypertension, ACE gene polymorphism (DD isoform) and tubulointerstitial fibrosis on renal biopsy.

Management

Patients with proteinuria over 1–3 g/day, mild glomerular changes only and preserved renal function should be treated with steroids. Steroids reduce proteinuria and stabilize renal function. The combination of cyclophosphamide, dipyridamole and warfarin should not be used, nor should ciclosporin. In patients with progressive disease (creatinine clearance less than 70 mL/min), fish oil or prednisolone with cyclophosphamide for 3 months followed by maintenance with prednisolone and azathioprine may be tried. A tonsillectomy can reduce proteinuria and haematuria in those patients with recurrent tonsillitis. All patients, with or without hypertension and proteinuria, should receive a combination of ACE inhibitor and angiotensin II receptor antagonist rather than each agent alone because reduction of proteinuria and preservation of renal function are better with combination therapy despite similar blood pressure control. Mesangial IgA deposits are commonly found in the allografts of transplanted patients but loss of graft function as a result is uncommon.

Alport's syndrome

Alport's syndrome is a rare condition characterized by an hereditary nephritis with haematuria, proteinuria (less than 1–2 g/day), progressive renal failure and high-frequency nerve deafness. Approximately 15% of cases may have ocular abnormalities such as bilateral anterior lenticonus and macular and perimacular retinal flecks. In about 85% of patients with Alport's syndrome there is X-linked inheritance of a mutation in the *COL4α5* gene encoding the *COL4α5* collagen chain. In female carriers, penetrance is variable and depends on the type of mutation or degree of mosaicism following hybridization of the X chromosome. Patients with autosomal recessive or dominant modes of inheritance have also been described with mutations in *COL4α3* or *COL4α4* genes. In families with stromal cell tumours there is an additional mutation in the *COL4α6* gene.

Mutations present in Alport's syndrome that produce post-translational defects in α3, α4 and α5 chains result in incorrect assembly or folding of monomers; such defective monomers are rapidly degraded. These mutations arrest the normal developmental switch and cause the persistence of embryonic α1, α1 and α2 networks in glomerular basement membrane. These networks are more susceptible to endoproteolysis and oxidative stress than the α3, α4 and α5 network. Over time, patients with Alport's syndrome probably become more sensitive to selective basement membrane proteolysis, which may explain why their glomerular membranes thicken unevenly, split and ultimately deteriorate.

The primary glomerular filtration barrier of the glomerular capillary consists of the basement membrane and the outer slit diaphragm formed between adjacent podocytes. Loss of slit function causes massive proteinuria (congenital nephrotic syndrome, p. 586) but deterioration of glomerular basement membrane produces only mild proteinuria. Proteinuria in Alport's syndrome is the result of glomerular sclerosis, rather than primary loss of slit pores. In pedigrees with a history of renal failure, disease progresses from concomitant interstitial fibrosis, macrophage and lymphocyte infiltration secondary to tubular basement disruption and transdifferentiation of epithelial mesenchymal cells to fibroblasts. This fibrogenic response destroys renal architecture. The renal histology characteristically shows split basement membrane. In some patients with Alport's syndrome and carriers, thin basement membrane, as seen in benign familial haematuria, is the only abnormality detected on histology. For this reason, the boundary between Alport's and benign familial haematuria has become increasingly vague.

Management

The disease is progressive and accounts for some 5% of cases of end-stage renal failure in childhood or adolescence. Patients with early renal failure can be treated with ACE inhibitors to attenuate proteinuria. Exciting experimental evidence suggests that mesenchymal stem cells can transdifferentiate into podocytes and repair basement abnormalities and slow the rate of progression. Anti-GBM antibody does not adhere normally to the glomerular basement membrane of affected individuals but development of crescentic glomerulonephritis in the transplanted kidney due to anti-GBM alloantibody is a well-recognized complication.

Thin glomerular basement membrane disease

This condition is inherited as an autosomal dominant and typically presents with persistent microscopic glomerular haematuria (RBC casts or dysmorphic RBCs). The diagnosis is made by renal biopsy, which shows thinning of the glomerular capillary basement membrane on electron microscopy. The condition was underdiagnosed and is much commoner than previously believed. The prognosis for renal function is usually very good but some patients develop renal insufficiency over decades. The cause of renal impairment in this condition is not known but may be due to secondary FSGS or concomitant IgA nephropathy. Misdiagnosis occurs with Alport's syndrome which shares similar histological features. No treatment is of known benefit.

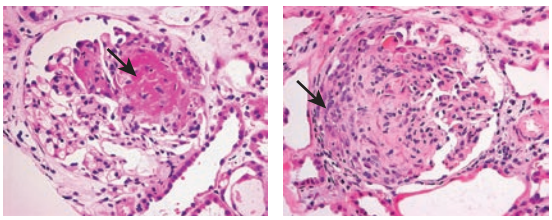
RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS (RPGN)

RPGN is a syndrome with glomerular haematuria (RBC casts or dysmorphic RBCs), rapidly developing acute renal failure over weeks to months and focal glomerular necrosis (Fig. 11.22) with or without glomerular crescent development on renal biopsy. The 'crescent' is an aggregate of macrophages and epithelial cells in Bowman's space (Fig. 11.22). RPGN can develop with immune deposits (anti-GBM or immune complex type, e.g. SLE) or without immune deposits (pauci-immune, e.g. anti-PR3 and or anti-MPO-ANCA positive vasculitides). It can also develop as an idiopathic primary glomerular disease or can be superimposed on secondary glomerular diseases such as IgA nephropathy, membranous GN and postinfective GN. The classification used here is based on the immunofluorescence information obtained from renal histology (Table 11.6) viz linear, granular and negative immunofluorescent patterns (Table 11.6).

Table 11.6 Types of rapidly progressive glomerulonephritis (RPGN)

Linear immunofluorescent pattern (Fig. 11.23a)
Idiopathic anti-GBM antibody-mediated RPGN
Goodpasture's syndrome

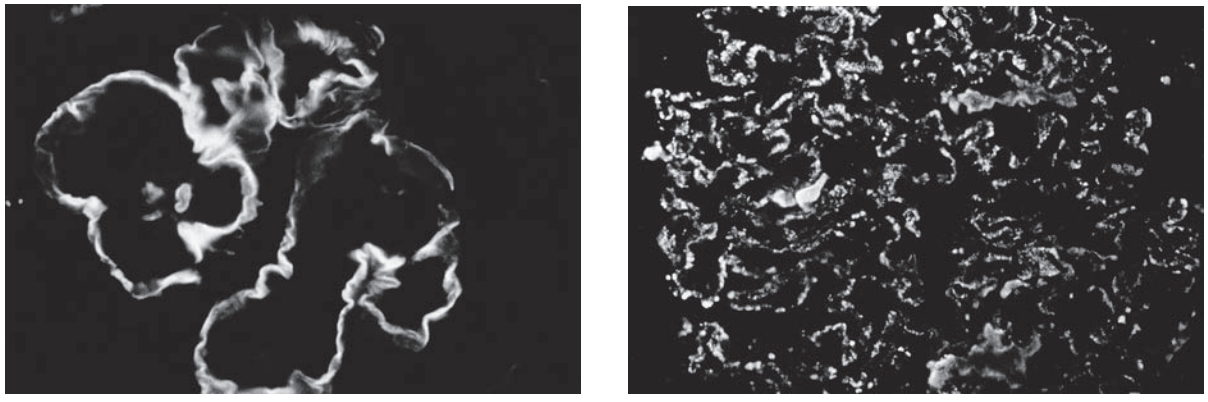
Granular immunofluorescent pattern (immune complex-mediated RPGN) (Fig. 11.23b)
Idiopathic immune complex-mediated RPGN
Associated with other primary GN
- Mesangiocapillary GN (type II > type I)
- IgA nephropathy
- Membranous glomerulopathy



Associated with secondary GN
- Post-infectious GN
- Systemic lupus erythematosus
- Henoch–Schönlein syndrome
- Cryoglobulinaemia

Negative immunofluorescent pattern (pauci-immune RPGN)
ANCA-associated systemic vasculitides

Anti-GBM glomerulonephritis (Fig. 11.23a)



Anti-GBM glomerulonephritis, characterized by linear capillary loop staining with IgG and C3 and extensive crescent formation, accounts for 15–20% of all cases of RPGN, although overall it accounts for less than 5% of all forms of glomerulonephritis. This condition is rare, with an incidence of 1 per 2 million in the general population. About two-thirds of these patients have Goodpasture's syndrome with associated lung haemorrhage (p. 874). The remainder have a renal restricted anti-GBM RPGN, which is seen in people over 50 years and affects both genders equally.

Anti-GBM antibodies (detected by ELISA) are present in serum and are directed against the *non-collagenous (NCI) component* of α3 (IV) collagen of basement membrane. This target antigen must be present as a component of the native α3, α4, α5 (IV) network of selected basement membrane in order for pulmonary and renal disease to develop. Consequently, there are no known cases of anti-GBM glomerulonephritis in patients with Alport's syndrome (p. 594). Anti-GBM RPGN is restricted by the major histocompatibility complex; HLA-DRB1*1501 and HLA-DRB1*1502 alleles increase susceptibility, whereas HLA-DR7 and HLA-DR1 are protective. The thymus expresses α3 (IV) NCI peptides that can eliminate autoreactive $CD4^+$ helper T cells, but a few such cells escape deletion and are kept in check by circulating regulatory cells. Breakdown of this peripheral tolerance (the mechanism of which is unknown) results in these autoreactive $CD4^+$ cells producing anti-GBM antibodies. These antibodies are very specific as shown by the fact that anti-

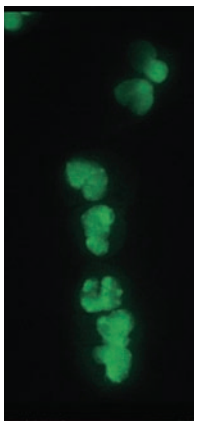
bodies against α1, α1 and α2 NCl domains do not cause RPGN. Since the α3 (IV) NCl epitope is hidden within the α3, α4 and α5 (IV) promoter, it is presumed that an environmental factor, such as exposure to hydrocarbons or tobacco smoke, is required in order to reveal cryptic epitopes to the immune system.



The mechanism of renal injury is complex. When anti-GBM antibody binds basement membrane it activates complement and proteases and results in disruption of the filtration barrier and Bowman's capsule, causing proteinuria and the formation of crescents. Crescent formation is facilitated by interleukin-12 and gamma-interferon which are produced by resident and infiltrating inflammatory cells.

Management

This is based on counteracting the factors involved in the pathogenesis. Thus plasma exchange is used to remove circulating antibodies, steroids to suppress inflammation from antibody already deposited in the tissue, and cyclophosphamide to suppress further antibody synthesis. The prognosis is directly related to the extent of glomerular damage (measured by percentage of crescents, serum creatinine and need for dialysis) at the initiation of treatment. When oliguria occurs or serum creatinine rises above 600–700 μmol/L, renal failure is usually irreversible. Once the active disease is treated, this condition, unlike other autoimmune diseases, does not follow a remitting/ relapsing course. Furthermore, if left untreated, autoantibodies diminish spontaneously within 3 years and autoreactive T cells cannot be detected in the convalescent patients. This is suggestive of re-establishment of peripheral tolerance which coincides with re-emergence of regulatory $CD25^+$ cells in the peripheral blood; these play a key role in inhibiting the autoimmune response. The emergence and persistence of these regulatory cells may underlie the 'single hit' nature of this condition.

(a) cANCA.

(b) pANCA.

Fig. 11.25 **ANCA positive glomerulonephritis – immunofluorescence.** From *The Shrier Atlas of Diseases of the Kidney* Vol IV with permission of Wiley-Blackwell.

ANCA-positive vasculitides (see also p. 551)

Inflammation and necrosis of the blood vessel wall occurs in many primary vasculitic disorders. *Wegener's granulomatosis, microscopic polyangiitis* and *Churg–Strauss syndrome* are described as small vessel vasculitides and are commonly associated with antineutrophil cytoplasm antibodies (ANCA). These diseases share common pathology with focal necrotizing lesions, which affect many different vessels and organs; in the lungs, a capillaritis may cause lung haemorrhage; within the glomerulus of the kidney, crescentic GN and/or focal necrotizing lesions may cause acute renal failure (Fig. 11.22a, b); in the dermis, a purpuric rash or vasculitic (Fig. 11.24) ulceration. Wegener's and Churg–Strauss syndrome may have additional granulomatous lesions.

Pathogenesis

There are two forms of ANCA (p. 504) viz PR3-ANCA (cANCA) and MPO-ANCA (pANCA). If ELISA and indirect immunofluorescence techniques (Fig. 11.25a,b) are combined, diagnostic specificity is 99%. Testing for antineutrophil cytoplasmic antibodies should be accompanied by appropriate tests of autoantibodies directed against DNA and the glomerular basement membrane antigen. The simultaneous occurrence of ANCA and anti-GMB antibody is well documented; such patients tend to follow the natural history of Goodpasture's disease. Variations in the ANCA titres have been used in the assessment of disease activity.

Fig. 11.24 **Vasculitic rash.**

- PR3-ANCA positivity is found in the large majority (>90%) of patients with active Wegener's granulomatosis and in up to 50% of patients with microscopic polyangiitis.
- Anti-MPO positivity is present in the majority of patients with idiopathic crescentic glomerulonephritis and in a variable number of cases of microscopic polyangiitis. There is some evidence to suggest that ANCA are pathogenic and not just markers of disease; for example, development of drug-induced ANCA is associated with vasculitic lesions in humans. Churg–Strauss syndrome may have either anti-MPO- or anti-PR3-ANCA.
- Positivity for both types of ANCA antibodies occurs in up to 10% of patients who have a variable clinical course but a worse renal outcome.
- *Drugs* (e.g. propylthiouracil, hydralazine, minocycline, penicillamine) may induce vasculitides associated with ANCA. Most patients reported with drug-induced ANCA-associated vasculitis have MPO-ANCA, often in very high titres. In addition to MPO-ANCA, most also have antibodies to elastase or to lactoferrin. A relatively small number have PR3-ANCA. Many cases of drug-induced ANCA-associated vasculitis present with constitutional symptoms, arthralgias/arthritis, and cutaneous vasculitis. However, the full range of clinical features associated with ANCA, including crescentic GN and lung haemorrhage, can also occur.
- *Autoimmunity.* It is unclear how and why autoimmunity causes the formation of ANCA antibodies. Patients with anti-PR3 also have autoantibodies to a peptide translated from the antisense DNA strand of PR-3 (complementary PR-3; cPR-3) or to a mimetic of this peptide. This suggests that autoimmunity can be initiated through an immune response against a peptide that is antisense or complementary to the autoantigen, which then induces anti-idiotypic antibodies (autoantibodies) that cross-react with the autoantigen.

There may be multiple factors that contribute to the initiation of an ANCA autoimmune response and the induction of injury by ANCA, such as genetic predisposition (α_1-antitrypsin deficiency; Pi-Z allele) and environmental factors (e.g. silica exposure, viral infection, *Staph. aureus* infection) can result in high local or systemic pro-inflammatory cytokines such as tumour necrosis factor (TNF).

Treatment

The sooner treatment is instituted the more chance there is of recovery of renal function.

- *Corticosteroids* and *cyclophosphamide* are of benefit: high-dose oral prednisolone (maximum 80 mg/day reducing over time to 15 mg/day by 3 months) and cyclophosphamide (2 mg/kg/day, adjusted for age, renal function and prevailing WBC count). Intravenous pulse, rather than daily oral, cyclophosphamide is associated with an equivalent response with better side-effect profile but is associated with higher relapse rate. The best indicators of prognosis are pulmonary haemorrhage and severity of renal failure at presentation.
- Patients who present with *fulminant disease* need intensification of immunosuppression with adjuvant plasma exchanges (7 × 3–4 L over 14 days) or intravenous pulse methyl prednisolone (1 g/day for 3 consecutive days). Plasma exchange appeared to have better outcome than pulse methyl prednisolone in one study.
- Once remission has been achieved, azathioprine should be substituted for cyclophosphamide. In cases of intolerance to azathioprine or cyclophosphamide, mycophenolate or methotrexate has been tried with some success.
- Colonization of the upper respiratory tract with *Staph. aureus* increases the risk of relapse, and treatment with sulfamethoxazole/trimethoprim reduces the relapse rate.
- Relapse after complete cessation of immunosuppressive therapy has been observed relatively frequently, and therefore long-term, albeit relatively low-dose, immunosuppression is necessary.
- Intravenous immunoglobulin (anti-thymocyte globulin, ATG, directed against activated T lymphocytes causes lymphopenia), lymphocyte-depleting anti-CD52 (campath-IH) antibodies, anti-CD20 antibody (Rituximab) a B lymphocyte depleting antibody and anti-TNF therapy have shown promise in the treatment of severe and drug-resistant cases as induction therapy. However, an anti-TNF agent, etanercept, has been ineffective as a sole agent for maintenance.

OTHER GLOMERULAR DISORDERS

HIV-associated nephropathy (HIVAN) (see p. 189)

A number of renal lesions have been described in association with HIV infection. These include glomerulonephritis of various histological types and the haemolytic uraemic syndrome. The most common (80–90%) histological abnormality is a focal glomerulosclerosis (FGS).

HIV-associated FGS

A characteristic 'collapsed' appearance of glomeruli is often seen on light microscopy similar to that seen in other causes of focal segmental glomerulosclerosis (see Fig. 11.14c). In HIVAN many visceral epithelial cells (podocytes) are enlarged, hyperplastic, coarsely vacuolated, contain protein absorption droplets and overlie capillaries with varying degrees of wrinkling and collapse of the walls. It is associated with loss of podocyte-specific markers such as Wilms' tumour factor and synaptopodin due to HIV-1 infection of podocytes of patients with HIVAN. HIVAN has striking predilection; over 90% of patients are black. Clinically HIVAN presents with proteinuria in the nephrotic range, oedema and a 'bland' urine. Hypertension is unusual. If untreated, patients go on to renal failure which can be rapid in progression.

IgA may be an integral feature of HIV-1 infection, as is IgA nephropathy. In this setting, HIV antigen may be a part of the glomerular immune complexes and circulating immune complexes.

Highly active antiretroviral therapy (HAART) may result in stabilization of renal function and prevention of progression to end-stage renal failure (efficacy 23%) and HIV-associated mortality in patients with end-stage renal failure. A cyclin-dependent kinase inhibitor, roscovitine, has been successfully used in the treatment of experimental HIVAN.

Fabry's disease

This is the result of deficiency of the enzyme α-galactosidase with accumulation of sphingolipids in many cells. In the kidney, accumulation of sphingolipids especially affects podocytes, which on light microscopy appear enlarged and vacuolated. Ultrastructurally, these inclusion bodies appear as zebra or myeloid bodies representing sphingolipids. Similar appearances have been described in patients taking chloroquine, hydroxychloroquine and amantidine because these can cause hyperlipidosis. These structures can also be found in endothelial, mesangial, and arterial and arteriolar smooth muscle cells. The most common renal manifestation is proteinuria and progressive renal failure.

Treatment (p. 1072).

Sickle nephropathy

Sickle disease or trait is complicated relatively commonly by papillary sclerosis or necrosis, nephrogenic diabetes insipidus and incomplete renal tubular acidosis. Glomerular lesions are rare and can sometimes be traced to hepatitis B or C infection acquired through repeated blood transfusions. Occasionally, proteinuria or nephrotic syndrome with progressive renal insufficiency is seen without prior infection. The rare glomerular lesion is that of membranous GN or membranoproliferative GN with IgG deposits. No form of effective therapy is known.

Glomerulopathy associated with pre-eclampsia

The glomerular lesion of pre-eclampsia is characterized by marked endothelial swelling and obliteration of capillary lumina. Fibrinogen–fibrin deposits may be found in the mesangium. The renal lesion may not be reversible and 30% of patients have changes for 6 months or longer. Patients who have had pre-eclampsia are more likely to develop hypertension in subsequent pregnancies. Severe proteinuria may occur during the course of pre-eclampsia and from time to time produce features of nephrotic syndrome. Ordinarily, proteinuria disappears after delivery.

In severe cases, associated with cortical necrosis, there may be microangiopathic haemolytic anaemia. Vascular endothelial growth factor (VEGF) and placental growth factor (PLGF) play a key role in the development of the placenta.

Relative deficiency of either factor can theoretically cause implantation abnormalities normally seen in pre-eclampsia. A soluble fms-like tyrosine kinase (sFlt1) receptor also called VEGF-receptor, which is an antagonist of PLGF and specifically of VEGF, is upregulated in the placenta of patients with pre-eclampsia. High circulating levels of these receptors antagonize angiopoeitic factors and cause endothelial dysfunction. Excessive free radical generation in the placenta of pre-eclamptic patients is due to upregulation of NADPH oxidase activity caused by generation of an angiotensin II receptor agonist antibody in some patients.

RENAL INVOLVEMENT IN OTHER DISEASES

Polyarteritis nodosa (PAN)

(see also p. 550)

Classical PAN is a multisystem disorder. Aneurysmal dilatation of medium-sized arteries may be seen on renal arteriography. The condition is more common in men and in the elderly and, typically, the patient is ANCA negative. Hypertension, polyneuropathy and features indicating ischaemic infarction of various organs including the kidney are presenting features. It may be associated with drug abuse and hepatitis B infection. This form of polyangiitis is associated with slowly progressive renal failure, often accompanied by severe hypertension. Rapidly progressive renal failure is rare. Treatment with immunosuppression is less effective than it is for microscopic polyangiitis.

Haemolytic uraemic syndrome (HUS)

HUS is characterized by intravascular haemolysis with red cell fragmentation (microangiopathic haemolysis), thrombocytopenia and acute kidney injury due to thrombosis in small arteries and arterioles (Fig. 11.26). These features are also seen in disseminated intravascular coagulation, but coagulation tests are typically normal in HUS. The syndrome often follows a febrile illness, particularly gastroenteritis (also known as *diarrhoea-associated HUS* (*D+HUS*) often associated with *Escherichia coli*, notably strain O157. This strain of *E. coli* produces verocytotoxin (shiga toxin), which has an A unit and five B units. The A unit is pathogenic by inhibiting protein synthesis and initiating endothelial damage. The role of B units is to facilitate the entry of the A unit into the endothelial cells by binding to a receptor (Gb3) on the endothelial cell. The toxins are transported to endothelial cells from the gut on neutrophils. Most patients with D+HUS recover renal function, but supportive care including maintenance of fluid and electrolyte balance, antihypertensive medication, nutritional support and dialysis is commonly required. Plasmapheresis is not beneficial but is usually tried as a last resort. About 5% die during the acute episode, 5% develop chronic renal failure and 30% exhibit evidence of long-term damage with persistent proteinuria. Antibiotic and antimotility agents for the diarrhoea increase the risk of HUS and its complications.

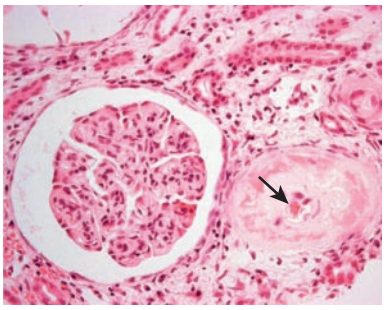

Fig. 11.26 **Typical haemolytic uraemic syndrome (HUS) renal lesion – light microscopy.** Arrow shows microthrombi.

Recurrent episodes of HUS have been described in the same individual, and familial forms of the disease (with both recessive and dominant inheritance) exist.

The *non-diarrhoeal-induced form of HUS (D–HUS)* may be a complement-driven illness due to a deficiency of complement factor H. Factor H is a soluble protein produced by the liver, which regulates the activity of the alternative complement activation pathway; in particular, it protects host cell surfaces from complement-mediated damage. In some families with D–HUS, a mutation has been traced to another complement regulatory protein known as membrane cofactor protein (MCP). This protein is highly expressed in the kidney and normally prevents glomerular C3 activation. A loss of function mutation in MCP results in unopposed complement activation and development of HUS. *Treatment* is often very difficult because of severe hypertension and the possibility of frequent recurrences. The course of the disease is often indolent and progressive. Plasmapheresis or plasma infusion, although unproven, is still used. Liver transplantation is potentially the only curative treatment.

Sporadic cases of D–HUS can be associated with pregnancy, SLE, scleroderma, malignant hypertension, metastatic cancer, HIV infection and various drugs including oral contraceptives, ciclosporin, tacrolimus, chemotherapeutic agents (e.g. cisplatin, mitomycin C, bleomycin) and heparin. Treatment is supportive with removal of the offending agent or specific treatment of the underlying cause. There is no

evidence in favour of plasma infusion or plasmapheresis in these sporadic cases but it is tried, usually as a last resort.

Pneumococcus-associated HUS. This rare complication of *Streptococcus pneumoniae* infection was previously associated with a high morbidity and mortality. This organism produces an enzyme (possibly neuroaminidase) which can expose an antigen (Thomsen antigen) present on RBCs, platelets and glomeruli. Antibodies to the Thomsen antigen result in an antigen–antibody reaction and can lead to HUS and anaemia. The improved outcome is due to increasing awareness of this complication, judicious use of blood products (washed blood products) and avoiding plasma infusion or plasmapheresis.

Thrombotic thrombocytopenic purpura (TTP) (see p. 437)

TTP is characterized by microangiopathic haemolysis, renal failure and evidence of neurological disturbance. Young adults are most commonly affected.

Antiphospholipid syndrome (APS) (see p. 544)

The central feature of APS is recurrent thrombosis (both venous and arterial) and fetal loss in the presence of antiphospholipid antibodies. Such antibodies may be primary or secondary to infections (HIV, hepatitis C) or autoimmune disease (SLE). Fifty per cent have renal involvement with proteinuria. Thrombotic microangiopathy is a rare but well-recognized presentation. In some cases a lupus nephritis-like (usually membranous GN) lesion is seen. The only proven treatment for APS is warfarin with an INR of 3–4. Use of steroids or plasmapheresis is reserved for patients with APS and life-threatening renal involvement with thrombotic microangiopathy. Treatment is variably successful (30–70%).

Multiple myeloma

Acute kidney injury is relatively common in myeloma, occurring in 20–30% of affected individuals at the time of diagnosis, and is mainly due to the nephrotoxic effects of the abnormal immunoglobulins. It is often irreversible. The following types of renal lesions are associated with myeloma.

1. *Light chain cast nephropathy* – intratubular deposition of light chains, particularly kappa chains facilitated by Tamm–Horsfall glycoprotein, which characteristically appear on renal histology as fractured casts with giant cell reaction (Fig. 11.27).
2. *AL amyloidosis* – deposition of amyloid fibrils of light chains (Congo red positive).
3. *Light chain deposition disease* – nodular glomerulosclerosis with granular deposits of usually lambda light chains (Congo red negative).
4. *Plasma cell infiltration* – often incidental finding at autopsy.
5. *Fanconi's syndrome* – tubular toxicity due to light chains.
6. *Hypercalcaemic nephropathy* – bone resorption causing hypercalcaemia.
7. *Hyperuricaemic nephropathy* – tumour lysis causing tubular crystallization of uric acid.

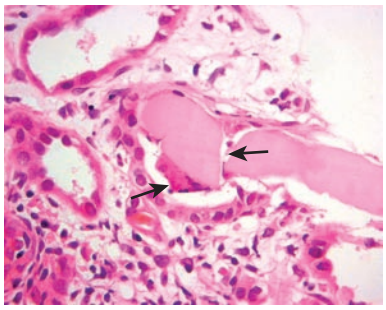

Fig. 11.27 **Cast nephropathy in a patient with multiple myeloma.** Light microscopy picture showing characteristic fractured cast and giant cell reaction (arrows).

8. *Radiocontrast nephropathy* – interaction between light chains and radiocontrast.

Treatment of underlying myeloma is indicated (p. 485).

URINARY TRACT INFECTION

Urinary tract infection (UTI) is common in women, in whom it usually occurs in an anatomically normal urinary tract. Conversely, it is uncommon in men and children, and the urinary tract is often abnormal and requires investigation. The incidence of UTI is 50 000 per million persons per year and accounts for 1–2% of patients in primary care. Recurrent infection causes considerable morbidity; if complicated, it can cause severe renal disease including end-stage renal failure. It is also a common source of life-threatening Gram-negative septicaemia.

Aetiology and pathogenesis

Infection is most often due to bacteria from the patient's own bowel flora (Table 11.7). Transfer to the urinary tract is most often via the ascending transurethral route but may be via the bloodstream, the lymphatics or by direct extension (e.g. from a vesicocolic fistula).

Symptomatic infection is related to the virulence of the organisms, which competes with the innate host defence system. However, inflammation and injury are determined by the host response and not by the bacterium.

Virulence. Ability to adhere to epithelial cells determines the degree of virulence of the organism. For *E. coli*, these adhesive factors include flagellae (for motility), aerobactin (for iron acquisition in the iron-poor environment of the urinary tract), haemolysin (for pore forming) and above all, the presence of adhesins on the bacterial fimbriae and on the cell surface.

There are two types of *E. coli*: those with *type 1 fimbriae* (with adhesin known as FimH) associated with cystitis; and those with *type P fimbriae* (with adhesin known as PapG) commonly responsible for pyelonephritis. Bacterial adhesins are necessary for attachment of bacteria to the mucous membranes of the perineum and urothelium. There are several molecular forms of adhesins. The most studied is the PapG adhesin, which is located on the tip of P fimbriae. This lectin (one of the P blood group antigens) structure recognizes binding sites consisting of oligosaccharide sequences present on the mucosal surface.

*Enterococcus faecalis**	6
Staphylococcus saprophyticus or *epidermidis*†	10

*More common in hospital practice
†More common in young women (20–30%)

Innate host defence. The following host defence mechanisms are necessary to prevent UTI:

- *Neutrophils* – adhesins activate receptors, e.g. Toll receptor 4, on the mucosal surface, resulting in IL-8 production and expression of its receptor CXCR1 on neutrophil surfaces. Activation of neutrophils is essential for bacterial killing. Defective IL-8 production or reduced expression of CXCR1 results in impaired function of neutrophils predisposing an individual to severe UTI.
- *Urine osmolality and pH* – urinary osmolality >800 mOsm/kg and low or high pH reduce bacterial survival.
- *Complement* – complement activation with IgA production by uroepithelium (acquired immunity) also plays a major role in defence against UTI.
- *Commensal organisms* – such as lactobacilli, corynebacteria, streptococci and bacteroides are part of the normal host defence. Eradication of these commensal organisms by spermicidal jelly or disruption by certain antibiotics results in overgrowth of *E. coli*.
- *Urine flow* – urine flow and normal micturition wash out bacteria. Urine stasis promotes UTI.
- *Uroepithelium* – mannosylated proteins such as Tamm–Horsfall proteins (THP), which are present in the mucus and glycocalyx covering uroepithelium, have antibacterial properties. These proteins interfere with bacterial binding to uroepithelium. Disruption of this uroepithelium by trauma (e.g. sexual intercourse or catheterization) predisposes to UTI. Cranberry juice and blueberry juice contain a large-molecular-weight factor (proanthrocyanidins) that prevents binding of *E. coli* to the uroepithelium (see p. 603).
- *Blood group antigens* – women who are non-secretors of ABH blood group antigens are three to four times more likely to have recurrent UTIs.

Natural history

UTI is commonly an isolated, rather than a repeated, event (Fig. 11.28).

Complicated versus uncomplicated infection (Fig. 11.29)

It is necessary to distinguish between UTI occurring in patients with functionally normal urinary tracts and in those with abnormal tracts.

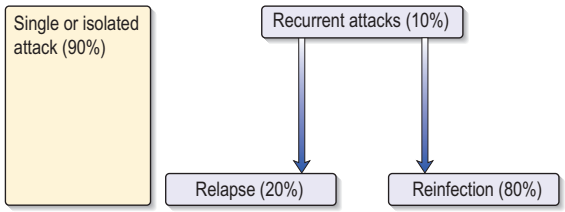

Fig. 11.28 **The natural history of urinary tract infection.**

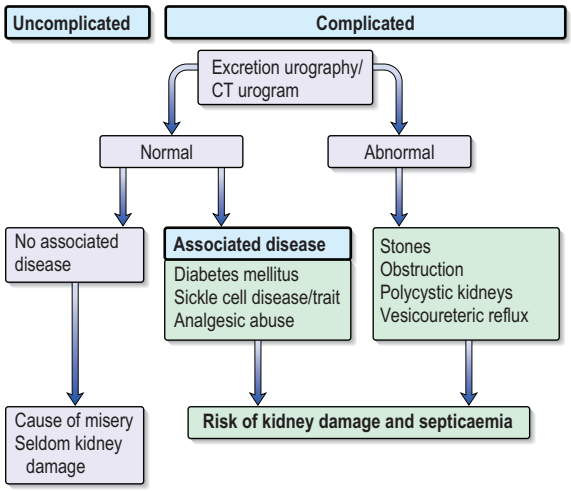

Fig. 11.29 **Complicated versus uncomplicated urinary tract infection.**

Functionally normal urinary tracts (with normal renal imaging). Here, persistent or recurrent infection seldom results in serious kidney damage (uncomplicated UTI).

Abnormal urinary tracts. Tracts with stones, or associated diseases such as diabetes mellitus which themselves cause kidney damage, may be made worse with infection (complicated UTI). UTI, particularly with *Proteus*, may predispose to stone formation. The combination of infection and obstruction results in severe, sometimes rapid, kidney damage (obstructive pyonephrosis) and is a major cause of Gram-negative septicaemia.

Acute pyelonephritis

The combination of fever, loin pain with tenderness and significant bacteriuria usually implies infection of the kidney (acute pyelonephritis). Small renal cortical abscesses and streaks of pus in the renal medulla are often present. Histologically there is focal infiltration by polymorphonuclear leucocytes and many polymorphs in tubular lumina.

Although, with antibiotics, significant permanent kidney damage in adults with normal urinary tracts is rare, CT scanning can show wedge-shaped areas of inflammation in the renal cortex (Fig. 11.30) and hence damage to renal function.

Reflux nephropathy

This was called chronic pyelonephritis or atrophic pyelonephritis, and it results from a combination of:

- vesicoureteric reflux, and
- infection acquired in infancy or early childhood.

Fig. 11.30 **CT scan showing a wedge-shaped area of renal cortical loss (arrow) following acute pyelonephritis.**

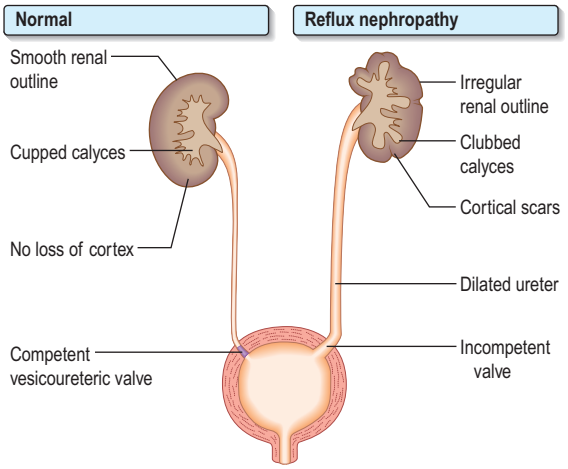

Fig. 11.31 **Findings in reflux nephropathy compared with normal.**

Normally the vesicoureteric junction acts as a one-way valve (Fig. 11.31), urine entering the bladder from above; the ureter is shut off during bladder contraction, thus preventing reflux of urine. In some infants and children – possibly even in utero – this valve mechanism is incompetent, bladder voiding being associated with variable reflux of a jet of urine up the ureter. A secondary consequence is incomplete bladder emptying, as refluxed urine returns to the bladder after voiding. This latter event predisposes to infection, and the reflux of infected urine leads to kidney damage.

Typically there is papillary damage, tubulointerstitial nephritis and cortical scarring in areas adjacent to 'clubbed calyces'.

Diagnosis is based on CT scan of the kidneys, which shows irregular renal outlines, clubbed calyces and a variable reduction in renal size. The condition may be unilateral or bilateral and affect all or part of the kidney.

Reflux usually ceases around puberty with growth of the bladder base. Damage already done persists and progressive renal fibrosis and further loss of function occur in severe cases even though there is no further infection.

Reflux nephropathy cannot occur in the absence of reflux and therefore does not begin in adult life. Consequently, adult females with bacteriuria and a normal urogram can be reassured that kidney damage will not develop.

Chronic reflux nephropathy acquired in infancy predisposes to hypertension in later life and, if severe, is a relatively common cause of end-stage renal failure in childhood or adult life. Meticulous early detection and control of infection, with or without ureteral reimplantation to create a competent valve, can prevent further scarring and allow normal growth of the kidneys. No proof exists, however, that reimplantation surgery confers long-term benefit.

Reinfection versus relapsing infection

When UTI is recurrent it is necessary to distinguish between relapse and reinfection.

Relapse is diagnosed by recurrence of bacteriuria with the same organism within 7 days of completion of antibacterial treatment and implies failure to eradicate infection (Fig. 11.32) usually in conditions such as stones, scarred kidneys, polycystic disease or bacterial prostatitis.

Reinfection is when bacteriuria is absent after treatment for at least 14 days, usually longer, followed by recurrence of infection with the same or different organisms. This is not due to failure to eradicate infection, but is the result of reinvasion of a susceptible tract with new organisms. Approximately 80% of recurrent infections are due to reinfection.

Symptoms and signs of UTI

The most typical symptoms of UTI are:

- frequency of micturition by day and night
- painful voiding (dysuria)
- suprapubic pain and tenderness
- haematuria
- smelly urine.

These symptoms relate to bladder and urethral inflammation, commonly called 'cystitis', and suggest lower urinary tract infection. Loin pain and tenderness, with fever and systemic upset, suggest extension of the infection to the pelvis and kidney, known as pyelitis or pyelonephritis. However, localization of the site of infection on the basis of symptoms alone is unreliable.

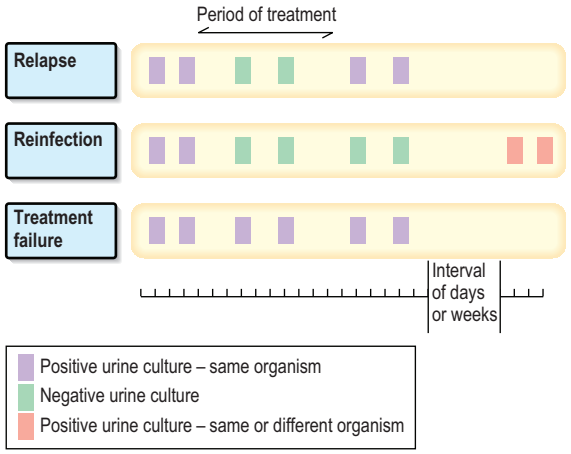

Fig. 11.32 **A comparison of reinfection, relapse and treatment failure in urinary tract infection.**

Ask the authors
www.studentconsult.com

UTI also presents with minimal or no symptoms or may be associated with atypical symptoms such as abdominal pain, fever or haematuria in the absence of frequency or dysuria.

In small children, who cannot complain of dysuria, symptoms are often 'atypical'. The possibility of UTI must always be considered in the fretful, febrile sick child who fails to thrive.

Diagnosis

This is based on quantitative culture of a clean-catch midstream specimen of urine and the presence or absence of pyuria. The criteria for the diagnosis of UTI, particularly in symptomatic women, are shown in Table 11.8. Most Gram-negative organisms reduce nitrates to nitrites and produce a red colour in the reagent square. False-negative results are common. Dipsticks that detect significant pyuria depend on the release of esterases from leucocytes. Dipstick tests positive for both nitrite and leucocyte esterase are highly predictive of acute infection (sensitivity of 75% and specificity of 82%).

Abacteriuric frequency or dysuria ('urethral syndrome')

Causes of truly abacteriuric frequency/dysuria include postcoital bladder trauma, vaginitis, atrophic vaginitis or urethritis in the elderly, and interstitial cystitis (Hunner's ulcer). In symptomatic young women with 'sterile pyuria', *Chlamydia* infection and tuberculosis must be excluded.

Interstitial cystitis is an uncommon but distressing complaint, most often affecting women over the age of 40 years. It presents with frequency, dysuria and often severe suprapubic pain. Urine cultures are sterile. Cystoscopy shows typical inflammatory changes with ulceration of the bladder base. It is commonly thought to be an autoimmune disorder. Various treatments are advocated with variable success. These include oral prednisolone therapy, bladder instillation of sodium cromoglicate or dimethyl sulphoxide and bladder stretching under anaesthesia.

Predominant frequency and passage of small volumes of urine ('irritable bladder') is possibly consequent on previous UTI or conditioned by psychosexual factors. Such patients must be distinguished from those with frequency due to polyuria. Repeated courses of antibiotics in patients with genuine abacteriuric frequency or dysuria are quite inappropriate and detract from identifying the true nature of the problem.

Table 11.8 Criteria for diagnosis of bacteriuria

Symptomatic young women

$\geq 10^2$ coliform organisms/mL urine plus pyuria (>10 WCC/mm^3)

OR

$\geq 10^5$ any pathogenic organism/mL urine

OR

any growth of pathogenic organisms in urine by suprapubic aspiration

Symptomatic men

$\geq 10^3$ pathogenic organisms/mL urine

Asymptomatic patients

$\geq 10^5$ pathogenic organisms/mL urine on two occasions

Special investigations

Uncomplicated UTI usually does not require radiological evaluation unless it is recurrent or affecting males and children or there are unusually severe symptoms. Patients with predisposing conditions such as diabetes mellitus or immunocompromised states benefit from early imaging.

- *Ultrasound* is used in the assessment of patients with suspected pyelonephritis that requires drainage. This allows the detection of calculi, obstruction and also incomplete emptying.
- *CT* is a more sensitive modality for diagnosis and follow-up of complicated renal tract infection. Contrast-enhanced CT allows different phases of excretion to be studied and can define the extent of disease and identify significant complications or obstruction.
- *MRI* is particularly useful in those with iodinated contrast allergies, offering an ionizing radiation-free alternative in the diagnosis of both medical and surgical diseases of the kidney.
- *Nuclear medicine* has a limited role in the evaluation of UTI in adults. Its main role is in the assessment of renal function and detection of scars by DMSA scan, often prior to surgery.

Treatment

Single isolated attack

Pretreatment urine culture is desirable.

- *Antibiotics* for 3–5 days with amoxicillin (250 mg three times daily), nitrofurantoin (50 mg three times daily), trimethoprim (200 mg twice daily) or an oral cephalosporin. The treatment regimen is modified in light of the result of urine culture and sensitivity testing, and/or the clinical response.
- For *resistant organisms* the alternative drugs are co-amoxiclav or ciprofloxacin.
- *Single-shot treatment* with 3 g of amoxicillin or 1.92 g of co-trimoxazole is used for patients with bladder symptoms of less than 36 hours' duration who have no previous history of UTI.
- A high (2 L daily) fluid intake should be encouraged during treatment and for some subsequent weeks. Urine culture should be repeated 5 days after treatment.
- If the patient is acutely ill with high fever, loin pain and tenderness (acute pyelonephritis), antibiotics are given intravenously, e.g. aztreonam, cefuroxime, ciprofloxacin or gentamicin (2–5 mg/kg daily in divided doses), switching to a further 7 days' treatment with oral therapy as symptoms improve. Intravenous fluids may be required to achieve a good urine output.
- In patients presenting for the first time with high fever, loin pain and tenderness, urgent renal ultrasound examination is required to exclude an obstructed pyonephrosis. If this is present it should be drained by percutaneous nephrostomy (p. 580).

Recurrent infection

Pre-treatment and post-treatment urine cultures are necessary to confirm the diagnosis and identify whether recurrent infection is due to relapse or reinfection.

Relapse a search should be made for a cause (e.g. stones or scarred kidneys), and this should be eradicated. Intense or prolonged treatment – intravenous or intramuscular

aminoglycoside for 7 days or oral antibiotics for 4–6 weeks – is required. If this fails, long-term antibiotics are required.

Reinfection implies that the patient has a predisposition to periurethral colonization or poor bladder defence mechanisms. Contraceptive practice should be reviewed and the use of a diaphragm and spermicidal jelly discouraged. Atrophic vaginitis should be identified in postmenopausal women, who should be treated (see below). All patients must undertake prophylactic measures:

- a 2 L daily fluid intake
- voiding at 2- to 3-hour intervals with double micturition if reflux is present
- voiding before bedtime and after intercourse
- avoidance of spermicidal jellies and bubble baths and other chemicals in bathwater
- avoidance of constipation, which may impair bladder emptying.

Evidence of impaired bladder emptying on excretion urography/ultrasound requires urological assessment. If UTI continues to recur, treatment for 6–12 months with low-dose prophylaxis (trimethoprim 100 mg, co-trimoxazole 480 mg, cefalexin 125 mg at night, or macrocrystalline nitrofurantoin) is required; it should be taken last thing at night when urine flow is low. Intravaginal oestrogen therapy has been shown to produce a reduction in the number of episodes of UTI in postmenopausal women. Cranberry juice is said to reduce the risk of symptoms and reinfection by 12–20% but studies are limited.

Urinary infections in the presence of an indwelling catheter

Colonization of the bladder by a urinary pathogen is common after a urinary catheter has been present for more than a few days, partly due to organisms forming biofilms. So long as the bladder catheter is in situ, antibiotic treatment is likely to be ineffective and will encourage the development of resistant organisms. Treatment with antibiotics is indicated only if the patient has symptoms or evidence of infection, and should be accompanied by replacement of the catheter.

Infection by *Candida* is a frequent complication of prolonged bladder catheterization. Treatment should be reserved for patients with evidence of invasive infection or those who are immunosuppressed, and should consist of removal or replacement of the catheter. In severe infections continuous bladder irrigation with amphotericin 50 μg/mL is used.

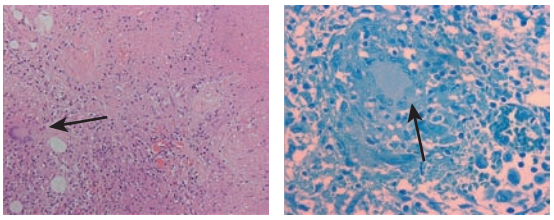
Bacteriuria in pregnancy

The urine of all pregnant women must be cultured as 2–6% have asymptomatic bacteriuria. Whilst asymptomatic bacteriuria in the non-pregnant female seldom leads to acute pyelonephritis and often does not require treatment, acute pyelonephritis frequently occurs in pregnancy under these circumstances. Failure to treat may thus result in severe symptomatic pyelonephritis later in pregnancy, with the possibility of premature labour. Asymptomatic bacteriuria, in the presence of previous renal disease, may predispose to pre-eclamptic toxaemia, anaemia of pregnancy, and small or premature babies. Therefore bacteriuria must always be treated and be shown to be eradicated. Reinfection may require prophylactic therapy. Tetracycline, trimethoprim, sulphonamides and 4-quinolones must be avoided in pregnancy. Amoxicillin and ampicillin, nitrofurantoin and oral cephalosporins may safely be used in pregnancy.

Bacterial prostatitis

Bacterial prostatitis is a relapsing infection which is difficult to treat. It presents as perineal pain, recurrent epididymo-orchitis and prostatic tenderness, with pus in expressed prostatic secretion. Treatment is for 4–6 weeks with drugs that penetrate into the prostate, such as trimethoprim or ciprofloxacin. Long-term low-dose treatment may be required. Prostadynia (prostatic pain in the absence of active infection) may be a very persistent sequel to bacterial prostatitis. Amitriptyline and carbamazepine may alleviate the symptoms.

Renal carbuncle



Renal carbuncle is an abscess in the renal cortex caused by a blood-borne *Staphylococcus*, usually from a boil or carbuncle of the skin. It presents with a high swinging fever, loin pain and tenderness, and fullness in the loin. The urine shows no abnormality as the abscess does not communicate with the renal pelvis, more often extending into the perirenal tissue. Staphylococcal septicaemia is common. Diagnosis is by ultrasound or CT scanning. Treatment involves antibacterial therapy with flucloxacillin and surgical drainage.

Tuberculosis of the urinary tract

Tuberculous infection is on the increase world-wide, partly due to the reservoir of infection in susceptible HIV-infected individuals and the emergence of drug-resistant strains. Tuberculosis of the urinary tract presents with frequency, dysuria or haematuria. In the UK it is mainly seen in the Asian immigrant population. Cortical lesions result from haematogenous spread in the primary phase of infection. Most heal, but in some, infection persists and spreads to the papillae, with the formation of cavitating lesions and the discharge of mycobacteria into the urine. Infection of the ureters and bladder commonly follows, with the potential for the development of ureteral stricture and a contracted bladder. Rarely, cold abscesses may form in the loin. In males the disease may present with testicular or epididymal discomfort and thickening.

Diagnosis depends on constant awareness, especially in patients with sterile pyuria. Imaging may show cavitating lesions in the renal papillary areas, commonly with calcification. There may also be evidence of ureteral obstruction with hydronephrosis. Diagnosis of active infection depends on culture of mycobacteria from early-morning urine samples. Imaging may be normal in diffuse interstitial renal tuberculosis when diagnosis is made by renal biopsy demonstrating caseating granuloma with mutinucleate giant cells and acid-fast bacilli on Ziehl–Neelsen staining (Fig. 11.33). Some patients present with small unobstructed kidneys, when the diagnosis is easy to miss.

Treatment. The treatment is as for pulmonary tuberculosis (see p. 866). Renal ultrasonography and/or CT scanning should be carried out 2–3 months after initiation of treatment as ureteric strictures may first develop in the healing phase.

(a) (b)

Fig 11.33 **Renal tuberculosis. (a)** Caseating granulomatous interstitial nephritis showing multinuclear giant cell (arrow). **(b)** Ziehl–Neelsen staining showing myobacteria (arrow).

Xanthogranulomatous pyelonephritis

This is an uncommon chronic interstitial infection of the kidney, most often due to *Proteus*, in which there is fever, weight loss, loin pain and a palpable enlarged kidney. It is usually unilateral and associated with staghorn calculi. CT scanning shows up intrarenal abscesses as lucent areas within the kidney. Nephrectomy is the treatment of choice; antibacterial treatment rarely, if ever, eradicates the infection.

Malakoplakia

This is a rare condition in which plaques of abnormal inflammatory tissue grow within the urinary tract in the presence of urinary infection. The histological appearances are characteristic. It is thought that the condition is caused by an acquired inability of macrophages to kill phagocytosed bacteria. Muscarinic agonists and ascorbic acid may improve macrophage function; ciprofloxacin penetrates the macrophage well and is the antibiotic of choice. Prolonged treatment is often needed.

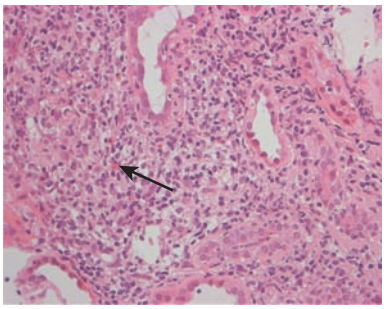

Fig. 11.34 **Tubulointerstitial nephritis showing diffuse interstitial infiltrate with red staining (arrow).**

TUBULOINTERSTITIAL NEPHRITIS (TIN)

Diseases of the kidney primarily affect the glomeruli, vasculature, or the remainder of the renal parenchyma that consists of the tubules and interstitium. Although the tubules and the interstitium are distinct functional entities, they are intimately related. Injury involving one of them invariably results in damage to the other.

Acute tubulointerstitial nephritis (TIN)

In approximately 70% of the cases, acute TIN is due to a hypersensitivity reaction to drugs (Table 11.9), most commonly drugs of the penicillin family and non-steroidal anti-inflammatory drugs (NSAIDs).

Drug induced acute TIN. Patients present with fever, arthralgia, skin rashes and acute oliguric or non-oliguric renal failure. Many have eosinophilia and eosinophiluria. Renal histology shows an intense interstitial cellular infiltrate, often including eosinophils, with variable tubular necrosis (Fig. 11.34). Rarely, NSAIDs can cause a glomerular minimal-change lesion in addition to TIN and present as the nephrotic syndrome. Treatment involves withdrawal of offending drugs. High-dose steroid therapy (prednisolone 60 mg daily) is commonly given but its efficacy has not been proven. Patients may require dialysis for management of the acute kidney injury. Most patients make a good recovery in kidney function, but some may be left with significant interstitial fibrosis and a persistent high serum creatinine.

Infection causing acute TIN. Acute pyelonephritis leads to inflammation of the tubules, producing a neutrophilic cellular infiltrate. TIN can complicate systemic infections with viruses (hantavirus, Epstein–Barr virus, HIV, measles, adenovirus), bacteria (*Legionella, Leptospira*, streptococci, *Mycoplasma, Brucella, Chlamydia*) and others (*Leishmania, Toxoplasma*). Hantavirus causes haemorrhagic fever with TIN and can be fatal. Epstein–Barr virus DNA has been found in renal biopsy tissue of cases of idiopathic TIN. In immunocompromised patients such as post-renal transplantation, CMV, polyoma, and HSV can cause acute TIN in the renal graft. Treatment involves eradication of infection by appropriate antibiotics or antiviral agents.

Acute TIN as part of multisystem inflammatory diseases. Several non-infectious inflammatory disorders such as Sjögren's syndrome, SLE and Wegener's granulomatosis can cause acute or chronic TIN rather than glomerulonephritis. Sjögren's syndrome may additionally present as renal tubular acidosis. Sarcoidosis presents as granulomatous TIN in up to 20% of patients. Associated hypercalcaemia causes acute kidney injury. These heterogeneous conditions with TIN generally respond to steroids.

TINU syndrome. In this syndrome, uveitis generally coincides with acute TIN. It is common in childhood, but has been reported in adulthood. Among adults it is more common in females, but its cause remains unknown. Patients present with weight loss, anaemia and raised ESR. A prolonged course of steroids leads to improvement in both renal function and uveitis.

Chronic tubulointerstitial nephritis

The major causes of chronic tubulointerstitial nephritis are given in Table 11.10. It is characterized by generalized chronic inflammatory cellular infiltation of the interstitium with tubular atrophy and generalized interstitial oedema or fibrosis. In many cases no cause is found. Chronic TIN changes evolve into progressive primary glomerular or vascular disease of the kidney, where its severity is a better predictor of long-term renal survival than the primary site of insult.

The patient usually presents with either polyuria and nocturia, or is found to have proteinuria or uraemia. Proteinuria is usually slight (less than 1 g daily). Papillary necrosis with ischaemic damage to the papillae occurs in a number of tubulointerstitial nephritides, for example in analgesic abuse, diabetes mellitus, sickle cell disease or trait. The papillae can separate and be passed in the urine. Microscopic or overt haematuria or sterile pyuria also occurs, and occasionally a sloughed papilla may cause ureteric colic or produce acute ureteric obstruction. The radiological appearances must be distinguished from those of reflux nephropathy (Fig. 11.35) or obstructive uropathy which is usually accompanied by tubular dilatation and atrophy and intense interstitial fibrosis with patchy inflammatory cellular infiltrate in the scarred areas.

Tubular damage to the medullary area of the kidney leads to defects in urine concentration and sodium conservation with polyuria and salt wasting. Fibrosis progressing into the cortex leads to loss of excretory function and uraemia.

†Acute tubulointerstitial nephritis

Analgesic nephropathy

The chronic consumption of large amounts of analgesics (especially those containing phenacetin) and NSAIDs leads to chronic tubulointerstitial nephritis and papillary necrosis. Analgesic nephropathy is twice as common in women as in men and presents typically in middle age. Patients are often depressed or neurotic. Presentation may be with anaemia, chronic kidney disease, UTIs, haematuria or urinary tract obstruction (owing to sloughing of a renal papilla). Salt and water-wasting renal disease may occur. Chronic analgesic abuse also predisposes to the development of uroepithelial tumours. Diagnosis is usually made on clinical grounds combined with the non-pathognomonic appearance on imaging (such as ultrasonography or CT scan), which demonstrates smallish irregularly outlined kidneys.

The consumption of the above analgesics should be discouraged. If necessary, dihydrocodeine or paracetamol is a reasonable alternative. This may result in the arrest of the

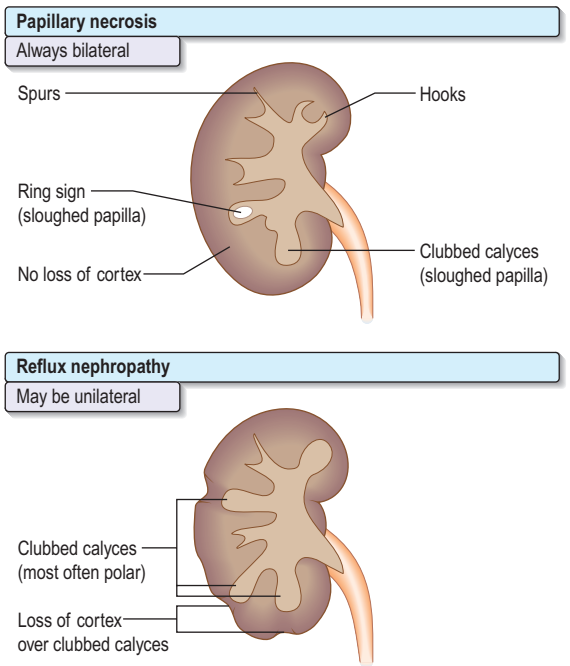

Fig. 11.35 **A comparison of radiological appearances of papillary necrosis and reflux nephropathy.**

disease and even in improvement in function. UTI, hypertension (if present) and saline depletion will require appropriate management. The development of flank pain or an unexpectedly rapid deterioration in renal function should prompt ultrasonography to screen for urinary tract obstruction due to a sloughed papilla.

Chinese herb nephropathy

Chinese herbal medicines have been increasingly used in the West, e.g. for slimming, and have caused a nephropathy. The renal histology is similar to Balkan nephropathy but the clinical course is very aggressive. The causal agent has been identified as aristolochic acid produced as a result of fungal contamination of the herbal medicine. It is characterized by relentless progression to end-stage renal failure. There is a high incidence of uroepithelial tumours.

Balkan nephropathy (BN)

This is a chronic TIN endemic in areas along the tributaries of the River Danube. Inhabitants of the low-lying plains, which are subjected to frequent flooding and where the water supply comes from shallow wells, are affected, whereas the disease does not occur in hillside villages where surface water provides the water supply. Its cause was essentially unknown. However, new research suggests that chronic dietary poisoning by aristolochic acid (AA) is responsible for BN and its associated urothelial cancer. AA-DNA adduct is found in tissue biopsies both from BN and associated urothelial cancers. This research suggests that AA is the environmental agent responsible for BN and its attendant transitional-cell cancer. The disease is insidious in onset, with mild proteinuria progressing to renal failure in 3 months to 10 years. There is no treatment.

Appel GB. The treatment of acute interstitial nephritis: More data at last. *Kidney International* 2008; **73**(8): 905–907.

Other forms of chronic tubulointerstitial nephritis

These are rare (see Table 11.10). Diagnosis of all forms depends on a history of drug ingestion or industrial exposure to nephrotoxins. In patients with unexplained renal impairment with normal-sized kidneys, renal biopsy must always be undertaken to exclude a treatable tubulointerstitial nephritis such as granulomatous TIN due to *renal sarcoidosis* (Fig. 11.36), which may be the first presentation of sarcoidosis (see p. 868). Renal sarcoidosis generally responds rapidly to steroids.

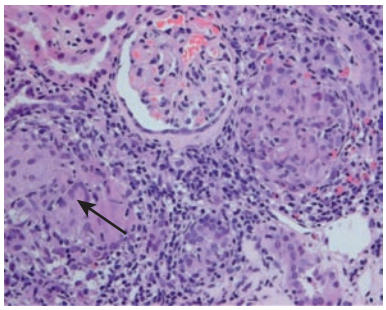

Fig. 11.36 **Granulomatous tubulointerstitial nephritis**. The granuloma consists of both giant cells (arrow) and epithelioid cells. These findings are characteristic of *renal sarcoid* but can be seen with any cause (drug or infection) of interstitial nephritis.

HYPERURICAEMIC NEPHROPATHY

(see p. 536)

Acute hyperuricaemic nephropathy is a well-recognized cause of acute kidney injury in patients with marked hyperuricaemia that is usually due to lymphoproliferative or myeloproliferative disorders. It may occur prior to treatment but most often follows commencement of treatment, when there is rapid lysis of malignant cells, release of large amounts of nucleoprotein and increased uric acid production. Renal failure is due to intrarenal and extrarenal obstruction caused by deposition of uric acid crystals in the collecting ducts, pelvis and ureters. The condition is manifest as oliguria or anuria with increasing uraemia. There may be flank pain or colic. Plasma urate levels are above 0.75 mmol/L and may be as high as 4.5 mmol/L. *Diagnosis* is based on the hyperuricaemia and the clinical setting. Ultrasound may demonstrate extrarenal obstruction due to stones, but a negative scan does not exclude this where there is coexistent intrarenal obstruction.

Allopurinol 100–200 mg three times daily for 5 days is given prior to and throughout treatment with radiotherapy or cytotoxic drugs. A high rate of urine flow must be maintained by oral or parenteral fluid and the urine kept alkaline by the administration of sodium bicarbonate 600 mg four times daily and acetazolamide 250 mg three times daily, since uric acid is more soluble in an alkaline than in an acid medium. *Rasburicase*, a recombinant urate oxidase, (p. 458) is occasionally used. In severely oliguric or anuric patients, dialysis is required to lower the plasma urate.

There is no convincing evidence for *chronic hyperuricaemia nephropathy*.

HYPERTENSION AND THE KIDNEY

Hypertension can be the cause or the result of renal disease. It is often difficult to differentiate between the two on clinical grounds. Routine tests as described on page 802 should be performed on all hypertensive patients, but renal imaging is usually unnecessary. A guide to how patients should be fully investigated is given on page 1022.

The *mechanisms* responsible for the normal regulation of arterial blood pressure and the development of essential primary hypertension are unclear (p. 798). One basic concept is that the long-term regulation of arterial pressure is closely linked to the ability of the kidneys to excrete sufficient salt to maintain normal sodium balance, extracellular fluid volume, and normal blood volume at normotensive arterial pressures. Several studies point to the kidney being involved in the genesis of essential primary hypertension. Cross-transplantation experiments suggest that hypertension travels with the kidney, in that hypertension will develop in a normotensive recipient of a kidney genetically programmed for hypertension. Likewise patients with end-stage renal failure due to hypertension become normotensive after receiving a renal allograft from normotensive donors, provided the new kidney works.

One of many renal factors involved in the genesis of hypertension is the total number of nephrons in the kidney. There is circumstantial as well direct evidence to suggest that patients with hypertension and normal renal function have a significantly reduced number of nephrons in each

kidney alongside enlargement of the remaining glomeruli due to glomerular hyperfiltration. Moreover, certain races (blacks, Hispanics) with predilection for hypertension have increased glomerular volume, a surrogate marker for a reduced number of nephrons.

Whether the reduced number of nephrons is caused by genetic or environmental factors is unclear. Changes in the intrauterine environment may lead to retarded renal growth before birth and low birth weight and hypertension during adult life. In humans, an association has been found between low birth weight and reduced renal volume, possibly indicating reduced numbers of nephrons.

Essential hypertension

Pathophysiology

In benign essential hypertension, arteriosclerosis of major renal arteries and changes in the intrarenal vasculature (nephrosclerosis) occur as follows:

- In small vessels and arterioles, intimal thickening with reduplication of the internal elastic lamina occurs and the vessel wall becomes hyalinized.
- In large vessels, concentric reduplication of the internal elastic lamina and endothelial proliferation produce an 'onion skin' appearance.
- Reduction in size of both kidneys occurs; this may be asymmetrical if one major renal artery is more affected than the other.
- The proportion of sclerotic glomeruli is increased compared with age-matched controls.

Deterioration in excretory function accompanies these changes, but severe renal failure is unusual in whites (1 in 10 000). In black Africans, by contrast, hypertension much more often results in the development of renal failure with a fourfold higher incidence of end-stage renal failure in blacks compared to whites. This racial difference in incidence of hypertensive renal disease may be due to overestimation of diagnosis on clinical grounds, poor compliance with medication, higher incidence of hypertension, which is usually a salt-sensitive type, and reduced number of nephrons.

In *accelerated, or malignant-phase hypertension*:

- Arteriolar fibrinoid necrosis occurs, probably as a result of plasma entering the media of the vessel through splits in the intima. It is prominent in afferent glomerular arterioles.
- Fibrin deposition within small vessels is often associated with thrombocytopenia and red-cell fragmentation seen in the peripheral blood film (microangiopathic haemolytic anaemia).

Microscopic haematuria, proteinuria, usually of modest degree (1–3 g daily), and progressive uraemia occur. If untreated, fewer than 10% of patients survive 2 years.

Management

The management of benign essential and malignant hypertension is described on page 802.

If treatment is begun before renal impairment has occurred, the prognosis for renal function is good. Stabilization or improvement in renal function with healing of intrarenal arteriolar lesions and resolution of microangiopathic haemolysis occur with effective treatment of malignant-phase hypertension. Lifelong follow-up of the patient is mandatory. In blacks with hypertensive nephrosclerosis and renal impairment, a blood pressure target of <140/85 mmHg should be achieved. ACE inhibitors appear to be more effective than beta-blockers, and, if possible, calcium-channel blockers of the dihydropyridine group (e.g. amlodipine) should be avoided as they have a negative intropic effect and can cause heart failure.

Renal hypertension

Hypertension commonly complicates bilateral renal disease such as chronic glomerulonephritis, bilateral reflux nephropathy, polycystic disease and analgesic nephropathy. Two main mechanisms are responsible:

- activation of the renin–angiotensin–aldosterone system
- retention of salt and water owing to impairment in excretory function, leading to an increase in blood volume and hence blood pressure.

The second of these assumes greater significance as renal function deteriorates.

Hypertension occurs earlier, is more common and tends to be more severe in patients with renal cortical disorders, such as glomerulonephritis, than in those with disorders affecting primarily the renal interstitium, such as reflux or analgesic nephropathy.

Management is described on page 802. Meticulous control of the blood pressure is necessary to prevent further deterioration of renal function secondary to vascular changes produced by the hypertension itself. There is good evidence that ACE-inhibitor drug treatment confers an additional renoprotective effect for a given degree of blood pressure control than other hypotensive drugs.

Renovascular disease

Mechanism of hypertension

Renal ischaemia results in a reduction in the pressure in afferent glomerular arterioles. This leads to an increase in the production and release of renin from the juxtaglomerular apparatus (see p. 572) with a consequent increase in angiotensin II, a very potent vasoconstrictor. Angiotensin II also causes hypertension by upregulating NADPH oxidase enzyme with excessive superoxide generation. Superoxide chelates nitric oxide (a potent vasodilator) resulting in reduced vasodilator activity and also hypertension.

Physiological changes in renal artery stenosis

In renal artery stenosis, renal perfusion pressure is reduced and nephron transit time is prolonged on the side of the stenosis; salt and water reabsorption is therefore increased. As a result, urine from the ischaemic kidney is more concentrated and has a lower sodium concentration than urine from the contralateral kidney. Creatinine clearance is decreased on the ischaemic side.

Pathology

Narrowing of the renal arteries (renal artery stenosis) is caused by one of two pathological entities: *fibromuscular disease* or *atherosclerotic renovascular disease (ARVD).*

Fibromuscular disease of the renal arteries

Fibromuscular disease accounts for 20–40% of renal vascular disease and encompasses *four distinct types*: **(1)** medial fibroplasia (65–85%); **(2)** perimedial fibroplasia (10–15%); **(3)** intimal fibroplasia (5–10%); and **(4)** medial hyperplasia (5%). Medial fibroplasia usually follows a benign course and never follows a progressive course after the age of 40 years. The other two types of fibroplasia follow a progressive course and may lead to total occlusion.

Medial hyperplasia is a distinct but rare entity, which accounts for only 1% of renovascular disease. It commonly affects young females, who exhibit elevated blood pressures but with well-preserved renal function.

MR angiography (gadolinium enhanced) reveals a characteristic string of beads appearance in fibroplasia. Angioplasty (occasionally stent insertion) is usually successful in improving or even curing hypertension in affected individuals, and overall prognosis is very good.

Atherosclerotic renovascular disease (ARVD)

This is a common cause of hypertension and chronic kidney disease due to ischaemic nephropathy. Its incidence increases with age, rising from 5% under 60 years to 16% in those over 60 years old. In most patients the atherosclerotic lesion is ostial (within 1 cm of the origin of the renal artery) and usually associated with symptomatic atherosclerotic vascular disease elsewhere. Patients with peripheral vascular disease (39%), coronary artery disease (10–29%), congestive cardiac failure (34%) and aortic aneurysm (38%) are at high risk of developing significant renal artery stenosis.

Many patients are asymptomatic and are discovered incidentally during investigation for other conditions. Aortography experience from the USA shows 11% of asymptomatic patients have significant unilateral stenosis and 4% have bilateral disease. The renal consequences of ARVD are functional, such as hypertension (present in 50%), sodium retention (ankle and flash pulmonary oedema), proteinuria (usually sub-nephrotic range) and decreased GFR. The morphological features of the affected kidneys include vascular sclerosis, tubular atrophy, interstitial fibrosis with inflammatory cellular infiltrate, atubular glomeruli, cholesterol emboli, and secondary focal segmental glomerulosclerosis (FSGS) changes. Baseline renal function is related to the extent of renal parenchymal injury rather than to the degree of stenosis, as is the response (improvement in hypertension and renal function) to revascularization.

Renovascular disease should be looked for in patients with hypertension and/or chronic kidney disease; patients with abdominal audible bruits, as well as bruits over carotid arteries suggestive of generalized arterial disease; doppler ultrasonography showing >1.5 cm renal asymmetry; recurrent flash pulmonary oedema without cardiopulmonary disease; progressive chronic renal failure in patients with evidence of generalized atherosclerosis.

Treatment

The *aim of treatment* is to correct hypertension and improve renal perfusion and excretory function. Renal artery stenosis can progress to occlusion, particularly in patients with stenosis >75% as shown by serial angiography, necessitating revascularization in ARVD.

- The *options in renal artery stenosis* include transluminal angioplasty to dilate the stenotic region, insertion of stents across the stenosis (sometimes the only endoscopic option when the stenosis occurs close to the origin of the renal artery from the aorta, rendering angioplasty technically difficult or impossible), reconstructive vascular surgery and nephrectomy.
- *Indications for revascularization*. Vessels with stenosis >75% and recurrent flash pulmonary oedema, drug resistant severe hypertension, ARVD affecting solitary functioning kidney, patients with cardiac failure needing ACE inhibitors, unexplained progressive renal failure and dialysis-dependent renal failure. With good selection of patients, hypertension is cured or improved by intervention in more than 50%. Occasional dramatic improvements in renal function ensue but results are generally disappointing.
- *Medication*. All patients with ARVD should be treated with a combination of aspirin, statins and optimal control of blood pressure as prophylaxis against progression of atherosclerosis.

Prognosis. Mortality is high because of other associated comorbidities, and ARVD patients have generalized endothelial dysfunction. ARVD patients with end-stage renal failure have higher rates than those with good renal function. Five-year survival is only 18% in patients with end-stage renal failure due to ARVD.

Screening for renovascular disease

Radionuclide studies (see p. 581). These can demonstrate decreased renal perfusion on the affected side. In unilateral renal artery stenosis, a disproportionate fall in uptake of isotope on the affected side following administration of captopril or aspirin is suggestive of the presence of significant renal artery stenosis. A completely normal result renders the diagnosis unlikely.

Doppler ultrasound. This method is very sensitive but highly operator-dependent and time-consuming. It generates data about intrarenal vascular resistance, which can be valuable in predicting the success of revascularization procedures. A resistive index of ≥80 is a predictor of poor response following intervention.

Magnetic resonance angiography. MRA can be used to visualize the renal arteries and there is a good – though not perfect – correlation between MRA findings and those of renal arteriography.

Helical ('spiral') CT scanning. This permits non-invasive imaging of the renal arteries. It is much less expensive than MRA but does expose the patient to ionizing radiation and to contrast injection and is less reliable than MRA.

Renal arteriography (see p. 581) remains the 'gold standard' investigation in the diagnosis of renal arterial disease.

Systemic sclerosis (see also p. 545)

Interlobular renal arteries are affected with intimal thickening, and fibrinoid changes occur in afferent glomerular arterioles similar to renal changes in malignant hypertension. Glomerular changes are non-specific. The pathogenesis is unknown and neither steroid nor immunosuppressive therapy is of

value. Serum ANCAs are not present. Treatment with ACE-inhibitor drugs is of immense benefit, reducing proteinuria and often halting or even partially reversing decline in renal function. 'Scleroderma renal crisis' is a term applied to rapid loss of renal function owing to rapid progression of renal microvascular disease in this condition. Early aggressive therapy with ACE inhibitors/blockers and continuous intravenous infusion of prostacyclin may help.

Prognosis. Fifty per cent will require renal dialysis which may be just temporary. Function can improve over 2 years. ACE inhibitors should be continued. Renal transplantation is sometimes required.

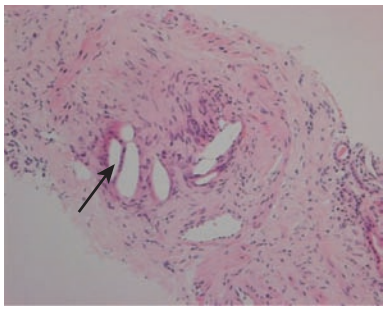

Fig 11.37 **Renal cholesterol emboli showing the characteristic cholesterol biconvex clefts.**

OTHER VASCULAR DISORDERS OF THE KIDNEY

Renal artery occlusion

This occurs from thrombosis in situ, usually in a severely damaged atherosclerotic vessel, or more commonly from embolization, e.g. in atrial fibrillation. Both lead to renal infarction, resulting in a wide spectrum of clinical manifestations depending on the size of the artery involved. Occlusion of a small branch artery may produce no effect, but occlusion of larger vessels results in dull flank pain and varying degrees of renal failure.

Intra-arterial thrombolytic therapy has been tried with mixed results.

Cholesterol embolization or atheroembolic renal disease (AERD)

Showers of cholesterol-rich atheromatous material from ulcerated plaques reach the kidney from the aorta and/or renal arteries, particularly after catheterization of the abdominal aorta or attempts at renal artery angioplasty. Anticoagulants and thrombolytic agents also precipitate cholesterol embolization. Renal failure from cholesterol emboli may be acute or slowly progressive. Clinical features include fever, eosinophilia, back and abdominal pain, and evidence of embolization elsewhere, for example to the retina or digits. The diagnosis can be confirmed by renal biopsy (Fig. 11.37). It is more common in males, the elderly (>70 years) and patients with cardiovascular disease. Over 80% have abnormal renal function at baseline. AERD occurs spontaneously in 25% of the cases. Two-year mortality is 30% and a similar percentage of patients develop chronic kidney disease. Baseline co-morbidities, i.e. reduced renal function, presence of diabetes, history of heart failure, acute/subacute presentation, and gastrointestinal tract involvement, are significant predictors of event occurrence. The risk of dialysis and death is 50% lower among those receiving statins.

Renal vein thrombosis

This is usually of insidious onset, occurring in patients with the nephrotic syndrome, with a renal cell carcinoma, and in thrombophilia (p. 437) with an increased risk of venous thrombosis. Anticoagulation is indicated.

RENAL CALCULI AND NEPHROCALCINOSIS

Renal and vesical calculi

Renal stones are very common world-wide with a lifetime risk of about 10%. Prevalence of stone disease is much higher in the Middle East. Most stones occur in the upper urinary tract.

Most stones are composed of calcium oxalate and phosphate; these are more common in men (Table 11.11). Mixed infective stones, which account for about 15% of all calculi, are twice as common in women as in men. The overall male to female ratio of stone disease is 2:1.

Stone disease is frequently a recurrent problem. More than 50% of patients with a history of nephrolithiasis will develop a recurrence within 10 years. The risk of recurrence increases if a metabolic or other abnormality predisposing to stone formation is present and is not modified by treatment.

Aetiology

Inhibitors of crystal formation are present in normal urine preventing the formation of stones, as the concentrations of stone-forming substances in many cases exceed their maximum solubility in water. Many stone-formers have no detectable metabolic defect, although microscopy of warm, freshly passed urine reveals both more and larger calcium oxalate crystals than are found in normal subjects. Factors predisposing to stone formation in these so-called 'idiopathic stone-formers' are:

Table 11.11 Type and frequency of renal stones in the UK

Type of renal stone	Percentage of stones
Calcium oxalate usually with calcium phosphate	65
Calcium phosphate alone	15
Magnesium ammonium phosphate (struvite)	10–15
Uric acid	3–5
Cystine	1–2

- Chemical composition of urine that favours stone crystallization.
- Production of a concentrated urine as a consequence of dehydration associated with life in a hot climate or work in a hot environment.
- Impairment of inhibitors that prevent crystallization in normal urine. Postulated inhibitors include inorganic magnesium, pyrophosphate and citrate. Organic inhibitors include glycosaminoglycans and nephrocalcin (an acidic protein of tubular origin). Tamm–Horsfall protein may have a dual role in both inhibiting and promoting stone formation.

Recognized causes of stone formation are listed in Table 11.12.

Hypercalcaemia

If the GFR is normal, hypercalcaemia almost invariably leads to hypercalciuria. The common causes of hypercalcaemia leading to stone formation are:

- primary hyperparathyroidism
- vitamin D ingestion
- sarcoidosis.

Of these, primary hyperparathyroidism (see p. 1019) is the most common cause of stones.

Hypercalciuria

This is by far the most common metabolic abnormality detected in calcium stone-formers.

Approximately 8% of men excrete in excess of 7.5 mmol of calcium in 24 hours. Calcium stone formation is more common in this group, but as the majority of even these individuals do not form stones the definition of 'pathological' hypercalciuria is arbitrary. A reasonable definition is 24-hour calcium excretion of more than 7.5 mmol in male stone-formers and more than 6.25 mmol in female stone-formers.

The kidney is the major site for plasma calcium regulation. Approximately 90% of the ionized calcium filtered by the kidney is reabsorbed. Renal tubular reabsorption is controlled largely by parathyroid hormone (PTH).

Approximately 65% of the filtered calcium is absorbed in the proximal convoluted tubule, 20% by the thick ascending limb of the loop of Henle, and 15% by the distal convoluted tubule and collecting ducts.

Causes of hypercalciuria are:

Table 11.12 Causes of urinary tract stone formation

Dehydration
Hypercalcaemia
Hypercalciuria
Hyperoxaluria
Hyperuricaemia and hyperuricosuria
Infection
Cystinuria
Renal tubular acidosis
Primary renal disease (polycystic kidneys, medullary sponge kidneys)
Drugs (see text)

- hypercalcaemia
- an excessive dietary intake of calcium
- excessive resorption of calcium from the skeleton, such as occurs with prolonged immobilization or weightlessness
- idiopathic hypercalciuria.

Idiopathic hypercalciuria is a common risk factor for the formation of stones, and uncontrolled hypercalciuria is a cause of recurrences. The majority of patients with idiopathic hypercalciuria have increased absorption of calcium from the gut. Moreover, studies have shown that animal protein and salt also have a considerable influence on calcium excretion.

Hyperoxaluria

There are two inborn errors of glyoxalate metabolism that cause increased endogenous oxalate biosynthesis, and are inherited in an autosomal recessive manner. In both types, calcium oxalate stone formation occurs.

The prognosis is poor owing to widespread calcium oxalate crystal deposition in the kidneys. Renal failure typically develops in the late teens or early twenties. Successful liver transplantation has been shown to cure the metabolic defect.

Much more common causes of mild hyperoxaluria are:

- excess ingestion of foodstuffs high in oxalate, such as spinach, rhubarb and tea
- dietary calcium restriction, with compensatory increased absorption of oxalate
- gastrointestinal disease (e.g. Crohn's), usually with an intestinal resection, associated with increased absorption of oxalate from the colon.

Dehydration secondary to fluid loss from the gut also plays a part in stone formation.

Hyperuricaemia and hyperuricosuria

Uric acid stones account for 3–5% of all stones in the UK, but in Israel the proportion is as high as 40%. Uric acid is the end-point of purine metabolism. Hyperuricaemia (see p. 537) can occur as a primary defect in idiopathic gout, and as a secondary consequence of increased cell turnover, for example in myeloproliferative disorders. Increased uric acid excretion occurs in these conditions, and stones will develop in some patients. Some uric acid stone-formers have hyperuricosuria (>4 mmol per 24 hours on a low-purine diet) without hyperuricaemia.

Dehydration alone may also cause uric acid stones to form. Patients with ileostomies are at particular risk both from dehydration and from the fact that loss of bicarbonate from gastrointestinal secretions results in the production of an acid urine (uric acid is more soluble in an alkaline than in an acid medium).

Some patients with calcium stones also have hyperuricaemia and/or hyperuricosuria; it is believed the calcium salts precipitate upon an initial nidus of uric acid in such patients.

Urinary tract infection

Mixed infective stones are composed of magnesium ammonium phosphate together with variable amounts of calcium. Such struvite stones are often large, forming a cast of the

collecting system (staghorn calculus). These stones are usually due to UTI with organisms such as *Proteus mirabilis* that hydrolyse urea, with formation of the strong base ammonium hydroxide. The availability of ammonium ions and the alkalinity of the urine favour stone formation. An increased production of mucoprotein from infection also creates an organic matrix on which stone formation can occur.

Cystinuria (see also p. 1070)

Cystinuria results in the formation of cystine stones. About 1–2% of all stones are composed of cystine.

Primary renal diseases

- *Polycystic renal disease* (see p. 642) shows a high prevalence of stone disease.
- *Medullary sponge kidney* is also associated with stones. There is dilatation of the collecting ducts with associated stasis and calcification (Fig. 11.38). Approximately 20% of these patients have hypercalciuria and a similar proportion have a renal tubular acidification defect.
- *Renal tubular acidoses,* both inherited and acquired, are associated with nephrocalcinosis and stone formation, owing, in part, to the production of a persistently alkaline urine and reduced urinary citrate excretion.

Drugs

Some drugs promote calcium stone formation (e.g. loop diuretics, antacids, glucocorticoids, theophylline, vitamins D and C, acetazolamide); some promote uric acid stones (e.g. thiazides, salicylates,); and some precipitate into stones (e.g. indinavir, triamterene, sulphadiazine).

Aetiology of bladder stones

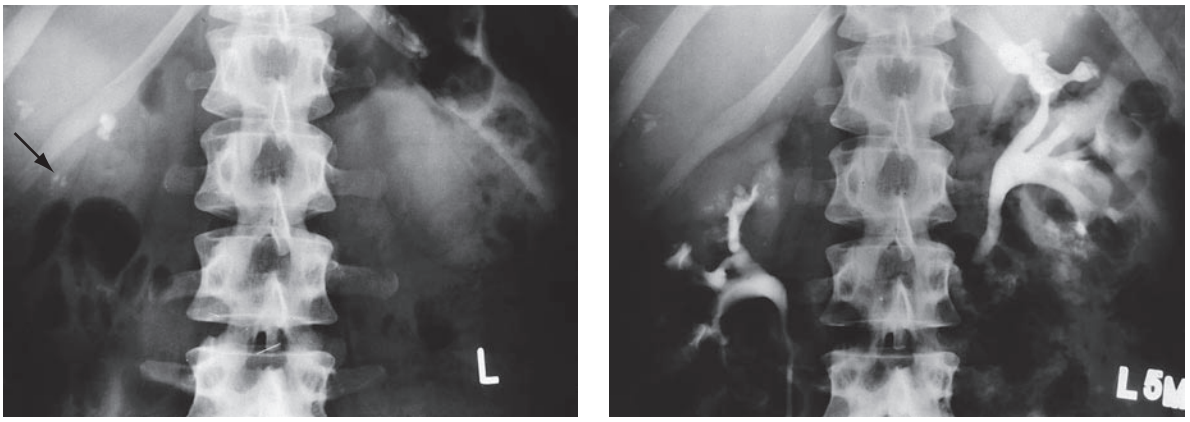
Bladder stones are endemic in some developing countries but the incidence is declining. The cause of this is unknown but dietary factors probably play a role. Bladder stones may be the result of:

- bladder outflow obstruction (e.g. urethral stricture, neuropathic bladder, prostatic obstruction)
- the presence of a foreign body (e.g. catheters, non-absorbable sutures).

Significant bacteriuria is usually found in patients with bladder stones. Some stones found in the bladder have been passed down from the upper urinary tract.

Pathology

Stones may be single or multiple and vary enormously in size from minute, sand-like particles to staghorn calculi or large stone concretions in the bladder. They may be located within the renal parenchyma or within the collecting system. Pressure necrosis from a large calculus can cause direct damage to the renal parenchyma, and stones regularly cause obstruction, leading to hydronephrosis. They may ulcerate through the wall of the collecting system, including the ureter. A combination of obstruction and infection accelerates damage to the kidney.



Clinical features

Most people with urinary tract calculi are asymptomatic. Pain is the most common symptom and may be sharp or dull, constant, intermittent or colicky (Table 11.13).

When urinary tract obstruction is present, measures that increase urine volume, such as copious fluid intake or diuretics, including alcohol, make the pain worse. Physical exertion may cause mobile calculi to move, precipitating pain and, occasionally, haematuria. Ureteric colic occurs when a stone enters the ureter and either obstructs it or causes spasm during its passage down the ureter. This is one of the most severe pains known. Radiation from the flank to the iliac fossa and testis or labium in the distribution of the first lumbar nerve root is common. Pallor, sweating and vomiting often occur and the patient is restless, tending to assume a variety of positions in an unsuccessful attempt to obtain relief

Table 11.13 Clinical features of urinary tract stones

Asymptomatic
Pain: renal colic
Haematuria
Urinary tract infection
Urinary tract obstruction

(a) (b)

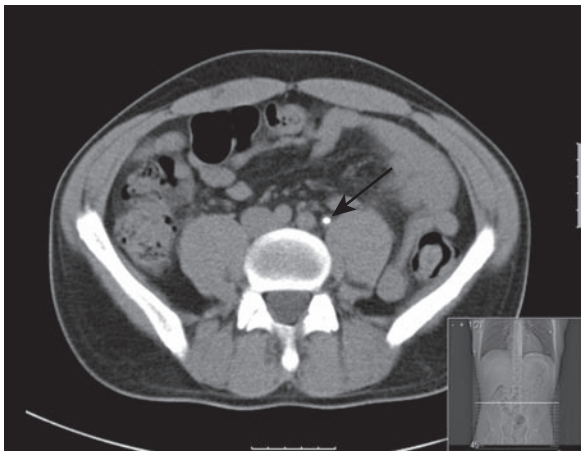
Fig. 11.38 **Medullary sponge kidney. (a)** Plain film showing 'spotty' calcification in the renal areas (arrow). **(b)** After injection of contrast, the calcification is shown to be small calculi in the papillary zones.

from the pain. Haematuria often occurs. Untreated, the pain of ureteric colic typically subsides after a few hours.

When urinary tract obstruction and infection are present, the features of acute pyelonephritis or of a Gram-negative septicaemia may dominate the clinical picture.

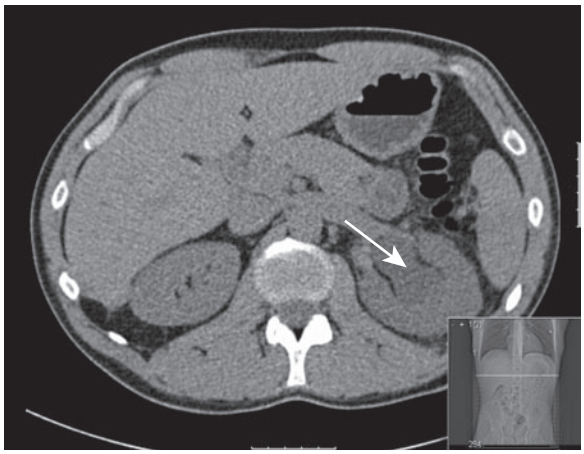
Vesical calculi associated with bladder bacteriuria present with frequency, dysuria and haematuria; severe introital or perineal pain may occur if trigonitis is present. A calculus at the bladder neck or an obstruction in the urethra may cause bladder outflow obstruction, resulting in anuria and painful bladder distension.

A history of possible aetiological factors should be obtained, including:



- occupation and residence in hot countries likely to be associated with dehydration
- a history of vitamin D consumption
- gouty arthritis.

Calcified papillae may mimic ordinary calculi, so that causes of papillary necrosis such as analgesic abuse should be considered.



Physical examination should include a search for corneal or conjunctival calcification, gouty tophi and arthritis and features of sarcoidosis.

Investigations

- A *mid-stream specimen of urine* for culture
- Serum urea, electrolyte, creatinine and calcium levels.
- *Plain abdominal X-ray*.
- Unenhanced helical (spiral) CT is the best diagnostic test available. Ureteric stones can be missed by ultrasound.
- CT-KUB (CT of kidney, ureter and bladder) is carried out during the episode of pain; a normal CT excludes the diagnosis of pain due to calculous disease. The CT-KUB appearances in a patient with acute left ureteric obstruction are shown in Figure 11.39 a and b.

(a) Left ureteric calculus.

(b) A dilated renal pelvis (arrow) proximal to the ureteric stone in (a).

Fig. 11.39 **CT-KUB in ureteric stone obstruction.**

Pure uric acid stones are radiolucent and show as a filling defect after injection of contrast medium if excretion urography is performed. Such stones are readily seen on CT scanning (Fig. 11.40). Mixed infective stones in which organic matrix predominates are barely radiopaque.

The urine of the patient should be passed through a sieve to trap any calculi for chemical analysis.

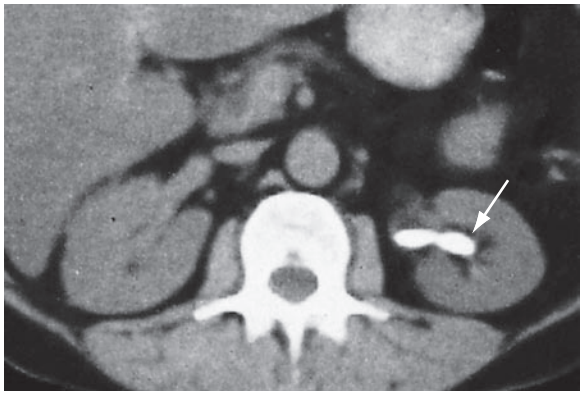


Fig. 11.40 **CT scan, showing a uric acid stone, which appears as a bright lesion in the left kidney (arrow).**

Management

Adequate analgesia should be given. An NSAID, e.g. diclofenac 75 mg by i.v. infusion, compares favourably with pethidine and does not cause nausea. Stones less than 0.5 cm diameter usually pass spontaneously. Stones greater than 1 cm diameter usually require urological or radiological intervention. Extracorporeal shock wave lithotripsy (ESWL) will fragment most stones, which then pass spontaneously. Ureteroscopy with a Yag laser can be used for larger stones. Percutaneous nephrolithotomy is also used. Open surgery is rarely needed.

Investigating the cause of stone formation

In an elderly patient who has had a single episode with one stone, only limited investigation is required. Younger patients and those with recurrent stone formation require detailed investigation.

- **Renal imaging** is necessary to define the presence of a primary renal disease predisposing to stone formation.
- **Significant bacteriuria** may indicate mixed infective stone formation, but relapsing bacteriuria may be a consequence of stone formation rather than the original cause.

- **Chemical analysis** of any stone passed is of great value and all that is required in the diagnosis of cystinuria or uric acid stone formation.
- **Serum calcium concentration** should be estimated and corrected for serum albumin concentration (see p. 593). Hypercalcaemia, if present, should be investigated further (see p. 1021).
- **Serum urate concentration** is often, but not invariably, elevated in uric acid stone-formers.
- A **screening test for cystinuria** should be carried out by adding sodium nitroprusside to a random unacidified urine sample; a purple colour indicates that cystinuria may be present. Urine chromatography is required to define the diagnosis precisely.
- **Urinary calcium, oxalate and uric acid output** should be measured in two consecutive carefully collected 24-hour urine samples. After withdrawing aliquots for estimation of uric acid, it is necessary to add acid to the urine in order to prevent crystallization of calcium salts upon the walls of the collection vessel, which would give falsely low results for urinary calcium and oxalate.
- **Plasma bicarbonate** is low in renal tubular acidosis. The finding of a urine pH that does not fall below 5.5 in the face of metabolic acidosis is diagnostic of this condition (see p. 675).

Prophylaxis

The age of the patient and the severity of the problem affect both the need for and the type of prophylaxis.

Idiopathic stone-formers

Where no metabolic abnormality is present, the mainstay of prevention is maintenance of a high intake of fluid throughout the day and night. The aim should be to ensure a daily urine volume of 2–2.5 L, which requires a fluid intake in excess of this, substantially so in the case of those who live in hot countries or work in a hot environment.

Idiopathic hypercalciuria

Severe dietary calcium restriction is inappropriate (see p. 610) and patients should be encouraged to consume a normal-calcium (30 mmol/day) diet. Dietary calcium restriction results in hyperabsorption of oxalate, and so foods containing large amounts of oxalate should also be limited. A high fluid intake should be advised as for idiopathic stone-formers. Patients who live in a hard-water area may benefit from drinking softened water.

If hypercalciuria persists and stone formation continues, a thiazide is used (e.g. bendroflumethiazide 2.5 or 5 mg each morning). Thiazides reduce urinary calcium excretion by a direct effect on the renal tubule. They may precipitate diabetes mellitus or gout and worsen hypercholesterolaemia. Reduction of animal proteins to 50 g/day and sodium intake to 50 mmol/day is also advisable.

Mixed infective stones

Recurrent stones should be prevented by maintenance of a high fluid intake and meticulous control of bacteriuria. This will require long-term follow-up and often the use of long-term low-dose prophylactic antibacterial agents.

Uric acid stones

Dietary measures are probably of little value and are difficult to implement. Effective prevention can be achieved by the long-term use of allopurinol to maintain the serum urate and urinary uric acid excretion in the normal range. A high fluid intake should also be maintained. Uric acid is more soluble at alkaline pH, and long-term sodium bicarbonate supplementation to maintain an alkaline urine is an alternative approach in those few patients unable to take allopurinol. However, alkalinization of the urine facilitates precipitation of calcium oxalate and phosphate.

Cystine stones

These can be prevented and indeed will dissolve slowly with a high fluid intake. Five litres of water is drunk each 24 hours, and the patient must wake twice during the night to ingest 500 mL or more of water. Many patients cannot tolerate this regimen. Alkalinization to a pH of 7 requires high doses of potassium citrate or bicarbonate. An alternative option is the long-term use of the chelating agent penicillamine; this causes cystine to be converted to the more soluble penicillamine–cysteine complex. Side-effects include drug rashes, blood dyscrasias and immune complex-mediated glomerulonephritis. However, it is especially effective in promoting dissolution of cystine stones already present. Other cystine-binding drugs include tiopronin.

Mild hyperoxaluria with calcium oxalate stones

A high fluid intake and dietary oxalate restriction are required. Dietary advice as in hypercalciuria is also advisable.

Nephrocalcinosis

The term ‘nephrocalcinosis’ means diffuse renal parenchymal calcification that is detectable radiologically (Fig. 11.41). The condition is typically painless. Hypertension and renal impairment commonly occur. The main causes of nephrocalcinosis are listed in Table 11.14.

Dystrophic calcification occurs following renal cortical necrosis. In *hypercalcaemia and hyperoxaluria*, deposition of calcium oxalate results from the high concentration of calcium and oxalate within the kidney.

In *renal tubular acidosis* (see p. 676) failure of urinary acidification and a reduction in urinary citrate excretion both favour calcium phosphate and oxalate precipitation, since

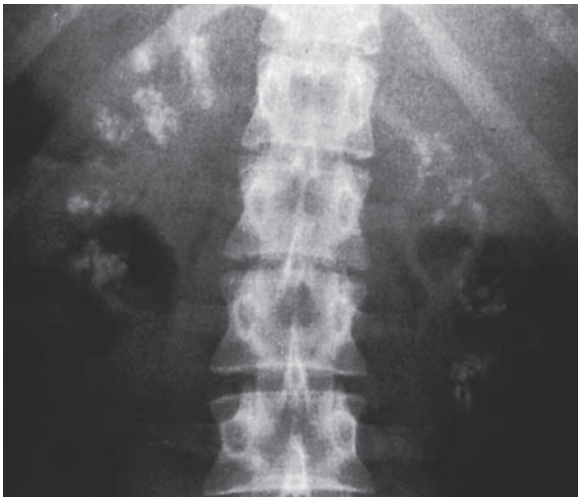

Fig. 11.41 **X-ray of nephrocalcinosis.**

Renal tubular acidosis (inherited and acquired)
Primary hyperoxaluria
Medullary sponge kidney
Tuberculosis

precipitation occurs more readily in an alkaline medium and the calcium-chelating action of urinary citrate is reduced.

Treatment and prevention of nephrocalcinosis consists of treatment of the cause.

URINARY TRACT OBSTRUCTION

The urinary tract can be obstructed at any point between the kidney and the urethral meatus. This results in dilatation of the tract above the obstruction. Dilatation of the renal pelvis is known as hydronephrosis.

Aetiology

Obstructing lesions may lie within the lumen, or in the wall of the urinary tract, or outside the wall, causing obstruction by external pressure. The major causes of obstruction are shown in Table 11.15. Overall, the frequency is the same in men and women. However, in the elderly, urinary tract obstruction is more common in men owing to the frequency of bladder outflow obstruction from prostatic disease.

Table 11.15 Causes of urinary tract obstruction

Within the lumen
Calculus
Blood clot
Sloughed papilla (diabetes; analgesia abuse; sickle cell disease or trait)
Tumour of renal pelvis or ureter
Bladder tumour
Within the wall
Pelviureteric neuromuscular dysfunction (congenital, 10% bilateral)
Ureteric stricture (tuberculosis, especially after treatment; calculus; after surgery)
Ureterovesical stricture (congenital; ureterocele; calculus; schistosomiasis)
Congenital megaureter
Congenital bladder neck obstruction
Neuropathic bladder
Urethral stricture (calculus; gonococcal; after instrumentation)
Congenital urethral valve
Pin-hole meatus
Pressure from outside
Pelviureteric compression (bands; aberrant vessels)
Tumours (e.g. retroperitoneal tumour or glands; carcinoma of colon; tumours in pelvis, e.g. carcinoma of cervix)
Diverticulitis
Aortic aneurysm
Retroperitoneal fibrosis (periaortitis)
Accidental ligation of ureter
Retrocaval ureter (right-sided obstruction)
Prostatic obstruction
Phimosis

Pathophysiology

Obstruction with continuing urine formation results in:

- progressive rise in intraluminal pressure
- dilatation proximal to the site of obstruction
- compression and thinning of the renal parenchyma, eventually reducing it to a thin rim and resulting in a decrease in the size of the kidney.

Acute obstruction is followed by transient renal arterial vasodilatation succeeded by vasoconstriction, probably mediated mainly by angiotensin II and thromboxane A_2. Ischaemic interstitial damage mediated by free oxygen radicals and inflammatory cytokines compounds the damage induced by compression of the renal substance.

Clinical features

Symptoms of upper tract obstruction

Loin pain occurs which can be dull or sharp, constant or intermittent. It is often provoked by measures that increase urine volume and hence distension of the collecting system, such as a high fluid intake or diuretics, including alcohol. Complete anuria is strongly suggestive of complete bilateral obstruction or complete obstruction of a single kidney.

Conversely, polyuria may occur in partial obstruction owing to impairment of renal tubular concentrating capacity. Intermittent anuria and polyuria indicates intermittent complete obstruction.

Infection complicating the obstruction may give rise to malaise, fever and septicaemia.

Symptoms of bladder outflow obstruction

Symptoms may be minimal. Hesitancy, narrowing and diminished force of the urinary stream, terminal dribbling and a sense of incomplete bladder emptying are typical features. The frequent passage of small volumes of urine occurs if a large volume of residual urine remains in the bladder after urination. Incontinence of such small volumes of urine is known as 'overflow incontinence' or 'retention with overflow'.

Infection commonly occurs, causing increased frequency, urgency, urge incontinence, dysuria and the passage of cloudy smelly urine. It may precipitate acute retention.

Signs

Loin tenderness may be present. An enlarged hydronephrotic kidney is often palpable. In acute or chronic retention the enlarged bladder can be felt or percussed. Examination of the genitalia, rectum and vagina is essential, since prostatic obstruction and pelvic malignancy are common causes of urinary tract obstruction. However, the apparent size of the

prostate on digital examination is a poor guide to the presence of prostatic obstruction.

Investigations

- **Routine blood and biochemical investigations** show a raised serum urea or creatinine, hyperkalaemia, anaemia of chronic disease or blood in the urine.
- **Plain abdominal X-ray** may detect radiolucent stones/calcification but can miss stones lying over the bone.
- **Helical (spiral) CT scanning** has a high sensitivity and can visualize uric acid (radiolucent) stones as small as 1 mm, as well as details of the obstruction.
- **Ultrasonography** (see p. 579) can rule out upper urinary tract dilatation. Ultrasound cannot distinguish a baggy, low-pressure unobstructed system from a tense, high-pressure obstructed one, so that false-positive scans are seen. Stones in the ureter can be missed.
- **Excretion urography**. In recent unilateral obstruction, the affected kidney is enlarged and smooth in outline. The nephrogram is delayed on the affected side, owing to a reduction in the GFR. With time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, and the site of obstruction with proximal dilatation is seen (Fig. 11.42). A full-length film should be taken after an attempt at bladder emptying by the patient. Complete emptying indicates either that no obstruction to bladder outflow exists or that intravesical pressure can be raised sufficiently to overcome it. Vesicoureteric reflux can result in contrast medium returning to the bladder from above, giving the appearance of a partially full bladder.
- **Radionuclide studies** (see p. 581). These have no place in the initial investigation of acute obstruction. Their main role is in possible long-standing obstruction to differentiate true obstructive nephropathy from retention of tracer in a baggy, low-pressure, unobstructed pelvicalyceal system.
- **Antegrade pyelography and ureterography** (see p. 580) defines the site and cause of obstruction. It can be combined with drainage of the collecting system by percutaneous needle nephrostomy.
- **Retrograde ureterography** (see p. 581) is indicated if antegrade examination cannot be carried out or if there is the possibility of dealing with ureteric obstruction from below at the time of examination. The technique carries the risk of introducing infection into an obstructed urinary tract. In obstruction due to neuromuscular dysfunction at the pelviureteric junction or retroperitoneal fibrosis, the collecting system may fill normally from below.
- **Cystoscopy, urethroscopy and urethrography** can visualize obstructing lesions within the bladder and urethra directly. Urethrography involves introducing contrast medium into the bladder by catheterization or suprapubic bladder puncture, and taking X-ray films during voiding to show obstructing lesions in the urethra. It is of particular value in the diagnosis of urethral valves and strictures.

Fig. 11.42 **Intravenous urographic X-ray taken 24 hours after injection of contrast, showing a delayed nephrogram and pyelogram on the left side and dilatation of the system to the level of the block.** By this time contrast medium has disappeared from the normal right side.

Treatment

The aim is to relieve symptoms and preserve renal function by:

- relieving the obstruction
- treating the underlying cause
- preventing and treating infection.

Temporary external drainage of urine by nephrostomy may be valuable, as this allows time for further investigation when the site and nature of the obstructing lesion are uncertain, doubt exists as to the viability of the obstructed kidney, or when immediate definitive surgery would be hazardous.

Recent, complete upper urinary tract obstruction demands urgent relief to preserve kidney function, particularly if infection is present.

In contrast, with partial urinary tract obstruction, particularly if spontaneous relief is expected – such as by passage of a calculus – there is no immediate urgency.

Surgical management depends on the cause of the obstruction (see below) and local expertise. Dialysis may be required in the ill patient prior to surgery.

Diuresis usually follows relief of obstruction at any site in the urinary tract. Massive diuresis may occur following relief of bilateral obstruction owing to previous sodium and water overload and the osmotic effect of retained solutes combined with a defective renal tubular reabsorptive capacity (as in the diuretic phase of recovering acute tubular necrosis). This diuresis is associated with increased blood volume and high levels of atrial natriuretic peptide (ANP). Defective renal tubular reabsorptive capacity cannot be the sole mechanism of severe diuresis since this phenomenon is not observed

Ask the authors
www.studentconsult.com

following relief of unilateral obstruction. The diuresis is usually self-limiting, but a minority of patients will develop severe sodium, water and potassium depletion requiring appropriate intravenous replacement. In milder cases, oral salt and potassium supplements together with a high water intake are sufficient.

Specific causes of obstruction

Calculi

These are discussed on page 609.

Pelviureteric junction obstruction

(Fig. 11.43)

This results from a functional disturbance in peristalsis of the collecting system in the absence of mechanical obstruction. Surgical attempts at correction of the obstruction by open or percutaneous pyeloplasty are indicated in patients with recurrent loin pain and those in whom serial scans or measurements of GFR indicate progressive kidney damage. Nephrectomy to remove the risk of developing pyonephrosis and septicaemia is indicated if long-standing obstruction has destroyed kidney function.

Obstructive megaureter

This childhood condition may become evident only in adult life. It results from the presence of a region of defective peristalsis at the lower end of the ureter adjacent to the ureterovesical junction. The condition is more common in males. It presents with UTI, flank pain or haematuria. The diagnosis is made on imaging with ultrasound, CT or, if necessary, ascending ureterography.

Excision of the abnormal portion of ureter with reimplantation into the bladder is always indicated in children, and in adults when the condition is associated with evidence of progressive deterioration in renal function, bacteriuria that cannot be controlled by medical means, or recurrent stone formation.

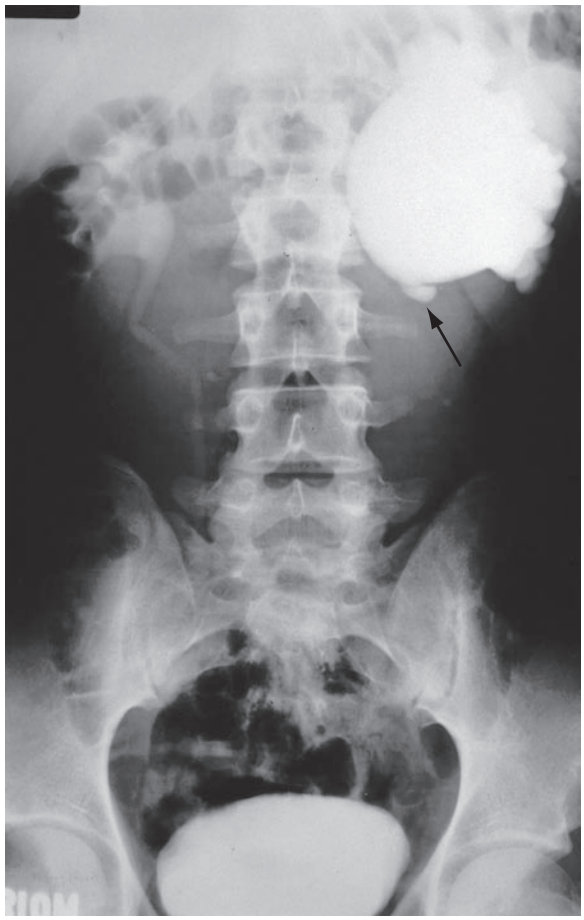

Fig. 11.43 **X-ray, showing left pelviureteric junction obstruction (arrow).**

Retroperitoneal fibrosis (RPF; chronic periaortitis)

The incidence and prevalence are 0.1 per 100 000 and 1.38 per 100 000, respectively. It is three times more common in men than in women.

The ureters become embedded in dense retroperitoneal fibrous tissue with resultant unilateral or bilateral obstruction. Obstruction is usually due to loss of peristalsis rather than occlusion. The condition may extend from the level of the second lumbar vertebra to the pelvic brim. In up to 15% of patients, the fibrotic process can extend outside the retroperitoneum, consistent with it being a systemic condition. Mediastinal fibrosis, Riedel fibrosing thyroiditis, sclerosing cholangitis, fibrotic orbital pseudotumor, fibrotic arthropathy, pleural, pericardial and lung fibrosis have been reported with increasing frequency.

Aetiology is either an autoallergic response to leakage of material, probably ceroid, from atheromatous plaques producing an inflammatory reaction, or a systemic autoimmune disease. There is an association with HLA-DRB1*03, an allele linked to various autoimmune diseases. RPF possibly is initiated as a vasa vasorum vasculitis in the aortic wall which is often seen in chronic periaortitis. This inflammatory process can cause medial wall thinning and promote atherosclerosis, and also extends into the surrounding retroperitoneum with a fibro-inflammatory reaction typical of chronic periaortitis. The autoimmune reaction to plaque antigens could be an epiphenomenon of this immune-mediated process. Activating antibodies against fibroblasts (detectable in one-third of patients) have also been implicated in the pathogenesis, as has the presence of IgG_4-bearing plasma cells; the latter is a common finding in sclerosing pancreatitis, a disorder sometimes associated with idiopathic retroperitoneal fibrosis. In addition, several infiltrating B cells show clonal or oligoclonal immunoglobulin heavy chain rearrangement. These findings raise the possibility of RPF being a primary B-cell disorder.

Pathology. The hallmark of idiopathic RPF is background sclerosis with myofibroblasts associated with a diffuse and perivascular infiltrate mainly consisting of T and B lymphocytes and IgG_4 isotype bearing plasma cells. Small vessel vasculitis may be found in approximately 50% of the patients.

Causes are many but 66% are idiopathic. *Secondary causes* include drugs (methysergide, lysergic acid, ergot derived dopamine receptor agonists (cabergoline), bromocriptine, pergolide, ergotamine, methyldopa, hydralazine, beta-blockers), malignant diseases (carcinomas of the colon, prostate, breast, stomach, carcinoid, Hodgkin's and non-

Hodgkin's lymphomas, sarcomas), infections (tuberculosis, syphilis, histoplasmosis, actinomycosis and fungal infections), and surgery/radiotherapy (lymph node resection, colectomy, hysterectomy, aortic aneurysm repair). Recognized associations include untreated abdominal aortic aneurysm, smoking and asbestosis.

Clinical. Malaise, low back pain, weight loss, testicular pain, claudication and haematuria occur.

Laboratory tests show normochromic anaemia, uraemia and a raised erythrocyte sedimentation rate (ESR) and CRP.

Imaging with ultrasound will show a poorly circumscribed periaortic mass. The test of choice is a contrast-enhanced CT, which will show the mass, lymph nodes and tumour (Fig. 11.44). MRI will show similar findings but does not require contrast. Intravenous urography is now rarely performed. Positron emission tomography (PET) is helpful (see below).

Treatment. Obstruction is relieved surgically by ureterolysis. A biopsy is performed to exclude an underlying lymphoma or carcinoma. Corticosteroids are of benefit, and in bilateral obstruction in frail patients it may be best to free only one ureter and to rely upon steroid therapy to induce regression of fibrous tissue on the contralateral side, since bilateral ureterolysis is a major operation. An alternative approach is placement of a ureteric stent or stents and corticosteroid therapy, but regular (usually 6-monthly) changes of the stent or stents are required if the periaortic mass does not regress.

Management. Response to treatment and disease activity are assessed by serial measurements of ESR and eGFR supplemented by isotopic and imaging techniques including CT scanning. Fluorodeoxyglucose-PET (FDG-PET), a functional imaging modality, assesses the metabolic activity of the retroperitoneal mass. FDG-PET also allows whole-body imaging and can detect occult malignant or infectious foci, particularly in secondary retroperitoneal fibrosis. In idiopathic RPF, FDG-PET can be used to monitor the residual inflammatory component following medical therapy Relapse after withdrawal of steroid therapy may occur and treatment may need to be continued for years. Mycophenolate or tamoxifen is also effective. Long-term follow-up is mandatory.

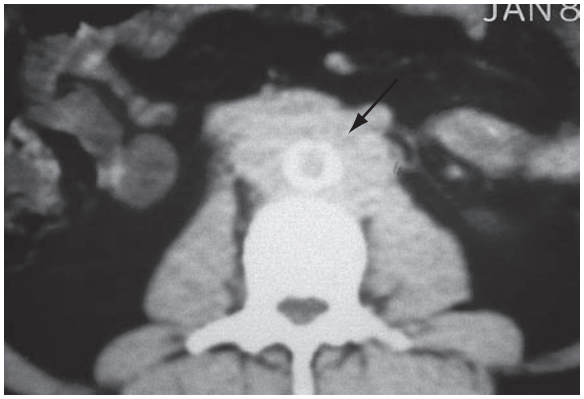

Fig. 11.44 **Retroperitoneal fibrosis (periaortitis).** Note the large mass surrounding the abdominal aorta on this CT scan (arrow).

Benign prostatic hypertrophy

Benign prostatic hypertrophy is a common cause of urinary tract obstruction. It is described on page 645.

Prognosis of urinary tract obstruction

The prognosis depends upon the cause and the stage at which obstruction is relieved. In obstruction, four factors influence the rate at which kidney damage occurs, its extent and the degree and rapidity of recovery of renal function after relief of obstruction. These are:

- whether obstruction is partial or complete
- the duration of obstruction
- whether or not infection occurs
- the site of obstruction.

Complete obstruction for several weeks will lead to irreversible or only partially reversible kidney damage. If the duration of complete obstruction is several months, total irreversible destruction of the affected kidney will result. Partial obstruction carries a better prognosis, depending upon its severity. Bacterial infection coincident with obstruction rapidly increases kidney damage. Obstruction at or below the bladder neck may induce hypertrophy and trabeculation of the bladder without a rise in pressure within the upper urinary tract, in which case the kidneys are protected from the effects of back-pressure.

DRUGS AND THE KIDNEY

Drug-induced impairment of renal function

Prerenal

Impaired perfusion of the kidneys can result from drugs that cause:

- hypovolaemia – for example:
  (a) potent loop diuretics such as furosemide, especially in elderly patients
  (b) renal salt and water loss, such as from hypercalcaemia induced by vitamin D therapy (since hypercalcaemia adversely affects renal tubular salt and water conservation)
- decrease in cardiac output, which impairs renal perfusion (e.g. beta-blockers)
- decreased renal blood flow (e.g. ACE inhibitors particularly in the presence of renovascular disease).

Renal

Several mechanisms of drug-induced renal damage exist and may coexist.

- *Acute tubular necrosis produced by direct nephrotoxicity.* Examples include prolonged or excessive treatment with aminoglycosides (e.g. gentamicin, streptomycin), amphotericin B, heavy metals or carbon tetrachloride. The combination of aminoglycosides with furosemide is particularly nephrotoxic.

- *Acute tubulointerstitial nephritis* (see p. 604) with interstitial oedema and inflammatory cell infiltration. This cell-mediated hypersensitivity nephritis occurs with many drugs, including penicillins, sulphonamides and NSAIDs (which have many other effects on the kidney; Box 11.3).
- *Chronic tubulointerstitial nephritis* due to drugs, see page 605.
- *Membranous glomerulonephritis*, e.g. penicillamine, gold, anti-TNF (p. 587).

Postrenal

Retroperitoneal fibrosis with urinary tract obstruction can result from the use of drugs (p. 616).

Use of drugs in patients with impaired renal function (Box 11.4)

Many aspects of drug handling are altered in patients with renal impairment.

Absorption

This may be unpredictable in uraemia as nausea and vomiting are frequently present.

Metabolism

Oxidative metabolism of drugs by the liver is altered in uraemia, although this is rarely of clinical significance.

The rate of drug metabolism by the kidney is reduced as a result of two factors:

- *Reduced drug catabolism*. Insulin, for example, is in part catabolized by the normal kidney. In renal disease, insulin catabolism is reduced. The insulin requirements of diabetics decline as renal function deteriorates, for this reason.
- *Reduced conversion of a precursor to a more active metabolite*, such as the conversion of 25-hydroxycholecalciferol to the more active 1,25-$(OH)_2D_3$. The 1α-hydroxylase enzyme responsible for this conversion is located in the kidney. In renal disease, production of the enzyme declines and deficiency of 1,25-$(OH)_2D_3$ results.

Protein binding

Reduced protein binding of a drug potentiates its activity and increases the potential for toxic side-effects. Measurement of the total plasma concentration of such a drug can give misleading results. For example, the serum concentration of phenytoin required to produce an antiepileptic effect is much higher in normal individuals than in those with renal failure, since in the latter proportionately more drug is present in the free form.

Some patients with renal disease are hypoproteinaemic and reduced drug-binding to protein results. This is not the sole mechanism of reduced drug-binding in such patients. For example, hydrogen ions, which are retained in renal failure, bind to receptors for acidic drugs such as sulphonamides, penicillin and salicylates, thus enhancing their potential for causing toxicity.

Volume of distribution

Salt and water overload or depletion may occur in patients with renal disease. This affects the concentration of drug obtained from a given dose.

End-organ sensitivity

The renal response to drug treatment may be reduced in renal disease. For example, mild thiazide diuretics have little diuretic effect in patients with severe renal impairment.

Box 11.3 Non-steroidal anti-inflammatory drugs and the kidney

Problem	Cause
Sodium and water retention	Reduction of prostaglandin production
Acute tubulointerstitial nephritis	Hypersensitivity reaction
Nephrotic syndrome	Membranous glomerulopathy
Analgesic nephropathy	Papillary necrosis after chronic use
Acute kidney injury	Acute tubular necrosis
Hyperkalaemia	Decreased renal excretion of K^+

Box 11.4 Safe prescribing in renal disease

Safe prescribing in renal failure demands knowledge of the clinical pharmacology of the drug and its metabolites in normal individuals and in uraemia. The clinician should ask the following questions when prescribing and discuss with the patient:

1 *Is treatment mandatory?* Unless it is, it should be withheld.
2 *Can the drug reach its site of action?* For example, there is little point in prescribing the urinary antiseptic, nitrofurantoin, in renal failure since bacteriostatic concentrations will not be attained in the urine.
3 *Is the drug's metabolism altered in uraemia?*
4 *Will accumulation of the drug or metabolites occur?* Even if accumulation is a potential problem owing to the drug or its metabolites being excreted by the kidneys, it is not necessarily an indication to change the drug given. The size of the loading dose will depend upon the size of the patient and is unrelated to renal function.
Avoidance of toxic levels of drug in blood and tissues subsequently requires the administration of normal doses of the drug at longer time intervals than usual or smaller doses at the usual time intervals.
5 *Is the drug toxic to the kidney?*
6 Are the *effective concentrations* of the drug in biological tissues similar to the toxic concentrations? Should blood levels of the drug be measured?
7 *Will the drug worsen the uraemic state* by means other than nephrotoxicity, e.g. steroids, tetracycline?
8 *Is the drug a sodium or potassium salt?* These are potentially hazardous in uraemia.

Not surprisingly, adverse drug reactions are more than twice as common in renal failure as in normal individuals. Elderly patients, in whom unsuspected renal impairment is common, are particularly at risk. Attention to the above and titration of the dose of drugs employed should reduce the problem.

The dose may be titrated by:

- observation of its clinical effect, e.g. hypotensive agents
- early detection of toxic effects
- measurement of drug levels in the blood, e.g. gentamicin levels.

Renal elimination

The major problem in the use of drugs in renal failure concerns the reduced elimination of many drugs normally excreted by the kidneys.

Water-soluble drugs such as gentamicin that are poorly absorbed from the gut, typically given by injection and not metabolized by the liver, give rise to far more problems than lipid-soluble drugs such as propranolol, which are well absorbed and principally metabolized by the liver. Metabolites of lipid-soluble drugs, however, may themselves be water-soluble and potentially toxic.

Drugs causing uraemia by effects upon protein anabolism and catabolism

Tetracyclines, with the exception of doxycycline, have a catabolic effect and as a result the concentration of nitrogenous waste products is increased. They may also cause impairment of GFR by a direct effect. Corticosteroids have a catabolic effect and so also increase the production of nitrogenous wastes. A patient with moderate impairment of renal function may therefore become severely uraemic if given tetracyclines or corticosteroid therapy.

Drugs and toxic agents causing specific renal tubular syndromes include mercury, lead, cadmium and vitamin D.

Problem patients

Particular problems are presented by patients in whom renal function is altering rapidly, such as those with recovering acute tubular necrosis. In addition, drugs may be removed by dialysis and haemofiltration, which will affect the dosage required.

ACUTE RENAL FAILURE (ARF)/ ACUTE KIDNEY INJURY (AKI)

The term 'renal failure' means failure of renal excretory function due to depression of the glomerular filtration rate. This is accompanied to a variable extent by failure of erythropoietin production (see p. 576), vitamin D hydroxylation (p. 577), regulation of acid–base balance (p. 674) and regulation of salt and water balance and blood pressure (p. 576).

Definition

Acute kidney injury has variably been defined as an abrupt deterioration in parenchymal renal function, which is usually, but not invariably, reversible over a period of days or weeks. In clinical practice, such deterioration in renal function is sufficiently severe to result in uraemia. Oliguria is usually, but not invariably, a feature. Acute kidney injury may cause sudden, life-threatening biochemical disturbances and is a medical emergency. The distinction between acute and chronic renal failure, or even acute-on-chronic renal failure, cannot be readily apparent in a patient presenting with uraemia. In view of these difficulties, the Acute Dialysis Quality Initiative group proposed the RIFLE (Risk, Injury, Failure, Loss, End-stage renal disease; Box 11.5) criteria utilizing either increases in serum creatinine or decreases in urine output. It characterizes three levels of renal dysfunction (R, I, F) and two outcome measures (L, E). These criteria indicate an increasing degree of renal damage and have a predictive value for mortality.

Box 11.5 RIFLE classification for acute kidney injury

Grade	GFR criteria	UO criteria
Risk	SCr × 1.5	UO <0.5 mL/kg/h × 6 h
Injury	SCr × 2	UO <0.5 mL/kg/h × 12 h
Failure	SCr × 3 or SCr >350 μmol/L with an acute rise >40 μmol/L	UO <0.3 mL/kg/h × 24 h
Loss	Persistent ARF >4 weeks	
ESKD	Persistent renal failure >3 months	

SCr, serum creatinine; UO, urinary output; ESKD, end-stage kidney disease
RIFLE, Risk, Injury, Failure, Loss, End-stage renal disease

Epidemiology

The observed incidence and outcomes of AKI are highly dependent upon the populations studied and the definition of AKI employed. The incidence of hospital-acquired AKI has increased. The incidence of community-acquired AKI on admission to hospital is approximately 1% in the UK, with AKI superimposed on chronic kidney disease accounting for 50% of these patients. The incidence of severe AKI (creatinine >500 μmol/L) is about 130–140/million population and that of less severe AKI (patients with creatinine levels of up to 177 μmol/L or a 50% rise from baseline) is about 200/million/year. Uncomplicated AKI can usually be managed outside the intensive care unit (ITU) setting and carries a good prognosis, with mortality rates less than 5–10%. In contrast, AKI complicating non-renal organ system failure (in the ITU setting) is associated with mortality rates of 50–70%, which have not changed for several decades. Moreover, sepsis-related AKI has a significantly worse prognosis than AKI in the absence of sepsis.

Classification

Renal failure results in reduced excretion of nitrogenous waste products, of which urea is the most commonly measured. A raised serum urea concentration (uraemia) is classified as: (i) prerenal, (ii) renal or (iii) postrenal. More than one category may be present in an individual patient. Other causes of altered serum urea and creatinine concentration are shown in Table 11.16.

Prerenal uraemia

In prerenal uraemia, there is impaired perfusion of the kidneys with blood. This results either from hypovolaemia, hypotension, impaired cardiac pump efficiency or vascular disease limiting renal blood flow, or combinations of these factors. Usually the kidney is able to maintain glomerular filtration close to normal despite wide variations in renal perfusion pressure and volume status – so-called 'autoregulation'. Further depression of renal perfusion leads to a drop in glomerular filtration and development of prerenal uraemia. Drugs which impair renal autoregulation, such as ACE inhibitors and NSAIDs, increase the tendency to develop prerenal uraemia.

Table 11.16 Causes of altered serum urea and creatinine concentration other than altered renal function

	Decreased concentration	Increased concentration
Urea	Low protein intake Liver failure Sodium valproate treatment	Corticosteroid treatment Tetracycline treatment Gastrointestinal bleeding
Creatinine	Low muscle mass	High muscle mass Red meat ingestion Muscle damage (rhabdomyolysis) Decreased tubular secretion (e.g. cimetidine, trimethoprim therapy)

All causes of prerenal uraemia may lead to established parenchymal kidney damage and the development of acute renal failure. By definition, excretory function in prerenal uraemia improves once normal renal perfusion has been restored.

A number of criteria have been proposed to differentiate between prerenal and intrinsic renal causes of uraemia (Table 11.17).

- *Urine specific gravity and urine osmolality* are easily obtained measures of concentrating ability but are unreliable in the presence of glycosuria or other osmotically active substances in the urine.
- *Urine sodium* is low if there is avid tubular reabsorption, but may be increased by diuretics or dopamine.
- *Fractional excretion of sodium (FENa)*, the ratio of sodium clearance to creatinine clearance, increases the reliability of this index but may remain low in some 'intrinsic' renal diseases, including contrast nephropathy and myoglobinuria.

Laboratory tests, however, are no substitute for clinical assessment. A history of blood or fluid loss, sepsis potentially leading to vasodilatation, or of cardiac disease may be helpful. Hypotension (especially postural), a weak rapid pulse and a low jugular venous pressure will suggest that the uraemia is prerenal. In doubtful cases, measurement of central venous pressure is often invaluable, particularly with fluid challenge (see p. 901).

Management

If the prerenal uraemia is a result of hypovolaemia and hypotension, prompt replacement with appropriate fluid is essential to correct the problem and prevent development of ischaemic renal injury and acute kidney disease (p. 904). Since prerenal and renal uraemia may coexist, and fluid challenge in the latter situation may lead to volume overload with pulmonary oedema, careful clinical monitoring is vital. Blood pressure should be checked regularly and signs of elevated jugular venous pressure and of pulmonary oedema sought frequently. Central venous pressure monitoring is usually advisable (see p. 901). If the problem relates to cardiac pump insufficiency or occlusion of the renal vasculature, appropriate measures – albeit often unsuccessful – need to be taken.

Table 11.17 Criteria for distinction between prerenal and intrinsic causes of renal dysfunction

	Prerenal	Intrinsic
Urine specific gravity	>1.020	<1.010
Urine osmolality (mOsm/kg)	>500	<350
Urine sodium (mmol/L)	<20	>40
$FE_{Na} = \frac{U_{Na}}{P_{Na}} \div \frac{U_{Cr}}{P_{Cr}} \times 100$	<1%	>1%

FE, fractional excretion; P, plasma; U, urine; Cr, creatinine; Na, sodium

Table 11.18 Some causes of acute tubular necrosis

- Haemorrhage
- Burns
- Diarrhoea and vomiting, fluid loss from fistulae
- Pancreatitis
- Diuretics
- Myocardial infarction
- Congestive cardiac failure
- Endotoxic shock
- Snake bite
- Myoglobinaemia
- Haemoglobinaemia (due to haemolysis, e.g. in falciparum malaria, 'blackwater fever')
- Hepatorenal syndrome
- Radiological contrast agents (see p. 624)
- Drugs, e.g. aminoglycosides, NSAIDs, ACE inhibitors, platinum derivatives
- Abruptio placentae
- Pre-eclampsia and eclampsia

Postrenal uraemia

Here, uraemia results from obstruction of the urinary tract at any point from the calyces to the external urethral orifice. The causes and presentation of urinary tract obstruction are dealt with on page 614. Screening for urinary tract obstruction is by renal ultrasonography. Urinary tract obstruction may present in an acute fashion (if obstruction of a single functioning kidney by, for example, a calculus occurs) but typically is of insidious onset.

Acute uraemia due to renal parenchymal disease

Causes

This is most commonly due to acute renal tubular necrosis (Table 11.18). Other causes include disease affecting the intrarenal arteries and arterioles as well as glomerular capillaries, such as a vasculitis (p. 548), accelerated hypertension, cholesterol embolism, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura (TTP), pre-eclampsia and crescentic glomerulonephritis. Acute tubulointerstitial nephritis (p. 604) may also cause acute renal failure. This also

occurs when renal tubules are acutely obstructed by crystals, for example following sulphonamide therapy in a dehydrated patient (sulphonamide crystalluria) or after rapid lysis of certain malignant tumours following chemotherapy (acute hyperuricaemic nephropathy). Acute bilateral suppurative pyelonephritis or pyelonephritis of a single kidney can cause acute uraemia.

Acute tubular necrosis

Causes

Acute tubular necrosis (ATN) is common, particularly in hospital practice. It results most often from renal ischaemia but can also be caused by direct renal toxins including drugs such as the aminoglycosides, lithium and platinum derivatives (Table 11.18).

Kidneys are particularly vulnerable to ischaemic injury when cholestatic jaundice is present, and more than one ischaemic factor appears to be present in some situations. For example, disseminated intravascular coagulation complicating Gram-negative septicaemia and complications of pregnancy such as placental rupture, pre-eclampsia and eclampsia may result in occlusion or partial occlusion of intrarenal vessels, exacerbating the ischaemic insult resulting from hypotension associated with the underlying condition.

Myoglobinaemia and haemoglobinaemia consequent upon muscle injury (rhabdomyolysis) complicating trauma, pressure necrosis or heroin use predispose to ATN, perhaps in part owing to occlusion of renal tubules by myoglobin and haemoglobin casts. In liver failure, acute renal failure appears to result from rapidly reversible vasomotor abnormalities within the kidney. A kidney removed from a patient with hepatic cirrhosis and liver failure dying with oliguric renal failure may function normally immediately after transplantation into a normal individual. Efferent glomerular arteriolar dilatation resulting from ACE-inhibitor drug therapy, with consequent lowering of glomerular filtration pressure, may cause acute deterioration in excretory function if renal arterial disease is also present. The effect is compounded by concomitant use of non-steroidal anti-inflammatory agents which reduce prostaglandin production, opposing this effect.

Pathogenesis

Factors postulated to be involved in the development of ATN include:

- *Intrarenal microvascular vasoconstriction:*
  (a) Vasoconstriction is increased in response to endothelin, adenosine, thromboxane A_2, leukotrienes and sympathetic nerve activity. However, endothelin antagonists failed to show any beneficial effect in the clinical setting.
  (b) Vasodilatation is impaired due to reduced sensitivity in response to:
    (i) Nitric oxide, prostaglandins (PGE_2), acetylcholine and bradykinin.
    (ii) Increased endothelial and vascular smooth muscle cell structural damage.
  (c) Increased leucocyte–endothelial adhesion, vascular congestion and obstruction, leucocyte activation and inflammation. After success in the prevention of ARF in animal models, anti-ICAM (intercellular adhesion molecule) in the clinical setting failed to live up to its initial promise.
- *Tubular cell injury*. Ischaemic injury results in rapid depletion of intracellular ATP stores resulting in cell death either by necrosis or apoptosis, due to the following:
  (i) entry of calcium into cells with an increase in cytosolic cell calcium concentration
  (ii) induction by hypoxia of inducible nitric oxide synthases with increased production of nitric oxide causing cell death
  (iii) increased production of intracellular proteases such as calpain, which cause proteolysis of cytoskeletal proteins and cell wall collapse
  (iv) activation of phospholipase A_2 with increased production of free fatty acids, particularly arachidonic acid, due to its action on the lipid layer of cell membranes
  (v) cell injury resulting from reperfusion with blood after initial ischaemia causing excessive free radical generation
  (vi) tubular obstruction by desquamated viable or necrotic cells and casts
  (vii) loss of cell polarity, i.e. integrins located on the basolateral side of the cell are translocated to the apical surface, which when combined with other desquamated cells forms casts, with tubular obstruction and back leak of tubular fluid.
- *Tubular cellular recovery*. Tubular cells have the capacity to regenerate rapidly and to reform the disrupted tubular basement membrane, which explains the reversibility of ATN. Multiple growth factors, including insulin-like growth factor 1, epidermal growth factor and hepatocyte growth factor, and their receptors are upregulated during the regenerative process after injury. Clinical utility of growth factors in the treatment of ARF is unproven.

In established ATN renal blood flow is much reduced, particularly blood flow to the renal cortex. Ischaemic tubular damage contributes to a reduction in glomerular filtration by a number of interrelated mechanisms:

- *Glomerular contraction* reducing the surface area available for filtration, due to reflex afferent arteriolar spasm mediated by increased solute delivery to the macula densa. Increased solute delivery is due to impaired sodium absorption in the proximal tubular cells because of loss of cell polarity with mislocalization of the Na^+/K^+-ATPase and impaired tight junction integrity, resulting in decreased apical-to-basal transcellular sodium absorption.
- *'Back leak' of filtrate* in the proximal tubule owing to loss of function of the tubular cells.
- *Obstruction of the tubule* by debris shed from ischaemic tubular cells; these appear on renal biopsy as flat rather than the normal tall appearance (Fig. 11.45).

Course

The clinical course of acute renal failure associated with ATN is variable depending on the severity and duration of the renal insult. Oliguria is common in the early stages: non-oliguric renal failure is usually a result of a less severe renal insult. Recovery of renal function typically occurs after 7–21 days, although recovery is delayed by continuing sepsis. In the recovery phase, GFR may remain low while urine output increases, sometimes to many litres a day owing to defective

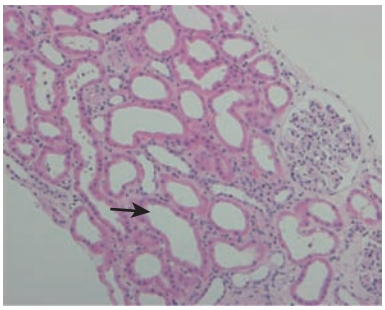

Fig. 11.45 **Acute tubular necrosis** showing effacement and loss of the proximal tubule brush border, patchy loss of tubular cells and focal areas of proximal tubule dilatation.

tubular reabsorption of filtrate. The clinical course is variable and ATN may last for up to 6 weeks, even after a relatively short-lived initial insult. Eventually renal function usually returns to almost normal or to normal, although exceptions exist (e.g. in renal cortical necrosis – see below).

No treatment is, as yet, known which will reduce the duration of acute renal tubular necrosis once it has occurred. The use of intravenous mannitol, furosemide or 'renal-dose' dopamine is not supported by controlled trial evidence, and none of these treatments is without risk. Trials with the synthetic analogue of atrial natriuretic factor, anaritide, and the use of exogenous IGF-1 have failed to show any beneficial effect in clinical ARF so far.

Whether a state of 'incipient' ATN exists in some patients with prerenal uraemia, and whether ATN can be prevented by administration of mannitol, furosemide or dopamine, also remain uncertain. Many nephrologists will administer one or more of these agents if correction of prerenal factors does not initiate a diuresis, but proof of benefit is lacking.

Clinical and biochemical features

These are the features of the causal condition together with features of rapidly progressive uraemia. The rate at which serum urea and creatinine concentrations increase is dependent upon the rate of tissue breakdown in the individual patient. This is increased in the presence of trauma, sepsis and following surgery. *Hyperkalaemia* is common, particularly following trauma to muscle and in haemolytic states. *Metabolic acidosis* is usual unless hydrogen ion loss by vomiting or aspiration of gastric contents is a feature. *Hyponatraemia* may be present owing to water overload if patients have continued to drink in the face of oliguria, or if overenthusiastic fluid replacement with 5% dextrose has been carried out. Pulmonary oedema owing to salt and water retention is not uncommon, particularly after inappropriate attempts to initiate a diuresis by infusion of 0.9% saline without adequate monitoring of the patient's volume status. Hypocalcaemia due to reduced renal production of 1,25-dihydroxycholecalciferol and hyperphosphataemia due to phosphate retention are common.

Symptoms of uraemia such as anorexia, nausea, vomiting and pruritus develop, followed by intellectual clouding, drowsiness, fits, coma and haemorrhagic episodes. Epistaxes and gastrointestinal haemorrhage are relatively common. Severe infection may have initiated the acute kidney disease or have complicated it owing to the impaired immune defences of the uraemic patient or ill-considered management, such as the insertion and retention of an unnecessary bladder catheter with complicating urinary tract infection and bacteraemia.

Investigation of the uraemic emergency

Investigations are aimed at defining whether the patient has acute or chronic uraemia, whether uraemia results from prerenal, renal or postrenal factors, and establishing the cause.

Acute or chronic uraemia?

The distinction between acute and chronic uraemia depends in part on the history, duration of symptoms and previous urinalysis or measurements of renal function.

A rapid rate of change of serum urea and creatinine with time suggests an acute process. A normochromic, normocytic anaemia suggests chronic disease, but anaemia may complicate many of the diseases that cause acute renal failure, owing to a combination of haemolysis, haemorrhage and deficient erythropoietin production.

Ultrasound assessment of renal echogenicity and size is helpful. Small kidneys of increased echogenicity are diagnostic of a chronic process, although the reverse is not true; the kidney may remain normal in size in diabetes and amyloidosis, for instance.

Evidence of renal osteodystrophy (for example, digital subperiosteal erosions due to hyperparathyroid bone disease) is indicative of chronic disease.

Measurement of carbamylated haemoglobin (a product of non-enzymatic reaction between urea and haemoglobin, cf. glycosylated haemoglobin) is not widely employed.

Prerenal, renal or postrenal uraemia?

Bladder outflow obstruction is ruled out by insertion of a urethral catheter or flushing of an existing catheter, which should then be removed unless a large volume of urine is obtained. Absence of upper tract dilatation on renal ultrasonography will, with very rare exceptions, rule out urinary tract obstruction.

The distinction between prerenal and renal uraemia may be difficult (see p. 619). Assessment of the patient's volume status is essential and central venous pressure measurement is extremely helpful. If volume status is low, appropriate corrective measures are indicated. If no diuresis ensues, acute intrinsic renal failure is present.

Other investigations

Urinalysis, urine microscopy, particularly for red cells and red-cell casts (indicative of glomerulonephritis), and urine culture. Urine should be tested for free haemoglobin and myoglobin, where appropriate.

Blood tests include measurement of serum urea, electrolytes, creatinine, calcium, phosphate, albumin, alkaline phosphatase and urate concentrations, as well as full blood count and examination of the peripheral blood film where necessary. Coagulation studies, blood cultures and measurements of nephrotoxic drug blood levels should be carried out.

Management

The aim of management of acute renal tubular necrosis is to keep the patient alive until spontaneous recovery of renal function occurs. Ideally patients should be managed by a

nephrologist or intensivist with access to facilities for blood purification and fluid removal (see below). Early specialist referral is advisable. Poor initial management and late referral result in the arrival in the specialist centre of a patient who is severely uraemic, acidotic and hyperkalaemic, with pulmonary oedema following overenthusiastic intravenous fluid administration and with a Gram-negative septicaemia complicating the presence of an unnecessary indwelling bladder catheter.

General measures

Good nursing and physiotherapy are vital. Regular oral toilet, chest physiotherapy and consistent documentation of fluid intake and output, and where possible measurement of daily bodyweight to assess fluid balance changes, all have a role. The patient should be confined to bed only if essential.

Emergency measures

Hyperkalaemia

This is a life-threatening complication owing to the risk of cardiac dysrhythmias, particularly ventricular fibrillation. Treatment is outlined in Emergency box 12.1. Correction of acidosis with intravenous sodium bicarbonate will also reduce serum potassium concentration, but administration of sodium may be inappropriate if the patient is salt and water overloaded. Rapid correction of acidosis in a hypocalcaemic patient may also trigger tetany, since hydrogen ions displace calcium from albumin-binding sites, thus increasing the physiologically active calcium concentration in blood. Ion exchange resins are used to prevent subsequent hyperkalaemia rather than to deal with the acute emergency. In many patients, hyperkalaemia will be controlled only by dialysis or haemofiltration.

Pulmonary oedema

Unless a diuresis can be induced with intravenous furosemide, dialysis or haemofiltration will be required.

Sepsis

Infections, when detected, should be treated promptly, bearing in mind the need to avoid nephrotoxic drugs and to use drugs with appropriate monitoring and drug levels (e.g. gentamicin, vancomycin). Prophylactic antibiotics or barrier nursing is not recommended in all cases.

Use of drugs

Great care must be exercised in the use of drugs (see p. 618).

Fluid and electrolyte balance

Twice-daily clinical assessment is needed. In general, once the patient is euvolaemic, daily fluid intake should equal urine output plus losses from fistulae and from vomiting, plus an allowance of 500 mL daily for insensible loss. Febrile patients will require an additional allowance. Sodium and potassium intake should be minimized. If abnormal losses of fluid occur, for example in diarrhoea, additional fluid and electrolytes will be required. The development of signs of salt and water overload (peripheral oedema, basal crackles, elevation of jugular venous pressure) or of hypovolaemia should prompt reappraisal of fluid intake. Large changes in daily weight reflecting change in fluid balance status should also prompt a reappraisal of the situation.

Diet

With rare exceptions, sodium and potassium restriction are appropriate. The place of dietary protein restriction is controversial. If it is hoped to avoid dialysis or haemofiltration, protein intake is sometimes restricted to approximately 40 g daily. This poses the risk of a negative nitrogen balance despite attempts to reduce endogenous protein catabolism by maintenance of a high energy intake in the form of carbohydrate and fat. Patients treated by blood purification techniques are more appropriately managed by providing 70 g protein daily or more. Hypercatabolic patients will require an even higher nitrogen intake to prevent negative nitrogen balance.

Routes of intake are, in preferred order, enteral by mouth, enteral by nasogastric tube, and parenteral. The last of these is, however, only necessary if vomiting or bowel dysfunction render the enteral route inappropriate.

Vitamin supplements are usually supplied. Vitamin D analogue therapy and pharmacological doses of erythropoietin are not employed routinely.

Dialysis and haemofiltration

The main indications for blood purification and/or excess fluid removal by these techniques are:

- symptoms of uraemia
- complications of uraemia, such as pericarditis
- severe biochemical derangement in the absence of symptoms (especially if a rising trend is observed in an oliguric patient and in hypercatabolic patients)
- hyperkalaemia not controlled by conservative measures
- pulmonary oedema
- severe acidosis
- for removal of drugs causing the acute renal failure, e.g. gentamicin, lithium, severe aspirin overdose.

The main options are peritoneal dialysis, intermittent haemodialysis (HD) combined with ultrafiltration, if necessary, intermittent haemofiltration, continuous arteriovenous or venovenous haemofiltration, and haemodiafiltration. For reasons that are incompletely understood, adverse cardiovascular effects are much less during haemofiltration than during haemodialysis. Continuous treatments are superior to intermittent ones in this respect.

Continuous renal replacement treatments (CRRT)

Blood flow is achieved either by using the patient's own blood pressure to generate arterial blood flow through a filter or by the use of a blood pump to draw blood from the lumen of a dual-lumen catheter placed in the jugular, subclavian or femoral vein.

Continuous arteriovenous or venovenous haemofiltration (CAVH, CVVH) refers to the continuous removal of ultrafiltrate from the patient, usually at rates of up to 1000 mL/h, combined with simultaneous infusion of replacement solution. For instance, in a fluid-overloaded patient one might remove filtrate at 1000 mL/h and replace at a rate of 900 mL/h, achieving a net fluid removal of 100 mL/h.

Continuous haemodiafiltration (CAVHDF, CVVHDF) is a combination of haemofiltration and haemodialysis, involving both the net removal of ultrafiltrate from the blood and its

replacement with a replacement solution, together with the countercurrent passage of dialysate (which may be identical to the replacement solution). Both the ultrafiltrate and the spent dialysate appear as 'waste'.

Comparisons of dialysis modalities

Peritoneal dialysis (PD) is used infrequently in the management of ARF, with decreasing utilization over the past 5–10 years. Drawbacks to the use of PD in ARF are:

(i) low efficiency in fluid and solute removal compared to CRRT or intermittent HD;
(ii) ARF complicating intra-abdominal pathology is unsuitable for PD;
(iii) increasing intra-abdominal pressure can compromise lung function;
(iv) use of dialysis fluids with a high dextrose content may produce hyperglycaemia and other metabolic derangements. Data suggest that PD is significantly less effective than CRRT in the management of ARF and should be reserved for situations where other modalities of therapy are not available.

Several randomized trials comparing intermittent HD to CRRT in ARF failed to demonstrate any difference in morbidity or mortality between the two modalities. There are thus insufficient data to favour either HD or CRRT as a superior mode of therapy in ARF. However, there is consensus that in haemodynamically unstable patients, CRRT is better tolerated.

Membrane biocompatibility

The concept of membrane 'biocompatibility' relates to the activation of cellular (neutrophils, platelets) and humoral (complement system and coagulation cascade) components upon contact between blood and dialysis membranes. As a general rule, unsubstituted cellulose membranes (cuprophan) are the least biocompatible, with biocompatibility improving with substitution of free hydroxyl groups by tertiary amino groups (hemophan), acetate (cellulose acetate, diacetate, triacetate) or the use of synthetic polymers (e.g. polysulphone, polyamide, polyacrilonitrile and polymethylmethacrylate).

Synthetic membranes appear to confer a significant survival advantage over unsubstituted cellulose (cuprophan)-based membranes but no benefit on recovery of renal function.

Acute kidney injury in the intensive care unit (ITU)

Increasing numbers of patients with acute renal failure are managed in the setting of an intensive care unit. Many such patients have multiorgan failure, sepsis or both, with associated cardiovascular instability. Continuous methods of blood purification and control of fluid balance, such as venovenous haemofiltration, are preferable to intermittent haemodialysis or peritoneal dialysis in such patients. Advantages include:

- much less disturbance of cardiovascular stability
- the ability to generate as much 'space' for fluid administration as is required, which can be adjusted flexibly to the needs of the patient (many patients require large volumes of fluid to be administered for nutritional and other reasons)
- the removal of potentially harmful substances such as inflammatory cytokines via the more porous membrane employed in haemofiltration.

Acute respiratory distress syndrome (ARDS) is not uncommon in patients with multiorgan failure, including acute kidney injury, requiring intensive therapy. In such patients the wish to remove as much fluid from the patient as possible to reduce pulmonary congestion must be balanced against the need of organs, including the kidneys, for an adequate blood flow, if recovery is to occur. Anaemia is relatively common in patients admitted to ITU and is managed by blood transfusions. In a study, erythropoietin (EPO) given weekly did not reduce the blood transfusion requirements but unexpectedly increased survival in trauma patients. This also showed that EPO has non-haemopoietic pleiotrophic effects by which it reduces the risk of acute ischaemia and reperfusion injury in multiple organs.

Management of the recovery phase

Usually, after 1–3 weeks, renal function improves, as evidenced by an increase in urine volume and improvement in serum biochemistry. Dialysis or haemofiltration, if they have been required, can be discontinued. A careful watch on clinical state, salt and water balance, and serum chemistry is required at this stage, particularly if a major diuretic phase develops owing to recovery of glomerular filtration at a time when renal tubular reabsorptive capacity for sodium, potassium and water remains impaired. Intravenous fluid replacement is sometimes required together with supplements of sodium chloride and potassium. Typically, the diuretic phase lasts for only a few days.

Acute cortical necrosis

Renal hypoperfusion results in diversion of blood flow from the cortex to the medulla, with a drop in GFR. Medullary ischaemic damage is largely reversible owing to the capacity of the tubular cells for regeneration. In contrast, glomerular ischaemic injury does not heal with regeneration but with scarring – glomerulosclerosis. Prolonged cortical ischaemia may lead to irreversible loss of renal function termed 'cortical necrosis'. This may be patchy or complete. Any cause of acute tubular necrosis, if sufficiently severe or prolonged, may lead to cortical necrosis. This outcome is particularly common if acute kidney injury has been accompanied by derangements of the vascular endothelial system or coagulation system, such as occurs in haemolytic uraemic syndrome and complications of pregnancy.

Contrast nephropathy

In patients with impaired renal function, iodinated radiological contrast media may be nephrotoxic, possibly by causing renal vasoconstriction and by a direct toxic effect upon renal tubules. The effect is dose-dependent and therefore more commonly seen in procedures that require large amounts of contrast media, such as angiography with or without angioplasty. In many patients the effect is mild, transient, fully reversible and of no clinical significance. The risk and severity of contrast nephropathy is amplified by the presence of hypovolaemia and renal impairment, especially if due to diabetic nephropathy. Diabetes per se is not a risk

factor. However, metformin can precipitate acidosis and should be stopped and not restarted until renal function returns to the baseline level.

Prevention involves minimization as far as possible of the dose of contrast employed and use of an iso-osmolar or low-osmolality contrast medium. Superiority of iso-osmolar agents has been questioned by randomized trials in patients with severe renal impairment (eGFR <30 mL/min) undergoing coronary angiogram, where no differences were seen between the two types of contrast agent. Pre-hydration with intravenous saline is of proven benefit. A popular regimen involves infusion of 1 L of 0.9% saline during the 12 hours before and 12 hours after contrast exposure. Care must be taken to avoid volume overload in susceptible patients.

N-acetylcysteine (NAC; a potent antioxidant) given 48 hours prior to radiological intervention may be of benefit in preventing worsening of re-existing renal impairment following intravenous contrast, but the effect on morbidity and mortality is unknown. Routine use of dopamine, theophylline (an adenosine antagonist) and prophylactic haemodialysis (removing contrast agent from circulation) is of no benefit. In patients with advanced CKD who are undergoing coronary angiography, periprocedural haemofiltration given in an ITU setting appears to be effective in preventing the deterioration of renal function due to contrast agent-induced nephropathy and is associated with improved in-hospital and long-term outcomes.

When deterioration in renal function occurs after intra-arterial injection of contrast (for example, after coronary angiography) it may be difficult to differentiate the effects of contrast-induced damage from those of atheromatous embolization (see p. 609). The latter carries a worse prognosis.

N.B. Gadolinium used in contrast MRI causes problems in chronic renal failure (see p. 580).

Hepatorenal syndrome (HRS)

The renal failure observed in HRS results from profound renal vasoconstriction with histologically normal kidneys (p. 354). Although many of the features of HRS resemble prerenal ARF, the defining feature is a lack of improvement in renal function with volume expansion. Renal recovery is usually observed after restoration of hepatic function after successful liver transplantation.

CHRONIC KIDNEY DISEASE (CKD)

The term 'CKD' is now replacing terms such as chronic renal failure or insufficiency. CKD implies long-standing, and usually progressive, impairment in renal function. In many instances, no effective means are available to reverse the primary disease process. Exceptions include correction of urinary tract obstruction, immunosuppressive therapy for systemic vasculitis and Goodpasture's syndrome, treatment of accelerated hypertension, and correction of critical narrowing of renal arteries causing renal impairment. The rate of deterioration in renal function can, however, be slowed (see p. 632). A list of causes of CKD is given in Table 11.19.

Table 11.19 Causes of chronic kidney disease

Congenital and inherited disease
- Polycystic kidney disease (adult and infantile forms)
- Medullary cystic disease
- Tuberous sclerosis
- Oxalosis
- Cystinosis
- Congenital obstructive uropathy

Glomerular disease
- *Primary glomerulonephritides* including focal glomerulosclerosis
- *Secondary glomerular disease* (systemic lupus, polyangiitis, Wegener's granulomatosis, amyloidosis, diabetic glomerulosclerosis, accelerated hypertension, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, systemic sclerosis, sickle cell disease)

Vascular disease
- Hypertensive nephrosclerosis (common in black Africans)
- Reno-vascular disease
- Small and medium-sized vessel vasculitis

Tubulointerstitial disease
- Tubulointerstitial nephritis – idiopathic, due to drugs (especially nephrotoxic analgesics), immunologically mediated
- Reflux nephropathy
- Tuberculosis
- Schistosomiasis
- Nephrocalcinosis
- Multiple myeloma (myeloma kidney)
- Balkan nephropathy
- Renal papillary necrosis (diabetes, sickle cell disease and trait, analgesic nephropathy)
- Chinese herb nephropathy

Urinary tract obstruction
- Calculus disease
- Prostatic disease
- Pelvic tumours
- Retroperitoneal fibrosis
- Schistosomiasis

Wide geographical variations in the incidence of disorders causing CKD exist. The most common cause of glomerulonephritis in sub-Saharan Africa is malaria. Schistosomiasis is a common cause of renal failure due to urinary tract obstruction in parts of the Middle East, including southern Iraq. The incidence of end-stage renal failure varies between racial groups. End-stage renal failure is three to four times as common in black Africans in the UK and USA as it is in whites, and hypertensive nephropathy is a much more frequent cause of end-stage renal failure in this group. The prevalence of diabetes mellitus and hence of diabetic nephropathy is higher in some Asian groups than in whites. The age is of relevance; CKD due to atherosclerotic renal vascular disease is much more common in the elderly than in the young. Over 70% of all cases with CKD are due to diabetes mellitus, hypertension and atherosclerosis.

Patients with CKD should be referred to a nephrologist with access to facilities for renal replacement therapy at an early stage since late referral has been shown to be associated with increased mortality and morbidity when such

Table 11.20 Stages of chronic kidney disease

Stage	Description	GFR (mL/min/1.73 m^2)
1	Kidney damage with normal or ↑ GFR	≥90
2	Kidney damage with mild ↓ GFR	60–89
3	Moderate ↓ GFR	30–59
4	Severe ↓ GFR	15–29
5	Kidney failure	<15 (or dialysis)

Chronic kidney disease is defined as either kidney damage or GFR <60 mL/min/1.73 m^2 for ≥3 months
Kidney damage is defined as pathological abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies
From Kidney Disease Outcomes Quality Initiative of the National Kidney Foundation, USA

patients commence renal replacement therapy. Old age is no bar to referral in the reasonably fit elderly patient.

For CKD referral and treatment pathways the Kidney Disease Outcomes Quality Initiative (K/DOQI) of the National Kidney Foundation established a classification of CKD in the USA in 2002, which is internationally accepted (Table 11.20). This classification defines CKD as a GFR <60 mL/min/1.73 m^2 or a GFR >60 mL/min/1.73 m^2 together with the presence of kidney damage, present for >3 months. Use of this classification requires doctors to estimate GFR, which has been made possible by the adoption of the MDRD formula in most chemical pathology laboratories. Large prevalences of CKD have now been found in population-based surveys using the MDRD method to estimate GFR.

Clinical approach to the patient with CKD or any other form of renal disease

History

Particular attention should be paid to:

- *duration of symptoms*
- *drug ingestion,* including non-steroidal anti-inflammatory agents, analgesic and other medications, and unorthodox treatments such as herbal remedies
- *previous medical and surgical history,* e.g. previous chemotherapy, multisystem diseases such as SLE, malaria
- *previous occasions* on which urinalysis or measurement of urea and creatinine might have been performed, e.g. pre-employment or insurance medical examinations, new patient checks
- *family history* of renal disease.

Symptoms

The early stages of renal failure are often completely asymptomatic, despite the accumulation of numerous metabolites. Serum urea and creatinine concentrations are measured in renal failure since methods for their determination are available and a rough correlation exists between urea and creatinine concentrations and symptoms. These substances are, however, in themselves not particularly toxic. The nature of the metabolites that are involved in the genesis of symptoms is unclear. Such metabolites must be products of protein catabolism (since dietary protein restriction may reverse symptoms associated with renal failure) and many of them must be of relatively small molecular size (since haemodialysis employing membranes which allow through only relatively small molecules improves symptoms). Little else is known with certainty.

Symptoms are common when the serum urea concentration exceeds 40 mmol/L, but many patients develop uraemic symptoms at lower levels of serum urea. Symptoms include:

- malaise, loss of energy
- loss of appetite
- insomnia
- nocturia and polyuria due to impaired concentrating ability
- itching
- nausea, vomiting and diarrhoea
- paraesthesiae due to polyneuropathy
- 'restless legs' syndrome (overwhelming need to frequently alter position of lower limbs) (p. 1197)
- bone pain due to metabolic bone disease
- paraesthesiae and tetany due to hypocalcaemia
- symptoms due to salt and water retention – peripheral or pulmonary oedema
- symptoms due to anaemia (see p. 392)
- amenorrhoea in women; erectile dysfunction in men.

In more advanced uraemia (serum urea >50–60 mmol/L), these symptoms become more severe, and CNS symptoms are common:

- mental slowing, clouding of consciousness, and seizures
- myoclonic twitching.

Severe depression of glomerular filtration can result in oliguria. This can occur with either acute kidney injury or in the terminal stages of chronic kidney disease. However, even if the GFR is profoundly depressed, failure of tubular reabsorption may lead to very high urine volumes; the urine output is therefore not a useful guide to renal function.

Examination

There are few physical signs of uraemia per se. Findings include short stature (in patients who have had chronic kidney disease in childhood), pallor (due to anaemia), increased photosensitive pigmentation (which may make the patient look misleadingly healthy), brown discoloration of the nails, scratch marks due to uraemic pruritus, signs of fluid overload (p. 655), pericardial friction rub, flow murmurs (mitral regurgitation due to mitral annular calcification, aortic and pulmonary regurgitant murmurs due to volume overload), and glove and stocking peripheral sensory loss (rare).

The kidneys themselves are usually impalpable unless grossly enlarged as a result of polycystic disease, obstruction or tumour. Rectal and vaginal examination may disclose evidence of an underlying cause of renal failure, particularly urinary obstruction, and should always be performed.

In addition to these findings, there may be physical signs of any underlying disease which may have caused the renal failure, for instance:

- cutaneous vasculitic lesions in systemic vasculitides
- retinopathy in diabetes
- evidence of peripheral vascular disease
- evidence of spina bifida or other causes of neurogenic bladder.

An assessment of the central venous pressure, skin turgor, blood pressure both lying and standing and peripheral circulation should also be made. The major symptoms and signs of chronic kidney disease are shown in Figure 11.46.

Investigations

The following investigations are common for all renal patients. This includes patients with glomerular or non-glomerular disease, renal involvement in systemic diseases, AKI and CKD, as renal symptoms and signs are non-specific.

Urinalysis

- *Haematuria* may indicate glomerulonephritis, but other sources must be excluded. Haematuria should not be assumed to be due to the presence of an indwelling catheter.
- *Proteinuria*, if heavy, is strongly suggestive of glomerular disease. Urinary infection may also cause proteinuria. *Glycosuria* with normal blood glucose is common in CKD.
- *Urine culture*, including early-morning urine samples for TB.

Urine microscopy (see p. 579)

- *White cells* in the urine usually indicate active bacterial urinary infection, but this is an uncommon cause of renal failure; sterile pyuria suggests papillary necrosis or renal tuberculosis.
- *Eosinophiluria* is strongly suggestive of allergic tubulointerstitial nephritis or cholesterol embolization.
- *Casts. Granular casts* are formed from abnormal cells within the tubular lumen, and indicate active renal disease. *Red-cell casts* are highly suggestive of glomerulonephritis.
- *Red cells in the urine* may be from anywhere between the glomerulus and the urethral meatus (Fig. 11.5).

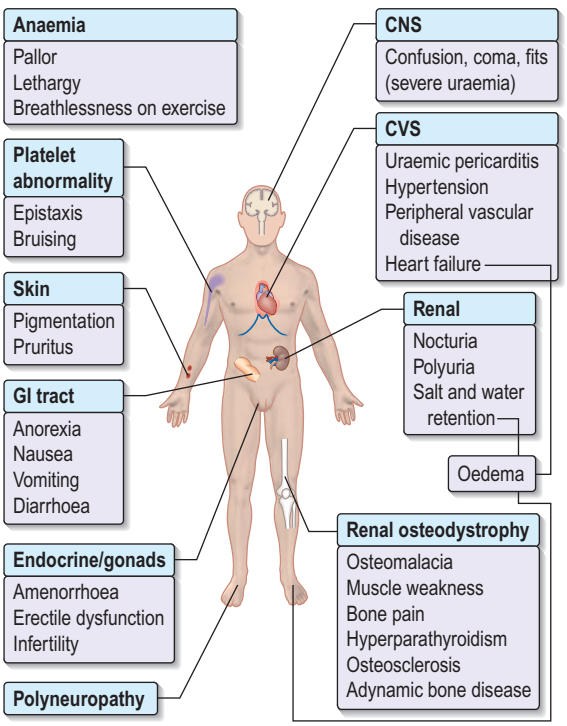

Fig. 11.46 **Symptoms and signs of chronic kidney disease.** Oedema may be due to a combination of primary renal salt and water retention and heart failure.

Urine biochemistry

- *24-hour creatinine clearance* is sometimes useful in assessing the severity of renal disease.
- *Measurements of urinary electrolytes* are unhelpful in chronic kidney disease. The use of urinary sodium concentration in the distinction between prerenal and intrinsic renal disease is discussed on page 619.
- *Urine osmolality* is a measure of concentrating ability. A low urine osmolality is normal in the presence of a high fluid intake but indicates renal disease when the kidney should be concentrating urine, such as in hypovolaemia or hypotension.
- *Urine electrophoresis and immunofixation* is necessary for the detection of light chains, which can be present without a detectable serum paraprotein.

Serum biochemistry

Urea and creatinine with calculation of eGFR. Electrophoresis and immunofixation for myeloma. Elevations of creatine kinase and a disproportionate elevation in serum creatinine and potassium compared to urea suggest rhabdomyolysis.

Haematology

- *Eosinophilia* suggests vasculitis, allergic tubulointerstitial nephritis, or cholesterol embolism.
- *Markedly raised viscosity* or ESR suggests myeloma or vasculitis.
- *Fragmented red cells and/or thombocytopenia* suggest intravascular haemolysis due to accelerated hypertension, haemolytic uraemic syndrome or thrombotic thrombocytopenic purpura.
- *Tests for sickle cell disease* should be performed when relevant.

Immunology

- *Complement components* may be low in active renal disease due to SLE, mesangiocapillary glomerulonephritis, post-streptococcal glomerulonephritis, and cryoglobulinaemia.
- *Autoantibody screening* is useful in detection of SLE (p. 541), scleroderma (p. 545), Wegener's granulomatosis and microscopic polyangiitis (p. 871), and Goodpasture's syndrome (p. 874).
- *Cryoglobulins* in unexplained glomerular disease, particularly mesangiocapillary glomerulonephritis.
- *Antibodies to streptococcal antigens* (antistreptolysin O titre (ASOT), anti-DNAase B) if post-streptococcal glomerulonephritis is possible.
- *Antibodies to hepatitis B and C* may point to polyarteritis or membranous nephropathy (hepatitis B) or to cryoglobulinaemic renal disease (hepatitis C).
- *Antibodies to HIV* raise the possibility of HIV-associated renal disease.

Radiological investigation

- *Ultrasound*. Every patient should undergo ultrasonography (for renal size and to exclude hydronephrosis), and plain abdominal radiography and CT (without contrast) to exclude low-density renal stones or nephrocalcinosis, which may be missed on ultrasound.
- *CT* is also useful for the diagnosis of retroperitoneal fibrosis and some other causes of urinary obstruction, and may also demonstrate cortical scarring.
- *MRI*. Magnetic resonance angiography in renovascular disease. For gadolinium used as contrast in renal failure, see page 580.
- *Intravenous urography* is seldom necessary in advanced renal disease.

Renal biopsy (see p. 582)

This should be performed in every patient with unexplained renal failure and normal-sized kidneys, unless there are strong contraindications. If rapidly progressive glomerulonephritis is possible, this investigation must be performed within 24 hours of presentation if at all possible.

COMPLICATIONS OF CHRONIC KIDNEY DISEASE

Anaemia

Several factors have been implicated:

- *erythropoietin deficiency* (the most significant)
- *bone marrow toxins* retained in renal failure
- *bone marrow fibrosis* secondary to hyperparathyroidism
- *haematinic deficiency* – iron, vitamin B_{12}, folate
- *increased red cell destruction*
- *abnormal red cell membranes* causing increased osmotic fragility
- *increased blood loss* – occult gastrointestinal bleeding, blood sampling, blood loss during haemodialysis or because of platelet dysfunction
- *ACE inhibitors* (may cause anaemia in CKD, probably by interfering with the control of endogenous erythropoietin release).

Red cell survival is reduced in renal failure. Increased red cell destruction may occur during haemodialysis owing to mechanical, oxidant and thermal damage.

Bone disease: renal osteodystrophy

The term 'renal osteodystrophy', more appropriately described as bone mineral disorder, embraces the various forms of bone disease that may develop alone or in combination in chronic kidney disease – hyperparathyroid bone disease, osteomalacia, osteoporosis, osteosclerosis and adynamic bone disease (Fig. 11.47). Most patients with chronic kidney disease are found, histologically, to have mixed bone disease. Covert renal osteodystrophy is present in many patients with moderate renal impairment and in almost all of those with end-stage renal failure.

Pathogenesis of bone disease

- Decreased renal production of the 1α-hydroxylase enzyme results in reduced conversion of 25-$(OH)_2D_3$ to the more metabolically active 1,25-$(OH)_2D_3$.

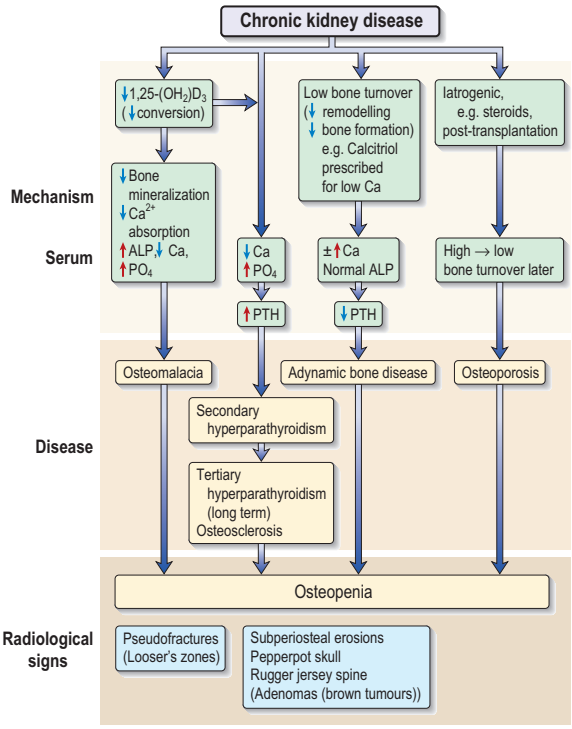

Fig. 11.47 **Renal osteodystrophy**: Pathogenesis and radiological features of renal bone disease. ALP, alkaline phosphatase.

- Reduced activation of vitamin D receptors (VDR) in the parathyroid glands leads to increased release of parathyroid hormone (*primary hyperparathyroidism*).
- The calcium sensing receptors (CaR), expressed in the parathyroid glands, react rapidly to acute changes in extracellular calcium concentrations and a low calcium also leads to increased release of PTH.
- 1,25-Dihydroxycholecalciferol deficiency also results in gut calcium malabsorption.
- Phosphate retention owing to reduced excretion by the kidneys, also indirectly by lowering ionized calcium (and probably directly via a putative but unrecognized phosphate receptor), results in an increase in PTH synthesis and release.
- PTH promotes reabsorption of calcium from bone and increased proximal renal tubular reabsorption of calcium, and this opposes the tendency to develop hypocalcaemia induced by 1,25-$(OH)_2D_3$ deficiency and phosphate retention. This 'secondary' hyperparathyroidism leads to increased osteoclastic activity, cyst formation and bone marrow fibrosis (osteitis fibrosa cystica).

Radiologically, digital subperiosteal erosions and 'pepperpot skull' are seen. Long-standing *secondary hyperparathyroidism* ultimately leads to hyperplasia of the glands with autonomous or '*tertiary*' *hyperparathyroidism* in which hypercalcaemia is present. Serum alkaline phosphatase concentration is raised in both secondary and tertiary hyperparathyroidism. Long-standing parathyroid hormone excess is also thought to cause increased bone density (osteosclerosis) seen particularly in the spine where alter-

nating bands of sclerotic and porotic bone give rise to a characteristic 'rugger jersey' appearance on X-ray.

$1,25\text{-}(OH)_2D_3$ deficiency and hypocalcaemia result in impaired mineralization of osteoid (osteomalacia). Such impaired mineralization also occurs when osteoblasts are inhibited by, for example, aluminium given as gut phosphorus binders, or accumulated in bone as a result of exposure to aluminium in source water used to make up dialysate for haemodialysis. In this situation, serum alkaline phosphatase concentration tends to be low or normal.

The condition of 'adynamic bone disease' in which both bone formation and resorption are depressed (in the absence of aluminium bone disease or overtreatment with vitamin D) is also seen. The pathogenesis of this condition is unclear and it is not known whether it leads to an increased risk of fractures or other complications. There may be hypercalcaemia; the serum alkaline phosphatase is normal, the PTH is low. X-rays and dual X-ray absorptiometry (DXA) scan show osteopenia. No treatment is of proven benefit.

Osteoporosis is commonly found in CKD, often after transplantation and the use of corticosteroids. Monitoring is with yearly DXA scan.

Management is discussed on page 563.

Skin disease

Pruritus (itching) is common in severe renal failure and is usually attributed in the main to retention of nitrogenous waste products of protein catabolism as it improves following the institution of dialysis. Other causes of pruritus include hypercalcaemia, hyperphosphataemia, elevated calcium × phosphate product, hyperparathyroidism (even if calcium and phosphate levels are normal) and iron deficiency.

In dialysis patients, inadequate dialysis is usually the cause of pruritus. Nevertheless, a significant number of dialysis patients who are well dialysed and in whom other causes of pruritus can be excluded suffer persistent itching. The cause is unknown and no effective treatment exists.

Many patients with renal failure suffer from dry skin for which simple aqueous creams are helpful. Eczematous lesions, particularly in relation to the region of an arteriovenous fistula, are relatively common. Chronic kidney disease may also cause porphyria cutanea tarda (PCT), a blistering photosensitive skin rash. This results from a decrease in hepatic uroporphyrinogen decarboxylase combined with a decreased clearance of porphyrins in the urine or by dialysis. Pseudoporphyria, a condition similar to PCT but without enzyme deficiency, is also seen in CKD with increased frequency.

Nephrogenic systemic fibrosis (NSF)

NSF is a systemic fibrosing disorder with predominant skin involvement and can simulate a variety of other disorders such as scleroderma, scleromyxoedema and eosinophilic fasciitis. It is seen only in patients with moderate to severe kidney failure (eGFR <30 mL/min), particularly patients on dialysis. Gadolinium-containing contrast agents, which are excreted exclusively by the kidney, have been implicated in the causation of over 95% cases of NSF. *Skin involvement* occurs universally with plaques, papules and/or nodules, the affected skin becoming thickened and firm and assuming a peau d'orange appearance. *Systemic involvement* occurs in a few patients with muscle stiffness, joint contracture, and fibrosis of the lungs, pleura, diaphragm, myocardium, pericardium and dura mater.

The *diagnosis* is based upon a biopsy of an involved site, showing proliferation of dermal fibrocytes with excessive collagen deposition. Special testing may show gadolinium.

NSF usually follows a chronic and unremitting course, with 30% having no improvement, 20% having modest improvement and 30% dying. No single therapy or combination of therapies has shown consistent benefit in NSF with exception of improvement in renal function. Although unproven, improvement in the NSF may follow renal transplantation. *Prevention* is by avoiding the use of gadolinium-based contrast agents in patents with severe renal impairment (eGFR <30 mL/min) or those on dialysis therapy.

Gastrointestinal complications

These include decreased gastric emptying and increased risk of reflux oesophagitis, peptic ulceration, acute pancreatitis and constipation, particularly in patients on continuous ambulatory peritoneal dialysis (CAPD).

Elevations of serum amylase of up to three times normal may be found in CKD without any evidence of pancreatic disease, owing to retention of high-molecular-weight forms of amylase normally excreted in the urine.

Metabolic abnormalities

Gout. Urate retention is a common feature of CKD. Treatment of clinical gout is complicated by the nephrotoxic potential of NSAIDs. Colchicine is useful for the acute attack, and allopurinol should be introduced under colchicine cover to prevent further attacks. The dose of allopurinol should be reduced in renal impairment, e.g. 100 mg on alternate days.

Insulin. Insulin is catabolized by and to some extent excreted via the kidneys. For this reason, insulin requirements in diabetic patients decrease as renal failure progresses. By contrast, end-organ resistance to insulin is a feature of advanced renal impairment resulting in modestly impaired glucose tolerance when a standard glucose tolerance test is carried out. Insulin resistance may contribute to hypertension and lipid abnormalities.

Lipid metabolism abnormalities. These are common in renal failure, and include:

- impaired clearance of triglyceride-rich particles
- hypercholesterolaemia (particularly in advanced renal failure).

The situation is further complicated in end-stage renal disease, when regular heparinization (in haemodialysis), excessive glucose absorption (in CAPD) and immunosuppressive drugs (in transplantation) may all contribute to lipid abnormalities. Correction of lipid abnormalities by, for example, HMG-CoA reductase inhibitor therapy (statins) is used in renal failure patients, although without formal proof of benefit derived from prospective controlled trials.

Endocrine abnormalities

These include:

- Hyperprolactinaemia, which may present with galactorrhoea in men as well as women.

- Increased luteinizing hormone (LH) levels in both sexes, and abnormal pulsatility of LH release.
- Decreased serum testosterone levels (only seldom below the normal level). Erectile dysfunction and decreased spermatogenesis are common.
- Absence of normal cyclical changes in female sex hormones, resulting in oligomenorrhoea or amenorrhoea.
- Complex abnormalities of growth hormone secretion and action, resulting in impaired growth in uraemic children (pharmacological treatment with recombinant growth hormone and insulin-like growth factor is used).
- Abnormal thyroid hormone levels, partly because of altered protein binding. Measurement of thyroid-stimulating hormone (TSH) is the best way to assess thyroid function. True hypothyroidism occurs with increased frequency in renal failure.

Posterior pituitary gland function is normal in renal failure.

Muscle dysfunction

Uraemia appears to interfere with muscle energy metabolism, but the mechanism is uncertain. Decreased physical fitness (cardiovascular deconditioning) also contributes.

Nervous system

Central nervous system

Severe uraemia causes an unusual combination of depressed cerebral function and decreased seizure threshold. However, convulsions in a uraemic patient are much more commonly due to other causes such as accelerated hypertension, thrombotic thrombocytopenic purpura or drug accumulation. Asterixis, tremor and myoclonus are also features of severe uraemia.

Rapid correction of severe uraemia by haemodialysis leads to '*dialysis disequilibrium*' owing to osmotic cerebral swelling. This can be avoided by correcting uraemia gradually by short, repeated haemodialysis treatments or by the use of peritoneal dialysis.

'*Dialysis dementia*' is a syndrome of progressive intellectual deterioration, speech disturbance, myoclonus and fits, which is due to aluminium intoxication; it may be accompanied by aluminium bone disease and by microcytic anaemia. Low-grade aluminium exposure may also cause more subtle, subclinical deterioration in intellectual function. Prevention involves removal of aluminium from source water used to manufacture dialysis fluid, and restriction or avoidance of aluminium-containing gut phosphorus binders. Treatment is with the chelating agent desferrioxamine.

Psychiatric problems are common. Patients can have anxiety, depression, phobias and psychoses.

Autonomic nervous system

Increased circulating catecholamine levels associated with down-regulation of α-receptors, impaired baroreceptor sensitivity and impaired efferent vagal function are common in renal impairment.

Overactivity of the sympathetic nervous system in chronic renal failure is believed to play a part in the genesis of hypertension in this condition. All of these abnormalities improve to some extent after institution of regular dialysis and resolve after successful renal transplantation.

Peripheral nervous system

Median nerve compression in the carpal tunnel is common, usually due to β_2-microglobulin-related amyloidosis. This can be avoided by haemofiltration and haemodiafiltration. 'Restless legs' syndrome (p. 1197) is common in uraemia. The syndrome is difficult to treat. Iron deficiency should be treated if present. Attention should be paid to adequacy of dialysis. Symptoms may improve with the correction of anaemia by erythropoietin. Clonazepam is sometimes useful. Renal transplantation cures the problem. A polyneuropathy occurs in patients who are inadequately dialysed.

Calciphylaxis

Also known as calcific uraemic arteriolopathy, this is a rare but serious life-threatening complication in CKD patients. It is increasingly recognized as a contributing factor to death in dialysis patients. Aetiological factors include reduced serum levels of a calcification inhibitory protein (fetuin-A) and abnormalities in smooth muscle cell biology in uraemia. It presents as painful non-healing eschars with panniculitis and dermal necrosis. The characteristic feature on histology is vascular calcification and superimposed small vessel thrombosis (Fig. 11.48).

Hyperparathyroidism and elevated concentrations of serum phosphate, morbid obesity and warfarin use remain consistent clinical features of most cases reported. Control of hyperparathyroidism is with either surgical intervention or with a calcimimetic agent.

Promising new treatment options include hyperbaric oxygen therapy and sodium thiosulfate infusion. Benefits from bisphosphonates and tissue plasminogen activator have also been reported.

Cardiovascular disease

Life expectancy remains severely reduced compared with the normal population owing to a greatly increased (16-fold) incidence of cardiovascular disease, particularly myocardial infarction, cardiac failure, sudden cardiac death and stroke.

Risk factors

Hypertension is a frequent complication of renal failure. Diabetes mellitus is the commonest cause of CKD. Dyslipidaemia is universal in uraemic patients. Furthermore, smoking is as common as in the general population and male gender is over-represented in patients with CKD. Ventricular hypertrophy is common, as is systolic and diastolic dysfunction. Diastolic dysfunction is largely attributable to left ventricular hypertrophy and contributes to hypotension during fluid removal on haemodialysis. Systolic dysfunction may be due to:

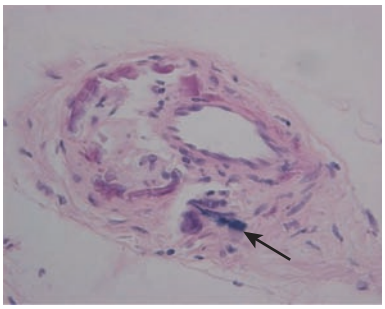

Fig. 11.48 **Calciphylaxis**: Characteristic arterial calcification of the skin microvasculature in the absence of vasculitic change (arrow).

- myocardial fibrosis
- abnormal myocyte function owing to uraemia
- calcium overload and hyperparathyroidism
- carnitine and selenium deficiency.

Left ventricular hypertrophy is a risk factor for early death in renal failure, as in the general population. Systolic dysfunction is also a marker for early death in renal failure.

Coronary artery calcification. Traditional risk factors (e.g. smoking, diabetes) can only partly explain the risk in patients with chronic nephropathies.

Coronary artery calcification is more common in patients with *end-stage renal failure* than in normal individuals and it is highly likely that this contributes significantly to cardiovascular mortality. Vascular calcification is frequent in all sizes of vessel in renal failure.

In addition to the classical risk factors for atherosclerosis:

- A *raised [calcium × phosphate] product* causes medial calcification.
- *Hyperparathyroidism* may also contribute independently to the pathogenesis by increasing intracellular calcium.
- *Vascular calcification* in uraemia is now thought to be an active process whereby vascular smooth muscle cells acquire osteoblast-like characteristics, possibly in response to elevated phosphate or [calcium × phosphate] product.
- *Inflammation* is a potent mediator of vascular calcification by inhibition of fetuin (a glycoprotein synthesized by liver, which is a potent inhibitor of vascular calcification).

The impact of vascular calcification is the *reduction of vascular compliance*, which manifests by increased pulse pressure and pulse wave velocity, and increased afterload contributes further to left ventricular hypertrophy. In addition to myocardial abnormalities, vascular calcification with its associated biomechanical vessel wall alterations is a strong predictor of all-cause and cardiovascular morbidity and mortality in patients with CKD. Diffuse calcification of the myocardium is also common; the causes are similar.

Other cardiovascular risk factors. These include hyperhomocysteinaemia, *Chlamydia pneumoniae* infection, oxidative stress and elevated endogenous inhibitor of nitric oxide synthase and asymmetric dimethyl arginine (ADMA) levels. High ADMA levels in uraemia are in part caused by oxidative stress and can possibly explain the 52% increase in the risk of death and 34% increase in the risk of cardiovascular events in uraemic patients. The use of antioxidants, vitamin E or *N*-acetylcysteine has been associated with a significant reduction in all-cause and cardiovascular mortality. However, recent trials to reduce levels of homocysteine with statins in dialysis patients with diabetes, and folic acid supplementation have been unsuccessful.

Pericarditis

This is common and occurs in two clinical settings:

- Uraemic pericarditis is a feature of severe, pre-terminal uraemia or of underdialysis. Haemorrhagic pericardial effusion and atrial arrhythmias are often associated. There is a danger of pericardial tamponade, and anticoagulants should be used with caution. Pericarditis usually resolves with intensive dialysis.
- Dialysis pericarditis occurs as a result of an intercurrent illness or surgery in a patient receiving apparently adequate dialysis.

Malignancy

The incidence of malignancy is raised in patients with CKD and with dialysis. Malignant change can occur in multicystic kidney disease. Lymphomas, primary liver cancer and thyroid cancers also occur.

Management

Successful renal transplantation improves some, but not all, of the complications of CKD, therefore attempts should be made to prevent these complications by careful monitoring with ECG, echocardiography, angiography (if necessary) and nuclear imaging. CT (spiral CT) and/or MRI are useful in the assessment of arterial calcification. Treatment is with the control of risk factors (p. 630) as well as the treatment of hypercalcaemia and hyperparathyroidism (p. 631).

PROGRESSION OF CHRONIC RENAL IMPAIRMENT

Chronic renal impairment tends to progress inexorably to end-stage renal failure, although the rate of progression may depend upon the underlying nephropathy. Patients with chronic glomerular diseases tend to deteriorate more quickly than those with chronic tubulointerstitial nephropathies. Hypertension and heavy proteinuria are bad prognostic indicators. A non-specific renal scarring process common to renal disorders of different aetiologies may be responsible for progression.

Possible causes of glomerular scarring and proteinuria include:

- a rise in intraglomerular capillary pressure
- adaptive glomerular hypertrophy due to reduced arteriolar resistance and increased glomerular blood flow when there is reduced nephron mass.

This glomerular hyperfiltration, in response to nephron loss, was postulated as a common pathway for the progression of renal failure.

Since the afferent arteriolar tone decreases more than efferent arteriolar tone, intraglomerular pressure and the amount of filtrate formed by a single nephron rises. Angiotensin II produced locally modulates intraglomerular capillary pressure and GFR, predominantly causing vasoconstriction of postglomerular arterioles, thereby increasing the glomerular hydraulic pressure and filtration fraction (Fig. 11.49). In addition, by its effect on mesangial cells and podocytes, it increases the pore sizes and impairs the size-selective function of basement membrane for macromolecules.

Angiotensin II also modulates cell growth directly and indirectly by upregulating TGF-β, a potent fibrogenic cytokine, increases collagen synthesis and also causes epithelial cell transdifferentiation to myofibroblasts which contribute to excessive matrix formation. Furthermore, angiotensin II by upregulating plasminogen activator inhibitor-1 (PAI-1) inhibits matrix proteolysis by plasmin, resulting in accumulation of excessive matrix and scarring both in the glomeruli and interstitium.

Renal interstitial scarring is also a factor. The cause of this progressive interstitial damage and fibrosis is mutifactorial. In addition to non-haemodynamic effects of angiotensin II, *proteinuria* per se (by exposing tubular cells to albumin and its bound fatty acids and cytokines) promotes secretion of pro-inflammatory mediators, which promote interstitial inflammatory cell infiltrate and further augment fibrosis and progression of renal failure. The prognosis for renal function in chronic glomerular disorders is judged more accurately by interstitial histological appearances than by glomerular morphology.

Therapeutic manoeuvres (Box 11.6) aimed at inhibiting angiotensin II and reducing proteinuria mainly by ACEI and angiotensin-receptor antagonists have beneficial effects in slowing the rate of progression of renal failure in both diabetic and non-diabetic renal diseases in humans.

Experimentally, hepatocyte growth factor and bone morphogenic protein 7, both potent inhibitors of TGF-β, have resulted in the reversal of fibrosis and restoration of normal renal achitecture with improvement in renal function. If clinical trials are performed then nephrologists for the first time will be talking of *reversal* of CKD rather than *halting* the progression of renal impairment.

MANAGEMENT OF CHRONIC KIDNEY DISEASE

The underlying cause of renal disease should be treated aggressively wherever possible.

Renoprotection

The multidrug approach to chronic nephropathies has been formalized in an international protocol (Box 11.6).

Correction of complications

Hyperkalaemia

Hyperkalaemia often responds to dietary restriction of potassium intake. Drugs which cause potassium retention (see p. 667) should be stopped. Occasionally it may be necessary to prescribe ion-exchange resins to remove potassium in the gastrointestinal tract. Emergency treatment of severe hyperkalaemia is described on page 668.

Acidosis

Correction of acidosis helps to correct hyperkalaemia in CKD, and may also decrease muscle catabolism. Sodium bicarbonate supplements are often effective (4.8 g (57 mmol) of Na^+ and HCO_3^- daily), and the possibility of oedema and hypertension owing to the so-called 'extracellular fluid expansion' was not borne out by a recent trial. Calcium carbonate, also used as a calcium supplement and phosphate binder, has a beneficial effect on acidosis.

Calcium and phosphate control and suppression of PTH

Hypocalcaemia and hyperphosphataemia should be treated aggressively, preferably with regular (e.g. 3-monthly) measurements of serum PTH to assess how effectively hyperparathyroidism is being suppressed. Suppression of PTH levels to below two or three times the upper limit of 'normal'

Box 11.6 Renoprotection

Goals of treatment

BP <120/80
Proteinuria <0.3 g/24 hours

Treatment

Patients with chronic kidney disease and proteinuria >1 g/24 hours:

- ACE inhibitor increasing to maximum dose
- Add angiotensin receptor antagonist if goals are not achieved*
- Add diuretic to prevent hyperkalaemia and help to control BP
- Add calcium-channel blocker (verapamil or diltiazem) if goals not achieved

Additional measures

- Statins to lower cholesterol to <4.5 mmol/L
- Stop smoking (threefold higher rate of deterioration in CKD)
- Treat diabetes (HbA1c <7%)
- Normal protein diet (0.8–1 g/kg bodyweight)

*In type 2 diabetes start with angiotensin receptor antagonist

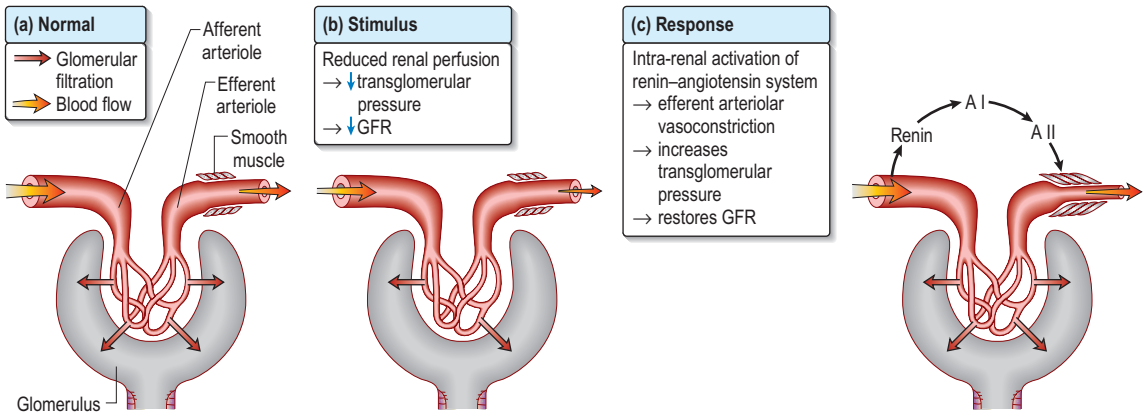

Fig. 11.49 **Glomerular dynamics**: Effect of the renin–angiotensin system. AI, angiotensin I; AII, angiotensin II.

carries a high risk of development of adynamic bone disease.

Dietary restriction of phosphate is seldom effective alone, because so many foods contain it. Oral calcium carbonate or acetate reduces absorption of dietary phosphate but is contraindicated where there is hypercalcaemia or hypercalciuria. Aluminium-containing gut phosphate binders are very effective but absorption of aluminium poses the risk of aluminium bone disease and development of cognitive impairment. They are now rarely used.

Treatment

- *Gut phosphate binders*. The polymer sevelamer reduces the calcium load and attenuates vascular calcification and also lowers cholesterol levels by 10%. However, it has not been shown to reduce mortality. Lanthanum carbonate is a new non-calcium, non-aluminium phosphate binder that is effective and has a good safety profile.
- *Nicotinamide*, an alternative to phosphate binders, blocks the intestinal sodium/inorganic phosphate (Na/Pi) cotransporter. Preliminary results show that it reduces phosphate levels and PTH levels alongside improvement in the lipid profile in dialysis patients.
- *Calcitriol or a vitamin D analogue,* such as alfacalcidol, used in early renal impairment has no deleterious effect upon renal function provided hypercalcaemia is avoided. New vitamin D metabolites (22-oxacalcitriol, paricalcitol, doxercalciferol) are less calcaemic. However, with the exception of paricalcitol (19-nor-1,25 dihydroxyvitamin D_2, which may have survival advantage), their usefulness over conventional but less expensive calcitriol or alfacalcidol remains to be established. (Treatment with vitamin D analogues should be started only if serum PTH level is three times or more above the upper limit of normal, in order to prevent the development of adynamic bone disease (see p. 628). Vitamin D therapy has the disadvantage that it increases not only calcium but also phosphate absorption and may therefore exacerbate hyperphosphataemia and ectopic calcification including calciphylaxis (calcification of small vessels)).
- *Calcimimetic agents* (e.g. cinacalcet, a calcium-sensing receptor agonist, see p. 628) have also been tried in established secondary hyperparathyroidism with successful suppression of PTH levels and lowering of calcium × phosphate product. The long-term safety and efficacy of these agents remains to be established.

Drug therapy

This should be minimized in patients with chronic renal impairment. Tetracyclines (with the possible exception of doxycycline) should be avoided in view of their anti-anabolic effect and tendency to worsen uraemia. Drugs excreted by the kidneys, such as gentamicin, should be prescribed with caution and drug levels monitored if feasible. Non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided. Potassium-sparing agents, such as spironolactone and amiloride, pose particular dangers, as do artificial salt substitutes, all of which contain potassium.

Anaemia

The anaemia of erythropoietin (EPO) deficiency can be treated with synthetic (recombinant) human EPO (epoetin-alfa or -beta, or the longer-acting darbopoetin-alfa or polyethylene glycol-bound epoetin-beta). The intravenous route is used, initially with 50 U/kg of epoetin-alfa over 1–5 minutes, three times weekly. Subcutaneous administration of *epoetin-alfa* can also be used (see below). Blood pressure, haemoglobin concentration and reticulocyte count are measured every 2 weeks and the dose adjusted to maintain a target haemoglobin of 11–12 g/dL. Darbepoietin-alfa can be used once a week. Continuous erythropoiesis receptor activator (CERA), a recently licensed epoietin in Europe, is a pegylated epoietin beta and can be given once a month. In trials, CERA has a similar activity to other types of epoietins. However, CERA use is extremely limited and data about loss of flexibility of dosing, overshooting the target haemoglobin and its efficacy in combination with short-acting epoietins are required before its widespread use.

The target haemoglobin to be achieved during the treatment of anaemia is being revised to between 11 and 12 g/dL as studies in pre-dialysis CKD patients have not revealed any outcome benefits in patients who were treated to achieve higher haemoglobin targets (>12 g/dL).

Failure to respond to 300 U/kg weekly, or a fall in haemoglobin after a satisfactory response, may be due to iron deficiency, bleeding, malignancy, infection, inflammation or formation of anti-EPO neutralizing antibodies. The demand for iron by the bone marrow is enormous when erythropoietin is commenced. Patients on EPO therapy are regularly monitored for iron status and considered iron deficient if plasma ferritin is <100 μg/L, hypochromic RBCs >10%, transferrin saturation <20%. Functional iron deficiency due to poor mobilization of iron, despite adequate iron stores (ferritin >500 μg/L) and a transferrin saturation of >20%, is a common finding in patients with chronic inflammation. It is caused by hepcidin (see p. 394), an acute phase reactant produced by the liver in response to cytokines, particularly IL-6. Intravenous (rather than oral) iron supplements optimize response to EPO treatment by repletion of iron stores. A recent randomized trial has demonstrated a beneficial effect of i.v. iron even in patients with ferritin >800 μg/L and transferrin saturation of 20%.

Correction of anaemia with EPO improves quality of life, exercise tolerance and sexual and cognitive function in dialysis patients, and leads to regression of left ventricular hypertrophy. Avoidance of blood transfusion also reduces the chance of sensitization to HLA antigens, which may otherwise be a barrier to successful renal transplantation.

The *disadvantages of erythropoietin therapy* are that it is expensive and causes a rise in blood pressure in up to 30% of patients, particularly in the first 6 months. Peripheral resistance rises in all patients, owing to loss of hypoxic vasodilatation and to increased blood viscosity. A rare complication is encephalopathy with fits, transient cortical blindness and hypertension. Several reports of anti-EPO antibody-mediated pure red cell aplasia in patients receiving subcutaneous EPO therapy (particularly EPO alpha) have been described. The exact cause is unknown but interventions such as using the intravenous route and changes in manufacture of prefilled syringes have reduced the number of cases by 80%. Other causes of anaemia should be looked for and treated appropriately (see p. 392).

Several new erythropoiesis-stimulating agents are in clinical trials. An EPO mimetic is an engineered peptide which stimulates EPO receptor but still has to be given by injection. Oral agents which inhibit prolyl hydoxlase and prolong the

life of HIF (hypoxia inducible factors) 1 alpha, a transcription factor for endogenous production of EPO, have shown promise in phase 2 trials.

Male erectile dysfunction

Testosterone deficiency should be corrected. The oral phosphodiesterase inhibitors, e.g. sildenafil, tadalafil and vardenafil, are effective in end-stage renal failure and are the first line of therapy. The use of nitrates is a contraindication to this treatment. Other treatments are discussed on page 1000.

EARLY REFERRAL OF PATIENTS WITH CHRONIC KIDNEY DISEASE

Patients need time to adjust to the demands of chronic renal failure and its treatment, and to absorb information. Veins required in the future for fashioning of an arteriovenous fistula should not be rendered useless by cannulation (Fig. 11.50).

If the patient opts for regular haemodialysis, fashioning of an arteriovenous fistula should be carried out well in advance of the need for dialysis, when serum creatinine is of the order 400–500 μmol/L in non-diabetics and at an even earlier stage in diabetics with poorer vasculature. Such fistulae require several weeks to mature and become usable for vascular access.

RENAL REPLACEMENT THERAPY

Approximately 100 white individuals per million population commence renal replacement therapy in the UK each year. The corresponding figure in black Africans and Asians in the UK is three to four times higher, largely owing to diabetic and hypertensive nephropathy. The aim of all renal replacement techniques is to mimic the excretory functions of the normal kidney, including excretion of nitrogenous wastes, maintenance of normal electrolyte concentrations, and maintenance of a normal extracellular volume.

Haemodialysis

Basic principles

In haemodialysis, blood from the patient is pumped through an array of semipermeable membranes (the dialyser, often called an 'artificial kidney') which bring the blood into close contact with dialysate, flowing countercurrent to the blood. The plasma biochemistry changes towards that of the dialysate owing to diffusion of molecules down their concentration gradients (Fig. 11.51).

The dialysis machine comprises a series of blood pumps, with pressure monitors and bubble detectors and a proportionating unit, also with pressure monitors and blood leak detectors. Blood flow during dialysis is usually 200–300 mL per minute and the dialysate flow usually 500 mL per minute. The efficiency of dialysis in achieving biochemical change depends on blood and dialysate flow and the surface area of the dialysis membrane.

Dialysate is prepared by a proportionating unit, which mixes specially purified water with concentrate, resulting in fluid with the composition described in Table 11.21. Bicarbonate has replaced acetate which contributed to hypotension. Highly permeable synthetic membranes allow more rapid haemodialysis than cellulose-based membranes (high-flux haemodialysis).

Access for haemodialysis

Adequate dialysis requires a blood flow of at least 200 mL per minute. The most reliable long-term way of achieving this is surgical construction of an arteriovenous fistula (Fig. 11.52a, b), using the radial or brachial artery and the cephalic vein. This results in distension of the vein and thickening ('arterialization') of its wall, so that after 6–8 weeks large-bore needles may be inserted to take blood to and from the dialysis machine. In patients with poor-quality veins or arterial disease (e.g. diabetes mellitus) arteriovenous polytetrafluoroethylene (PTFE) grafts are used for access. However, these grafts have a very high incidence of thrombosis and 2-year graft patency is only 50–60%. Dipyridamole or fish oils

In particular, the fistula should not be compressed during surgery to avoid thrombosis within it.

improve graft patency but warfarin, aspirin and clopidogrel do not and are associated with a high incidence of complications.

If dialysis is needed immediately, a large-bore double-lumen cannula may be inserted into a central vein – usually the subclavian, jugular or femoral. *Semipermanent dual-lumen venous catheters* can also be used, usually inserted via a skin tunnel to lessen the risk of infection. Nevertheless, local and systemic sepsis is high, with increased morbidity and mortality. Stenosis of the subclavian vein is also common, and the jugular route is preferred.

Dialysis prescription

Dialysis must be tailored to an individual patient to obtain optimal results.

Dry weight

This is the weight at which a patient is neither fluid overloaded nor depleted. Patients are weighed at the start of each dialysis session and the transmembrane pressure adjusted to achieve fluid removal equal to the amount by which they exceed their dry weight.

The dialysate buffer

The dialysate buffer is usually acetate or bicarbonate. The sodium and calcium concentrations of the dialysate buffer are carefully monitored. A high dialysate sodium causes thirst and hypertension. A high dialysate calcium causes hypercalcaemia, whilst a low-calcium dialysate combined with poor compliance of medication with oral calcium carbonate and vitamin D may result in hyperparathyroidism.

Frequency and duration

Frequency and duration of dialysis are adjusted to achieve adequate removal of uraemic metabolites and to avoid excessive fluid overload between dialysis sessions. An adult of average size usually receives 4–5 hours' treatment three times a week. Twice-weekly dialysis is adequate only if the patient has considerable residual renal function.

Short-duration dialysis using very biocompatible high-flux membranes is commonly employed. Advantages include shorter duration of treatment and hence increased patient convenience. Disadvantages include higher cost of the membranes employed and, in all probability, higher prevalence of hypertension in such patients, requiring hypotensive medication. It should not be forgotten that normal kidneys work for 24 hours a day, 7 days a week, and that dialysis is a poor substitute for the natural state.

Adequate/optimal dialysis should be adjusted to individual patients' needs. All patients are anticoagulated (usually with heparin) during treatment as contact with foreign surfaces activates the clotting cascade. In the UK, a small number of patients manage self-supervised home haemodialysis.

Complications

Hypotension during dialysis is the major complication. Contributing factors include: an excessive removal of extracellular fluid, inadequate 'refilling' of the blood compartment from the interstitial compartment during fluid removal, abnormalities of venous tone, autonomic neuropathy, acetate intolerance (acetate acts as a vasodilator) and left ventricular hypertrophy.

Very rarely patients may develop anaphylactic reactions to ethylene oxide, which is used to sterilize most dialysers. Patients receiving ACE inhibitors are at risk of anaphylaxis if polyacrylonitrile dialysers are used.

Other potential, rare, complications include the hard-water syndrome (caused by failure to soften water resulting in a high calcium concentration prior to mixing with dialysate concentrate), haemolytic reactions and air embolism.

Adequacy of dialysis

Dialysis treatment is empirical since the size, number and nature of 'uraemic toxins' is unclear. The only true measure of adequacy is patient mortality and morbidity. Adequate nutrition of the patient as well as adequate dialysis is necessary to reduce morbidity and mortality.

Symptoms of underdialysis are non-specific and include insomnia, itching, fatigue despite adequate correction of anaemia, restless legs and a peripheral sensory neuropathy.

Adequacy of dialysis may be assessed by computerized calculation of urea kinetics, requiring measurement of the residual renal urea clearance, the rate of rise of urea concentration between dialysis sessions, and the reduction in urea concentration during dialysis. The dialysis dose is normally defined in terms of urea reduction ratio (URR) and/or equilibrated urea clearance, *eKt/V* (where *K* is the dialyser clearance, *t* is the duration of dialysis in minutes, and *V* is the urea distribution volume estimated as total body water). *Kt/V* of 1.0–1.2 and/or URR of 65% per dialysis session is the minimum threshold required for well-nourished dialysis patients dialysed three times per week. It is unclear whether a higher e*Kt/V* is associated with a better outcome, although no additional benefits of high (1.53) compared to standard

(1.16) e*Kt/V* were seen over 5 years' follow-up. It is likely that duration of haemodialysis session is a factor in itself in addition to the efficiency with which small molecules such as urea are cleared. The best haemodialysis outcome data are seen in renal units where long hours (8 hours per session) of dialysis are routinely practised.

Haemodialysis is the most efficient way of achieving rapid biochemical improvement, for instance in the treatment of acute kidney injury or severe hyperkalaemia. This advantage is offset by disadvantages such as haemodynamic instability, especially in acutely ill patients with multiorgan disease, and over-rapid correction of uraemia can lead to 'dialysis disequilibrium'. This is characterized by nausea and vomiting, restlessness, headache, hypertension, myoclonic jerking, and in severe instances seizures and coma owing to rapid changes in plasma osmolality leading to cerebral oedema.

These problems have led to the increasing adoption of gentler continuous methods for the treatment of acute kidney injury (see below).

Haemofiltration

This involves removal of plasma water and its dissolved constituents (e.g. K^+, Na^+, urea, phosphate) by convective flow across a high-flux semipermeable membrane, and replacing it with a solution of the desired biochemical composition (Fig. 11.53). Lactate is used as buffer in the replacement solution because rapid infusion of acetate causes vasodilatation, and bicarbonate may cause precipitation of calcium carbonate.

Haemofiltration can be used for both acute and chronic renal failure and is used in mainland Europe for CKD patients with haemodynamic instability. High volumes need to be exchanged in order to achieve adequate small molecule removal, typically a 22 L exchange three times a week for maintenance treatment and 1 L per hour in acute kidney injury. Financial costs of disposable items (such as filters and replacement fluid) are high and only a selected group of patients with end-stage renal failure are managed in this way. Modern dialysis machines have built-in facilities to generate online ultrapure water which has minimized the cost of the procedure and given an option to the clinician to use this technique either as haemofiltration or in combination with dialysis as haemodiafiltration to increase middle molecule clearance (e.g. β_2-microglobulin) and prevent long-term dialysis complications such as dialysis-related amyloidosis, particularly in young, highly sensitized, non-transplantable patients.

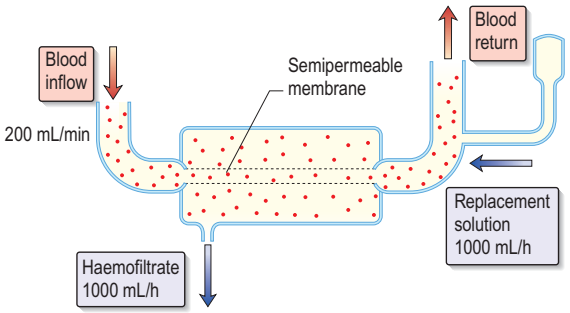

Fig. 11.53 **Principles of haemofiltration.**

Peritoneal dialysis

Peritoneal dialysis utilizes the peritoneal membrane as a semipermeable membrane, avoiding the need for extracorporeal circulation of blood. This is a very simple, low-technology treatment compared to haemodialysis. The principles are simple (Fig. 11.54).

- A tube is placed into the peritoneal cavity through the anterior abdominal wall (Fig. 11.55).
- Dialysate is run into the peritoneal cavity, usually under gravity.
- Urea, creatinine, phosphate and other uraemic toxins pass into the dialysate down their concentration gradients.
- Water (with solutes) is attracted into the peritoneal cavity by osmosis, depending on the osmolarity of the dialysate. This is determined by the glucose or polymer (icodextrin) content of the dialysate (Table 11.22).
- The fluid is changed regularly to repeat the process.

Chronic peritoneal dialysis requires insertion of a soft catheter, with its tip in the pelvis, exiting the peritoneal cavity in

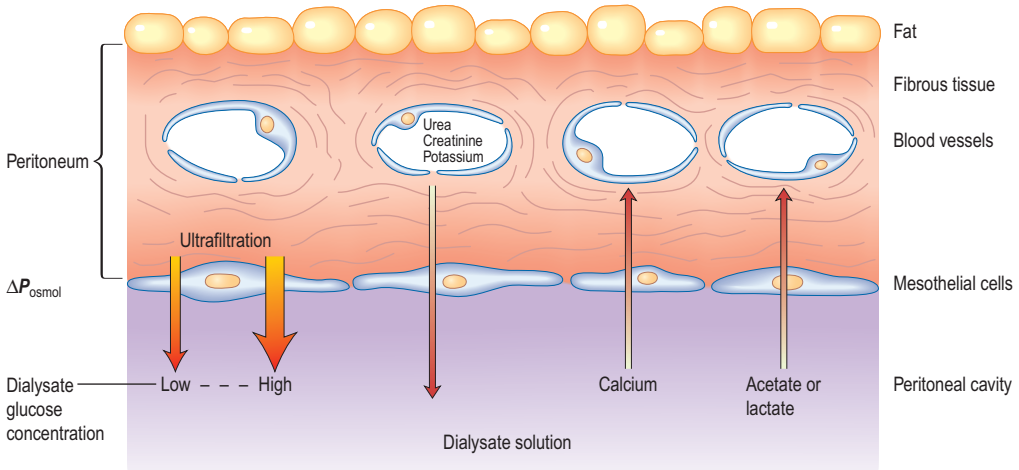

Fig. 11.54 **Principles of peritoneal dialysis.** Water is attracted into the peritoneal cavity depending on the osmolarity of the dialysate.

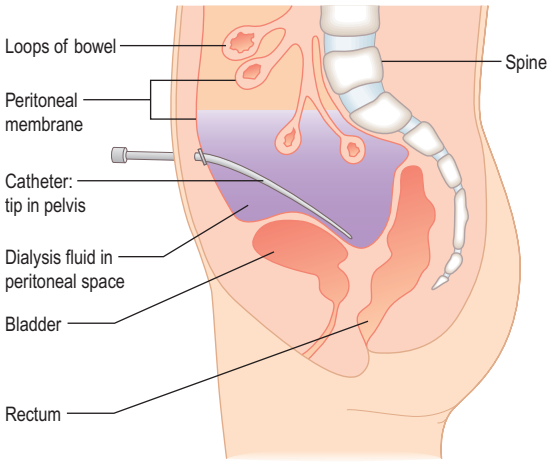

Fig. 11.55 **The siting of a Tenckhoff peritoneal dialysis catheter.**

Table 11.22 **Range of concentrations (mmol/L) in routinely available CAPD dialysate***

Sodium	130–134
Potassium	0
Calcium	1.0–1.75
Magnesium	0.25–0.75
Chloride	95–104
Lactate	35–40
Glucose	77–236
Total osmolality	356–511 mOsm/kg

*Glucose content is often expressed as g/dL of anhydrous glucose (e.g. 1.36% = 77 mmol/L). An even more hypertonic dialysate (6.36%) is available for acute (intermittent) peritoneal dialysis

the midline and lying in a skin tunnel with an exit site in the lateral abdominal wall (Fig. 11.55).

This form of dialysis can be adapted in several ways.

- *Continuous ambulatory peritoneal dialysis (CAPD).* Dialysate is present within the peritoneal cavity continuously, except when dialysate is being exchanged. Dialysate exchanges are performed three to five times a day, using a sterile no-touch technique to connect 1.5–3 L bags of dialysate to the peritoneal catheter; each exchange takes 20–40 minutes. This is the technique most often used for maintenance peritoneal dialysis in patients with end-stage renal failure.
- *Nightly intermittent peritoneal dialysis (NIPD),* also called automated peritoneal dialysis (APD). An automated device is used to perform exchanges each night while the patient is asleep. Sometimes dialysate is left in the peritoneal cavity during the day in addition, to increase the time during which biochemical exchange is occurring. Few trials have demonstrated superiority of APD over CAPD with regards to complications such as peritonitis, fluid status and in anuric patients.
- *Tidal dialysis.* A residual volume is left within the peritoneal cavity with continuous cycling of smaller volumes in and out.

Table 11.23 **Some causes of CAPD peritonitis***

	Approximate percentage of cases
Staphylococcus epidermidis	40–50
Escherichia coli, Pseudomonas and other Gram-negative organisms	25
Staphylococcus aureus	15
Mycobacterium tuberculosis	2
Candida and other fungal species	2

*In approximately 20%, no bacteria are found

Osmotic removal of excess plasma water and solutes is achieved using hypertonic dialysate (either due to high glucose concentration or icodextrin), which exerts an osmotic 'drag'. Depending on the patient's fluid intake and residual urine output, it may be necessary to use one or more hypertonic dialysate bags daily to achieve fluid balance in CAPD. Fluid overload is a relatively common problem in CAPD, and is due to failure of transport across the peritoneal membrane.

Complications

Peritonitis

Bacterial peritonitis is the most common serious complication of CAPD and other forms of peritoneal dialysis. Clinical presentations include abdominal pain of varying severity (guarding and rebound tenderness are unusual), and a cloudy peritoneal effluent, without which the diagnosis cannot be made. Microscopy reveals a neutrophil count above 100 cells per mL. Nausea, vomiting, fever and paralytic ileus may be seen if peritonitis is severe. The incidence of CAPD-associated peritonitis has been much reduced (to about one episode every two patient years) by use of a Y-disconnect system in preference to previous methods.

CAPD peritonitis must be investigated with culture of peritoneal effluent. Empirical antibiotic treatment is started, with a spectrum which covers both Gram-negative and Gram-positive organisms. Antibiotics may be given by the oral, intravenous or intraperitoneal route; most centres rely on intraperitoneal antibiotics. Common causative organisms are listed in Table 11.23.

Staph. aureus peritonitis should lead to a search for nasal carriage of this organism, and *Staph. epidermidis* peritonitis may indicate contamination from the patient's (or helper's) skin. Relapsing *Staph. epidermidis* peritonitis with an organism with the same antibiotic sensitivity pattern on each occasion may indicate that the Tenckhoff catheter has become colonized: often this is difficult to eradicate without replacement of the catheter under antibiotic cover.

Gram-negative peritonitis may complicate septicaemia from urinary or bowel infection. A mixed growth of Gram-negative and anaerobic organisms strongly suggests bowel perforation, and is an indication for laparotomy.

Fungal peritonitis often follows antibacterial treatment but may occur de novo. Clinical presentation is very variable. It is rare to be able to cure fungal peritonitis without catheter removal as well as antifungal treatment. Intraperitoneal amphotericin has been associated with the formation of peritoneal adhesions.

Infection around the catheter site

Infection where the catheter exits through the skin is relatively common. It should be treated aggressively (with systemic and/or local antibiotics) to prevent spread of the infection into the subcutaneous tunnel and the peritoneum. The most common causative organisms are staphylococci, including MRSA. Exit site infections can be reduced by routine use of mupirocin or gentamicin ointments locally and intranasally in those with colonized nares. Exit site infection due to *Pseudomonas* is treated by antibiotics and resiting the exit following catheter exchange.

Other complications

CAPD is often associated with constipation, which in turn may impair flow of dialysate in and out of the pelvis. Occasionally dialysate may leak through a diaphragmatic defect into the thoracic cavity, causing a massive pleural 'effusion'. The glucose content of the effusion is usually diagnostic, or the diagnosis may be made by instillation of methylthioninium chloride (methylene blue) with dialysate and the demonstration of a blue colour on pleural tap. Dialysate may also leak into the scrotum down a patent processus vaginalis.

Failure of peritoneal membrane function is a predictable complication of long-term CAPD, resulting in worsening biochemical exchange and decreased ultrafiltration with hypertonic dialysate. It is thought that this problem may be accelerated by excessive reliance on hypertonic dialysate to remove fluid.

Sclerosing peritonitis is a potentially fatal complication of CAPD. The cause is often unclear, but recurrent peritonitis and exposure of the peritoneum to unphysiological high glucose concentrations is responsible in most cases. Progressive thickening of the peritoneal membrane occurs in association with adhesions and strictures, turning the small bowel into a mass of matted loops and causing repeated episodes of small bowel obstruction. CAPD should be abandoned. Improvement may follow renal transplantation or treatment with prednisolone or azathioprine.

Contraindications

There are few absolute contraindications apart from unwillingness or inability on the patient's part to learn the technique.

- Previous peritonitis causing peritoneal adhesions may make peritoneal dialysis impossible, but the extent of adhesions is difficult to predict and it may be worth an attempted surgical placement of a dialysis catheter.
- The presence of a stoma (colostomy, ileostomy, ileal urinary conduit) makes successful placement of a dialysis catheter extremely unlikely.
- Active intra-abdominal sepsis, for instance due to diverticular abscesses, is an absolute contraindication to peritoneal dialysis although diverticular disease per se is not.
- Abdominal hernias may often expand during CAPD as a result of increased intra-abdominal pressure, and should ideally be repaired before or at the time of CAPD catheter insertion.
- Visual impairment may make it difficult for a patient to perform dialysate exchanges, but completely blind patients can be trained in the technique if adequately motivated.
- Severe arthritis makes it difficult to perform the exchanges, but a large number of mechanical aids are available. Sterilization of connections by heat or ultraviolet light reduces the risk of peritonitis.
- Some studies suggest that end-stage renal failure patients with coronary artery disease or congestive heart failure have significantly higher morbidity and mortality on CAPD compared to HD. Moreover, elderly patients do worse on CAPD than younger patients. It is advisable to consider HD as the first-choice dialysis modality in these patients where it is possible.

Adequacy of peritoneal dialysis

No consensus exists on the optimum degree of removal of urea and other waste products to be obtained in unit time but there is general agreement that minimum dose delivered should not be less than 1.7. Based on observational studies, weekly *Kt/V* of 2.0 coupled with a creatinine clearance target of 60 L per week had been recommended. However, in a randomized prospective study (ADEMEX), standard daily exchanges of 8 L in total (creatinine clearance 40 L per week) compared to a creatinine clearance of 60 L per week yielded similar patient and technique survival. Peritoneal dialysis inadequacy becomes common when residual renal function declines to zero. With increasing time on treatment, adequacy may become impaired owing to alterations in the efficiency of the peritoneal membrane in transporting waste products, fluid and electrolytes.

Complications of all long-term dialysis

Cardiovascular disease (see p. 630) and sepsis are the leading causes of death in long-term dialysis patients.

Causes of fatal sepsis include peritonitis complicating peritoneal dialysis and *Staph. aureus* infection (including endocarditis) complicating the use of indwelling access devices for haemodialysis.

Dialysis amyloidosis

This is the accumulation of amyloid protein (p. 1073) as a result of failure of clearance of β_2-microglobulin, a molecule of 11.8 kDa. This protein is the light chain of the class I HLA antigens and is normally freely filtered at the glomerulus but is not removed by cellulose-based haemodialysis membranes. The protein polymerizes, possibly after modification by non-enzymic glycosylation, to form amyloid deposits, which may cause median nerve compression in the carpal tunnel or a dialysis arthropathy – a clinical syndrome of pain and disabling stiffness in the shoulders, hips, hands, wrists and knees. β_2-microglobulin-related amyloid may be demonstrated in the synovium. Amyloid deposits (see p. 1072) can also cause pathological bone cysts and fractures, pseudotumours and gastrointestinal bleeding caused by amyloid deposition around submucosal blood vessels. The extent of amyloid deposition is best assessed by nuclear imaging, either using [^{99m}Tc]DMSA, or, more specifically, by the use of radiolabelled serum amyloid P component.

Rapid improvement after renal transplantation is probably due to steroid therapy as low-dose prednisolone alone can also cause an improvement. A change to a biocompatible synthetic membrane has also been reported to be of benefit: again, the mechanism for this improvement is not clear. β_2-microglobulin clearance is several times higher in patients treated with haemofiltration or haemodiafiltration and these

techniques are increasingly used in patients at high risk of developing this complication.

Transplantation

Successful renal transplantation offers the potential for almost complete rehabilitation in end-stage renal failure. This mode of renal replacement therapy has significant survival advantage compared to dialysis patients on transplant waiting lists. It allows freedom from dietary and fluid restriction; anaemia and infertility are corrected; and the need for parathyroidectomy is reduced. It is the treatment of choice for most patients with end-stage renal failure. The supply of donor organs (in the UK, 30/million/year) is greatly exceeded by demand (48/million/year), and donor organs are therefore scarce and a valuable resource that must be used optimally.

The technique involves the anastomosis of an explanted human kidney, usually either from a cadaveric donor or from a living close relative, on to the iliac vessels of the recipient (Fig. 11.56). The donor ureter is placed into the recipient's bladder. Unless the donor is genetically identical (i.e. an identical twin), immunosuppressive treatment is needed, for as long as the transplant remains in place, to prevent rejection. Refinements in patient selection and assessment of donor–recipient compatibility, improvements in surgical techniques and the development of more efficient immunosuppressive regimens have increased patient and graft survival. Eighty per cent of grafts now survive for 5–10 years in the best centres, and 50% for 10–30 years. However the half-life of renal allografts is still 13–16 years. The three most common causes of late graft loss are death with functioning graft, recurrence of renal disease and chronic allograft nephropathy.

Factors affecting success

ABO (blood group) compatibility between donor and recipient is required. However, in some centres, particularly in Japan where a cadaveric organ donation programme is not well established, ABO-incompatible renal transplants are increasingly performed. These transplants follow with immunoadsorption to remove preformed antibodies, splenectomy, anti-CD20 antibodies to remove B lymphocytes, and intravenous pooled immunoglobulins for immunomodulation or anti-idiotypic antibodies. In experienced hands, results are acceptable.

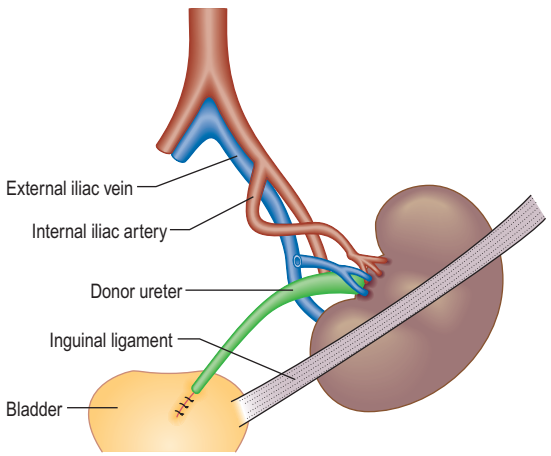

Fig. 11.56 **Anatomy of a renal transplant operation.**

Matching donor and recipient for HLA type

Matching for HLA-DR antigens appears to have the most impact on graft survival. Studies have shown that matching at the HLA-B locus has only a minor effect on graft outcomes. Complete compatibility at A, B and DR offers the best chance of success, followed by a single HLA mismatch (i.e. antigen possessed by the donor and not possessed by the recipient). The effect of further degrees of mismatching upon graft survival in first transplants is of modest degree. Nationwide matching schemes for kidneys retrieved from cadaver donors are in existence. However, with availability of more efficient immunosuppressive agents, the value of HLA matching in the overall transplant outcome is, if any, only modest. Transplantation with completely mismatched kidneys, particularly when the donor is the patient's partner, is routinely practised and results are as good as, if not better than, properly matched cadaveric kidneys.

A newly identified donor factor, an allotype of the C3 complement molecule, may be associated with better long-term outcomes for cadaveric kidney grafts. The C3 allotypes have distinct electrophoretic migration patterns: C3F (fast), present in about 20% of white patients, and C3S (slow). This report raises the possibility that the presence of the C3F allele in a kidney allograft is associated with a better outcome.

Adequate immunosuppressive treatment

See below.

The donor kidney

Cadaveric donation

Most countries allow the removal of kidneys and other organs from patients who have suffered irretrievable brain damage ('brainstem death') while their hearts are still beating (see p. 920).

Living related donation

A close relative may volunteer as a potential donor. A sibling donor may be HLA identical or share one or no haplotypes with the potential recipient. In the UK, donor age must be 18 years or more.

Potential living related donors are subjected to an intensive preoperative evaluation, including clinical examination and measurement of renal function, tests for carriage of hepatitis B, C, HIV and cytomegalovirus, and detailed imaging of renal anatomy, to be sure that transplantation will be technically feasible.

Unrelated living donors may be accepted provided no inducement (financial or otherwise) is involved. Paid live non-related donor transplantation is illegal in the UK.

Immunosuppression for transplantation

Long-term drug treatment for the prevention of rejection is employed in all cases apart from living related donation from an identical twin. Some degree of immunological tolerance does develop, and the risk of rejection is highest in the first 3 months after transplantation. In the early months rejection

episodes occur in less than 30% of cadaver kidney recipients. Most are reversible. A combination of immunosuppressive drugs is usually used.

Corticosteroids. Corticosteroids have a non-specific anti-inflammatory (inhibition of phospholipase A_2 and arachidonic acid cascade) and immunosuppressive action (inhibition of gamma-interferon-dependent adhesion molecules and thereby dendritic cell and T lymphocyte interaction). High-dose methylprednisolone is used as the primary treatment for acute rejection.

Azathioprine. Azathioprine and its metabolite 6-mercaptopurine prevent cell-mediated rejection by blocking purine synthesis and replication of lymphocytes. They can convert a CD28-dependent costimulatory Rac1 signal (proliferation and differentiation) upon dendritic cells and T-lymphocyte interaction into an apoptotic response by their ability to form 6-thio-GTP. 6-Thio-GTP competes with GTP for Rac1, preventing its anti-apoptotic action. Adverse effects (see p. 290) include suppression of red cell and platelet production, an increased incidence of infections (particularly viral), and hepatotoxicity. It also interacts with allopurinol, which increases levels of its active metabolite (6-mercaptopurine), resulting in toxicity.

Mycophenolate mofetil is metabolized to mycophenolic acid and blocks inosine monophosphate dehydrogenase (IMPD), an enzyme in the de novo synthetic pathway of purine synthesis. It may be more specific for lymphocytes because, unlike in other cells, an alternative purine synthetic salvage pathway is absent from lymphocytes. It is more potent than azathioprine, as trials have shown a reduction in rejection episodes. Gastrointestinal symptoms such as nausea, vomiting and diarrhoea are more common than with azathioprine but the drug can be used with allopurinol.

Ciclosporin (CSA). Ciclosporin, a calcineurin inhibitor, prevents the activation of T lymphocytes in response to new antigens and is highly effective in preventing rejection, while leaving the functioning of the rest of the immune system largely intact. Intracellularly, CSA forms complexes with cyclophilin (isomerase) and inhibits calmodulin–calcineurin-induced phosphorylation of NF-AT transcription factor for IL-2 and possibly other T-cell activation genes. Its introduction has revolutionized organ transplantation. Disadvantages include high cost and nephrotoxicity. Even with careful adjustment of the dose in response to trough blood levels, renal function may be adversely affected.

Tacrolimus, also a calcineurin inhibitor, blocks T-cell activation by a mechanism very similar to that of ciclosporin with the exception that tacrolimus forms a complex with immunophilin FK binding protein-12 (FKBP-12) instead of cyclophilin. The downstream actions are the same as with CSA. It is more potent than CSA and is therefore used both as a rescue agent for treating rejection and as a maintenance agent. Its side-effects are broadly similar to those of CSA except it is more diabetogenic.

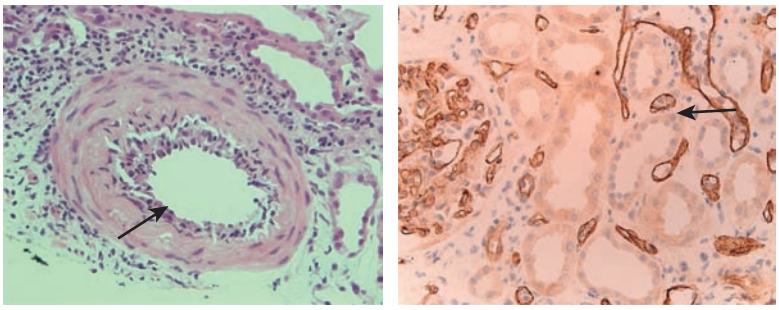
Sirolimus and the structural analogue everolimus are immunosuppressants that are synergistic with CSA but lack nephrotoxicity. Sirolimus, like tacrolimus, binds to FKBP (particularly the -25 rather than the -12 isoform) but instead of calcineurin inhibition, acts on targets of rapamycin signalling (mammalian target of rapamycin – mTOR) and prevents cell entry into G1 phase of the cell cycle. It may lead to poor wound healing and delay the recovery of proximal tubular cell injury sustained during transplantation. Its main side-effects are thrombocytopenia and hyperlipidaemia. Its role in renal transplantation is being explored.

Antibodies. Both polyclonal anti-thymocytic globulin (ATG) and anti-lymphocytic globulin (ALG) and monoclonal (OKT3) and anti-CD52 (CAMPATH) antibodies are potent immunosuppressive agents. Antibodies may be derived from mouse, rabbit, horse, or 'humanized', and directed against any of a number of lymphocyte surface marker proteins, enabling neutralization or killing of lymphocytes with certain functions (e.g. T cells, activated T cells, cells expressing adhesion molecules). They are mainly used for the treatment of steroid-resistant rejections and as an induction therapy for high immunological risk patients (previously sensitized with circulating anti-HLA antibodies). Basiliximab (chimeric) and dacluzumab (humanized) anti-CD25 monoclonal antibodies bind to IL-2 receptors on activated T lymphocytes only (therefore having few side-effects), inhibiting IL-2-driven proliferative responses. They have largely replaced ATG and ALG in transplant induction protocols of patients with low or intermediate immunological risk for rejection.

A new anti-B7 monoclonal antibody, LEA29Y (belatacept), given by a monthly injection and lacking the nephrotoxicity of other calcineurin inhibitors, has been found to be as effective as ciclosporin. It prevents T-cell activation induced by CD28.

Complications

Acute tubular necrosis (ATN)



ATN is the commonest cause of cadaveric graft dysfunction (up to 40–50%), particularly after asystolic donation and prolonged cold ischaemia time (>24 hours). Kidneys from elderly (>55 years) donors and those with a history of hypertension are liable to develop ATN. Delayed graft function due to ATN is associated with worse long-term outcome and also predisposes the graft to rejection. It is usual practice to use induction with antibodies and use 50% of the starting dose of calcineurin inhibitors in recipient of grafts at high risk for ATN.

Technical failures

There may be occlusion or stenosis of the arterial anastomosis, occlusion of the venous anastomosis, and urinary leaks owing to damage to the lower ureter, or defects in the anastomosis between ureter and recipient bladder. If urine output drops, Doppler ultrasonography, DTPA scanning and/or renal angiography is used. Surgical re-implantation may be required.

Acute rejection (AR)

AR is seen in between 10 and 30% of transplant recipients and usually presents with declining renal function within the first 3 months. Renal biopsy confirms the diagnosis and also assesses the severity and type of rejection (cellular or vascular or antibody mediated, also called humoral rejection). Therapy in cellular rejection is high-dose pulse steroid; in acute vascular rejection (diagnosed by the presence of additional endothelial inflammation), ATG, ALG or OKT3 is used.

(a) (b)

Fig. 11.57 **Histology of kidney in rejection. (a) Acute vascular rejection**: The mononuclear inflammatory cell infiltrate is limited to the expanded intima and does not involve the entire vascular wall as in systemic vasculitis. **(b) Antibody mediated rejection**: An acute tubular necrosis with capillary glomerulitis and peritubular and glomerular capillary C4d positivity.

Histological appearances similar to vascular rejection are seen in a small number of patients where the culprit is an agonistic antibody directed against angiotensin receptor 1 (ATR 1) which usually presents with sudden decline in renal function but unlike vascular rejection also manifests with malignant phase hypertension and seizures. It responds to angiotensin receptor blockers in addition to conventional antirejection strategies (Fig. 11.57a). Humoral rejection (diagnosed by the presence of circulating donor-specific anti-HLA antibodies and evidence of complement activation on renal biopsy by C4 staining) (Fig. 11.57b) is usually treated empirically by a combination of i.v. polyclonal immunoglobulin infusion to neutralize and promote the clearance of anti-HLA antibodies, plasmapheresis (to remove antibodies) and anti-CD20 antibody administration (to deplete B lymphocytes) with variable success.

More than one rejection within the first 3 months, vascular and/or humoral rejection, delayed rejection (requirement of dialysis within the first week after transplantation), and failure of serum creatinine to return to baseline (less than 130 μmol/L) are associated with worse long-term outcome. The outcome of renal transplantation during an episode of acute rejection is difficult to predict, even with an allograft biopsy. Urinary levels of messenger RNA (mRNA) for FOXP3, a specification and functional factor for regulatory T lymphocytes, improve the prediction of outcome of acute rejection of renal transplants by a noninvasive means. It predicts with a reasonable degree of sensitivity and specificity successful outcome or otherwise in a renal transplant with acute rejections.

Infections

In the first month post transplantation, infections tend to be from bacterial sources seen typically in the surgical population. Cytomegalovirus (CMV) infections develop weeks or months after transplantation in 70% of CMV-seronegative recipients receiving grafts from a seropositive donor and in patients receiving biological agents (antibodies) as induction or therapy for rejection, unless prophylaxis with valganciclovir or valaciclovir is given. Prophylaxis is also routinely given against *Pneumocystis jiroveci* (co-trimoxazole) and oral candidiasis (nystatin or amphotericin lozenges). Polyomavirus infections (*BK nephropathy*) result in graft dysfunction and eventual loss due to mainly tubulointerstitial nephritis diagnosed by renal biopsy and presence of cellular inclusion bodies positive for SV40 (Fig. 11.58). There is no known specific treatment with the exception of tapering immunosuppression and with cautious use of leflunomide and cidofovir.

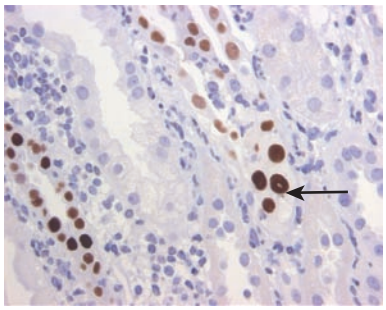


Fig. 11.58 **BK nephropathy** showing the characteristic intranuclear viral inclusion with positive immunohistological stain for SV40.

Post-transplantation lymphoproliferative disorders

Epstein–Barr virus-associated malignancies are common in patients who received biological agents and in children. Tapering of ciclosporin or tacrolimus and monitoring for the reappearance of cytotoxic lymphocytes has improved the outcome.

Chronic allograft nephropathy (CAN)

CAN remains the most common cause of late graft failure. The process is mediated by immunological and non-immunological factors and results in a progressive irreversible decline in graft function with mild to modest proteinuria (<3 g/day). Unfortunately there is no established therapy of proven efficiency.

Malignancy

Immunosuppressive therapy increases the risk of skin tumours, including basal and squamous cell carcinoma. In white recipients, exposure to ultraviolet light should be minimized and sun-block creams employed. Other common cancers are renal, cervical and vaginal. In female recipients, regular yearly cervical smears should be carried out.

Cardiovascular disease

Cardiovascular disease is the cause of death post transplantation in 50% of cases. This is due to increased incidence of hypertension, obesity, diabetes and insulin resistance lipid disorders. Use of a statin (fluvastatin) was associated with reduction in cardiac end-points (myocardial infarction or revascularization) post transplantation but overall mortality remained unchanged in a randomized prospective study.

Post-transplant osteoporosis

This is common following transplantation owing to treatment with steroids. Maximum bone loss occurs within the first 3 months and regular DXA scans are necessary. Bisphosphonates (alendronate, pamidronate), and alfacalcidol with or without calcium carbonate have proven to be effective in control studies.

Recurrent disease

Recurrence of renal disease is surprisingly common. Primary FSGS often recurs and causes early graft loss. Mesangiocapillary GN, diabetic nephropathy and IgA nephropathy also commonly recur but seldom cause renal insufficiency.

CYSTIC RENAL DISEASE

Solitary or multiple renal cysts are common, especially with advancing age: 50% of those aged 50 years or more have one or more such cysts. They have no special significance except in the differential diagnosis of renal tumours (see p. 644). Such cysts are often asymptomatic and are found on ultrasound examination performed for some other reason. Occasionally they may cause pain and/or haematuria owing to their large size, or bleeding may occur into the cyst. Cystic degeneration (the formation of multiple cysts which enlarge with time) occurs regularly in the kidneys of patients with end-stage renal failure treated by dialysis and/or transplantation. Malignant tumour formation seems to be more common in such kidneys than in the general population.

Autosomal-dominant polycystic kidney disease

Autosomal-dominant polycystic kidney disease (ADPKD) is an inherited disorder usually presenting in adult life. It is characterized by the development of multiple renal cysts, variably associated with extrarenal (mainly hepatic and cardiovascular) abnormalities. ADPKD is by far the most common inherited nephropathy, with a prevalence rate ranging from 1:400 to 1:1000 in white populations. It accounts for 3–10% of all patients commencing regular dialysis in the West.

In about 85% of cases, the gene responsible (*PKD1*) has been located on chromosome 16. A second gene, *PKD2*, which has been mapped to chromosome 4, accounts for the vast majority of other cases. These genetic abnormalities are distinct from the autosomal recessive form of polycystic disease (due to mutations in the *PKHD1* gene on chromosome 6p21.1–p12), which is often lethal in early life.

The protein corresponding to the *PKD1* gene, polycystin 1, is an integral membrane glycoprotein involved in cell-to-cell and/or cell-to-matrix interaction and functions as a mechanosensor. The protein corresponding to the *PKD2* gene appears to function as a calcium ion channel, regulating calcium influx and/or release from intracellular stores. Polycystin-1 acts as the regulator of PKD2 channel activity by its co-localization on cilia of collecting tubular cells. Disruption of the polycystin pathway results in reduced cytoplasmic calcium, which in principal cells (p. 653) of the collecting duct causes an increase in cAMP via stimulation of calcium-inhibitable adenyl cyclase and inhibition of cAMP phosphodiesterases. Defective ciliary signalling results in disoriented division of the cells along the nephron, resulting in cyst formation. In ADPKD, <1% of all nephrons acquire a second somatic mutation that in combination with a germline mutation results in cystogenesis. Progressive loss of renal function is usually attributed to mechanical compression, apoptosis of the healthy tissue and reactive fibrosis. Patients with ADPKD experience declining renal function at a variable rate which is due to discrepancy in the growth and size of the cysts; patients with rapid growth in cyst size as determined by MRI lose renal function more rapidly. Strategies to slow the growth rate of cysts have been very effective in preserving renal function in animal models. These therapies include the vasopressin V_2 receptor inhibitor (to reduce cAMP in the principal cells), roscovitine (a cyclin-dependent kinase inhibitor) and antiproliferative therapy with sirolimus (mTOR inhibitor).

Clinical features

Clinical presentation may be at any age from the second decade. Presenting symptoms include:

- acute loin pain and/or haematuria owing to haemorrhage into a cyst, cyst infection or urinary tract stone formation
- loin or abdominal discomfort owing to the increasing size of the kidneys
- subarachnoid haemorrhage associated with berry aneurysm rupture
- complications of hypertension
- complications of associated liver cysts
- symptoms of uraemia and/or anaemia associated with chronic renal failure.

Erythraemia is a rare complication and presentation of ADPKD.

The natural history of the disease is one of progressive renal impairment, sometimes punctuated by acute episodes of loin pain and haematuria, and commonly associated with the development of hypertension. The rate of progression to

renal failure (see above) is variable. The determinants of progression are both genetic and non-genetic. In the PKD2 form, renal cysts develop more slowly and end-stage renal failure (ESRF) occurs 10–15 years later than in the PKD1 form. Gender affects renal prognosis. Males with ADPKD reach end-stage renal failure 5–6 years earlier than females. There is a large variability in the age at ESRF within families, even between affected monozygotic twins.

Complications and associations

Pain

A minority of patients suffer chronic renal pain resistant to common analgesics, presumably owing to the pressure effect of large cysts. Surgical decompression of such cysts appears to be of benefit in about two-thirds of patients. Laparoscopic cyst decortication is a minimally invasive alternative technique.

Cyst infection

The response to standard antibacterial therapy is often poor owing to poor penetration of conventional antibiotics across the cyst wall. Lipophilic antibiotics active against Gram-negative bacteria, such as co-trimoxazole and fluoroquinolones, penetrate into the cysts better and their use has greatly improved the treatment of this complication.

Renal calculi

These are diagnosed in about 10–20% of patients with ADPKD. Frequently they are composed of uric acid and hence radiolucent (see Fig. 11.40). Obstructing or painful stones are treated no differently than are stones in patients with normal urinary tracts. Percutaneous stone removal and extracorporeal lithotripsy is safe.

Hypertension

Hypertension is an early and very common feature of ADPKD. Elevation of blood pressure, still within the normal range, is detectable in young affected individuals and is associated with an increase in left ventricular mass. Left ventricular hypertrophy occurs to a greater degree for a given rise in blood pressure in ADPKD compared with other renal disorders and with essential hypertension. Intrarenal activation of the renin–angiotensin system is involved in pathogenesis, and ACE inhibitors are logical first-line agents in treatment. Early control of blood pressure is essential as cardiovascular complications are a major cause of death in ADPKD.

Progressive renal failure

This is the most serious complication of ADPKD. At glomerular filtration rates below 50 mL/min, the rate of decline in GFR averages 5 mL/min each year, which is more rapid than in other primary renal disorders. The probability of being alive without requiring dialysis or transplantation by the age of 70 years is of the order of 30%. Survival rates on regular haemodialysis and after renal transplantation in ADPKD are better than those in patients with other primary renal diseases.

Hepatic cysts

Approximately 30% of patients have hepatic cysts and in a minority of the patients massive enlargement of the polycystic liver is seen. Pain, infection of cysts and, more rarely, compression of the bile duct, portal vein or hepatic venous outflow occur. Rarely, percutaneous drainage of painful cysts, laparoscopic fenestration or even partial hepatectomy is necessary. Infected cysts may require drainage.

Intracranial aneurysm formation

About 10% of ADPKD patients have an asymptomatic intracranial aneurysm (see p. 1134) and the prevalence is twice as high in the subgroup of patients with a family history of such aneurysms or of subarachnoid haemorrhage. Such haemorrhage is preceded in from 20% to 40% of cases by premonitory headaches from a few hours up to 2 weeks before the onset of subarachnoid bleeding. Headache of sudden onset or unusual character or severity in a patient with ADPKD should prompt investigation. Contrast-enhanced spiral CT or MR angiography are the best investigations. Screening for intracranial aneurysm in ADPKD is currently recommended for patients aged 18–40 years who have a positive family history.

Mitral valve prolapse

This is found in 20% of individuals with ADPKD.

Diagnosis

Physical examination commonly reveals large, irregular kidneys and possibly hepatomegaly. Definitive diagnosis is established by ultrasound examination (Fig. 11.59). However, such renal imaging techniques may be equivocal, especially in subjects under the age of 20 years.

Screening

The children and siblings of patients with established ADPKD should, in general, be offered screening. Affected individuals should have regular blood pressure checks and should be offered genetic counselling. Screening by ultrasonography should not be carried out before the age of 20 years, as excluding the condition may be difficult and hypertension is unusual before this age. Even at age 20, renal ultrasonography may give a false-negative result. Gene linkage analysis can be utilized in many families.

Therapy

No therapy is yet available but potential agents include *vasopressin receptor antagonists*, which have been studied in animal models of polycystic kidney disease, closely related to human ADPKD, where they have halted cyst progression or caused disease regression. ADPKD kidneys may be particularly vulnerable to *adenylyl cyclase agonists* or *cAMP phosphodiesterase inhibitors*. Caffeine at clinically relevant

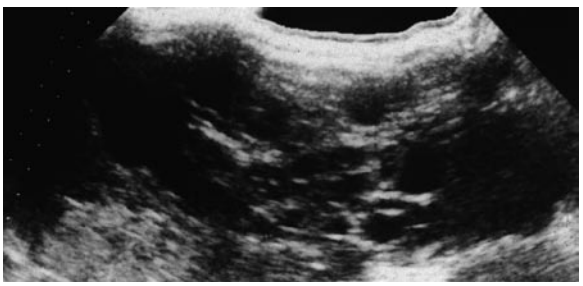

Fig. 11.59 **Ultrasound scan of a polycystic kidney,** showing an enlarged kidney with many cysts of varying size.

concentrations has been found to enhance the effect of desmopressin to stimulate chloride secretion in cultured epithelial cells from ADPKD cysts. These conditions were long considered untreatable hereditable defects. Over the last couple of years, several therapeutic approaches have emerged, e.g. sirolimus, tolvaptan which are already being used in clinical trials and their results are eagerly awaited.

Medullary cystic disease ('juvenile nephronophthisis')

Juvenile nephronophthisis that develops early in childhood is commonly inherited in an autosomal recessive manner. Mutations in the genes *NPHP1–4* are present. The proteins mutated, nephrocystin and inversin, are co-localized in the cilia of the renal tubules. A similar condition developing later in childhood (medullary cystic disease) is inherited as an autosomal dominant trait, but sporadic cases occur in both conditions. Despite its name, the dominant histological finding is interstitial inflammation and tubular atrophy, with later development of medullary cysts. Progressive glomerular failure is a secondary consequence.

The dominant features are polyuria, polydipsia and growth retardation. Diagnosis is based on the family history and renal biopsy, the cysts rarely being visualized by imaging techniques.

Medullary sponge kidney

Medullary sponge kidney is an uncommon but not rare condition that usually presents with renal colic or haematuria. Although it is most often sporadic, a few affected families have been reported. The condition is characterized by dilatation of the collecting ducts in the papillae, sometimes with cystic change. In severe cases the medullary area has a sponge-like appearance. The condition may affect one or both kidneys or only part of one kidney. Cyst formation is commonly associated with the development of small calculi within the cyst. In about 20% of patients there is associated hypercalciuria or renal tubular acidosis (see p. 676). Hemihypertrophy of the skeleton has been described in this condition.

The diagnosis is made by excretion urography, which shows small calculi in the papillary zones with an increase in radiodensity around these following injection of contrast medium as the dilated or cystic collecting ducts are filled with contrast (see Fig. 11.38).

The natural history is one of intermittent colic with passage of small stones or haematuria. Renal function is usually well maintained and renal failure is unusual, except where obstructive nephropathy develops owing to the presence of stones in the pelvis or ureters.

TUMOURS OF THE KIDNEY AND GENITOURINARY TRACT

MALIGNANT RENAL TUMOURS

These comprise 1–2% of all malignant tumours, and the male to female ratio is 2:1.

Renal cell carcinoma

Renal cell carcinomas (RCC) arise from proximal tubular epithelium. They are the most common renal tumour in adults. They rarely present before the age of 40 years, the average age of presentation being 55 years.

In von Hippel–Lindau disease, an autosomal dominant disorder, bilateral renal cell carcinomas are common and haemangioblastomas, phaeochromocytomas and renal cysts are also found. Polymorphic probes from chromosome 3p, the region implicated in renal cell carcinoma, have demonstrated genetic linkage between this tumour and von Hippel–Lindau disease. It seems likely, therefore, that mutation of the same tumour suppressor gene is responsible for both renal cell carcinoma and von Hippel–Lindau disease. Deletion of the short arm of chromosome 3 is the most consistent cytogenetic finding in sporadic tumours.

Renal cell carcinomas are highly vascular tumours; microscopically most tumours are composed of large cells containing clear cytoplasm.

Clinical features

Patients are often asymptomatic but can present with haematuria, loin pain and a mass in the flank. Malaise, anorexia and weight loss (30%) occur, and 5% of patients have polycythaemia (see p. 419). Thirty per cent of patients have hypertension (due to secretion of renin by the tumour) and anaemia, due to depression of erythropoietin in approximately the same number. Pyrexia is present in about one-fifth of patients and approximately one-quarter present with metastases. Rarely, a left-sided varicocele may be associated with left-sided tumours that have invaded the renal vein and caused obstruction to drainage of the left testicular vein.

Diagnosis

Ultrasonography is used to demonstrate the solid lesion and to examine the patency of the renal vein and inferior vena cava. CT scanning is used to identify the renal lesion and involvement of the renal vein or inferior vena cava. MRI is better than CT for tumour staging. Renal arteriography will reveal the tumour's circulation but is now seldom employed. Urine cytology for malignant cells is of no value. The ESR is usually raised. Liver biochemistry may be abnormal, returning to normal after surgery.

Treatment

- A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery such as partial nephrectomy may be indicated. If metastases are present, nephrectomy may still be warranted since regression of metastases has been reported after removal of the main tumour mass.
- Medroxyprogesterone acetate is of some value in controlling metastatic disease.
- Interleukin-2 and interferon produce a remission in about 20% of cases. A striking regression of metastases has been reported after non-myeloablative chemotherapy followed by allogeneic (sibling) peripheral blood stem cell transplantation.
- Newer therapies. Temsirolimus, a specific inhibitor of rapamycin kinase, has been shown to improve overall survival among patients with metastatic renal cell carcinoma and a poor prognosis and was more effective

than interferon. Everolimus, a similar drug, is also available.

- Bevacizumab (a neutralizing antibody to VEGF) has been used in trials (due to increased mutations in the tumour suppression gene *VHL* and the oversecretion of vascular endothelial growth factor (VEGF)). This has shown significant slowing in the rate of progression of metastatic renal cell carcinoma but did not prolong overall patient survival. In a recent study, *adjuvant autologous renal tumour cell vaccine* given intradermally every 4 weeks for 6 months at the time of radical nephrectomy for non-metastatic RCC was associated with an increase in 5-year disease progression-free survival – 77% compared to 68% in the placebo group. Sunitinib and sorafenib, tyrosine kinase inhibitors, have also improved clinical outcomes in randomized trials. Combinations of these agents are being evaluated.

Prognosis

The prognosis depends upon the degree of differentiation of the tumour and whether or not metastases are present. The 5-year survival rate is 60–70% with tumours confined to the renal parenchyma, 15–35% with lymph node involvement, and only approximately 5% in those who have distant metastases.

Nephroblastoma (Wilms' tumour)

This tumour is seen mainly within the first 3 years of life and may be bilateral. It presents as an abdominal mass, rarely with haematuria. Diagnosis is established by ultrasound, CT and MRI. A combination of nephrectomy, radiotherapy and chemotherapy has much improved survival rates, even in children with metastatic disease. Overall, the 5-year survival rate is 90%.

UROTHELIAL TUMOURS

The calyces, renal pelvis, ureter, bladder and urethra are lined by transitional cell epithelium. Transitional cell tumours account for about 3% of deaths from all forms of malignancy. Such tumours are uncommon below the age of 40 years, and the male to female ratio is 4:1. Bladder tumours are about 50 times as common as those of the ureter or renal pelvis.

Predisposing factors include:

- cigarette smoking
- exposure to industrial carcinogens such as β-naphthylamine and benzidine (workers in the chemical, cable and rubber industries are at particular risk) or ingestion of aristolochic acid found in some herbal weight-loss preparations
- exposure to drugs (e.g. phenacetin, cyclophosphamide)
- chronic inflammation (e.g. schistosomiasis, usually associated with squamous carcinoma).

Presentation

Painless haematuria is the most common presenting symptom of bladder malignancy, although pain may occur owing to clot retention. Symptoms suggestive of UTI develop in the absence of significant bacteriuria. In patients with bladder cancer, pain also results from local nerve involvement. Presenting symptoms may result from local metastases.

Transitional cell carcinomas in the kidney and ureter also present with haematuria. They may also give rise to flank pain, particularly if urinary tract obstruction is present.

Investigations

Cytological examination of urine for malignant cells and renal imaging (ultrasonography, CT and MRI) should be performed in all patients. Cystoscopy is necessary unless pathology is found in the upper urinary tract. It may be omitted in men under 20 and women under 30 years if significant bacteriuria accompanies the haematuria and ceases following control of the infection, provided urine cytology and renal imaging are normal. With these exceptions, haematuria should always be investigated. In cases where the tumour is not clearly outlined on ultrasonography or CT, retrograde ureterography may be helpful.

Treatment

Pelvic and ureteric tumours

These are treated by nephroureterectomy. Radiotherapy and chemotherapy appear to be of little or no value. Subsequently, cystoscopy should be regularly carried out, since about half the patients will develop bladder tumours.

Bladder tumours

Treatment depends upon the stage of the tumour (in particular whether it has penetrated the bladder muscle) and its degree of differentiation.

Superficial bladder tumours are treated by transurethral resection or local diathermy with follow-up check cystoscopies and cytological examination of the urine. Bladder instillation of doxorubicin, mitomycin and thiotepa is used for recurrent tumours, as is instillation of BCG (bacille Calmette–Guérin).

Invasive bladder tumours are treated with radical cystectomy in patients under 70 years and radical radiotherapy in those over 70 years with salvage cystectomy for recurrences. Cystectomy requires a new bladder to be made out of small bowel, joining this to the urethra if possible or making an ileal conduit.

Prognosis

The prognosis ranges from a 5-year survival rate of 80–90% for lesions not involving bladder muscle to 5% for those presenting with metastases.

Testicular tumours are discussed on page 492.

DISEASES OF THE PROSTATE GLAND

Benign enlargement of the prostate gland

Benign prostatic enlargement occurs most often in men over the age of 60 years. Such enlargement is much less common in Asian individuals. It is unknown in eunuchs. The aetiology of the condition is unknown. Microscopically, hyperplasia affects the glandular and connective tissue elements of the prostate. Enlargement of the gland stretches and distorts the urethra, obstructing bladder outflow.

Clinical features

Frequency of urination, usually first noted as nocturia, is a common early symptom. Difficulty or delay in initiating urination, with variability and reduced forcefulness of the urinary stream and post-void dribbling, are often present. Acute retention of urine (see below) or retention with overflow incontinence may occur. Occasionally, severe haematuria results from rupture of prostatic veins or as a consequence of bacteriuria or stone disease. Occasional patients present with severe renal failure.

Abdominal examination for bladder enlargement together with examination of the rectum is essential. A benign prostate feels smooth. An accurate impression of prostatic size cannot be obtained on rectal examination.

Management and prognosis

Patients with mild-to-moderate symptoms should be managed by 'watchful waiting', because symptoms following therapy are sometimes greater than those with no therapy at all.

Patients with moderate prostatic symptoms can be treated medically. A number of drugs have been employed, including alpha-blockers such as tamsulosin. Finasteride is a competitive inhibitor of 5α-reductase, which is the enzyme involved in the conversion of testosterone to dihydrotestosterone. This is the androgen primarily responsible for prostatic growth and enlargement. Finasteride decreases prostatic volume with an increase in urine flow. Deterioration in renal function or the development of upper tract dilatation requires surgery.

In acute retention or retention with overflow, the first priorities are to relieve pain and to establish urethral catheter drainage. If urethral catheterization is impossible, suprapubic catheter drainage should be carried out. The choice of further management is then between immediate prostatectomy, a period of catheter drainage followed by prostatectomy, or the acceptance of a permanent indwelling suprapubic or urethral catheter.

Prostatic carcinoma

Prostatic carcinoma accounts for 7% of all cancers in men and is the sixth most common cancer in the world. Malignant change within the prostate becomes increasingly common with advancing age. By the age of 80 years, 80% of men have malignant foci within the gland, but most of these appear to lie dormant. Histologically, the tumour is an adenocarcinoma. Hormonal factors are thought to play a role in the aetiology.

Clinical features

Presentation is usually with symptoms of lower urinary tract obstruction; less common are symptoms of metastatic spread, e.g. back pain, weight loss or anaemia. The diagnosis is also made by the incidental finding of a hard irregular gland on rectal examination, or as an unexpected histological result after prostatectomy for what was believed to be benign prostatic hypertrophy. In developed countries, patients now present as a result of screening for prostate cancer by measurement of prostate-specific antigen (PSA). However, on the evidence available, national programmes of screening are not justified. Treatment of well people carries a high morbidity of urinary incontinence and sexual dysfunction with no evidence as yet of increased overall survival. In future, screening of 'at-risk' groups may be useful. PSA >4 ng/mL is abnormal but between 4 and 10 ng/mL this can be due to benign hypertrophy and cancer. If PSA is over 10 ng/mL, a prostatic biopsy will show cancer in over 50% of cases.

Investigations

These include transrectal ultrasound of the prostate and prostatic biopsy. A histological diagnosis is essential before treatment. The Gleason scoring system is based on the histological appearances. If metastases are present, serum prostate-specific antigen levels are usually markedly elevated (>16 ng/mL) but can be normal; it is a myth that elevated levels occur as a result of rectal examination.

Ultrasonography and transrectal ultrasonography are also of value in defining the size of the gland and staging any tumour present. Endorectal coil MRI helps to detect extraprostatic extension. The upper renal tracts can be examined by ultrasonography for evidence of dilatation. Bone metastases appear as osteosclerotic lesions on X-ray and are also detected by isotopic bone scans.

Treatment (see also p. 492)

Prophylactic finasteride therapy can prevent or delay the appearance of prostatic carcinoma in men above the age of 55 years but usually at the expense of sexual side-effects and increased risk of high-grade prostatic cancer. Microscopic, impalpable tumours can sometimes be managed expectantly. Treatment for disease confined to the gland is radical prostatectomy (provided the patient is fit for the procedure) or radiotherapy. A randomized trial comparing radical prostatectomy with active surveillance in early prostate cancer revealed that radical prostatectomy significantly reduced disease-specific mortality, but there was no significant difference between surgery and active surveillance in terms of overall survival. Locally extensive disease is managed with radiotherapy with or without androgen ablation therapy. Metastatic disease can be treated with orchidectomy, but many men refuse. Luteinizing hormone-releasing hormone (LHRH) analogues such as buserelin or goserelin are equally effective and preferred by many. Abiraterone inhibits CYP17A1, an enzyme necessary for androgen production and has been used for aggressive prostate cancer. Non-hormonal chemotherapy is usually unhelpful. The duration of survival depends on the age of the patient and the degree of differentiation and extent of the tumour.

RENAL DISEASE IN THE ELDERLY

Progressive sclerosis of glomeruli occurs with ageing and this, together with the development of atheromatous renal vascular disease, accounts for the progressive reduction in GFR seen with advancing years. A GFR of 50–60 mL/min (about half the normal value for a young adult) may be regarded as 'normal' in patients in their eighties. The reduction in muscle mass often seen with ageing may mask this deterioration in renal function in that the serum creatinine concentration may be less than 120 μmol/L in an elderly patient whose eGFR is 50 mL/min or lower. The use of serum creatinine as a measure of renal function in the elderly must take this into account. This is especially so in the elderly when prescribing drugs whose excretion is in whole or in part by the kidney.

www.studentconsult.com
Ask the authors

Urinary tract infections

UTIs are common in the elderly, in whom impaired bladder emptying due to prostatic disease in males and neuropathic bladder – especially common in females – is frequently found. Symptoms may be atypical, the major complaints being incontinence, nocturia, smelly urine or vague change in well-being with little in the way of dysuria. Demonstration of significant bacteriuria in the presence of such symptoms requires treatment.

Urinary incontinence

This is defined as involuntary passage of urine sufficient to be a health or social problem. It is common in the elderly with 25% of women and 15% of men over 65 having a problem.

- *Urge incontinence* is usually due to detrusor overactivity with leakage of urine because the bladder is perceived to be full. This is common in the elderly; it occurs as an isolated event or secondary to local factors, e.g. bladder infection or stones, or to central factors, e.g. stroke, dementia or Parkinson's disease.
- *Stress incontinence* occurs when the intra-abdominal pressure is increased, e.g. after a cough or sneeze and there is a weak pelvic floor or urethral sphincter. It is common in women after childbirth.
- *Overflow incontinence* occurs with leakage of urine from a full distended bladder. It occurs commonly in men with prostatic obstruction, following spinal cord injury or in women with cystoceles or after gynaecological surgery.
- *Functional incontinence*. Passage of urine occurs owing to inability to get to a toilet because of disability, e.g. stroke, trauma, the unavailability of toilet facilities or dementia.

Management

- Physical examination for local problems, e.g. prostatic enlargement in men, gynaecological disorders in women, and for central problems, e.g. neurological disorders or dementia.
- Urine analysis, e.g. glycosuria and culture for UTI.
- Treatment of contributing causes, e.g. constipation, drug therapy, other co-existing disease.
- Urge incontinence – bladder training, antimuscarinics, e.g. oxybutynin, tolterodine, solifenacin and darifenacin.
- Stress incontinence – pelvic floor exercises. Moreover, recently it was demonstrated that transurethral injections of autologous myoblasts can aid in regeneration of the rhabdosphincter, and fibroblasts in reconstruction of the urethral submucosa. Effectiveness and tolerability of ultrasonography-guided injections of autologous cells was much superior compared with those of endoscopic injections of collagen for stress incontinence.
- Overflow – removal of obstruction.
- Functional – improve facilities, regular urine voiding, absorbent padding.

Further evaluation with urodynamics is necessary in patients who do not respond and have a potentially curable problem. An expert and committed incontinence advisory and treatment service combining nursing and medical skills is invaluable for elderly patients with this distressing problem. Home visits to ensure the availability of commodes and toilets are essential. For established incontinence, catheterization may be necessary but should be avoided if at all possible. Incontinence and its treatment are matters of major importance and are by no means confined solely to the elderly.

Questions and case studies 679

In health, the volume and biochemical composition of both extracellular and intracellular fluid compartments in the body remains remarkably constant. Many different disease states result in changes of control, either of extracellular fluid volume or of the electrolyte composition of extracellular fluid. An understanding of these abnormalities is therefore essential for the management of a wide range of clinical disorders.

DISTRIBUTION AND COMPOSITION OF BODY WATER

In normal persons, the total body water constitutes 50–60% of lean bodyweight in men and 45–50% in women. In a healthy 70 kg male, total body water is approximately 42 L. This is contained in three major compartments:

- intracellular fluid (28 L, about 35% of lean bodyweight)
- extracellular – the interstitial fluid that bathes the cells (9.4 L, about 12%)
- plasma (also extracellular) (4.6 L, about 4–5%).

In addition, small amounts of water are contained in bone, dense connective tissue, and epithelial secretions, such as the digestive secretions and cerebrospinal fluid.

The intracellular and interstitial fluids are separated by the cell membrane; the interstitial fluid and plasma are separated by the capillary wall (Fig. 12.1). In the absence of solute, water molecules move randomly and in equal numbers in either direction across a permeable membrane. However, if solutes are added to one side of the membrane, the intermolecular cohesive forces reduce the activity of the water molecules. As a result, water tends to stay in the solute-containing compartment because there is less free diffusion across the membrane. This ability to hold water in the compartment can be measured as the osmotic pressure.

Osmotic pressure

Osmotic pressure is the primary determinant of the distribution of water among the three major compartments. The concentrations of the major solutes in these fluids differ, with each compartment having one solute that is primarily limited to that compartment and therefore determines its osmotic pressure. The intracellular fluid contains mainly potassium (K^+) (most of the cell Mg^{2+} is bound and osmotically inactive) and in the extracellular compartment, Na^+ salts predominate in the *interstitial fluid*, and proteins in the plasma. Regulation of the plasma volume is somewhat more complicated because of the tendency of the plasma proteins to hold water in the vascular space by an oncotic effect which is in part counterbalanced by the hydrostatic pressure in the capillaries that is generated by cardiac contraction (Fig. 12.1). The composition of intracellular and extracellular fluids is shown in Table 12.1.

A characteristic of an osmotically active solute is that it cannot freely leave its compartment. The capillary wall, for example, is relatively impermeable to plasma proteins, and the cell membrane is 'impermeable' to Na^+ and K^+ because the Na^+/K^+-ATPase pump largely restricts Na^+ to the extracellular fluid and K^+ to the intracellular fluid. By contrast, Na^+ freely crosses the capillary wall and achieves similar concentrations in the interstitium and plasma; as a result, it does not contribute to fluid distribution between these compartments. Similarly, urea crosses both the capillary wall and the cell membrane and is osmotically inactive. Thus, the retention of urea in renal failure does not alter the distribution of the total body water.

A conclusion from these observations is that body Na^+ stores are the primary determinant of the extracellular fluid volume. Thus the extracellular volume – and therefore tissue perfusion – are maintained by appropriate alterations in Na^+ excretion. For example, if Na^+ intake is increased, the extra Na^+ will initially be added to the extracellular fluid. The associated increase in extracellular osmolality will cause water to

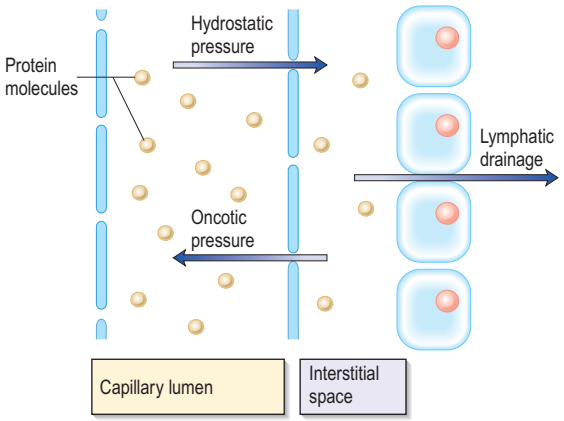

Fig. 12.1 **Distribution of water between the vascular and extravascular (interstitial) spaces.** This is determined by the equilibrium between hydrostatic pressure, which tends to force fluid out of the capillaries, and oncotic pressure, which acts to retain fluid within the vessel. The net flow of fluid outwards is balanced by 'suction' of fluid into the lymphatics, which returns it to the bloodstream. Similar principles govern the volume of the peritoneal and pleural spaces.

Table 12.1 **Electrolyte composition of intracellular and extracellular fluids**

	Plasma (mmol/L)	Interstitial fluid (mmol/L)	Intracellular fluid (mmol/L)
Na^+	142	144	10
K^+	4	4	160
Ca^{2+}	2.5	2.5	1.5
Mg^{2+}	1.0	0.5	13
Cl^-	102	114	2
HCO_3^-	26	30	8
PO_4^{2-}	1.0	1.0	57
SO_4^{2-}	0.5	0.5	10
Organic acid	3	4	3
Protein	16	0	55

move out of the cells, leading to extracellular volume expansion. Balance is restored by excretion of the excess Na^+ in the urine.

Distribution of different types of replacement fluids

Figure 12.2 shows the relative effects on the compartments of the addition of identical volumes of water, saline and colloid solutions. Thus, 1 L of water given intravenously as 5% dextrose is distributed equally into all compartments, whereas the same amount of 0.9% saline remains in the extracellular compartment. The latter is thus the correct treatment for extracellular water depletion – sodium keeping the water in this compartment. The addition of 1 L of colloid with its high oncotic pressure stays in the vascular compartment and is the treatment for hypovolaemia.

Regulation of extracellular volume (Fig. 12.3)

The extracellular volume is determined by the sodium concentration. The regulation of extracellular volume is dependent upon a tight control of sodium balance, which is exerted by normal kidneys. Renal Na^+ excretion varies directly with the effective circulating volume. In a 70 kg man, plasma fluid constitutes one-third of extracellular volume (4.6 L), of which 85% (3.9 L) lies in the venous side and only 15% (0.7 L) resides in the arterial circulation. The unifying hypothesis of extracellular volume regulation in health and disease proposed by Schrier states that the fullness of the arterial vascular compartment – or the so-called *effective arterial blood volume (EABV)* – is the primary determinant of renal sodium and water excretion. Thus effective arterial blood volume constitutes effective circulatory volume for the purposes of body fluid homeostasis. The fullness of the arterial compartment depends upon a normal ratio between cardiac output and peripheral arterial resistance. Thus, diminished EABV is initiated by a fall in cardiac output or a fall in peripheral arterial resistance (an increase in the holding capacity of the arterial vascular tree). When the EABV is expanded, the urinary Na^+ excretion is increased and can exceed 100 mmol/L. By contrast, the urine can be rendered virtually free of Na^+ in the presence of EABV depletion and normal renal function.

These changes in Na^+ excretion can result from alterations both in the filtered load, determined primarily by the glomerular filtration rate (GFR), and in tubular reabsorption, which is affected by multiple factors. In general, it is changes in tubular reabsorption that constitute the main adaptive response to fluctuations in the effective circulating volume. How this occurs can be appreciated from Table 12.2 and

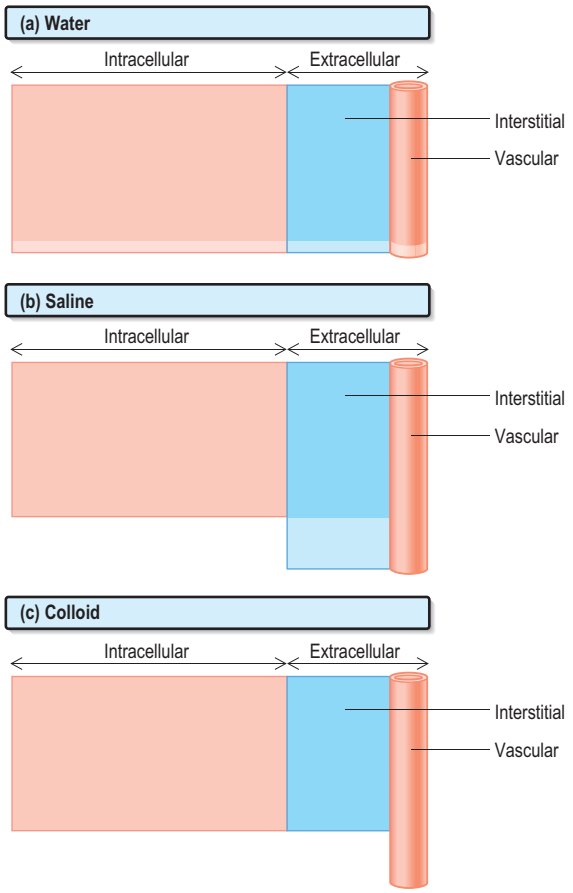

Fig. 12.2 **Relative effects of the addition of 1 L of (a) water, (b) saline 0.9% and (c) a colloid solution.**

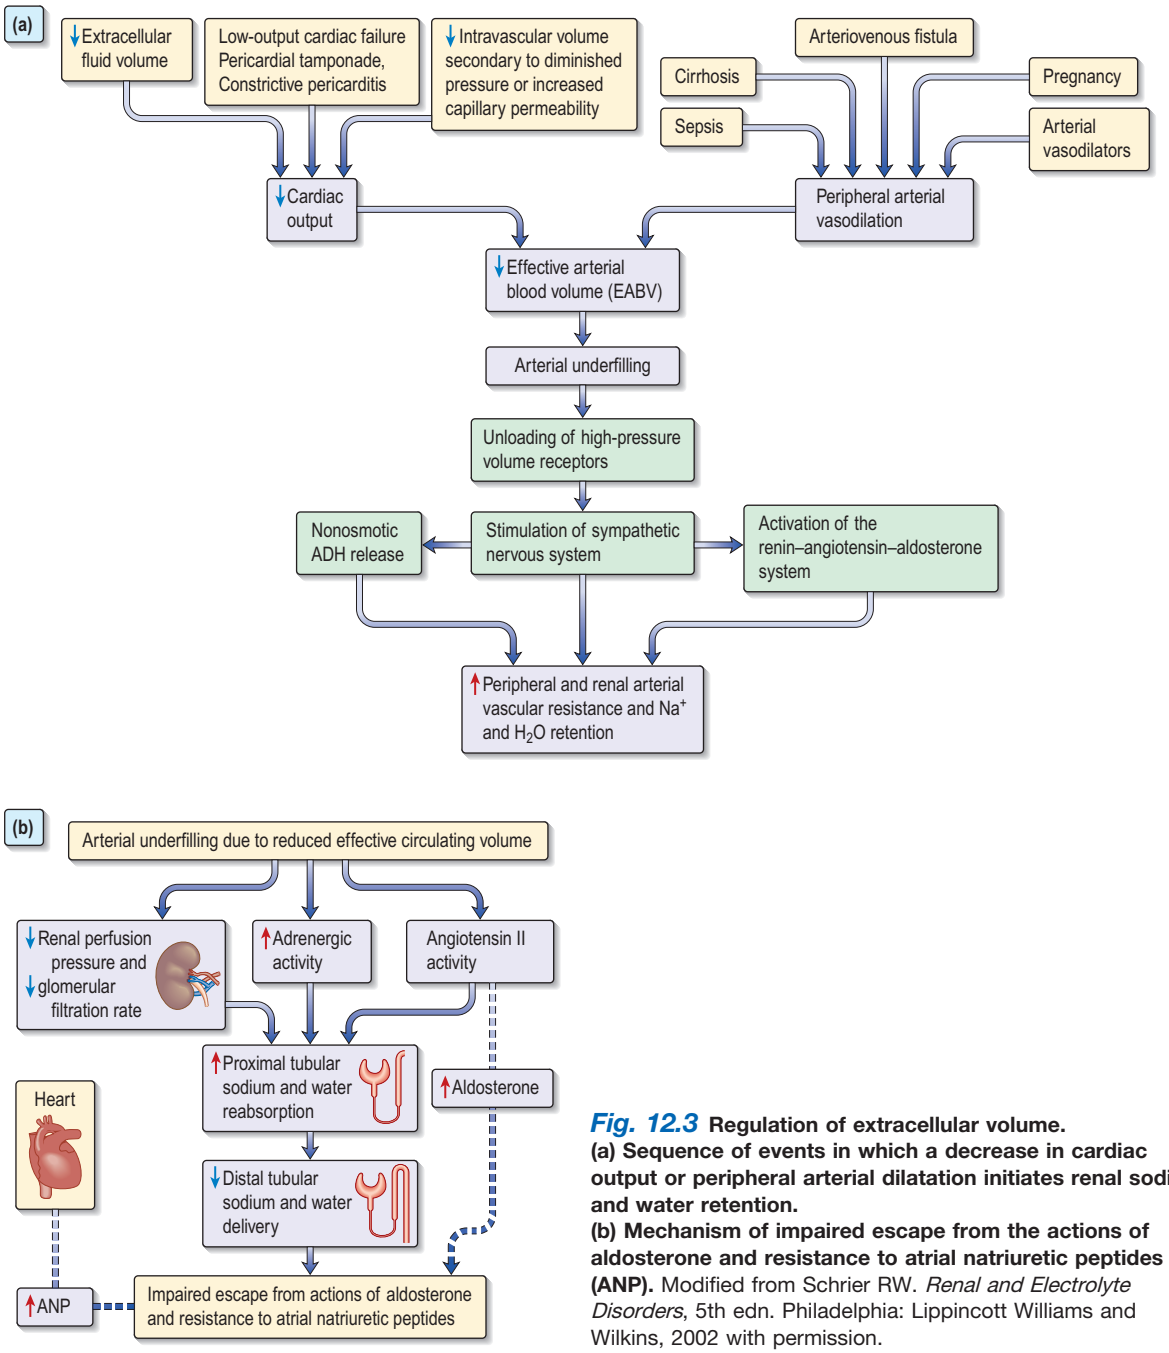

Fig. 12.3 **Regulation of extracellular volume.**
(a) Sequence of events in which a decrease in cardiac output or peripheral arterial dilatation initiates renal sodium and water retention.
(b) Mechanism of impaired escape from the actions of aldosterone and resistance to atrial natriuretic peptides (ANP). Modified from Schrier RW. *Renal and Electrolyte Disorders*, 5th edn. Philadelphia: Lippincott Williams and Wilkins, 2002 with permission.

Figure 12.4 and Figure 11.2 (see p. 573), which depicts the sites and determinants of segmental Na^+ reabsorption. Although the loop of Henle and distal tubules make a major overall contribution to net Na^+ handling, transport in these segments primarily varies with the amount of Na^+ delivered; that is, reabsorption is flow-dependent. In comparison, the neurohumoral regulation of Na^+ reabsorption according to body needs occurs primarily in the proximal tubules and collecting ducts.

Neurohumoral regulation of extracellular volume

This is mediated by volume receptors that sense changes in the EABV rather than alterations in the sodium concentration. These receptors are distributed in both the renal and cardiovascular tissues.

- *Intrarenal receptors*. Receptors in the walls of the afferent glomerular arterioles respond, via the juxtaglomerular apparatus, to changes in renal perfusion, and control the activity of the renin–angiotensin–aldosterone system (see p. 1023). In addition, sodium concentration in the distal tubule and sympathetic nerve activity alter renin release from the juxtaglomerular cells. Prostaglandins I_2 and E_2 are also generated within the kidney in response to angiotensin II, acting to maintain glomerular filtration rate and sodium and water excretion, modulating the sodium-retaining effect of this hormone.

Table 12.2 Mechanisms of sodium transport in the various nephron segments

	Reabsorbed (%)	Luminal Na^+ entry	Transport
Proximal tubule	60–70	Na^+–H^+ exchange and cotransport of Na^+ with glucose, phosphate and other organic solutes	Angiotensin II Norepinephrine (noradrenaline)
Loop of Henle	20–25	Na^+–K^+–$2Cl^-$ cotransport	Flow dependent Pressure natriuresis mediated by nitric oxide
Distal tubule	5	Na^+–Cl^- cotransport	Flow dependent
Collecting ducts	4	Na^+ channels	Aldosterone Atrial natriuretic peptide

- *Extrarenal receptors*. These are located in the vascular tree in the left atrium and major thoracic veins, and in the carotid sinus body and aortic arch. These volume receptors respond to a slight reduction in effective circulating volume and result in increased sympathetic nerve activity and a rise in catecholamines. In addition, volume receptors in the cardiac atria control the release of a powerful natriuretic hormone – atrial natriuretic peptide (ANP) – from granules located in the atrial walls (see p. 1023).

High-pressure arterial receptors (carotid, aortic arch, juxtaglomerular apparatus) predominate over low-pressure volume receptors in volume control in mammals. The low-pressure volume receptors are distributed in thoracic tissues (cardiac atria, right ventricle, thoracic veins, pulmonary vessels) and their role in the volume regulatory system is marginal.

Aldosterone and possibly ANP are responsible for day-to-day variations in Na^+ excretion, by their respective ability to augment and diminish Na^+ reabsorption in the collecting ducts.

A *salt load*, for example, leads to an increase in the effective circulatory and extracellular volume, raising both renal perfusion pressure, and atrial and arterial filling pressure. The increase in the renal perfusion pressure reduces the secretion of renin, and subsequently that of angiotensin II and aldosterone (Fig. 18.27), whereas the rise in atrial and arterial filling pressure increases the release of ANP. These factors combine to reduce Na^+ reabsorption in the collecting duct, thereby promoting excretion of excess Na^+.

By contrast, in patients on a *low* Na^+ intake or in those who become volume-depleted as a result of vomiting and diarrhoea, the ensuing decrease in effective volume enhances the activity of the renin–angiotensin–aldosterone system and reduces the secretion of ANP. The net effect is enhanced Na^+ reabsorption in the collecting ducts, leading to a fall in Na^+ excretion. This increases the extracellular volume towards normal.

With more marked hypovolaemia, a decrease in GFR leads to an increase in proximal and thin ascending limb Na^+ reabsorption which contributes to Na^+ retention. This is brought about by enhanced sympathetic activity acting directly on the kidneys and indirectly by stimulating the secretion of renin/angiotensin II (see Fig. 12.3b) and non-osmotic release of antidiuretic hormone (ADH), also called vasopressin. The pressure natriuresis phenomenon may be the final defence against changes in the effective circulating volume. Marked persistent hypovolaemia leads to systemic hypotension and increased salt and water absorption in the

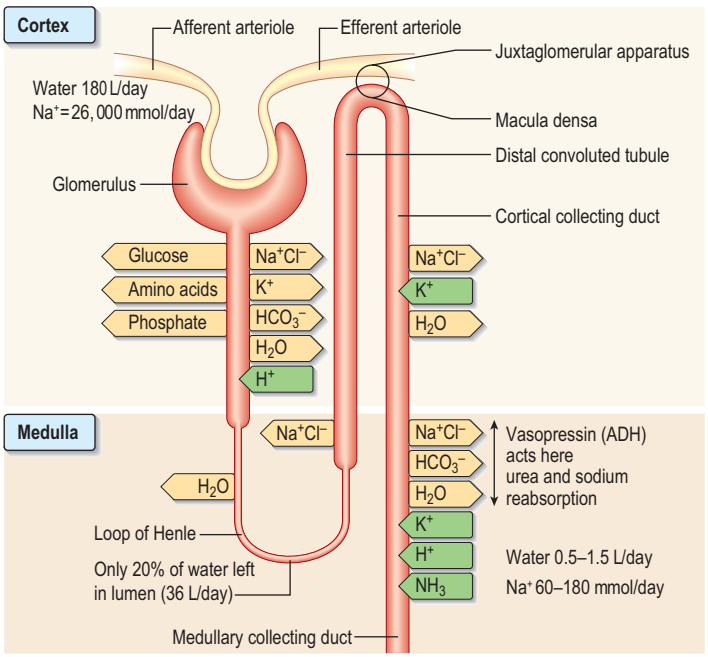

Fig. 12.4 **The nephron – electrolyte and water exchange.** 180 L of water and 26 000 mmol of sodium per day enter the nephrons via the afferent arterioles to the kidneys. Removal or addition of electrolytes results in the excretion of approximately 1 L of water and 60–180 mmol of sodium per day.

proximal tubules and ascending limb of Henle. This process is partly mediated by changes in renal interstitial hydrostatic pressure and local prostaglandin and nitric oxide production.

Volume regulation in oedematous conditions

Sodium and water are retained despite increased extracellular volume in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia. Here the principal mediator of salt and water retention is the concept of arterial underfilling due either to reduced cardiac output or diminished peripheral arterial resistance. Arterial underfilling in these settings leads to reduction of pressure or stretch (i.e. 'unloading' of arterial volume receptors), which results in activation of the sympathetic nervous system, activation of the renin–angiotensin–aldosterone system and non-osmotic release of ADH. These neurohumoral mediators promote salt and water retention in the face of increased extracellular volume. The common nature of the degree of arterial fullness and neurohumoral pathway in the regulation of extracellular volume in health and disease states forms the basis of Schrier's unifying hypothesis of volume homeostasis (Fig. 12.3a).

Mechanism of impaired escape from actions of aldosterone and resistance to ANP

Not only is the activity of the renin–angiotensin–aldosterone system increased in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia, but also the action of aldosterone is more persistent than in normal subjects and patients with Conn's syndrome, who have increased aldosterone secretion (see p. 1023).

In normal subjects, high doses of mineralocorticoids initially increase renal sodium retention so that the extracellular volume is increased by 1.5–2 L. However, renal sodium retention then ceases, sodium balance is re-established, and there is no detectable oedema. This escape from mineralocorticoid-mediated sodium retention explains why oedema is not a characteristic feature of primary hyperaldosteronism (Conn's syndrome). The escape is dependent on an increase in delivery of sodium to the site of action of aldosterone in the collecting ducts. The increased distal sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in renal perfusion pressure and GFR. The net result of these events is reduced sodium absorption in the proximal tubules and increased distal sodium delivery which overwhelms the sodium-retaining actions of aldosterone.

In patients with the above oedematous conditions, escape from the sodium-retaining actions of aldosterone **does not occur** and therefore they continue to retain sodium in response to aldosterone. Accordingly they have substantial natriuresis when given spironolactone, which blocks mineralocorticoid receptors. Alpha-adrenergic stimulation and elevated angiotensin II increase sodium transport in the proximal tubule, and reduced renal perfusion and GFR further increase sodium absorption from the proximal tubules by presenting less sodium and water in the tubular fluid. Sodium delivery to the distal portion of the nephron, and thus the collecting duct, is reduced. Similarly, increased cardiac ANP release in these conditions requires optimum sodium concentration at the site of its action in the collecting duct for its desired natriuretic effects. Decreased sodium delivery to the collecting duct is therefore the most likely explanation for the persistent aldosterone-mediated sodium retention, absence of escape phenomenon and resistance to natriuretic peptides in these patients (Fig. 12.3b).

Regulation of water excretion

Body water homeostasis is effected by thirst and the urine concentrating and diluting functions of the kidney. These in turn are controlled by intracellular osmoreceptors, principally in the hypothalamus, to some extent by volume receptors in capacitance vessels close to the heart, and via the renin–angiotensin system. Of these, the major and best-understood control is via osmoreceptors. Changes in the plasma Na^+ concentration and osmolality are sensed by osmoreceptors that influence both thirst and the release of ADH (vasopressin) from the supraoptic and paraventricular nuclei.

ADH plays a central role in urinary concentration by increasing the water permeability of the normally impermeable cortical and medullary collecting ducts. There are three major G-protein coupled receptors for vasopressin (ADH):

- V_{1A} found in vascular smooth muscle cells
- V_{1B} in anterior pituitary and throughout the brain
- V_2 receptors in the principal cells of the kidney distal convoluting tubule and collecting ducts.

Activation of the V_{1A} receptors induces vasoconstriction while V_{1B} receptors appear to mediate the effect of ADH on the pituitary, facilitating the release of ACTH. The V_2 receptors mediate the antidiuretic response as well as other functions.

The ability of ADH to increase the urine osmolality is related indirectly to transport in the ascending limb of the loop of Henle, which reabsorbs NaCl without water. This process, which is the primary step in the countercurrent mechanism, has two effects: it makes the tubular fluid dilute and the medullary interstitium concentrated. In the absence of ADH, little water is reabsorbed in the collecting ducts, and a dilute urine is excreted. By contrast, the presence of ADH promotes water reabsorption in the collecting ducts down the favourable osmotic gradient between the tubular fluid and the more concentrated interstitium. As a result, there is an increase in urine osmolality and a decrease in urine volume.

The cortical collecting duct has two cell types (see also p. 573) with very different functions:

- *Principal cells* (about 65%) have sodium and potassium channels in the apical membrane and, as in all sodium-reabsorbing cells, Na^+/K^+-ATPase pumps in the basolateral membrane.
- *Intercalated cells*, in comparison, do not transport NaCl (since they have a lower level of Na^+/K^+-ATPase activity) but play a role in hydrogen and bicarbonate handling and in potassium reabsorption in states of potassium depletion.

The ADH-induced increase in collecting duct water permeability occurs primarily in the principal cells. ADH acts on V_2 (vasopressin) receptors located on the basolateral surface of principal cells, resulting in the activation of adenyl cyclase. This leads to protein kinase activation and to preformed cytoplasmic vesicles that contain unique water channels (called aquaporins) moving to and then being inserted into the luminal membrane. Four renal aquaporins have been well

characterized and are localized in different areas of the cells of the collecting duct. The water channels span the luminal membrane and permit water movement into the cells down a favourable osmotic gradient (Fig. 12.5). This water is then rapidly returned to the systemic circulation across the basolateral membrane. When the ADH effect has worn off, the water channels aggregate within clathrin-coated pits, from which they are removed from the luminal membrane by endocytosis and returned to the cytoplasm. A defect in any step in this pathway, such as in attachment of ADH to its receptor or the function of the water channel, can cause resistance to the action of ADH and an increase in urine output. This disorder is called *nephrogenic diabetes insipidus*.

Plasma osmolality

In addition to influencing the rate of water excretion, ADH plays a central role in osmoregulation because its release is directly affected by the plasma osmolality. At a plasma osmolality of less than 275 mOsm/kg, which usually represents a plasma Na^+ concentration of less than 135–137 mmol/L, there is essentially no circulating ADH. As the plasma osmolality rises above this threshold, however, the secretion of ADH increases progressively.

Two simple examples will illustrate the basic mechanisms of osmoregulation, which is so efficient that the plasma Na^+ concentration is normally maintained within 1–2% of its baseline value.

1. *Ingestion of a water load* leads to an initial reduction in the plasma osmolality, thereby diminishing the release of ADH. The ensuing reduction in water reabsorption in the collecting ducts allows the excess water to be excreted in a dilute urine.
2. *Water loss* resulting from sweating is followed by, in sequence, a rise in both plasma osmolality and ADH secretion, enhanced water reabsorption, and the appropriate excretion of a small volume of concentrated urine. This renal effect of ADH minimizes further water loss but does not replace the existing water deficit. Thus, optimal osmoregulation requires an increase in water intake, which is mediated by a concurrent stimulation of thirst. The importance of thirst can also be illustrated by studies in patients with central diabetes insipidus, who are deficient in ADH. These patients often complain of marked polyuria, which is caused by the decline in water reabsorption in the collecting ducts. However, they do not typically become hypernatraemic, because urinary water loss is offset by the thirst mechanism.

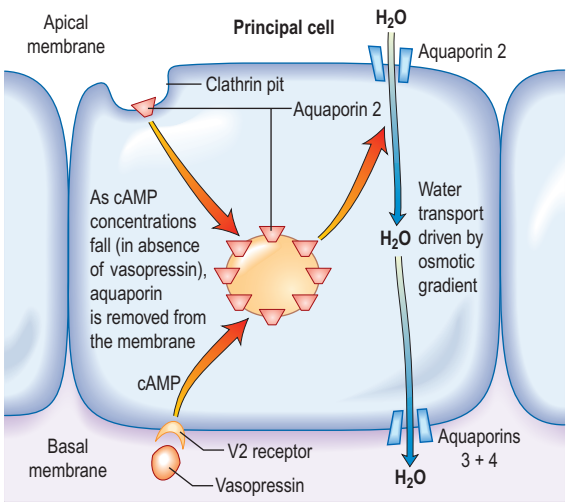

Fig. 12.5 **Aquaporin-mediated water transport in the renal collecting duct.** Stimulation of the vasopressin 2 receptor causes cAMP-mediated insertion of the aquaporin into the apical membrane, allowing water transport down the osmotic gradient. Adapted from Connolly DL, Shanahan CM, Weissberg PL. Water channels in health and disease. *Lancet* 1996; **347**: 211 with permission from Elsevier.

Osmoregulation versus volume regulation

A common misconception is that regulation of the plasma Na^+ concentration is closely correlated with the regulation of Na^+ excretion. However, it is related to volume regulation, which has different sensors and effectors (volume receptors) from those involved in water balance and osmoregulation (osmoreceptors).

The roles of these two pathways should be considered separately when evaluating patients.

- A *water load* is rapidly excreted (in 4–6 hours) by inhibition of ADH release so that there is little or no water reabsorption in the collecting ducts. This process is normally so efficient that volume regulation is not affected and there is no change in ANP release or in the activity of the renin–angiotensin–aldosterone system. Thus, a dilute urine is excreted, and there is little alteration in the excretion of Na^+.
- *Isotonic saline* administration, by contrast, causes an increase in volume but no change in plasma osmolality. In this setting, ANP secretion is increased, aldosterone secretion is reduced and ADH secretion does not change. The net effect is the appropriate excretion of the excess Na^+ in a relatively iso-osmotic urine.

In some cases, both volume and osmolality are altered and both pathways are activated. For example, if a person with normal renal function eats salted potato chips and peanuts without drinking any water, the excess Na^+ will increase the plasma osmolality, leading to osmotic water movement out of the cells and increased extracellular volume. The rise in osmolality will stimulate both ADH release and thirst (the main reason why many restaurants and bars supply free salted foods), whereas the hypervolaemia will enhance the secretion of ANP and suppress that of aldosterone. The net effect is increased excretion of Na^+ without water.

This principle of separate volume and osmoregulatory pathways is also evident in the **syndrome of inappropriate ADH secretion (SIADH)**. Patients with SIADH (see p. 1018) have impaired water excretion and hyponatraemia (dilutional) caused by the persistent presence of ADH. However, the release of ANP and aldosterone is not impaired and, thus, Na^+ handling remains intact. These findings have implications for the correction of the hyponatraemia in this setting which initially requires restriction of water intake.

ADH is also secreted by non-osmotic stimuli such as stress (e.g. surgery, trauma), markedly reduced effective circulatory volume (e.g. cardiac failure, hepatic cirrhosis), psychiatric disturbance and nausea, irrespective of plasma osmolality. This is mediated by the effects of sympathetic overactivity on supraoptic and paraventricular nuclei. In addition to water retention, ADH release in these conditions promotes vasoconstriction owing to the activation of V_{1B}

(vasopressin) receptors distributed in the vascular smooth muscle cells.

Regulation of cell volume

Maintenance of a constant volume in the face of extracellular and intracellular osmotic alterations is a critical problem faced by all cells. Most cells respond to swelling or shrinkage by activating specific metabolic or membrane-transport processes that return cell volume to its normal resting state. Within minutes after exposure to hypotonic solutions and resulting cell swelling, a common feature of many cells is the increase in plasma membrane potassium and chloride conductance. Although extrusion of intracellular potassium certainly contributes to a regulatory volume decrease, the role of chloride efflux itself is modest, given the relatively low intracellular chloride concentration. Other intracellular osmolytes, such as taurine and other amino acids, are transported out of the cell to achieve a regulatory volume decrease. By contrast, these regulatory mechanisms are operative in reverse to protect cell volume under hypertonic conditions, as is the case in the renal medulla. The tubular cells at the tip of renal papillae, which are constantly exposed to a hypertonic extracellular milieu, maintain their cell volume on a long-term basis by actively taking up smaller molecules, such as betaine, taurine and myoinositol, and by synthesizing more sorbitol and glycerophosphocholine.

Increased extracellular volume

Increased extracellular volume occurs in numerous disease states. The physical signs depend on the distribution of excess volume and on whether the increase is local or systemic. According to Starling principles, distribution depends on:

- venous tone, which determines the capacitance of the blood compartment and thus hydrostatic pressure
- capillary permeability
- oncotic pressure – mainly dependent on serum albumin
- lymphatic drainage.

Depending on these factors, fluid accumulation may result in expansion of interstitial volume, blood volume, or both.

Clinical features

Peripheral oedema is caused by expansion of the extracellular volume by at least 2 L (15%). The ankles are normally the first part of the body to be affected, although they may be spared in patients with lipodermatosclerosis (where the skin is tethered and cannot expand to accommodate the oedema). Oedema may be noted in the face, particularly in the morning. In a patient in bed, oedema may accumulate in the sacral area. Expansion of the interstitial volume also causes pulmonary oedema, pleural effusion, pericardial effusion and ascites. Expansion of the blood volume (overload) causes a raised jugular venous pressure, cardiomegaly, added heart sounds, basal crackles as well as a raised arterial blood pressure in certain circumstances.

Causes

Extracellular volume expansion is due to sodium chloride retention. Increased oral salt intake does not normally cause volume expansion because of rapid homeostatic mechanisms which increase salt excretion. However, a rapid intravenous infusion of a large volume of saline will cause volume expansion. Most causes of extracellular volume expansion are associated with renal sodium chloride retention.

Heart failure

Reduction in cardiac output and the consequent fall in effective circulatory volume and arterial filling lead to activation of the renin–angiotensin–aldosterone system, non-osmotic release of ADH, and increased activity of the renal sympathetic nerves via volume receptors and baroreceptors (Fig. 12.3a). Sympathetic overdrive also indirectly augments ADH and renin–angiotensin–aldosterone response in these conditions. The cumulative effect of these mediators results in increased peripheral and renal arteriolar resistance and water and sodium retention. These factors result in extracellular volume expansion and increased venous pressure, causing oedema formation.

Hepatic cirrhosis

The mechanism is complex, but involves peripheral vasodilatation (possibly owing to increased nitric oxide generation) resulting in reduced effective arterial blood volume (EABV) and arterial filling. This leads to an activation of a chain of events common to cardiac failure and other conditions with marked peripheral vasodilatation (Fig. 12.3). The cumulative effect results in increased peripheral and renal resistance, water and sodium retention, and oedema formation.

Nephrotic syndrome

Interstitial oedema is a common clinical finding with hypoalbuminaemia, particularly in the nephrotic syndrome. Expansion of the interstitial compartment is secondary to the accumulation of sodium in the extracellular compartment. This is due to an imbalance between oral (or parenteral) sodium intake and urinary sodium output, as well as alterations of fluid transfer across capillary walls. The intrarenal site of sodium retention is the cortical collecting duct (CCD) where Na^+/K^+-ATPase expression and activity are increased threefold along the basolateral surface (Fig. 12.4). In addition, amiloride-sensitive epithelial sodium channel activity is also increased in the CCD. The renal sodium retention should normally be counterbalanced by increased secretion of sodium in the inner medullary collecting duct, brought about by the release of ANP. This regulatory pathway is altered in patients with nephrotic syndrome by enhanced *kidney specific* catabolism of cyclic GMP (the second messenger for ANP) following phosphodiesterase activation.

Oedema generation was classically attributed to the decrease in the plasma oncotic pressure and the subsequent increase in the transcapillary oncotic gradient. However, the oncotic pressure and transcapillary oncotic gradient remain unchanged and the transcapillary hydrostatic pressure gradient is not altered. Conversely, capillary hydraulic conductivity (a measure of permeability) is increased. This is determined by intercellular macromolecular complexes between the endothelial cells consisting of tight junctions (made of occludins, claudins and ZO proteins) and adherens junctions (made of cadherin, catenins and actin cytoskeleton). Elevated TNF-α levels in nephrotic syndrome activate protein kinase C, which changes phosphorylation of occludin and capillary permeability. In addition, increased circulating ANP can increase capillary hydraulic conductivity by altering the permeability of intercellular junctional complexes. Furthermore, reduction in effective circulatory volume and the

consequent fall in cardiac output and arterial filling can lead to a chain of events as in cardiac failure and cirrhosis (see above and Fig. 12.3). These factors result in extracellular volume expansion and oedema formation.

Sodium retention

A decreased GFR decreases the renal capacity to excrete sodium. This may be acute, as in the acute nephritic syndrome (see p. 592), or may occur as part of the presentation of chronic kidney disease. In end-stage renal failure, extracellular volume is controlled by the balance between salt intake and its removal by dialysis.

Numerous drugs cause renal sodium retention, particularly in patients whose renal function is already impaired:

- *Oestrogens* cause mild sodium retention, due to a weak aldosterone-like effect. This is the cause of weight gain in the premenstrual phase.
- *Mineralocorticoids and liquorice* (the latter potentiates the sodium-retaining action of cortisol) have aldosterone-like actions.
- *NSAIDs* cause sodium retention in the presence of activation of the renin–angiotensin–aldosterone system by heart failure, cirrhosis and in renal artery stenosis.
- *Thiazolidinediones* (TZD) (see p. 1039) are widely used to treat type 2 diabetes. Their mechanism of action is attributed to binding and activation of the PPAR-γ system. PPARs are nuclear transcription factors essential to the control of energy metabolism that are modulated via binding with tissue-specific fatty acid metabolites. Of the three PPAR isoforms, γ has been extensively studied and is expressed at high levels in adipose and liver tissues, macrophages, pancreatic-β cells and principal cells of the collecting duct. These drugs have been asociated with salt and water retention and are contraindicated in patients with heart failure. Recent evidence suggests that TZD induced oedema (like insulin) is also due to upregulation of epithelial Na transporter channel (ENaC) but by different pathways. Diuretics of choice for TZD induced oedema are amiloride, triamterene and spironolactone.

Substantial amounts of sodium and water may accumulate in the body without clinically obvious oedema or evidence of raised venous pressure. In particular, several litres may accumulate in the pleural space or as ascites; these spaces are then referred to as ‘third spaces’. Bone may also act as a ‘sink’ for sodium and water.

Other causes of oedema

- Initiation of insulin treatment for type 1 diabetes and refeeding after malnutrition are both associated with the development of transient oedema. The mechanism is complex but involves upregulation of ENaC in the principal cell of the collecting duct. This transportor is amiloride sensitive which makes amiloride or triamterene the diuretic of choice in insulin induced oedema.
- Oedema may result from increased capillary pressure owing to relaxation of precapillary arterioles. The best example is the peripheral oedema caused by dihydropyridine calcium-channel blockers such as nifedipine which affects up to 10% of the patients. Oedema is usually resolved by stopping the offending drug.
- Oedema is also caused by increased interstitial oncotic pressure as a result of increased capillary permeability to proteins. This can occur as part of a rare complement-deficiency syndrome; with therapeutic use of interleukin 2 in cancer chemotherapy; or in ovarian hyperstimulation syndrome (see p. 1005).

Idiopathic oedema of women

This, by definition, occurs in women without heart failure, hypoalbuminaemia, renal or endocrine disease. Oedema is intermittent and often worse in the premenstrual phase. The condition remits after the menopause. Patients complain of swelling of the face, hands, breasts and thighs, and a feeling of being bloated. Sodium retention during the day and increased sodium excretion during recumbency are characteristic; an abnormal fall in plasma volume on standing caused by increased capillary permeability to proteins may be the cause of this. The oedema may respond to diuretics, but returns when they are stopped. A similar syndrome of diuretic-dependent sodium retention can be caused by abuse of diuretics, for instance as part of an attempt to lose weight; but not all women with idiopathic oedema admit to having taken diuretics, and the syndrome was described before diuretics were introduced for clinical use, so the cause remains unclear.

Local increase in oedema

This does not reflect disturbances of extracellular volume control per se, but can cause clinical confusion. Examples are ankle oedema due to venous damage following thrombosis or surgery, ankle or leg oedema due to immobility, oedema of the arm due to subclavian thrombosis, and facial oedema due to superior vena caval obstruction. Local loss of oncotic pressure may result from increased capillary permeability to proteins, caused by inflammatory mediators such as histamine and interleukins (e.g. a bee sting). Lastly, local loss of lymphatic drainage causes lymphoedema (see p. 1263).

Treatment

The underlying cause should be treated where possible. Heart failure, for example, should be treated, and offending drugs such as NSAIDs withdrawn.

Sodium restriction has only a limited role, but is useful in patients who are resistant to diuretics. Sodium intake can easily be reduced to approximately 100 mmol (2 g) daily; reductions below this are often difficult to achieve without affecting the palatability of food.

Manoeuvres that increase venous return stimulate salt and water excretion by effects on cardiac output and ANP release. This is the rationale for strict bed rest in congestive cardiac failure. Water immersion also causes redistribution of blood towards the central veins, but is seldom of practical use. Venous compression stockings or bandages may help to mobilize oedema in heart failure.

The *mainstay of treatment is the use of diuretic agents*, which increase sodium, chloride and water excretion in the kidney (Table 12.3). These agents act by interfering with membrane ion pumps which are present on numerous cell types; they mostly achieve specificity for the kidney by being secreted into the proximal tubule, resulting in much higher concentrations in the tubular fluid than in other parts of the body.

Table 12.3 Types and clinical uses of diuretics

Class	Major action	Examples	Clinical uses	Potency
Loop diuretics	↓ Na^+–Cl^-–K^+ cotransport in thick ascending limb of loop of Henle	Furosemide Bumetanide Torasemide	Volume overload (CCF, nephrotic syndrome, CKD) ?Acute renal failure SIADH	+++
Thiazide and related diuretics	↓ Na^+–Cl^- cotransport in early distal convoluted tubule	Bendroflumethiazide Chlortalidone Metolazone Indapamide	Hypertension Volume overload (CCF) Hypercalciuria	++
Potassium sparing	↓ Na^+ reabsorption (in exchange for K^+) in collecting duct (principal cells)	Aldosterone antagonists, e.g. spironolactone, eplerenone Others: amiloride, triamterene	Hyperaldosteronism (primary and secondary) Bartter's syndrome Heart failure Cirrhosis with fluid overload Prevention of K^+ deficiency in combination with loop or thiazide	+
Carbonic anhydrase inhibitors	↓ Na^+ HCO_3^- reabsorption in proximal collecting duct ↓ Aqueous humour formation	Acetazolamide	Metabolic alkalosis Glaucoma	+
Vasopressin/ADH Receptor blockers (Aquaretics)	Block V_2 receptor in collecting ducts producing free water diuresis	Lixivaptan Tolvaptan Satavaptan Conivaptan	In trials for heart failure, cirrhosis, SIADH	

CCF, congestive cardiac failure; CKD, chronic kidney disease; SIADH, syndrome of inappropriate antidiuretic hormone secretion

Clinical use of diuretics

Loop diuretics

These potent diuretics are useful in the treatment of any cause of systemic extracellular volume overload. They stimulate excretion of both sodium chloride and water by blocking the sodium–potassium–2-chloride (NKCC2) channel in the thick ascending limb of Henle (Fig. 12.6) and are useful in stimulating water excretion in states of relative water overload. They also act by causing increased venous capacitance, resulting in rapid clinical improvement in patients with left ventricular failure, preceding the diuresis. Unwanted effects include:

- urate retention causing gout
- hypokalaemia
- hypomagnesaemia
- decreased glucose tolerance
- allergic tubulo-interstitial nephritis and other allergic reactions
- myalgia – especially with bumetanide
- ototoxicity (due to an action on sodium pump activity in the inner ear) – particularly with furosemide
- interference with excretion of lithium, resulting in toxicity.

In most situations there is little to choose between the drugs in this class. Bumetanide has a better oral bioavailability than furosemide, particularly in patients with severe peripheral oedema, and has more beneficial effects than furosemide on venous capacitance in left ventricular failure. It can cause severe muscle cramps when used in high doses.

Thiazide diuretics (see p. 738)

These are less potent than loop diuretics. They act by blocking a sodium chloride channel in the *distal convoluted tubule* (Fig. 12.7). They cause relatively more urate retention, glucose intolerance and hypokalaemia than loop diuretics. They interfere with water excretion and may cause hyponatraemia, particularly if combined with amiloride or triamterene. This effect is clinically useful in diabetes insipidus. Thiazides reduce peripheral vascular resistance by mechanisms that are not completely understood but do not appear to depend on their diuretic action, and are widely used in the treatment of essential hypertension. They are also used extensively in mild to moderate cardiac failure. Thiazides reduce calcium excretion. This effect is useful in patients with idiopathic hypercalciuria, but may cause hypercalcaemia. Numerous agents are available, with varying half-lives but little else to choose between them. Metolazone is not dependent for its action on glomerular filtration, and therefore retains its potency in renal impairment.

Potassium-sparing diuretics (see Fig. 12.8)

These are relatively weak and are most often used in combination with thiazides or loop diuretics to prevent potassium depletion. They are of two types.

- *Aldosterone antagonists*, which compete with aldosterone in the *collecting ducts* and reduce sodium absorption, e.g. spironolactone and eplerenone (which has a shorter half-life). Spironolactone is used in patients with heart failure because it significantly reduces the mortality in these patients by antagonizing the fibrotic effect of aldosterone on the heart. Eplerenone is devoid of antiandrogenic or antiprogesterone properties.
- *Amiloride and triamterene* inhibit sodium uptake by blocking epithelial sodium channels in the collecting duct and reduce renal potassium excretion by reducing lumen-negative transepithelial voltage. They are mainly used as potassium sparing agents with thiazide or loop diuretics.

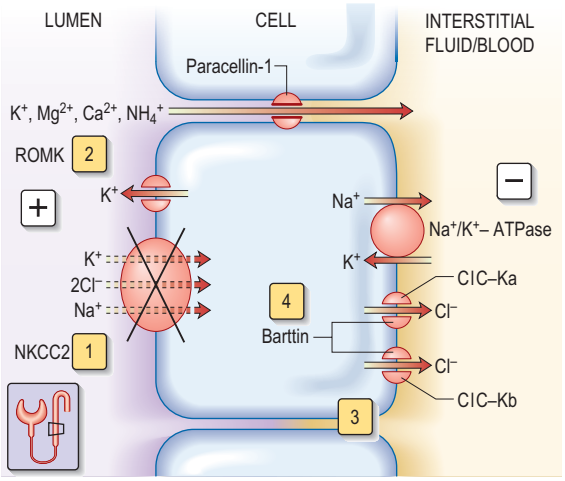

Fig. 12.6 **Transport mechanisms in the thick ascending limb of the loop of Henle.** Sodium chloride is reabsorbed in the thick ascending limb by the *bumetanide-sensitive* sodium–potassium–2-chloride cotransporter (NKCC2). The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na^+/K^+-ATPase and the kidney-specific basolateral chloride channel (ClC-Kb). The availability of luminal potassium is rate-limiting for NKCC2, and recycling of potassium through the ATP-regulated potassium channel (ROMK – renal outer medulla K^+ channel) ensures the efficient functioning of the NKCC2 and generates a lumen-positive transepithelial potential.

Genetic studies have identified putative loss-of-function mutations in the genes encoding NKCC2 [1], ROMK [2], ClC-Kb [3], and barttin [4] in subgroups of patients with **Bartter's syndrome**. In contrast to the normal condition, loss of function of NKCC2 impairs reabsorption of sodium and potassium. Inactivation of the basolateral ClC-Kb and *barttin* reduces transcellular reabsorption of chloride. Loss of function of any of these will reduce the transepithelial potential and thus decrease the driving force for the paracellular reabsorption of cations (K^+, Mg^{2+}, Ca^{2+} and Na^{4+}).

Paracellin-1 is necessary for the paracellular transport of Ca^{2+} and Mg^{2+}. In most patients with **Bartter's syndrome**, urinary calcium excretion is increased. Hypercalcaemia or increased activation of calcium-sensing receptor inactivates ROMK and causes Bartter's syndrome. Ka and Kb, kidney-specific basolateral chloride channel. ROMK, renal outer medullary potassium channel.

Carbonic anhydrase inhibitors

These are relatively weak diuretics and are seldom used except in the treatment of glaucoma. They cause metabolic acidosis and hypokalaemia.

Aquaretics (vasopressin or ADH receptor blockers)

Vasopressin V_2 receptor antagonists may become very useful agents in the treatment of conditions associated with elevated levels of vasopressin, such as heart failure, cirrhosis and SIADH (see p. 1018). Non-peptide vasopressin V_2 receptor antagonists are efficacious in producing free water diuresis in humans. Studies in patients with heart failure and cirrhosis suggest that such agents will allow normalization of serum osmolality with less water restriction (see p. 663).

Resistance to diuretics

Resistance may occur as a result of:

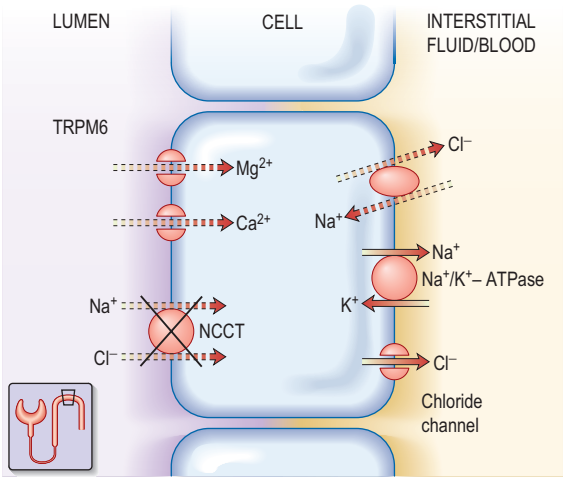

Fig. 12.7 **Transport mechanisms in the distal convoluted tubule.** Under normal conditions, sodium chloride is reabsorbed by the apical *thiazide-sensitive* sodium–chloride cotransporter (NCCT) in the distal convoluted tubule. The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na^+/K^+-ATPase and an, as yet, undefined basolateral chloride channel. In this nephron segment, there is an apical calcium channel and a basolateral sodium-coupled exchanger. Physiological evidence indicates that the mechanisms for the transport of magnesium are similar to those for calcium.

In **Gitelman's syndrome**, putative loss-of-function mutations in the sodium–chloride cotransporter (NCCT (**X**)) lead to decreased reabsorption of sodium chloride and increased reabsorption of calcium. Functional overactivity of NCCT leads to **Gordon's syndrome** by a new mechanism (see text). TRPM6, a member of the transient receptor potential family.

- poor bioavailability
- reduced GFR, which may be due to decreased circulating volume despite oedema (e.g. nephrotic syndrome, cirrhosis with ascites) or intrinsic renal disease
- activation of sodium-retaining mechanisms, particularly aldosterone.

Management. **Intravenous administration** of diuretics may establish a diuresis. **High doses** of loop diuretics are required to achieve adequate concentrations in the tubule if GFR is depressed. However, the daily dose of furosemide must be limited to a maximum of 2 g for an adult, because of ototoxicity. Intravenous albumin solutions restore plasma oncotic pressure temporarily in the nephrotic syndrome and allow mobilization of oedema but do not increase the natriuretic effect of loop diuretics.

Combinations of various classes of diuretics are extremely helpful in patients with resistant oedema. A loop diuretic plus a thiazide inhibit two major sites of sodium reabsorption; this effect may be further potentiated by addition of a potassium-sparing agent. Metolazone in combination with a loop diuretic is particularly useful in refractory congestive cardiac failure, because its action is less dependent on glomerular filtration. However, this potent combination can cause severe electrolyte imbalance. Both aminophylline and dopamine increase renal blood flow and may be useful in refractory cardiogenic sodium retention. In addition, theophyllines, by inhibiting phosphodiesterase activity in the inner medullary collecting

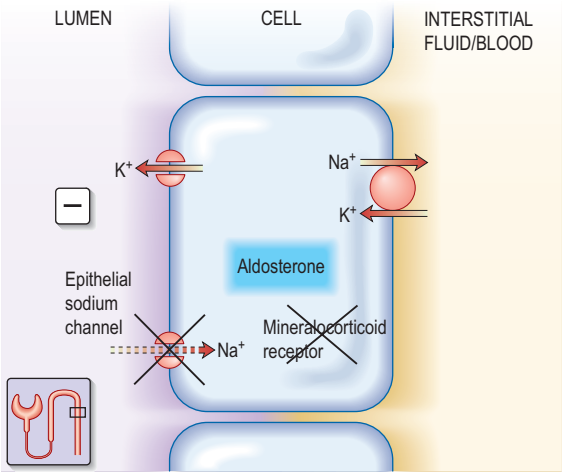

Fig. 12.8 **Aldosterone-regulated transport in the cortical collecting ducts.** Under normal conditions, the epithelial sodium channel is the rate-limiting barrier for the normal entry of sodium from the lumen into the cell. The resulting lumen-negative transepithelial voltage (indicated by the minus sign) drives potassium secretion from the principal cells and proton secretion from the α-intercalated cells (see Fig. 12.12).

In **Liddle's syndrome**, a mutation in the gene encoding the epithelial sodium channel results in persistent unregulated reabsorption of sodium and increased secretion of potassium (not shown).

In **pseudo-hypoaldosteronism type I autosomal recessive**, loss-of-function mutations (X) in this gene inactivate the channel. In the **autosomal dominant variety**, the mutation is in the gene encoding the mineralocorticoid regulation of the activity of the epithelial sodium channel. Either mechanism reduces the activity of the epithelial sodium channel, thus causing salt wasting and decreasing the secretion of potassium and protons.

duct, prolong the action of cyclic GMP (a second messenger of ANP).

Effects on renal function

All diuretics may increase plasma urea concentrations by increasing urea reabsorption in the medulla. Thiazides may also promote protein breakdown. In certain situations diuretics also decrease GFR:

- Excessive diuresis causes volume depletion and prerenal failure.
- Diuretics can cause allergic tubulo-interstitial nephritis.
- Thiazides may directly cause a drop in GFR; the mechanism is complex and not fully understood.

Decreased extracellular volume

Deficiency of sodium and water causes shrinkage both of the interstitial space and of the blood volume and may have profound effects on organ function.

Clinical features

Symptoms are variable. Thirst, muscle cramps, nausea and vomiting, and postural dizziness occur. Severe depletion of circulating volume causes hypotension and impairs cerebral perfusion, causing confusion and eventual coma.

Signs can be divided into those due to loss of interstitial fluid and those due to loss of circulating volume.

Table 12.4 Postural hypotension: some causes of a fall in blood pressure from lying to standing

Decreased circulating volume (hypovolaemia)

Autonomic failure
Diabetes mellitus
Systemic amyloidosis
Shy–Drager syndrome
Parkinson's disease
Ageing

Interference with autonomic function by drugs
Ganglion blockers
Tricyclic antidepressants

Interference with peripheral vasoconstriction by drugs
Nitrates
Calcium-channel blockers
α-Adrenoreceptor blocking drugs

Prolonged bed rest (cardiovascular deconditioning)

- *Loss of interstitial fluid* leads to loss of skin elasticity ('turgor') – the rapidity with which the skin recoils to normal after being pinched. Skin turgor decreases with age, particularly at the peripheries. The turgor over the anterior triangle of the neck or on the forehead is a very useful sign in all ages.
- *Loss of circulating volume* leads to decreased pressure in the venous and (if severe) arterial compartments. Loss of up to 1 L of extracellular fluid in an adult may be compensated for by venoconstriction and may cause no physical signs. Loss of more than this causes the following:

Postural hypotension

Normally the blood pressure rises if a subject stands up, as a result of increased venous return due to venoconstriction (this maintains cerebral perfusion). Loss of extracellular fluid (underfill) prevents this and causes a fall in blood pressure. This is one of the earliest and most reliable signs of volume depletion, as long as the other causes of postural hypotension are excluded (Table 12.4).

Low jugular venous pressure

In hypovolaemic patients, the jugular venous pulsation can be seen only with the patient lying completely flat, or even head down, because the right atrial pressure is lower than 5 cmH_2O.

Peripheral venoconstriction

This causes cold skin with empty peripheral veins, which are difficult to cannulate just when the patient needs intravenous therapy the most! This sign is often absent in sepsis, where peripheral vasodilatation contributes to effective hypovolaemia.

Tachycardia

This is not always a reliable sign. Beta-blockers and other antiarrhythmics may prevent tachycardia, and hypovolaemia may activate vagal mechanisms and actually cause bradycardia.

Causes

Salt and water may be lost from the kidneys, from the gastrointestinal tract, or from the skin. Examples are given in Table 12.5.

In addition, there are a number of situations where signs of volume depletion occur despite a normal or increased body content of sodium and water.

Table 12.5 Causes of extracellular volume depletion

Haemorrhage	**Renal losses**
External	Diuretic use
Concealed, e.g. leaking aortic aneurysm	Impaired tubular sodium conservation
Burns	Reflux nephropathy
Gastrointestinal losses	Papillary necrosis
Vomiting	Analgesic nephropathy
Diarrhoea	Diabetes mellitus
Ileostomy losses	Sickle cell disease
Ileus	

- Septicaemia causes vasodilatation of both arterioles and veins, resulting in greatly increased capacitance of the vascular space. In addition, increased capillary permeability to plasma proteins leads to loss of fluid from the vascular space to the interstitium.
- Diuretic treatment of heart failure or nephrotic syndrome may lead to rapid reduction in plasma volume. Mobilization of oedema may take much longer.
- There may be inappropriate diuretic treatment of oedema (e.g. when the cause is local rather than systemic).

Investigations

Blood tests are in general not helpful in the assessment of extracellular volume. Plasma urea may be raised owing to increased urea reabsorption and, later, to prerenal failure (when the creatinine rises as well), but this is very non-specific. Urinary sodium is low if the kidneys are functioning normally, but is misleading if the cause of the volume depletion involves the kidneys (e.g. diuretics, intrinsic renal disease). Urine osmolality is high in volume depletion (owing to increased water reabsorption), but may also often mislead.

Assessment of volume status is shown in Information box 12.1.

Treatment

The overriding principle is to replace what is missing.

Haemorrhage

The rational treatment of acute haemorrhage is the infusion of a combination of red cells and a plasma substitute or (if unavailable) whole blood. (Chronic anaemia causes salt and water retention rather than volume depletion by a mechanism common to conditions with peripheral vasodilatation.)

Box 12.1 Assessment of volume status

Best achieved by simple clinical observations which you should do yourself. Check:

- Jugular venous pressure
- Central venous pressure both basal and after intravenous fluid challenge (p. 901)
- Serial weights of the patient
- Postural changes in blood pressure
- A chest X-ray.

Loss of plasma

Loss of plasma, as occurs in burns or severe peritonitis, should be treated with human plasma or a plasma substitute (see p. 429).

Loss of water and electrolytes

Loss of water and electrolytes, as occurs with vomiting, diarrhoea, or excessive renal losses, should be treated by replacement of the loss. If possible, this should be with oral water and sodium salts. These are available as slow sodium (600 mg, approximately 10 mmol of each Na^+ and Cl^- per tablet), the usual dose of which is 6–12 tablets per day with 2–3 L of water. It is used in mild or chronic salt and water depletion, such as that associated with renal salt wasting.

Sodium bicarbonate (500 mg, 6 mmol each of Na^+ and HCO_3^- per tablet) is used in doses of 6–12 tablets per day with 2–3 L of water. This is used in milder chronic sodium depletion with acidosis (e.g. chronic renal failure, post-obstructive renal failure, renal tubular acidosis). Sodium bicarbonate is less effective than sodium chloride in causing positive sodium balance. Oral rehydration solutions are described in Box 4.9.

Intravenous fluids are sometimes required (Table 12.6). Rapid infusion (e.g. 1000 mL per hour or even faster) is necessary if there is hypotension and evidence of impaired organ perfusion (e.g. oliguria, confusion); in these situations, plasma expanders (colloids) are often used in the first instance to restore an adequate circulating volume (see p. 904). Repeated clinical assessments are vital in this situation, usually complemented by frequent measurements of central venous pressure (see p. 901, for the management of shock). Severe hypovolaemia induces venoconstriction, which maintains

Table 12.6 Intravenous fluids in general use for fluid and electrolyte disturbances

	Na^+ (mmol/L)	K^+ (mmol/L)	HCO_3^- (mmol/L)	Cl^- (mmol/L)	Indication (see footnote)
Normal plasma values	142	4.5	26	103	
Sodium chloride 0.9%	150	–	–	150	1
Sodium chloride 0.18% + glucose 4%	30	–	–	30	2
Glucose 5% + potassium chloride 0.3%	–	40	–	40	3
Sodium bicarbonate 1.26%	150	–	150	–	4

1. Volume expansion in hypovolaemic patients. Rarely to maintain fluid balance when there are large losses of sodium. The sodium (150 mmol/L) is higher than in plasma and hypernatraemia can result. It is often necessary to add KCl 20–40 mmol/L.
2. Maintenance of fluid balance in normovolaemic, normonatraemic patients.
3. To replace water. Can be given with or without potassium chloride. May be alternated with 0.9% saline as an alternative to (2).
4. For volume expansion in hypovolaemic, acidotic patients alternating with (1). Occasionally for maintenance of fluid balance combined with (2) in salt-wasting, acidotic patients.

venous return; over-rapid correction does not give time for this to reverse, resulting in signs of circulatory overload (e.g. pulmonary oedema) even if a total body extracellular fluid (ECF) deficit remains. In less severe ECF depletion (such as in a patient with postural hypotension complicating acute tubular necrosis), the fluid should be replaced at a rate of 1000 mL every 4–6 hours, again with repeated clinical assessment. If all that is required is avoidance of fluid depletion during surgery, 1–2 L can be given over 24 hours, remembering that surgery is a stimulus to sodium and water retention and that over-replacement may be as dangerous as under-replacement. Regular monitoring by fluid balance charts, bodyweight and plasma biochemistry is mandatory.

Loss of water alone

This causes extracellular volume depletion only in severe cases, because the loss is spread evenly among all the compartments of body water. In the rare situations where there is a true deficiency of water alone, as in diabetes insipidus or in a patient who is unable to drink (after surgery, for instance), the correct treatment is to give water.

If intravenous treatment is required, water is given as 5% dextrose with K^+, because pure water would lead to osmotic lysis of blood cells.

DISORDERS OF SODIUM CONCENTRATION

These are best thought of as disorders of body water content. As discussed above, sodium content is regulated by volume receptors; water content is adjusted to maintain, in health, a normal osmolality and (in the absence of abnormal osmotically active solutes) a normal sodium concentration. Disturbances of sodium concentration are caused by disturbances of water balance.

HYPONATRAEMIA

Hyponatraemia (Na < 135 mmol/L) is a common biochemical abnormality. The causes depend on the associated changes in extracellular volume:

- hyponatraemia with hypovolaemia (Table 12.7)
- hyponatraemia with euvolaemia (Table 12.8)
- hyponatraemia with hypervolaemia (Table 12.9).

Rarely, hyponatraemia may be a 'pseudo-hyponatraemia'. This occurs in hyperlipidaemia (either high cholesterol or high triglyceride) or hyperproteinaemia where there is a spuriously low measured sodium concentration, the sodium being confined to the aqueous phase but having its concentration expressed in terms of the total volume of plasma. In this situation, plasma osmolality is normal and therefore treatment of 'hyponatraemia' is unnecessary. Artefactual 'hyponatraemia' caused by taking blood from the limb into which fluid of low sodium concentration is being infused should be excluded!

Hyponatraemia with hypovolaemia

This is due to salt loss in excess of water loss; the causes are listed in Table 12.7. In this situation, ADH secretion is initially suppressed (via the hypothalamic osmoreceptors);

Table 12.7 Causes of hyponatraemia with decreased extracellular volume (hypovolaemia)

Extra-renal (urinary sodium < 20 mmol/L)	Kidney (urinary sodium > 20 mmol/L)
Vomiting	Osmotic diuresis (e.g. hyperglycaemia, severe uraemia)
Diarrhoea	Diuretics
Haemorrhage	Adrenocortical insufficiency
Burns	Tubulo-interstitial renal disease
Pancreatitis	Unilateral renal artery stenosis
	Recovery phase of acute tubular necrosis

Ask the authors
www.studentconsult.com

but as fluid volume is lost, volume receptors override the osmoreceptors and stimulate both thirst and the release of ADH. This is an attempt by the body to defend circulating volume at the expense of osmolality.

With extrarenal losses and normal kidneys, the urinary excretion of sodium falls in response to the volume depletion, as does water excretion, leading to concentrated urine containing less than 10 mmol/L of sodium. However, in salt-wasting kidney disease, renal compensation cannot occur and the only physiological protection is increased water intake in response to thirst.

Clinical features

With sodium depletion the clinical picture is usually dominated by features of volume depletion (see p. 659). The diagnosis is usually obvious where there is a history of gut losses, diabetes mellitus or diuretic abuse. Examination of the patient is often more helpful than the biochemical investigations, which include plasma and urine electrolytes and osmolality.

Table 12.10 shows the potential daily losses of water and electrolytes from the gut. Losses due to renal or adrenocortical disease may be less easily identified and a urinary sodium concentration of more than 20 mmol/L, in the presence of clinically evident volume depletion, suggests a renal loss.

Treatment

This is directed at the primary cause whenever possible.

In a healthy patient:

- give oral electrolyte–glucose mixtures (see p. 132)
- increase salt intake with slow sodium 60–80 mmol/day.

In a patient with vomiting or severe volume depletion:

- give intravenous fluid with potassium supplements, i.e. 1.5–2 L 5% Dextrose (with 20 mmol K^+) and 1 L 0.9% saline over 24 hours PLUS measurable losses
- correction of acid–base abnormalities is usually not required.

Hyponatraemia with euvolaemia

(see Table 12.8)

This results from an intake of water in excess of the kidney's ability to excrete it (dilutional hyponatraemia) with no change in body sodium content but the plasma osmolality is low. With normal kidney function, dilution hyponatraemia is uncommon even if a patient drinks approximately 1 L per hour. The most common iatrogenic cause is overgenerous infusion of 5% glucose into postoperative patients; in this situation it is exacerbated by an increased ADH secretion in response to stress. Postoperative hyponatraemia is a common clinical problem (almost 1% of patients) with symptomatic hyponatraemia occurring in 20% of these patients. Marathon runners drinking excess water and 'sports drinks' can become hyponatraemic. Premenopausal females are at most risk for developing hyponatraemic encephalopathy postoperatively, with postoperative ADH values in young females being 40 times higher than in young males. To prevent hyponatraemia, avoid using hypotonic fluids postoperatively and administer isotonic saline unless otherwise clinically contraindicated. The serum sodium should be measured daily in any patient receiving continuous parenteral fluid.

Some degree of hyponatraemia is usual in acute oliguric renal failure, while in chronic renal failure it is most often due to ill-given advice to 'push' fluids.

Table 12.10 Average concentrations and potential daily losses of water and electrolytes from the gut

	Na^+ mmol/L	K^+ mmol/L	Cl^- mmol/L	Volume (mL in 24 hours)
Stomach	50	10	110	2500
Small intestine				
Recent ileostomy	120	5	110	1500
Adapted ileostomy	50	4	25	500
Bile	140	5	105	500
Pancreatic juice	140	5	60	2000
Diarrhoea	130	10–30	95	1000–2000+

Clinical features

Dilutional hyponatraemia symptoms are common when this develops *acutely* (<48 hours, often postoperatively). Symptoms rarely occur until the serum sodium is less than 120 mmol/L and are more usually associated with values around 110 mmol/L or lower, particularly when *chronic*. They are principally neurological and are due to the movement of water into brain cells in response to the fall in extracellular osmolality.

Hyponatraemic encephalopathy symptoms and signs include headache, confusion and restlessness leading to drowsiness, myoclonic jerks, generalized convulsions and eventually coma. MRI scan of the brain reveals cerebral oedema but, in the context of electrolyte abnormalities and neurological symptoms, it can help to make a confirmatory diagnosis.

Risk factors for developing hyponatraemic encephalopathy. The brain's adaptation to hyponatraemia initially involves extrusion of blood and CSF, as well as sodium, potassium and organic osmolytes, in order to decrease brain osmolality. Various factors can interfere with successful adaptation. These factors rather than the absolute change in serum sodium predict whether a patient will suffer hyponatraemic encephalopthy.

- *Children* under 16 years are at increased risk due to their relatively larger brain-to-intracranial volume ratio compared to adults.
- *Premenopausal women* are more likely to develop encephalopthy than postmenopausal females and males because of inhibitory effects of sex hormones and the effects of vasopressin on cerebral circulation resulting in vasoconstriction and hypoperfusion of brain.
- *Hypoxaemia* is a major risk factor for hyponatraemic encephalopathy. Patients with hyponatraemia, who develop hypoxia due to either non-cardiac pulmonary oedema or hypercapnic respiratory failure, have a high risk of mortality. Hypoxia is the strongest predictor of mortality in patients with symptomatic hyponatraemia.

Investigations

The cause of hyponatraemia with apparently normal extracellular volume requires investigation:

- Plasma and urine electrolytes and osmolalities. The plasma concentrations of sodium, chloride and urea are low, giving a low osmolality. The urine sodium concentration is usually high and the urine osmolality is typically higher than the plasma osmolality. However, maximal dilution (<50 mosmol/kg) is not always present.
- Further investigations to exclude Addison's disease, hypothyroidism, 'syndrome of inappropriate ADH secretion' (SIADH) and drug-induced water retention, e.g. chlorpropamide.

Remember, potassium and magnesium depletion potentiate ADH release and are causes of diuretic-associated hyponatraemia.

The syndrome of inappropriate ADH secretion is often over-diagnosed. Some causes are associated with a lower set-point for ADH release, rather than completely autonomous ADH release – an example is chronic alcohol abuse.

Treatment

The underlying cause should be corrected where possible.

- Most cases are simply managed by restriction of water intake (to 1000 or even 500 mL per day) with review of diuretic therapy. Magnesium and potassium deficiency must be corrected. In mild sodium deficiency, 0.9% saline given slowly (1 L over 12 hours) is sufficient.
- *Acute onset with symptoms*. Hypertonic saline (3%, 513 mmol/L) is used with extreme care and restricted only for patients in whom there are severe neurological signs, such as fits or coma. It should be given very slowly (not more than 70 mmol per hour), the aim being to increase the serum sodium by 8–10 mmol/L in the first 4 hours, but the absolute change should not exceed 15–20 mmol/L over 48 hours. In general, the plasma sodium should not be corrected to greater than 125–130 mmol/L. 1 mL/kg of 3% sodium chloride will raise the plasma sodium by 1 mmol/L, assuming that total body water comprises 50% of total bodyweight. In some cases furosemide can be used to prevent pulmonary congestion and to increase the rate of sodium correction. Hypertonic saline must **not** be given to patients who are already fluid overloaded because of the risk of acute heart failure; in this situation, 100 mL of 20% mannitol may be infused in an attempt to increase renal water excretion (see below).
- *Chronic/asymptomatic*. If hyponatraemia has developed slowly, as it does in the majority of patients, the brain will have adapted by decreasing intracellular osmolality and the hyponatraemia can be corrected slowly.

A rapid rise in extracellular osmolality, particularly if there is an 'overshoot' to high serum sodium and osmolality, will result in severe shrinking of brain cells and the syndrome of '*central pontine myelinolysis*', which may be fatal. This is diagnosed by the appearance of characteristic hypointense lesions on T1-weighted images and hyperintense on T2-weighted images on MRI; these take up to 2 weeks or longer to appear. The evidence to suggest that these demyelinating lesions are associated with the rate of correction of sodium in hyponatraemic states is controversial. Other factors associated with demyelination are pre-existing hypoxaemia, liver disease and CNS radiation (see above).

Vasopressin V_2 receptor antagonists (see p. 658) which produce a free water diuresis are being used in clinical trials for the treatment of hyponatraemic encephalopathy. Three oral agents, lixivaptan, tolvaptan, and satavaptan, are selective for the V_2 (antidiuretic) receptor, while conivaptan blocks both the V_{1A} and V_2 receptors.

These agents produce a selective water diuresis without affecting sodium and potassium excretion; they raise the plasma sodium concentration in patients with hyponatraemia caused by the SIADH, heart failure, and cirrhosis.

The efficacy of oral tolvaptan in ambulatory patients was demonstrated in a recent report in which patients with hyponatraemia (mean plasma sodium 129 mmol/L) caused by the SIADH, heart failure, or cirrhosis had a sustained rise in plasma sodium to 136 mmol/L for 4 weeks. Oral vasopressin antagonists are likely to be useful in the management of mild to moderate asymptomatic hyponatremia if approved for clinical use. At present, only intravenous conivaptan is available and is approved only for the treatment of euvolaemic hyponatraemia (i.e. SIADH) in some countries. Side-effects include an increase in thirst and urinary frequency but the need for water restriction may still be required during long-term therapy. Careful monitoring is required initially since there is a potential risk of rapid correction of the hyponatraemia if the serum sodium is very low.

Hyponatraemia with hypervolaemia

(see Table 12.9)

The common causes of hyponatraemia due to water excess are shown in Table 12.9. In all these conditions there is usually an element of reduced glomerular filtration rate with avid reabsorption of sodium and chloride in the proximal tubule. This leads to reduced delivery of chloride to the 'diluting' ascending limb of Henle's loop and a reduced ability to generate 'free water', with a consequent inability to excrete dilute urine. This is commonly compounded by the administration of diuretics that block chloride reabsorption and interfere with the dilution of filtrate either in Henle's loop (loop diuretics) or distally (thiazides).

Syndrome of inappropriate ADH secretion

This is described in Chapter 18. There is inappropriate secretion of ADH, causing water retention and hyponatraemia.

HYPERNATRAEMIA

This is much rarer than hyponatraemia and nearly always indicates a water deficit. This may be due to (Table 12.11):

- impaired thirst or impaired conscious state
- pituitary diabetes insipidus (see p. 1017) (failure of ADH secretion)
- nephrogenic diabetes insipidus (failure of response to ADH)
- osmotic diuresis, e.g. hyperglycaemic, hyperosmolar state (see p. 1048)
- excessive loss of water through the skin or lungs.

Excessive administration of sodium may also contribute, for example:

Table 12.11 Causes of hypernatraemia

ADH deficiency
Diabetes insipidus

Iatrogenic
Administration of hypertonic sodium solutions

Insensitivity to ADH (nephrogenic diabetes insipidus)
Lithium
Tetracyclines
Amphotericin B
Acute tubular necrosis

Osmotic diuresis
Total parenteral nutrition
Hyperosmolar hyperglycaemic state

PLUS
Deficient water intake

- excessive reliance on 0.9% (150 mmol/L) saline for volume replacement
- administration of drugs with a high sodium content (e.g. piperacillin)
- use of 8.4% sodium bicarbonate after cardiac arrest.

Hypernatraemia is always associated with increased plasma osmolality, which is a potent stimulus to thirst. None of the above cause hypernatraemia unless thirst sensation is abnormal or access to water limited. For instance, a patient with diabetes insipidus will maintain a normal serum sodium concentration by maintaining a high water intake until an intercurrent illness prevents this. Thirst is frequently deficient in elderly people, making them more prone to water depletion. Hypernatraemia may occur in the presence of normal, reduced or expanded extracellular volume, and does not necessarily imply that total body sodium is increased.

Clinical features

Symptoms of hypernatraemia are non-specific. Nausea, vomiting, fever and confusion may occur. A history of long-standing polyuria, polydipsia and thirst suggests diabetes insipidus. There may be clues to a pituitary cause. A drug history may reveal ingestion of nephrotoxic drugs. Assessment of extracellular volume status guides resuscitation. Mental state should be assessed. Convulsions occur in severe hypernatraemia.

Investigations

Simultaneous urine and plasma osmolality and sodium should be measured. Plasma osmolality is high in hypernatraemia. Passage of urine with an osmolality lower than that of plasma in this situation is clearly abnormal and indicates diabetes insipidus. In pituitary diabetes insipidus, urine osmolality will increase after administration of desmopressin; the drug (a vasopressin analogue) has no effect in nephrogenic diabetes insipidus. If urine osmolality is high this suggests either an osmotic diuresis due to an unmeasured solute (e.g. in parenteral feeding) or excessive extrarenal loss of water (e.g. heat stroke).

Treatment

Treatment is that of the underlying cause, for example:

- in ADH deficiency, replace ADH in the form of desmopressin, a stable non-pressor analogue of ADH
- remember to withdraw nephrogenic drugs where possible and replace water either orally or, if necessary, intravenously.

In *severe* (>170 mmol/L) hypernatraemia, 0.9% saline (150 mmol/L) should be used initially. Avoid too rapid a drop in serum sodium concentration; the aim is correction over 48 hours, as over-rapid correction may lead to cerebral oedema.

In *less severe* (e.g. >150 mmol/L) hypernatraemia, the treatment is 5% dextrose or 0.45% saline; the latter is obviously preferable in hyperosmolar diabetic coma. Very large volumes – 5 L a day or more – may need to be given in diabetes insipidus.

If there is clinical evidence of volume depletion (see p. 661, this implies that there is a sodium deficit as well as a water deficit. Treatment of this is discussed on page 662.

DISORDERS OF POTASSIUM CONCENTRATION

Regulation of serum potassium concentration

The usual dietary intake varies between 80 and 150 mmol daily, depending upon fruit and vegetable intake. Most of the body's potassium (3500 mmol in an adult man) is intracellular. Serum potassium levels are controlled by:

- uptake of K^+ into cells
- renal excretion
- extrarenal losses (e.g. gastrointestinal).

Uptake of potassium into cells is governed by the activity of the Na^+/K^+-ATPase in the cell membrane and by H^+ concentration.

Uptake is *stimulated* by:

- insulin
- β-adrenergic stimulation
- theophyllines.

Uptake is decreased by:

- α-adrenergic stimulation
- acidosis – K^+ exchanged for H^+ across cell membrane
- cell damage or cell death – resulting in massive K^+ release.

Renal excretion of potassium is increased by aldosterone, which stimulates K^+ and H^+ secretion in exchange for Na^+ in the collecting duct (Fig. 12.8). Because H^+ and K^+ are interchangeable in the exchange mechanism, acidosis decreases and alkalosis increases the secretion of K^+. Aldosterone secretion is stimulated by hyperkalaemia and increased angiotensin II levels, as well as by some drugs, and this acts to protect the body against hyperkalaemia and against extracellular volume depletion. The body adapts to dietary deficiency of potassium by reducing aldosterone secretion. However, because aldosterone is also influenced by volume status, conservation of potassium is relatively inefficient, and significant potassium depletion may therefore result from prolonged dietary deficiency.

A number of drugs affect K^+ homeostasis by affecting aldosterone release (e.g. heparin, NSAIDs) or by directly affecting renal potassium handling (e.g. diuretics).

Normally only about 10% of daily potassium intake is excreted in the gastrointestinal tract. Vomit contains around

5–10 mmol/L of K^+, but prolonged vomiting causes hypokalaemia by inducing sodium depletion, stimulating aldosterone, which increases renal potassium excretion. Potassium is secreted by the colon, and diarrhoea contains 10–30 mmol/L of K^+; profuse diarrhoea can therefore induce marked hypokalaemia. Colorectal villous adenomas may rarely produce profuse diarrhoea and K^+ loss.

HYPOKALAEMIA

Causes

The most common causes of chronic hypokalaemia are diuretic treatment (particularly thiazides) and hyperaldosteronism. Acute hypokalaemia is often caused by intravenous fluids without potassium and redistribution into cells. The common causes are shown in Table 12.12.

Table 12.12 Causes of hypokalaemia

Increased renal excretion (urinary K^+ > 20 mmol/day)
Diuretics:
Thiazides
Loop diuretics

Increased aldosterone secretion
Liver failure
Heart failure
Nephrotic syndrome
Cushing's syndrome
Conn's syndrome
ACTH-producing tumours

Exogenous mineralocorticoid
Corticosteroids
Carbenoxolone
Liquorice (potentiates renal actions of cortisol)

Renal disease
Renal tubular acidosis
Types 1 and 2
Renal tubular damage (diuretic phase)
Acute leukaemia
Nephrotoxicity
Amphotericin
Aminoglycosides
Cytotoxic drugs
Release of urinary tract obstruction
Bartter's syndrome
Liddle's syndrome
Gitelman's syndrome

Reduced intake of K^+
Intravenous fluids without K^+
Dietary deficiency

Redistribution into cells
β-Adrenergic stimulation
Acute myocardial infarction
Beta-agonists: e.g. fenoterol, salbutamol
Insulin treatment, e.g. treatment of diabetic ketoacidosis
Correction of megaloblastic anaemia, e.g. B_{12} deficiency
Alkalosis
Hypokalaemic periodic paralysis

Gastrointestinal losses (urinary K^+ < 20 mmol/day)
Vomiting
Severe diarrhoea
Purgative abuse
Villous adenoma
Ileostomy or uterosigmoidostomy
Fistulae
Ileus/intestinal obstruction

Rare causes

These rare causes are discussed in detail because they show the mechanisms of how diuretics can affect the kidney.

Bartter's syndrome (similar to loop diuretics)

This consists of metabolic alkalosis, hypokalaemia, hypercalciuria, normal blood pressure, and an elevated plasma renin and aldosterone. The primary defect in this disorder is an impairment in sodium and chloride reabsorption in the thick ascending limb of the loop of Henle (Fig. 12.6). Mutation in the genes encoding either the sodium–potassium–2-chloride cotransporter (NKCC2), the ATP-regulated renal outer medullary potassium channel (ROMK) or kidney-specific basolateral chloride channels (ClC-Kb) – Bartter's types I, II and III respectively – causes loss of function of these channels, with consequent impairment of sodium and chloride reabsorption. There is also an increased intrarenal production of prostaglandin E_2 which is secondary to sodium and volume depletion, hypokalaemia and the consequent neurohumoral response rather than a primary defect. PE_2 causes vasodilatation and may explain why the blood pressure remains normal.

Barttin, a beta-subunit for ClC-Ka and ClC-Kb chloride channels, is encoded by the BSND (Bartter's syndrome with sensorineural deafness) gene. Loss of function mutations causes type IV Bartter's syndome associated with sensorineural deafness and renal failure. Barttin co-localizes with a subunit of the chloride channel in basolateral membranes of the renal tubule and inner ear epithelium. It appears to mediate chloride exit in the thick ascending limb (TAL) of the loop of Henle and chloride recycling in potassium-secreting strial marginal cells in the inner ear. A very rare variant of type IV is a disorder with an impairment of both chloride channels (ClC-Ka and ClC-Kb) producing the same phenotypic defects.

A gain of function mutation of the calcium sensing receptor (CaSR) which leads to autosomal dominant hypocalcaemia has also been recognized in Bartter's syndrome. In the kidney, the CaSR is expressed mainly in the basolateral membrane of cortical TAL. Activation of CaSR by high calcium or magnesium or by gain-of-function mutation triggers intracellular signalling, including release of arachidonic acid and inhibition of adenylate cyclase. Both actions result in inhibition of ROMK activity, which in turn leads to reduction in the lumen-positive electrical potential and transcellular absorption of calcium. This effect of CaSR explains why patients with mutations in this receptor may present with both hypocalcaemia, hypercalciuria and renal wasting of NaCl, resulting in a Bartter-like syndrome.

In summary, these defects in sodium chloride transport are thought to initiate the following sequence, which is almost identical to that seen with chronic ingestion of a loop diuretic. The initial salt loss leads to mild volume depletion, resulting in activation of the renin–angiotensin–aldosterone system. The combination of hyperaldosteronism and increased distal flow (owing to the reabsorptive defect) enhances potassium and hydrogen secretion at the secretory sites in the collecting tubules, leading to hypokalaemia and metabolic alkalosis.

Diagnostic pointers include high urinary potassium and chloride despite low serum values as well as increased plasma renin (NB: in primary aldosteronism, renin levels are low). Hyperplasia of the juxtaglomerular apparatus is seen on renal biopsy (careful exclusion of diuretic abuse is necessary). Hypercalciuria is a common feature but magnesium wasting, though rare, also occurs. *Treatment* is with combinations of potassium supplements, amiloride and indometacin.

Gitelman's syndrome (similar to thiazide diuretics)

Gitelman's syndrome is a phenotype variant of Bartter's syndrome characterized by hypokalaemia, metabolic alkalosis, hypocalciuria, hypomagnesaemia, normal blood pressure, and elevated plasma renin and aldosterone. There are striking similarities between the Gitelman syndrome and the

biochemical abnormalities induced by chronic thiazide diuretic administration. Thiazides act in the distal convoluted tubule to inhibit the function of the apical sodium–chloride cotransporter (NCCT) (Fig. 12.7). Analysis of the gene encoding the NCCT has identified loss of function mutations in Gitelman's syndrome.

Like Bartter's syndrome, defective NCCT function leads to increased solute delivery to the collecting duct, with resultant solute wasting, volume contraction and an aldosterone-mediated increase in potassium and hydrogen secretion. Unlike Bartter's syndrome, the degree of volume depletion and hypokalaemia is not sufficient to stimulate prostaglandin E_2 production. Impaired function of NCCT is predicted to cause hypocalciuria, as does thiazide administration. Impaired sodium reabsorption across the apical membrane, coupled with continued intracellular chloride efflux across the basolateral membrane, causes the cell to become hyperpolarized. This in turn stimulates calcium reabsorption via apical, voltage-activated calcium channels. Decreased intracellular sodium also facilitates calcium efflux via the basolateral sodium–calcium exchanger. The mechanism for urinary magnesium losses is not known. *Treatment* consists of potassium and magnesium supplementation ($MgCl_2$) and a potassium-sparing diuretic. Volume resuscitation is usually not necessary, because patients are not dehydrated. Elevated prostaglandin E_2 does not occur (see above) and, therefore, NSAIDs are not indicated in this disorder.

Liddle's syndrome

This is characterized by potassium wasting, hypokalaemia and alkalosis, but is associated with low renin and aldosterone production, and high blood pressure. There is a mutation in the gene encoding for the amiloride-sensitive epithelial sodium channel in the distal tubule/collecting duct. This leads to constitutive activation of the epithelial sodium channel, resulting in excessive sodium reabsorption with coupled potassium and hydrogen secretion. Unregulated sodium reabsorption across the collecting tubule results in volume expansion, inhibition of renin and aldosterone secretion and development of low renin hypertension (Fig. 12.8).

Therapy consists of sodium restriction along with amiloride or triamterene administration. Both are potassium-sparing diuretics which directly close the sodium channels. The mineralocorticoid antagonist spironolactone is ineffective, since the increase in sodium-channel activity is not mediated by aldosterone.

Hypokalaemic periodic paralysis (see p 1182)

This condition may be precipitated by carbohydrate intake, suggesting that insulin-mediated potassium influx into cells may be responsible. This syndrome also occurs in association with hyperthyroidism in Chinese patients.

Clinical features

Hypokalaemia is usually asymptomatic, but severe hypokalaemia (<2.5 mmol) causes muscle weakness. Potassium depletion may also cause symptomatic hyponatraemia (see p. 661).

Hypokalaemia is associated with an increased frequency of atrial and ventricular ectopic beats. This association may not always be causal, because adrenergic activation (for instance after myocardial infarction) causes both hypokalaemia and increased cardiac irritability. Hypokalaemia in patients without cardiac disease is unlikely to lead to serious arrhythmias.

Hypokalaemia seriously increases the risk of digoxin toxicity by increasing binding of digoxin to cardiac cells, potentiating its action, and decreasing its clearance.

Chronic hypokalaemia is associated with interstitial renal disease, but the pathogenesis is not completely understood.

Treatment

The underlying cause should be identified and treated where possible. Table 12.13 shows some examples.

Acute hypokalaemia may correct spontaneously. In most cases, withdrawal of oral diuretics or purgatives, accompanied by the oral administration of potassium supplements in the form of slow-release potassium or effervescent potassium, is all that is required. Intravenous potassium replacement is required only in conditions such as cardiac arrhythmias, muscle weakness or severe diabetic ketoacidosis. When using intravenous therapy in the presence of poor renal function, replacement rates <2 mmol per hour should be used only, with hourly monitoring of serum potassium and ECG changes. Ampoules of potassium should be thoroughly mixed in 0.9% saline; do not use a glucose solution as this would make hypokalaemia worse.

The treatment of adrenal disorders is described on page 1013.

Failure to correct hypokalaemia may be due to concurrent hypomagnesaemia. Serum magnesium should be measured and any deficiency corrected.

Hyperkalaemia

Causes

Acute self-limiting hyperkalaemia occurs normally after vigorous exercise and is of no pathological significance. Hyperkalaemia in all other situations is due either to increased release from cells or to failure of excretion (Table 12.14). The most common causes are renal impairment and drug interference with potassium excretion. The combination of ACE inhibitors with potassium-sparing diuretics or NSAIDs is particularly dangerous.

Table 12.13 Treatment of hypokalaemia

Cause	Treatment
Dietary deficiency	Increase intake of fresh fruit/vegetables or oral potassium supplements (20–40 mmol daily). (Potassium supplements can cause gastrointestinal irritation)
Hyperaldosteronism, e.g. cirrhosis, thiazide therapy	Spironolactone/eplerenone Co-prescription of a potassium-sparing diuretic with a similar onset and duration of action
Intravenous fluid replacement	Add 20 mmol of K^+ per litre of fluid with monitoring

Table 12.14 Causes of hyperkalaemia

Decreased excretion
Renal failure*
Drugs:*
- Amiloride
- Triamterene
- Spironolactone/eplerenone
- ACE inhibitors/ACE blockers*
- NSAIDs

Ciclosporin treatment
Heparin treatment
Aldosterone deficiency
Hyporeninaemic hypoaldosteronism (RTA type 4)
Addison's disease
Acidosis*
Gordon's syndrome

Increased release from cells (decreased Na^+/K^+-ATPase activity)
Acidosis
Diabetic ketoacidosis
Rhabdomyolysis/tissue damage
Tumour lysis
Succinylcholine (amplified by muscle denervation)
Digoxin poisoning
Vigorous exercise (α-adrenergic; transient)

Increased extraneous load
Potassium chloride
Salt substitutes
Transfusion of stored blood*

Spurious
Increased in vitro release from abnormal cells
- Leukaemia
- Infectious mononucleosis
- Thrombocytosis

Familial pseudohyperkalaemia, e.g. haemolysis in syringe
Increased release from muscles
- Vigorous fist clenching during phlebotomy

*Common causes

Rare causes

Hyporeninaemic hypoaldosteronism

This is also known as type 4 renal tubular acidosis (see p. 676). Hyperkalaemia occurs because of acidosis and hypoaldosteronism.

Pseudo-hypoaldosteronism type 1 (autosomal recessive and dominant types)

This is a disease of infancy, apparently due to resistance to the action of aldosterone. It is characterized by hyperkalaemia and evidence of sodium wasting (hyponatraemia, extracellular volume depletion). Autosomal recessive forms result from loss of function because of mutations in the gene for epithelial sodium channel activity (opposite to Liddle's syndrome). This disorder involves multiple organ systems and is especially marked in the neonatal period. With aggressive salt replacement and control of hyperkalaemia, these children can survive and the disorder appears to become less severe with age. The autosomal dominant type is due to mutations affecting the mineralocorticoid receptor (Fig. 12.8). These patients present with salt wasting and hyperkalaemia but do not have other organ-system involvement.

Hyperkalaemic periodic paralysis (see p. 1182)

This is precipitated by exercise, and is caused by an autosomal dominant mutation of the skeletal muscle sodium channel gene.

Gordon's syndrome (familial hyperkalaemic hypertension, pseudohypoaldosteronism type 2)

This appears to be a mirror image of Gitelman's syndrome (see p. 665), in which primary renal retention of sodium causes hypertension, volume expansion, low renin/aldosterone, hyperkalaemia and metabolic acidosis. There is also an increased sensitivity of sodium reabsorption to thiazide diuretics, suggesting that the thiazide-sensitive sodium–chloride cotransporter (NCCT) is involved. Genetic analyses, however, have excluded abnormalities in NCCT. The involvement of two loci on chromosomes 1 and 12 and further genetic heterogeneity has also been found. These genes do not correspond to ionic transporters but to unexpected proteins, WNK (With No lysine Kinase) 1 and WNK 4, which are two closely related members of a novel serine – threonine kinase family. WNK 4 normally inhibits NCCT by preventing its membrane translocation from the cytoplasm. Loss of function mutation in WNK 4 results in escape of NCCT from normal inhibition and its overactivity as seen from the patient's phenotype. WNK 1 is an inhibitor of WNK 4 and in some patients with Gordon's syndrome, gain of function mutation in WNK 1 results in functional deficiency of WNK 4 and overactivity of NCCT.

Suxamethonium and other depolarizing muscle relaxants

These cause release of potassium from cells. Induction of muscle paralysis during general anaesthesia may result in a rise of plasma potassium of up to 1 mmol/L. This is not usually a problem unless there is pre-existing hyperkalaemia.

Clinical features

Serum potassium of greater than 7.0 mmol/L is a medical emergency and is associated with ECG changes (Fig. 12.9). Severe hyperkalaemia may be asymptomatic and may predispose to sudden death from asystolic cardiac arrest. Muscle weakness is often the only symptom, unless (as is commonly the case) the hyperkalaemia is associated with metabolic acidosis, causing Kussmaul respiration. Hyperka-

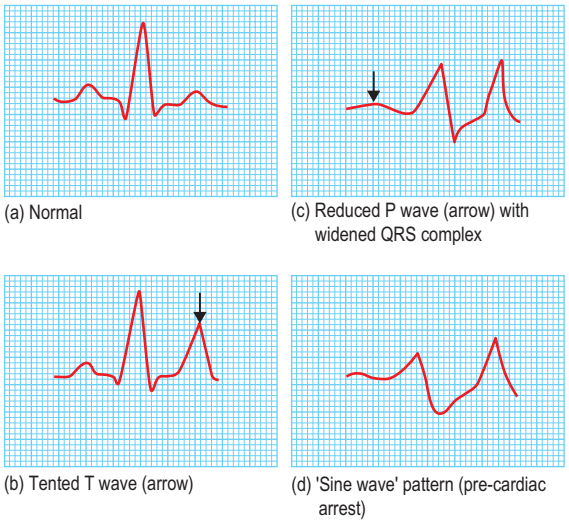

Fig. 12.9 Progressive ECG changes with increasing hyperkalaemia.

laemia causes depolarization of cell membranes, leading to decreased cardiac excitability, hypotension, bradycardia, and eventual asystole.

Treatment

Treatment for severe hyperkalaemia requires both urgent measures to save lives and maintenance therapy to keep potassium down, as summarized in Emergency box 12.1. The cause of the hyperkalaemia should be found and treated.

High potassium levels are cardiotoxic as they inactivate sodium channels. Divalent cations, e.g. calcium, restore the voltage dependability of the channels. *Calcium ions* protect the cell membranes from the effects of hyperkalaemia but do not alter the potassium concentration.

Supraphysiological insulin (20 units) drives potassium into the cell and lowers plasma potassium by 1 mmol in 60 minutes, but must be accompanied by glucose to avoid hypoglycaemia. Regular measurements of blood glucose for at least 6 hours after use of insulin should be performed and extra glucose must be available for immediate use. The use of glucose alone in non-diabetic patients, to stimulate endogenous insulin release, does not produce the high levels of insulin required and therefore is not recommended.

Intravenous or nebulized salbutamol (10–20 mg) has not yet found widespread acceptance and may cause disturbing muscle tremors at the doses required.

Correction of acidosis with hypertonic (8.4%) sodium bicarbonate causes volume expansion and should not be used; 1.26% is used with severe acidosis (pH < 6.9) (see p. 678). Gastric aspiration will remove potassium and leads to alkalosis.

Ion-exchange resins (polystyrene sulphonate resins) are used as maintenance therapy to keep potassium down after emergency treatment. They make use of the ion fluxes which occur in the gut to remove potassium from the body, and are the only way short of dialysis of removing potassium from the body. They may cause fluid overload (resonium contains Na^+) or hypercalcaemia (calcium resonium). Resins do not appear to significantly enhance the excretion of potassium beyond the effect of diarrhoea induced by osmotic or secretory cathartics.

In *general*, all of these measures are simply ways of buying time either to correct the underlying disorder or to arrange removal of potassium by dialysis, which is the definitive treatment for hyperkalaemia in renal failure.

Emergency Box 12.1

Correction of severe hyperkalaemia

IMMEDIATE

ECG monitor and i.v. access

Protect myocardium

10 mL of 10% calcium gluconate i.v. over 5 min
Effect is temporary but dose can be repeated after 15 min

Drive K^+ into cells

Insulin 10 units + 50 mL of 50% glucose i.v. over 10–15 min followed by regular checks of blood glucose and plasma K^+
Repeat as necessary:
and/or correction of severe acidosis (pH < 6.9) – infuse $NaHCO_3$ (1.26%)
and/or salbutamol 0.5 mg in 100 mL of 5% glucose over 15 min (rarely used)

LATER
Deplete body K^+ (to decrease plasma K^+ over next 24 h)

Polystyrene sulphonate resins:
15 g orally up to three times daily with laxatives
30 g rectally followed 9 hours later by an enema
Haemodialysis or peritoneal dialysis if the above fails

DISORDERS OF MAGNESIUM CONCENTRATION

Plasma magnesium levels are normally maintained within the range 0.7–1.1 mmol/L (1.4–2.2 meq/L). The average daily magnesium intake is 15 mmol, one-third of which is absorbed, principally in the small bowel. In the healthy adult, there is no net gain or loss of magnesium from bone, so that balance is achieved by the urinary excretion of the net magnesium absorbed.

Primary disturbance of magnesium balance is uncommon; hypo- or hypermagnesaemia usually developing on a background of more obvious fluid and electrolyte disturbances. Disturbance in magnesium balance should always be suspected in association with other fluid and electrolyte disturbances when the patient develops unexpected neurological signs or symptoms.

Renal handling of magnesium

Magnesium transport differs from that of most other ions in that the proximal tubule is not the major site of reabsorption with only 15–25% of the filtered magnesium being reabsorbed here passively. The major site of magnesium transport is the cortical thick ascending limb (cTAL) of the loop of Henle, where 60–70% of the filtered load is reabsorbed (Fig. 12.6). This transport is passive and paracellular, driven by the lumen positive electrochemical gradient, characteristic of this segment. Conversely, magnesium reabsorption in the distal convoluted tubule (DCT) is transcellular and active (Fig. 12.7), mediated by TRPM6, a member of the transient receptor potential channel family. TRPM6 is a Mg^{2+}-permeable channel that is also expressed in the luminal membrane of the intestinal epithelium. Inactivating mutations of TRPM6 thus causes a combination of impaired gut absorption of Mg^{2+} and renal wasting as seen in hypomagnesemia with secondary hypocalcemia (HSH). HSH is a rare autosomal recessive disease typified by low serum Mg^{2+} levels and high urinary fractional Mg^{2+} excretion. The reabsorption rate in the DCT (5–15%) is much lower than in the cTAL, but it defines the final urinary excretion, as there is no significant reabsorption in the collecting duct. Three to five per cent of filtered magnesium is finally excreted in the urine. cTAL magnesium reabsorption varies with changes in the plasma magnesium concentration, which is the main physiological regulator of urinary magnesium excretion. Hypermagnesaemia inhibits loop transport, while hypomagnesaemia stimulates magnesium transport. Hypercalcaemia inhibits magnesium loop transport by an unknown mechanism.

Another factor that can influence loop magnesium transport is the rate of sodium chloride reabsorption. This effect is relatively unimportant in normal subjects, but decreased reabsorption and magnesium wasting can be induced by the administration of a loop diuretic (Fig. 12.6).

HYPOMAGNESAEMIA

This most often develops as a result of deficient intake, defective gut absorption, or excessive gut or urinary loss (Table 12.15). It can also occur with acute pancreatitis, possibly owing to the formation of magnesium soaps in the areas of fat necrosis. Calcium deficiency usually develops with hypomagnesaemia. The serum magnesium is usually <0.7 mmol/L (1.4 mEq/L).

Isolated dominant hypomagnesaemia (IDH)

IDH follows an autosomal dominant mode of inheritance, presenting as hypomagnesaemia and hypocalciuria. It has similarities with Gitelman's syndrome but lacks hypokalaemia and metabolic alkalosis. The FXYD2 gene, encoding the gamma-subunit of Na^+/K^+-ATPase which is mainly expressed in TAL and DCT, is mutated, resulting in the inhibition of Na^+/K^+-ATPase activity and limiting the amount of potassium entry into the cell. Closing of potassium-sensitive apical magnesium channels causes reduced magnesium absorption and hypomagnesaemia in patients with IDH.

Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis (FHHNC)

This disorder is characterized by excessive renal magnesium and calcium wasting. In addition, affected individuals develop bilateral nephrocalcinosis and progressive renal failure. Patients also have elevated PTH levels, which precedes any reduction in GFR. A substantial proportion of patients show incomplete distal renal tubular acidosis, hypocitraturia and hyperuricaemia. Extrarenal involvement such as myopia, nystagmus, chorioretinitis has been reported. Based on clinical observation and clearance studies, the main defect in magnesium and calcium reabsorption lies in cTAL. Ten different mutations have been identified in a novel gene which encodes for paracellin-1 and claudin 19, members of the claudin family of tight junction proteins (see p. 25).

Table 12.15 Causes of hypomagnesaemia

Decreased magnesium absorption	**Gut losses**
Malabsorption (severe)	Prolonged nasogastric suction
Malnutrition	Excessive purgation
Alcohol excess	Gastrointestinal/biliary fistulae
Increased renal excretion	Severe diarrhoea
Drugs:	**Miscellaneous**
loop diuretics	Acute pancreatitis
thiazide diuretics	Inherited tubular wasting
digoxin	Isolated dominant hypomagnesaemia
Diabetic ketoacidosis	Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis
Gitelman's syndrome (p. 665)	Hypomagnesaemia with secondary hypocalcaemia (HSH)
Hyperaldosteronism	
SIADH	
Alcohol excess	
Hypercalciuria	
1,25-(OH)-vitamin D_3 deficiency	
Drug toxicity:	
amphotericin	
aminoglycosides	
cisplatin	
ciclosporin	

SIADH, syndrome of inappropriate antidiuretic hormone secretion

Clinical features

Symptoms and signs (indicating a deficit of 0.5–1 mmol/kg) include irritability, tremor, ataxia, carpopedal spasm, hyperreflexia, confusional and hallucinatory states, and epileptiform convulsions. An ECG may show a prolonged QT interval, broad flattened T waves, and occasional shortening of the ST segment.

Treatment

This involves the withdrawal of precipitating agents such as diuretics or purgatives. If symptomatic (or with hypocalcaemia), give a parenteral infusion of 50 mmol of magnesium chloride in 1 L of 5% dextrose or other isotonic fluid over 12–24 hours. This should be repeated daily and continued for 2 days after normal plasma levels have been achieved.

HYPERMAGNESAEMIA

This primarily occurs in patients with acute or chronic renal failure given magnesium-containing laxatives or antacids. It can also be induced by magnesium-containing enemas. Mild hypermagnesaemia may occur in patients with adrenal insufficiency. Causes are given in Table 12.16.

Clinical features

Symptoms and signs relate to neurological and cardiovascular depression, and include weakness with hyporeflexia proceeding to narcosis, respiratory paralysis and cardiac conduction defects. Symptoms usually develop when the plasma magnesium level exceeds 2 mmol/L (4 mEq/L).

Treatment

Treatment requires withdrawal of any magnesium therapy. An intravenous injection of 10 mL of calcium gluconate 10% (2.25 mmol calcium) is given to antagonize the effects of hypermagnesaemia, along with dextrose and insulin (as for hyperkalaemia) to lower the plasma magnesium level. Dialysis may be required in patients with severe renal failure.

Table 12.16 Causes of hypermagnesaemia

Impaired renal excretion
Chronic renal failure
Acute renal failure
Increased magnesium intake
Purgatives, e.g. magnesium sulphate
Antacids, e.g. magnesium trisilicate
Haemodialysis with high [Mg^{2+}] dialysate

DISORDERS OF PHOSPHATE CONCENTRATION

Phosphate forms an essential part of most biochemical systems, from nucleic acids downwards. The regulation of plasma phosphate level is closely linked to calcium.

About 80% of all body phosphorus is within bone, plasma phosphate normally ranging from 0.80 to 1.40 mmol/L (2.5 to 4.5 mg/dL). Phosphate reabsorption from the kidney (85% from the proximal tubule) is decreased by parathyroid hormone (PTH), mediated by a cyclic AMP-dependent mechanism; thus hyperparathyroidism is associated with low plasma levels of phosphate. Other factors that are known to control phosphate reabsorption in the proximal tubule are 1,25-dihydroxyvitamin D_3, sodium delivery to the proximal tubule, serum concentrations of calcium, bicarbonate, carbon dioxide tension, glucose, alanine, serotonin, dopamine and sympathetic activity. Osteoblast secreted phosphaturic factors (phosphatonins) such as fibroblast growth factor 23 (FGF-23), matrix extracellular phosphoglycoprotein (MEPG) and frizzled related protein 4 (FRP-4) are being investigated for a normal physiological role in phosphate homeostasis. FGF 23 binds to its receptors in the kidney and causes phosphaturia and also regulates vitamin D activation by 1 alpha hydroxylase (CYP27B1) and 24 hydroxylase (CYP24A1) enzymes. Moreover, FGF 23 requires *Klotho* (130 kDa anti-ageing protein predominantly expressed in the kidney) as a cofactor for its activity. Loss of function mutation in either FGF 23 or Klotho results in a similar phenotype of shortened life span, premature ageing (p. 37) including hyperphosphataemia and paradoxically increased 1-25 vitamin D levels.

HYPOPHOSPHATAEMIA

Significant hypophosphataemia (<0.4 mmol/L or <1.25 mg/dL) occurs in a number of clinical situations, owing to redistribution into cells, to renal losses, or to decreased intake (Table 12.17). Clinical features include:

- muscle weakness, e.g. diaphragmatic weakness, decreased cardiac contractility, skeletal muscle rhabdomyolysis
- a left-shift in the oxyhaemoglobin dissociation curve (reduced 2,3-bisphosphoglycerate (2,3-BPG)) and rarely haemolysis
- confusion, hallucinations, and convulsions.

Mild hypophosphataemia often resolves without specific treatment. However, diaphragmatic weakness may be severe in acute hypophosphataemia, and may impede weaning a patient from a ventilator. Interestingly, chronic hypophosphataemia (in X-linked hypophosphataemia) is associated with normal muscle power.

Table 12.17 Causes of hypophosphataemia

Redistribution	**Renal losses**
Respiratory alkalosis	Hyperparathyroidism
Treatment of diabetic ketoacidosis (insulin drives phosphate into cells)	Renal tubular defects
	Diuretics
	Hypophosphataemic rickets
Refeeding (particularly with carbohydrate) after fasting or starvation	Vitamin D-dependent rickets Types I and II
	Tumour induced

Malabsorption	
Vomiting	
Gut phosphate binders, e.g. sevelamer	
Vitamin D deficiency	
Alcohol withdrawal	

Causes

Hypophosphataemia can be part of osteomalacia and rickets due to vitamin D deficiency either dietary or genetic and is usually accompanied by hypocalcaemia (calcipenic).

Vitamin D-dependent rickets type I

Also known as pseudovitamin D-deficient rickets, this is caused by 1-alpha hydroxylase deficiency due to inactivating mutations in its gene. It can be corrected with high daily doses of vitamin D. This condition manifests clinically in the first year of life with severe hypocalcaemia often complicated by tetany, moderate hypophospataemia and enamel hypoplasia. The characteristic biochemical findings are normal serum levels of 25 hydroxyvitamin D and low values of 1-25 hydroxyvitamin D. The treatment of choice is replacement therapy with calcitriol. The aim of therapy is to maintain serum levels of calcium, phosphorus, and alkaline phosphatase within normal limits. Close monitoring is mandatory because of possible side-effects of calcitriol therapy including hypercalciuria, hypercalcaemia, nephrocalcinosis, and intraocular calcifications.

Vitamin D-dependent rickets type II

This is a form of vitamin D resistance and is now known as hereditary vitamin D-resistant rickets. It is an autosomal recessive disorder and is usually caused by loss of function mutations in the gene encoding the vitamin D receptor. The clinical manifestations vary widely, depending upon the type of mutation within the vitamin D receptor and the amount of residual vitamin D receptor activity. Affected children usually develop rickets within the first 2 years of life with alopecia in two-thirds of cases which is due to lack of vitamin D receptor action within keratinocytes. The treatment involves a therapeutic trial of calcitriol and calcium supplementation. The individual response is difficult to predict because the severity of the receptor defect varies among patients. Long-term infusion of calcium into a central vein is a possible alternative for severely resistant patients. This infusion must be maintained for many months. Oral calcium therapy may be sufficient once radiographic healing has been observed.

Decreased reabsorption of phosphate

This condition also occurs in patients with *tumour-induced osteomalacia* (TIO), *X-linked dominant hypophosphataemic rickets* (XLR), and *autosomal-dominant hypophosphataemic rickets* (ADHR). These syndromes have similar biochemical and osseous phenotypes. Patients have osteomalacia or rickets, reduced tubular phosphate reabsorption, hypophos-

phataemia, normal or low serum calcium, normal PTH and PTH-related protein concentrations, and normal or low 1,25-dihydroxyvitamin D_3. Urinary cyclic AMP levels are generally in the normal range.

In *TIO*, there is excessive production of phosphatonins (which are normally produced by osteoblasts and act as hormones by acting on kidneys and regulating phosphate absorption and vitamin D activation), e.g. fibroblast growth factor 23 (FGF-23), matrix extracellular phosphoglycoprotein (MEPG), and frizzled related protein 4 (FRP-4). These cannot be degraded by normal concentrations of PHEX (phosphate regulating gene with homologies to endopeptidases on the X chromosome). This results in net excess of inhibitors of the sodium–phosphate cotransporter in the proximal tubule, and phosphaturia.

In *ADHR*, FGF-23 is mutated so that it is resistant to PHEX proteolysis. In XLR, mutations in PHEX prevent binding to FGF-23 and FRP-4, resulting in a net relative excess of phosphatonins.

Normal adaptive increases in 1,25-dihydroxyvitamin D_3 synthesis in response to low phosphate levels do not occur in TIO, ADHR and XLR, aggravating phosphaturia (Fig. 12.10).

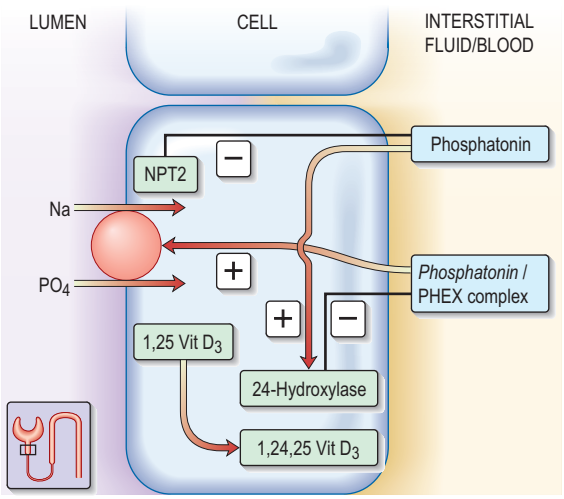

Fig. 12.10 **PHEX regulation of phosphate transport and vitamin D metabolism in the proximal tubule.** The hormone phosphatonin is an inhibitor of sodium–phosphate cotransporter (NPT2). When bound to PHEX (phosphate-regulating gene with homologies to endopeptidase on the X chromosome) it is bioinactive and is thought to stimulate phosphate reabsorption via the sodium–phosphate cotransporter (NPT2) and to retard the degradation of 1,25-dihydroxyvitamin D by downregulating 24-hydroxylase activity.

Over-production of phosphatonins occurs in tumour-induced osteomalacia, gain of function mutation as in autosomal dominant hypophosphataemic rickets and loss of function mutation in PHEX as X-linked hypophosphataemia. This causes renal phosphate wasting, as well as increased 1,25-dihydroxyvitamin D degradation. Modified from Rowe PSN. The role of the PHEX gene (PEX) in families with X-linked hypophosphataemic rickets. *Current Opinion in Nephrology and Hypertension* 1998; **7**(4): 367–376 with permission from Lippincott Williams and Wilkins.

Dent's disease

Dent's disease is the generally accepted name for a group of hereditary tubular disorders including X-linked recessive nephrolithiasis with renal failure, X-linked recessive hypophosphataemic rickets, and idiopathic low-molecular-weight proteinuria. Dent's disease is characterized by low-molecular-weight proteinuria, hypercalciuria, hyperphosphaturia, nephrocalcinosis, kidney stones and eventual renal failure, with some patients developing rickets or osteomalacia. It is caused by loss of function mutation of a proximal tubular endosomal chloride channel, Cl^-C5. This chloride channel, along with the proton pump, is essential for acidification of proximal tubular endosomes. The process is linked with normal endocytosis, degradation and recycling of absorbed proteins, vitamins and hormones. Defective endosomal acidification (owing to the mutated Cl^-C5 gene) results in impaired endosomal degradation and recycling of endocytosed hormones such as PTH. High PTH concentration activates apical receptors, increases endocytosis of the sodium–phosphate cotransporter and produces increased phosphaturia. It also results in increased 1α-hydoxylase activity, causing excess production of 1,25-$(OH)_2$ D_3, hypercalciuria, renal stones and nephrocalcinosis. Moreover, the receptors (megalin and cubilin) for reabsorption of low-molecular-weight proteins and albumin in the proximal tubules are decreased in Dent's disease. This is secondary to the defective acidification of endosomes, which can explain low-molecular-weight proteinuria and excessive urinary leaks of cytokines, hormones and chemokines. This urinary profile is associated with progressive renal fibrosis and more rapid decline in renal function.

Treatment

Treatment for hypophosphataemia includes combined therapy with phosphate supplementation and calcitriol (1,25-dihydroxyvitamin D) administration.

Treatment of acute hypophosphataemia, if warranted, is with intravenous phosphate at a maximum rate of 9 mmol every 12 hours, with repeated measurements of calcium and phosphate, as over-rapid administration of phosphate may lead to severe hypocalcaemia, particularly in the presence of alkalosis. *Chronic hypophosphataemia* can be corrected, if warranted, with oral effervescent sodium phosphate.

HYPERPHOSPHATAEMIA

Hyperphosphataemia is common in patients with chronic renal failure (see p. 628 and Table 12.18). Hyperphosphataemia is usually asymptomatic but may result in precipitation of calcium phosphate, particularly in the presence of a normal or raised calcium or of alkalosis. Uraemic itching may be caused by a raised calcium phosphate product. Prolonged

hyperphosphataemia causes hyperparathyroidism, and periarticular and vascular calcification.

Usually no treatment is required for acute hyperphosphataemia, as the causes are self-limiting. Treatment of chronic hyperphosphataemia is with gut phosphate binders and dialysis (see p. 633).

ACID–BASE DISORDERS

The concentration of hydrogen ions in both extracellular and intracellular compartments is extremely tightly controlled, and very small changes lead to major cell dysfunction. The blood pH is tightly regulated and is normally maintained at between 7.38 and 7.42. Any deviation from this range indicates a change in the hydrogen ion concentration $[H^+]$ because blood pH is the negative logarithm of $[H^+]$ (Table 12.19). The $[H^+]$ at a physiological blood pH of 7.40 is 40 nmol/L. An increase in the $[H^+]$ – a fall in pH – is termed acidaemia. A decrease in $[H^+]$ – a rise in the blood pH – is termed alkalaemia. The disorders that cause these changes in the blood pH are acidosis and alkalosis, respectively.

Normal acid–base physiology

The normal adult diet contains 70–100 mmol of acid. Throughout the body, there are buffers that minimize any changes in blood pH that these ingested hydrogen ions might cause. Such buffers include intracellular proteins (e.g. haemoglobin) and tissue components (e.g. the calcium carbonate and calcium phosphate in bone) as well as the bicarbonate–carbonic acid buffer pair generated by the hydration of carbon dioxide. This buffer pair is clinically most relevant, in part because its contribution can be measured and because alterations in this buffer pair reveal changes in all other buffer systems. Bicarbonate ions $[HCO_3^-]$ and carbonic acid (H_2CO_3) exist in equilibrium; and in the presence of carbonic anhydrase, carbonic acid dissociates to carbon dioxide and water, as expressed in the following equation:

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \overset{\text{carbonic anhydrase}}{\rightleftharpoons} CO_2 + H_2O$$

The addition of hydrogen ions drives the reaction to the right, decreasing the plasma bicarbonate concentration $[HCO_3^-]$ and increasing the arterial carbon dioxide pressure (P_{aCO_2}). As shown in the following Henderson– Hasselbalch equation, a fall in the plasma $[HCO_3^-]$ increases $[H^+]$ and thus lowers blood pH:

$$[H^+] = 181 \times P_{aCO_2} [HCO_3^-]$$

where $[H^+]$ is expressed in nmol per litre, P_{aCO_2} in kilopascals, $[HCO_3^-]$ in mmol per litre, and 181 is the dissociation coefficient of carbonic acid. Alternatively the equation can be expressed as:

$$pH = pK + \log[HCO_3^-]/[H_2CO_3]$$

where pK = 6.1. Thus, the bicarbonate used in the buffering process must be regenerated to maintain normal acid–base balance.

Although the acidaemia stimulates an increase in ventilation, which blunts this change in pH, increased ventilation does not regenerate the bicarbonate used in the buffering process. Consequently, the kidney must excrete hydrogen ions to return the plasma $[HCO_3^-]$ to normal. Maintenance of a normal plasma $[HCO_3^-]$ under physiological conditions depends not only on daily regeneration of bicarbonate but also on reabsorption of all bicarbonate filtered across the glomerular capillaries.

Renal reabsorption of bicarbonate

The plasma $[HCO_3^-]$ is normally maintained at approximately 25 mmol/L. In individuals with a normal glomerular filtration rate (120 mL/min), about 4500 mmol of bicarbonate is filtered each day. If this filtered bicarbonate were not reabsorbed, the plasma $[HCO_3^-]$ would fall, along with blood pH. Thus, maintenance of a normal plasma $[HCO_3^-]$ requires that essentially all of the bicarbonate in the glomerular filtrate be reabsorbed (Fig. 12.11).

The proximal convoluted tubule reclaims 85–90% of filtered bicarbonate; by contrast, the distal nephron reclaims very little. This difference is caused by the greater quantity

Table 12.19 Relationship between $[H^+]$ and pH

pH	$[H^+]$ (nmol/L)

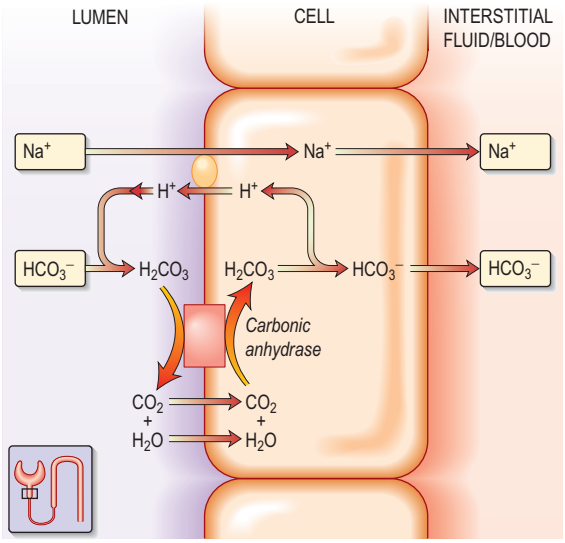

Fig. 12.11 **Resorption of sodium bicarbonate in the renal (mainly proximal) tubule.** Bicarbonate is reclaimed by the secretion of H^+ in exchange for Na^+ into the tubule. This results in the formation of H_2CO_3, which is then broken down to CO_2. This is reabsorbed and converted back to H_2CO_3, which now dissociates into H^+ and HCO_3^-. The net result is reabsorption of Na^+ and HCO_3^-. This process is dependent on carbonic anhydrase within the cells and on the luminal surface of the tubular cell.

of luminal (brush border) carbonic anhydrase in the proximal tubule than in the distal nephron. As a result of these quantitative differences, bicarbonate that escapes reabsorption in the proximal tubule is excreted in the urine.

Proximal tubular bicarbonate reabsorption is catalysed by the Na^+/K^+-ATPase pump located in the basolateral cell membrane. By exchanging peritubular potassium ions for intracellular sodium ions, the pump keeps the intracellular sodium concentration low, allowing sodium ions to enter the cell by moving down the sodium concentration gradient from the tubule lumen to the cell interior. Hydrogen ions are transported in the opposite direction (at the Na^+–H^+ antiporter), thereby maintaining electroneutrality. Before bicarbonate enters the proximal tubule, it combines with secreted hydrogen ions, forming carbonic acid. In the presence of luminal carbonic anhydrase (CA-IV) carbonic acid rapidly dissociates into carbon dioxide and water, which can then rapidly enter the proximal tubular cell. In the cell, carbon dioxide is hydrated by cytosolic carbonic anhydrase (CA-II), ultimately forming bicarbonate, which is then transported down an electrical gradient from the cell interior, across the membrane into the peritubular fluid, and into the blood. In this process, each hydrogen ion secreted into the proximal tubule lumen is reabsorbed and can be resecreted; there is no net loss of hydrogen ions or net gain of bicarbonate ions.

Renal excretion of [H^+] (Fig. 12.12)

More acid is secreted into the proximal tubule (up to 4500 nmol of hydrogen ions each day) than into any other nephron segment. However, the hydrogen ions secreted into the proximal tubule are almost completely reabsorbed with bicarbonate; consequently, proximal tubular hydrogen ion secretion does not contribute significantly to hydrogen ion elimination from the body. The excretion of the daily acid load requires hydrogen ion secretion in more distal nephron segments.

Most dietary hydrogen ions come from sulphur-containing amino acids that are metabolized to sulphuric acid (H_2SO_4), which then reacts with sodium bicarbonate as follows:

$$H_2SO_4 + 2NaHCO_3 \rightarrow Na_2SO_4 + 2CO_2 + 2H_2O.$$

Excess sulphate is excreted in the urine, whereas excess hydrogen ions are buffered by bicarbonate and lower the plasma [HCO_3^-]. This fall in plasma [HCO_3^-] leads to a slight decrease in the blood pH, although a smaller decrease in the blood pH than would have occurred if buffer were unavailable. The subsequent excretion of hydrogen ions takes place primarily in the collecting duct and results in the regeneration of 1 mmol of bicarbonate for every mmol of hydrogen ions excreted in the urine.

The *collecting duct* has three types of cells:

- The *principal cell* with an aldosterone-sensitive Na^+ absorption site. These cells reabsorb Na^+ and H_2O and secrete K^+ under the influence of aldosterone.
- The *α-intercalated cell*, which possesses the proton pump for the active secretion of hydrogen ions in exchange for reabsorption of K^+ ions. Aldosterone increases H^+ ion secretion.
- The *β-intercalated cells* are mirror images of α-intercalated cells where the H^+-ATPase pump is located in the basolateral rather than the apical membrane whereby H^+ ions are secreted into the peritubular capillary. The HCO_3^- ions, on the other hand, are secreted into the tubular lumen by an anion exchanger in the apical membrane. The identity of this transporter is uncertain, however, as it does not appear to represent the same Cl^--HCO_3^- exchanger that is present in the basolateral membrane of the H^+-secreting intercalated cells.

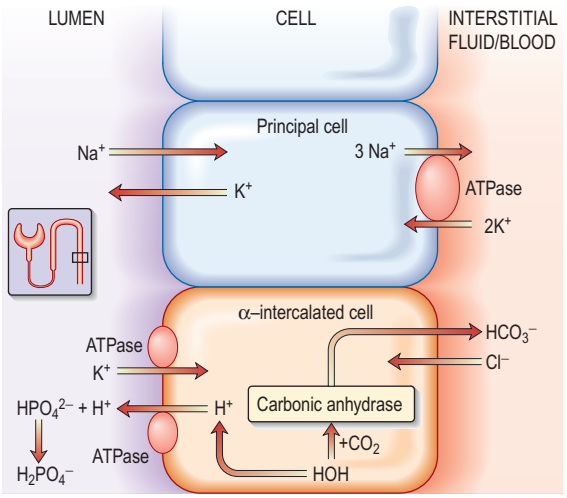

Fig. 12.12 **Renal excretion of H^+.** Secretion of H^+ from the cortical collecting ducts is indirectly linked to Na^+ reabsorption. Intracellular potassium is exchanged for sodium in the principal cell.

Aldosterone stimulates H^+ secretion by entering the principal cell, where it opens Na^+ channels in the luminal membrane and increases Na^+/K^+-ATPase activity. The movement of cationic Na^+ into the principal cells then creates a negative charge within the tubule lumen. K^+ moves from the electrochemical gradient and into the lumen.

Aldosterone apparently also stimulates the H^+-ATPase directly in the intercalated cell, further enhancing H^+ secretion. When the urinary pH falls to 4.0–4.5, further H^+ secretion by the α-intercalated cells ceases. The filtration of titratable acids (e.g. phosphoric acid, H_2PO_4) raises the intraluminal pH and permits this process to continue. Secreted H^+ binds to the conjugate anion of a titratable acid (HPO_4^{2-} in this case) and is excreted in the urine. The H^+ to be secreted arises from the reassociation of H_2O and CO_2 in the presence of carbonic anhydrase; thus, a bicarbonate molecule is regenerated each time an H^+ is eliminated in the urine.

Secretion of hydrogen ions from the cortical collecting duct is indirectly linked to sodium reabsorption. Aldosterone has several facilitating effects on hydrogen ion secretion. Aldosterone opens sodium channels in the luminal membrane of the principal cell and increases Na^+/K^+-ATPase activity. The subsequent movement of cationic sodium into the principal cell creates a negative charge within the tubule lumen. Potassium ions from the principal cells and hydrogen ions from the α-intercalated cells move out from the cells down the electrochemical gradient and into the lumen. Aldosterone also stimulates directly the H^+-ATPase in the α-intercalated cell, further enhancing hydrogen ion secretion.

When hydrogen ions are secreted into the lumen of the collecting tubule, a tiny, but physiologically critical, fraction

of these excess hydrogen ions remains in solution. Here, they increase the urinary [H^+] and lower urinary pH below 4.0. Nevertheless, below this urine pH, inhibition of proton-secreting pumps such as H^+-ATPase severely restricts kidney secretion of more hydrogen ions. Consequently, secretion of hydrogen ions depends on the presence of buffers in the urine that maintain the urine pH at a level higher than 4.0.

In the presence of alkali excess, the homeostatic needs are reversed. Although the kidney can excrete excess alkaline load by reducing reabsorption of filtered bicarbonate in the proximal and distal tubule, the collecting ducts also contribute by secreting bicarbonate brought about by switching to β-intercalated cells. This switch enables kidneys to secrete bicarbonate and conserve H^+ ions.

Buffer systems in acid excretion

Two buffer systems are involved in acid excretion: the titratable acids such as phosphate, and the ammonia system. Each system is responsible for excreting about half of the daily acid load of 50–100 mmol under physiological conditions (Fig. 12.12).

Titratable acid

A titratable acid is a filtered buffer substance having a conjugate anion that can be titrated within the pH range occurring physiologically in the urine. Phosphoric acid (pK_a 6.8) is the usual titratable urinary buffer. Hydrogen ions bind to the conjugate anions of the titratable acids and are excreted in the urine. For each hydrogen ion excreted in this form, a bicarbonate ion is regenerated within the cell and returned to the blood (Fig. 12.12).

Ammonium ($NH4^+$)

In the setting of metabolic acidosis, titratable acids cannot increase significantly because the availability of titratable acid is fixed by the plasma concentration of the buffer and by the GFR. The ammonia buffer system, by contrast, can increase several hundred fold when necessary. Consequently, impaired renal excretion of hydrogen ions is always associated with a defect in ammonium excretion (Fig. 12.13).

All ammonia used to buffer urinary hydrogen ions in the collecting tubule is synthesized in the proximal convoluted tubule. Glutamine is the primary source of ammonia. It undergoes deamination catalysed by glutaminase, resulting in α-ketoglutaric acid (Fig. 12.13) and ammonia. Once formed, ammonia can diffuse into the proximal tubule lumen and become acidified, forming ammonium. Once in the proximal tubule lumen, ammonium flows along the tubule to the thick ascending limb of Henle's loop. Here, it is transported out of the tubule into the medullary interstitium. Ammonium then dissociates to ammonia, leading to a high interstitial ammonia concentration. Ammonia diffuses down its concentration gradient into the lumen of the collecting tubule. Here, it reacts with the hydrogen ions secreted by the collecting tubular cells to form ammonium. Because ammonium (NH_4) is not lipid-soluble, it is trapped in the lumen and excreted in the urine as ammonium chloride. Two conditions predominantly promote ammonia synthesis by the proximal tubular cell: systemic acidosis and hypokalaemia.

Whether glutamine metabolism and ureagenesis in the liver play a role in acid–base homeostasis is controversial. Ureagenesis in the liver consumes up to 1000 mmol of bicarbonate/day in humans as a result of $2NH_4 + 2HCO_3$ = urea + $CO_2 + H_2O$. The liver was believed to contribute to regulation of acid–base balance by controlling the rate of ureagenesis and therefore bicarbonate consumption in response to changes in plasma acidity. Studies in human volunteers have shown that metabolic acidosis increases ureagenesis and potentially makes it worse by consuming more bicarbonate. Similarly, metabolic alkalosis decreases ureagenesis whereby less bicarbonate is consumed, resulting in an increase of alkali load in the face of alkalosis. It is therefore concluded that ureagenesis is a maladaptive process for acid–base regulation and that ureagenesis has no discernible homeostatic effect on acid–base equilibrium in humans.

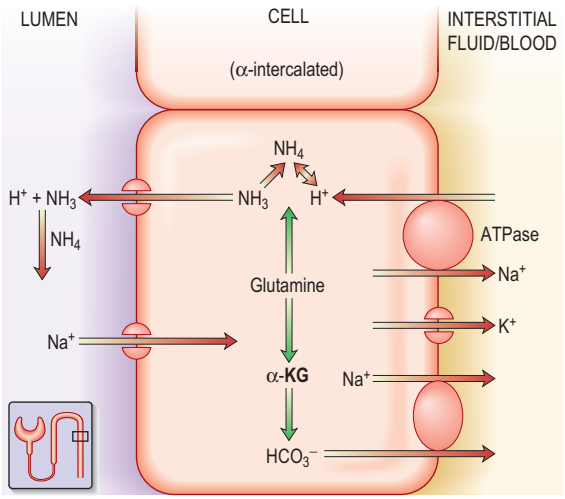

Fig. 12.13 **The ammonia buffering system in the kidney.** All ammonia used to buffer H^+ in the collecting duct is synthesized in the proximal convoluted tubule, and glutamine is the main source of this ammonia. As glutamine is metabolized, α-ketoglutarate (α-KG) is formed, which ultimately breaks down to bicarbonate that is then secreted into the peritubular fluid at an Na^+–HCO_3^- cotransporter.

Causes of acid–base disturbance

Acid–base disturbance may be caused by:

- abnormal CO_2 removal in the lungs ('respiratory' acidosis and alkalosis)
- abnormalities in the regulation of bicarbonate and other buffers in the blood ('metabolic' acidosis and alkalosis).

Both may, and usually do, coexist. For instance, metabolic acidosis causes hyperventilation (via medullary chemoreceptors, see p. 815), leading to increased removal of CO_2 in the lungs and partial compensation for the acidosis. Conversely, respiratory acidosis is accompanied by renal bicarbonate retention, which could be mistaken for primary metabolic alkalosis. The situation is even more complex if a patient has both respiratory disease and a metabolic disturbance.

Diagnosis

Clinical history and examination usually point to the correct diagnosis. Table 12.20 shows the typical blood changes, but in complicated patients the acid–base nomogram (Fig. 12.14) is invaluable. The [H^+] and P_aCO_2 are measured in arterial

Table 12.20 Changes in arterial blood gases

	pH	P_aCO_2	HCO_3^-
Respiratory acidosis	N or ↓	↑↑	↑ (compensated)
Respiratory alkalosis	N or ↑	↓↓	↓ (slight)
Metabolic acidosis	N or ↓	↓	↓↓
Metabolic alkalosis	N or ↑	↑ (slight)	↑↑

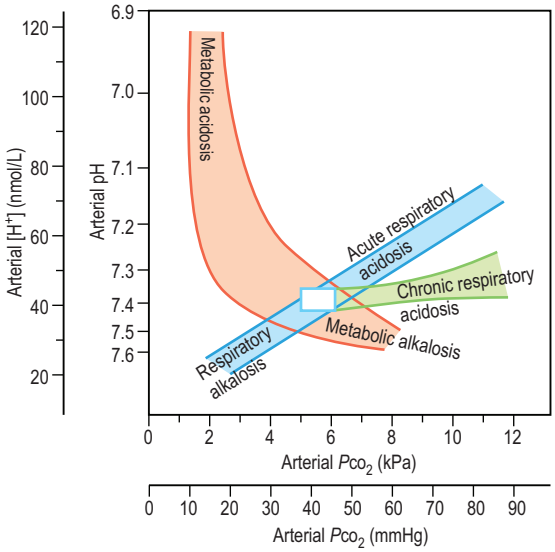

Fig. 12.14 **The Flenley acid–base nomogram.** This was derived from a large number of observations in patients with 'pure' respiratory or metabolic disturbances. The bands show the 95% confidence limits representing the individual varieties of acid–base disturbance. The central white box shows the approximate limits of arterial pH and P_{CO_2} in normal individuals.

blood (for precautions see p. 672) as well as the bicarbonate. If the values from a patient lie in one of the bands in the diagram, it is likely that only one abnormality is present. If the $[H^+]$ is high (pH low) but the P_aCO_2 is normal, the intercept lies between two bands: the patient has respiratory dysfunction, leading to failure of CO_2 elimination, but this is partly compensated for by metabolic acidosis, stimulating respiration and CO_2 removal (this is the most common 'combined' abnormality in practice).

RESPIRATORY ACIDOSIS AND ALKALOSIS

Respiratory acidosis

This is caused by retention of CO_2. The P_aCO_2 and $[H^+]$ rise. Renal retention of bicarbonate may partly compensate, returning the $[H^+]$ towards normal (see p. 893).

Respiratory alkalosis

Increased removal of CO_2 is caused by hyperventilation, so there is a fall in P_aCO_2 and $[H^+]$ (see p. 893).

METABOLIC ACIDOSIS

This is due to the accumulation of any acid other than carbonic acid, and there is a primary decrease in the plasma $[HCO_3^-]$. Several disorders can lead to metabolic acidosis: acid administration, acid generation (e.g. lactic acidosis during shock or cardiac arrest), impaired acid excretion by the kidneys, or bicarbonate losses from the gastrointestinal tract or kidneys. From a diagnostic viewpoint, calculation of the plasma anion gap is extremely useful in narrowing this differential diagnosis.

The anion gap

The first step is to identify whether the acidosis is due to retention of H^+Cl^- or to another acid. This is achieved by calculation of the anion gap. The principles underlying this calculation are straightforward:

- The normal cations present in plasma are Na^+, K^+, Ca^{2+}, Mg^{2+}.
- The normal anions present in plasma are Cl^-, HCO_3^-, negative charges present on albumin, phosphate, sulphate, lactate, and other organic acids.
- The sums of the positive and negative charges are equal.
- Measurement of plasma $[Na^+]$, $[K^+]$, $[Cl^-]$ and $[HCO_3^-]$ is usually easily available.

$$\text{ANION GAP} = \{[Na^+] + [K^+]\} - \{[HCO_3^-] + [Cl^-]\}$$

Because there are more unmeasured anions than cations, the normal anion gap is 10–18 mmol/L, although calculations with more sensitive methods place this at 6–12 mmol/L. Albumin normally makes up the largest portion of these unmeasured anions. As a result, a fall in the plasma albumin concentration from the normal value of about 40 g/L to 20 g/L may reduce the anion gap by as much as 6 mmol/L, because each 1 g/L of albumin has a negative charge of 0.2–0.28 mmol/L.

Metabolic acidosis with a normal anion gap

If the anion gap is normal in the presence of acidosis, this suggests that H^+Cl^- is being retained or that $Na^+HCO_3^-$ is being lost. Causes of a normal-anion-gap acidosis are given in Table 12.21. In these conditions, plasma bicarbonate decreases and is replaced by chloride to maintain electroneutrality. Consequently, these disorders are sometimes referred to collectively as hyperchloraemic acidoses.

Table 12.21 Causes of metabolic acidosis with a normal anion gap

Increased gastrointestinal bicarbonate loss
Diarrhoea
Ileostomy
Ureterosigmoidostomy

Increased renal bicarbonate loss
Acetazolamide therapy
Proximal (type 2) renal tubular acidosis
Hyperparathyroidism
Tubular damage, e.g. drugs, heavy metals, paraproteins

Decreased renal hydrogen ion excretion
Distal (type 1) renal tubular acidosis
Type 4 renal tubular acidosis (aldosterone deficiency)

Increased HCl production
Ammonium chloride ingestion
Increased catabolism of lysine, arginine

Renal tubular acidosis (RTA)

This term refers to systemic acidosis caused by impairment of the ability of the renal tubules to maintain acid–base balance. This group of disorders is uncommon and only rarely a cause of significant clinical disease.

Type 4 renal tubular acidosis

Also called 'hyporeninaemic hypoaldosteronism', this is probably the most common of these disorders. The cardinal features are hyperkalaemia and acidosis occurring in a patient with mild chronic renal insufficiency, usually caused by tubulo-interstitial disease (e.g. reflux nephropathy) or diabetes (Gordon's syndrome (see p. 667) shares biochemical abnormalities but differs in having normal GFR and hypertension). Plasma renin and aldosterone are found to be low, even after measures which would normally stimulate their secretion. The features for the diagnosis are shown in Table 12.22. An identical syndrome is caused by chronic ingestion of NSAIDs, which impair renin and aldosterone secretion. In the presence of acidosis, urine pH may be low. Treatment is with fludrocortisone, sodium bicarbonate, diuretics, or ion exchange resins to remove potassium, or a combination of these. Dietary potassium restriction alone is ineffective.

Type 3 renal tubular acidosis (RTA)

This condition is vanishingly rare, and represents a combination of type 1 and type 2. Inherited type 3 RTA is caused by mutations resulting in carbonic anhydrase type II deficiency, which is characterized by osteopetrosis, RTA of mixed type, cerebral calcification, and mental retardation. Typical radiographic features of osteopetrosis are present and histopathological study of the iliac crest reveals unreabsorbed calcified primary spongia.

Type 2 ('proximal') renal tubular acidosis

This is very rare in adult practice. It is caused by failure of sodium bicarbonate reabsorption in the proximal tubule. The cardinal features are acidosis, hypokalaemia, an inability to lower the urine pH below 5.5 despite systemic acidosis, and the appearance of bicarbonate in the urine despite a subnormal plasma bicarbonate. This disorder normally occurs as part of a generalized tubular defect, together with other features such as glycosuria and amino-aciduria. Inherited forms of isolated type 2 RTA are described as both autosomal dominant and recessive patterns of inheritance, where putative mutations are in the Na^+–H^+ antiporter in the apical membrane and Na^+–HCO_3^- cotransporter in the basolateral membrane of proximal tubular cells respectively (see Fig. 12.11). Treatment is with sodium bicarbonate: massive doses may be required to overcome the renal 'leak'.

Type 1 ('distal') renal tubular acidosis

This is due to a failure of H^+ excretion in the distal tubule (Table 12.23). It consists of:

- acidosis
- hypokalaemia (few exceptions)
- inability to lower the urine pH below 5.3 despite systemic acidosis
- low urinary ammonium production.

These features may be present only in the face of increased acid production; hence the need for an acid load test in diagnosis (Practical box 12.1). Other features include:

- low urinary citrate (owing to increased citrate absorption in the proximal tubule where it can be converted to bicarbonate)
- hypercalciuria.

These abnormalities result in osteomalacia, renal stone formation and recurrent urinary infections. *Osteomalacia* is

*May also cause proximal renal tubular acidosis

Practical Box 12.1 Diagnosis of renal tubular acidosis

Plasma HCO_3^- < 21 mmol/L, urine pH > 5.3 = renal tubular acidosis
To differentiate between proximal (very rare) and distal (rare) requires bicarbonate infusion test
Plasma HCO_3^- > 21 mmol/L but suspicion of partial renal tubular acidosis (e.g. nephrocalcinosis-associated diseases): **acid load test** required as follows:

- Give 100 mg/kg ammonium chloride by mouth
- Check urine pH hourly and plasma HCO_3^- at 3 hours
- Plasma HCO_3^- should drop below 21 mmol/L unless the patient vomits (in which case the test should be repeated with an antiemetic)
- If urine pH remains > 5.3 despite a plasma HCO_3^- of 21 mmol/L, the diagnosis is confirmed

caused by buffering of H^+ by Ca_2^+ in bone, resulting in depletion of calcium from bone. *Renal stone formation* is caused by hypercalciuria, hypocitraturia (citrate inhibits calcium phosphate precipitation), and alkaline urine (which favours precipitation of calcium phosphate). *Recurrent urinary infections* are caused by renal stones.

Both autosomal dominant and recessive inheritance patterns have been reported in primary distal RTA. Patients in South East Asia with an autosomal dominant type have a milder phenotype and may have an associated ovalocytosis. In this form the Cl^-–HCO_3^- exchanger in the basolateral surface of intercalated cells is mutated. However, in the autosomal recessive distal RTA, a substantial proportion of patients have sensorineural deafness, and this is associated with a loss of function mutation in the H^+-ATPase at the apical surface of intercalated cells.

Treatment is with sodium bicarbonate, potassium supplements and citrate. Thiazide diuretics are useful by causing volume contraction and increased proximal sodium bicarbonate reabsorption.

Urinary anion gap

Another useful tool in the evaluation of metabolic acidosis with a normal anion gap is the urinary anion gap:

$$\text{URINARY ANION GAP} = \{\text{urinary } [Na^+] + \text{urinary } [K^+]\} - \text{urinary } [Cl^-].$$

This calculation can be used to distinguish the normal-anion-gap acidosis caused by diarrhoea (or other gastrointestinal alkali loss) from that caused by distal renal tubular acidosis. In both disorders, the plasma $[K^+]$ is characteristically low. In patients with renal tubular acidosis, urinary pH is always greater than 5.3.

Although excretion of urinary hydrogen ions in the patient with diarrhoea should acidify the urine, hypokalaemia leads to enhanced ammonia synthesis by the proximal tubular cells. Despite acidaemia, the excess urinary buffer increases the urine pH to a value above 5.3 in some patients with diarrhoea.

Whenever urinary acid is excreted as ammonium chloride, the increase in urinary chloride excretion decreases the urinary anion gap. Thus, the urinary anion gap should be negative in the patient with diarrhoea, regardless of the urine pH. On the other hand, although hypokalaemia may result in enhanced proximal tubular ammonia synthesis in distal renal tubular acidosis, the inability to secrete hydrogen ions into the collecting duct in this condition limits ammonium chloride formation and excretion; thus, the urinary anion gap is positive in distal renal tubular acidosis.

Metabolic acidosis with a high anion gap

If the anion gap is increased, there is an unmeasured anion present in increased quantities. This is either one of the acids normally present in small, but unmeasured quantities, such as lactate, or an exogenous acid. Causes of a high-anion-gap acidosis are given in Table 12.24.

Lactic acidosis

Increased lactic acid production occurs when cellular respiration is abnormal, because of either a lack of oxygen in the tissues ('type A') or a metabolic abnormality, such as drug-induced ('type B') (Table 12.24). The most common cause in clinical practice is type A lactic acidosis, occurring in septic or cardiogenic shock. Significant acidosis can occur despite a normal blood pressure and P_aCO_2, owing to splanchnic and peripheral vasoconstriction. Acidosis worsens cardiac function and vasoconstriction further, contributing to a downward spiral and fulminant production of lactic acid.

Table 12.24 Causes of metabolic acidosis with an increased anion gap

Renal failure (sulphate, phosphate)

Accumulation of organic acids

Lactic acidosis
L-lactic
- Type A – anaerobic metabolism in tissues
  - Hypotension/cardiac arrest
  - Sepsis
- Poisoning – e.g. ethylene glycol, methanol
- Type B – decreased hepatic lactate metabolism
  - Insulin deficiency (decreased pyruvate dehydrogenase activity)
  - Metformin accumulation (chronic kidney disease)
  - Haematological malignancies
  - Rare inherited enzyme defects

D-lactic (fermentation of glucose in bowel by abnormal bowel flora, complicating abnormal small bowel anatomy, e.g. blind loops)

Ketoacidosis
Insulin deficiency
Alcohol excess
Starvation

Exogenous acids
Salicylate

Diabetic ketoacidosis (see p. 1046)

There is a high-anion-gap acidosis due to the accumulation of acetoacetic and hydroxybutyric acids, owing to increased production and some reduced peripheral utilization.

Uraemic acidosis

Kidney disease causes acidosis in several ways. Reduction in the number of functioning nephrons decreases the capacity to excrete ammonia and H^+ in the urine. In addition, tubular disease may cause bicarbonate wasting. Acidosis is a particular feature of those types of chronic renal failure in which the tubules are particularly affected, such as reflux nephropathy and chronic obstructive uropathy.

Chronic acidosis is most often caused by chronic kidney disease, where there is a failure to excrete fixed acid. Up to 40 mmol of hydrogen ions may accumulate daily. These are buffered by bone, in exchange for calcium. Chronic acidosis is therefore a major risk factor for renal osteodystrophy and hypercalciuria.

Chronic acidosis has also been shown to be a risk factor for muscle wasting in renal failure, and may also contribute to the inexorable progression of some types of renal disease.

Uraemic acidosis should be corrected because of these effects on growth, muscle turnover and bones. Oral sodium bicarbonate 2–3 mmol/kg daily is usually enough to maintain serum bicarbonate above 20 mmol/L, but may contribute to sodium overload. Calcium carbonate improves acidosis and also acts as a phosphate binder and calcium supplement, and is commonly used. Acidosis in end-stage renal failure is usually fully corrected by adequate dialysis.

Mixed metabolic acidosis

Both types of acidosis may coexist. For instance, cholera would be expected to cause a normal-anion-gap acidosis owing to massive gastrointestinal losses of bicarbonate, but the anion gap is often increased owing to renal failure and lactic acidosis as a result of hypovolaemia.

Clinical features

Clinically the most obvious effect is stimulation of respiration, leading to the clinical sign of 'air hunger', or Kussmaul respiration. Interestingly, patients with profound hyperventilation may not complain of breathlessness, although in others it may be a presenting complaint.

Acidosis increases delivery of oxygen to the tissues by shifting the oxyhaemoglobin dissociation curve to the right, but it also leads to inhibition of 2,3-BPG production, which returns the curve towards normal (see p. 892). Cardiovascular dysfunction is common in acidotic patients, although it is often difficult to dissociate the numerous possible causes of this. Acidosis is negatively inotropic. Severe acidosis also causes venoconstriction, resulting in redistribution of blood from the peripheries to the central circulation, and increased systemic venous pressure, which may worsen pulmonary oedema caused by myocardial depression. Arteriolar vasodilatation also occurs, further contributing to hypotension.

Cerebral dysfunction is variable. Severe acidosis is often associated with confusion and fits, but numerous other possible causes are usually present.

As mentioned earlier, acidosis stimulates potassium loss from cells, which may lead to potassium deficiency if renal function is normal, or to hyperkalaemia if renal potassium excretion is impaired.

General treatment of acidosis

Treatment should be aimed at correcting the primary cause. In lactic acidosis caused by poor tissue perfusion ('type A'), treatment should be aimed at maximizing oxygen delivery to the tissues by protecting the airway, improving breathing and circulation. This usually requires inotropic agents, mechanical ventilation and invasive monitoring. In 'type B' lactic acidosis, treatment is that of the underlying disorder; e.g.:

- insulin in diabetic ketoacidosis
- treatment of methanol and ethylene glycol poisoning with ethanol
- removal of salicylate by dialysis.

The question of whether severe acidosis should be treated with bicarbonate is extremely controversial. Severe acidosis ($[H^+] > 100$ nmol/L, pH < 7.0) is associated with a very high mortality, which makes many doctors keen to correct it. Since acidosis is known to impair cardiac contractility, it would seem sensible to correct acidosis with bicarbonate in a sick patient. However:

- Rapid correction of acidosis may result in tetany and fits owing to a rapid decrease in ionized calcium.
- Administration of sodium bicarbonate (8.4%) provides 1 mmol/mL of sodium, which may lead to extracellular volume expansion, exacerbating pulmonary oedema.
- Bicarbonate therapy increases CO_2 production and will therefore correct acidosis only if ventilation can be increased to remove the added CO_2 load.
- The increased amounts of CO_2 generated may diffuse more readily into cells than bicarbonate, worsening intracellular acidosis.

Administration of sodium bicarbonate (50 mmol, as 50 mL of 8.4% sodium bicarbonate intravenously) is still occasionally given during cardiac arrest and is often necessary before arrhythmias can be corrected. Correction of hyperkalaemia associated with acidosis is also of undoubted benefit. In other situations there is no clinical evidence to show that correction of acidosis improves outcome, but it is standard practice to administer sodium bicarbonate when $[H^+]$ is above 126 nmol/L (pH < 6.9), using intravenous 1.26% (150 mmol/L) bicarbonate infused over 2–3 hours with electrolyte and pH monitoring. Intravenous sodium lactate should never be given.

METABOLIC ALKALOSIS

Metabolic alkalosis is common, comprising half of all the acid–base disorders in hospitalized patients. This observation should not be surprising since vomiting, the use of diuretics, and nasogastric suction are common among hospitalized patients. The mortality associated with metabolic alkalosis is substantial; the mortality rate is 45% in patients with an arterial pH of 7.55 and 80% when the pH is greater than 7.65. Although this relationship is not necessarily causal, severe alkalosis should be viewed with concern.

Classification and definitions

Metabolic alkalosis has been classified on the basis of underlying pathophysiology (Table 12.25).

The most common group is due to chloride depletion which can be corrected without potassium repletion. The other major grouping is that due to potassium depletion,

Table 12.25 Causes of metabolic alkalosis

Chloride depletion
Gastric losses: vomiting, mechanical drainage, bulimia
Chloruretic diuretics: e.g. bumetanide, furosemide, chlorothiazide, metolazone
Diarrhoeal states: villous adenoma, congenital chloridorrhoea
Cystic fibrosis (high sweat chloride)

Potassium depletion/mineralocorticoid excess
Primary aldosteronism
Secondary aldosteronism
Apparent mineralocorticoid excess
Primary deoxycorticosterone excess: 11α- and 17α-hydroxylase deficiencies
Drugs: liquorice (glycyrrhizic acid) as a confection or flavouring, carbenoxolone
Liddle's syndrome
Bartter's and Gitelman's syndromes and their variants
Laxative abuse, clay ingestion

Hypercalcaemic states
Hypercalcaemia of malignancy
Acute or chronic milk–alkali syndrome

Others
Ampicillin, penicillin therapy
Bicarbonate ingestion: massive or with renal insufficiency
Recovery from starvation
Hypoalbuminaemia

usually with mineralocorticoid excess. Metabolic alkalosis due to both potassium and chloride depletion also occurs.

Chloride may be lost from the gut, kidney or skin. The loss of gastric fluid rich in acid results in alkalosis because bicarbonate generated during the production of gastric acid returns to the circulation. In Zollinger–Ellison syndrome (see p. 385) or gastric outflow obstruction these losses can be massive. Although sodium and potassium loss in the gastric juice is variable, the obligate urinary loss of these cations is intensified by bicarbonaturia, which occurs during disequilibrium.

Chloruretic agents all directly produce loss of chloride, sodium and fluid in the urine. These losses in turn promote metabolic alkalosis by several mechanisms:

- diuretic-induced increases in sodium delivery to the distal nephron enhance potassium and hydrogen ion secretion
- extracellular volume contraction stimulates renin and aldosterone secretion, which blunts sodium losses but accelerates potassium and hydrogen ion secretion
- potassium depletion augments bicarbonate reabsorption in the proximal tubule and
- stimulates ammonia production which in turn will increase urinary net acid excretion.

Urinary losses of chloride exceed those for sodium and are associated with alkalosis even when potassium depletion is prevented. The cessation of events that generate alkalosis is not necessarily accompanied by resolution of the alkalosis. A widely accepted hypothesis for the maintenance of alkalosis is chloride depletion rather than volume depletion. Although normal functioning of the proximal tubule is essential for bicarbonate absorption, the collecting duct appears to be the major nephron site for altered electrolyte and proton transport in both maintenance and recovery from metabolic alkalosis. During maintenance, the α-intercalated cells in the cortical collecting duct do not secrete bicarbonate because insufficient chloride is available for bicarbonate exchange. When chloride is administered and luminal or cellular chloride concentration increases, bicarbonate is promptly excreted and alkalosis is corrected.

Metabolic alkalosis in *hypokalaemia* is generated primarily by an increased intracellular shift of hydrogen ion causing intracellular acidosis. Potassium depletion is also associated with enhanced ammonia production with increased obligate net acid excretion. However, the role of intracellular acidosis is supported by the correction of the alkalosis by infusion of potassium without any suppression of renal net excretion. The correction is assumed to occur by the movement of potassium into and hydrogen ion out of the cell, which titrates extracellular fluid bicarbonate.

Milk–alkali syndrome in which both bicarbonate and calcium are ingested produces alkalosis by vomiting, calcium-induced bicarbonate absorption and reduced GFR. Cationic antibiotics in high doses can cause alkalosis by obligatory bicarbonate loss in the urine.

Clinical features

The symptoms of metabolic alkalosis per se are difficult to separate from those of chloride, volume or potassium depletion. Tetany (see p. 1022), apathy, confusion, drowsiness, cardiac arrhythmias and neuromuscular irritability are common when alkalosis is severe. The oxyhaemoglobin dissociation curve is shifted to the left. Respiration may be depressed.

Treatment

Chloride-responsive metabolic alkalosis

Although replacement of the chloride deficit is essential in chloride depletion states, selection of the accompanying cation – sodium, potassium or proton – is dependent on the assessment of extracellular fluid volume status (see p. 659), the presence or absence of associated potassium depletion, and the degree and reversibility of any depression of GFR. If kidney function is normal, bicarbonate and base equivalents will be excreted with sodium or potassium, and metabolic alkalosis will be rapidly corrected as chloride is made available.

If chloride and extracellular depletion coexist then isotonic saline solution is appropriate therapy.

In the clinical settings of fluid overload, saline is contraindicated. In such situations, intravenous use of hydrochloride acid or ammonium chloride can be given. If GFR is adequate, acetazolamide, which causes bicarbonate diuresis by inhibiting carbonic anhydrase, can also be used. When the kidney is incapable of responding to chloride repletion, dialysis is necessary.

Chloride-resistant metabolic alkalosis

Metabolic alkalosis due to potassium depletion is managed by the correction of the underlying cause (see hypokalaemia). Mild to moderate alkalosis requires oral potassium chloride administration. However, the presence of cardiac arrhythmia or generalized weakness requires intravenous potassium chloride.

QUESTIONS AND CASE STUDIES

Case 12.1

A 44-year-old patient with known chronic liver disease secondary to hepatitis B presented with marked exertional dyspnoea. Examination revealed: blood pressure 130/80, elevated JVP at 8 cm, bilateral pleural effusions, ascites and marked pitting pedal oedema. Investigations revealed: plasma sodium 136 mmol/L, potassium 3.6 mmol/L, bicarbonate 32 mmol/L, chloride 96 mmol/L, urinary sodium <10 mmol/day, urinary potassium 60 mmol/day.

Question

(a) Explain the persistent retention of sodium in the face of salt and water overload?

Answer

(a) In cirrhosis, arterial vasodilatation due to nitric oxide overactivity leads to arterial underfilling. This is perceived by the pressure and volume receptors as hypovolaemia, with consequent activation of the sympathetic system, non-osmotic release of ADH and activation of the renin–angiotensin–aldosterone system. These mediators lead to salt and water reduction (see Fig. 12.3a).

Case 12.2

A 32-year-old patient was referred for investigation of refractory hypertension. His blood pressure was elevated at 210/110 with grade 3 hypertensive retinopathy despite taking beta-blockers, a calcium antagonist and an ACE inhibitor. The rest of the examination was normal. Investigations revealed: sodium 148 mmol/L, potassium 3 mmol/L, bicarbonate 32 mmol/L, urea 4 mmol/L, glucose 4 mmol/L, urine dipstick negative for proteins.

Questions

(a) What is the likely diagnosis?
(b) What is the cause of absence of oedema in this patient?

Answers

(a) Conn's syndrome (see p. 1023).
(b) This is due to the escape from the action of aldosterone. The escape is dependent on an increase in delivery of sodium to the site of aldosterone in the collecting duct. The increase in sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in renal perfusion pressure and GFR. The net result of these events is reduced sodium absorption in the proximal tubules and increased sodium delivery, which overwhelms the sodium-retaining actions of aldosterone (see Fig. 12.3b).

Case 12.3

A 62-year-old woman is found lying on the floor of her house. On examination she is bradycardic and peripherally shut down. ECG confirms sinus bradycardia with changes consistent with inferior myocardial infarction. Emergency electrolyte measurements revealed: sodium 136 mmol/L, potassium 4 mmol/L, bicarbonate 10 mmol/L, chloride 102 mmol/L, urea 7.5 mmol/L.

Question

(a) Comment on the biochemistry and how you will confirm your diagnosis?

Answer

(a) The biochemical picture is one of high-anionic-gap metabolic acidosis. In the presence of myocardial infarction and hypotension, the likely cause would be lactic acidosis. Measurement of plasma lactate (normally <2 mmol/L) would confirm the diagnosis. Correction of the underlying cause will correct the acidosis by itself.

Case 12.4

The plasma biochemistry of a patient who presented with severe loin pain is as follows: sodium 138 mmol/L, potassium 2.5 mmol/L, urea 3.8 mmol/L, chloride 114 mmol/L, bicarbonate 14.5 mmol/L, urinary pH 6.5.

Questions

(a) What is the cause of this metabolic abnormality?
(b) What is the cause of the loin pain?

Answers

(a) Distal renal tubular acidosis (see the section on 'Renal tubular acidosis').
(b) Nephrocalcinosis and renal colic due to renal stones are characteristic features of renal tubular acidosis.

Case 12.5

An 18-year-old boy was referred for the investigation of chronic fatigue syndrome. His mother comments that he is easily tired by sport and is not doing well at school. He is normotensive. Investigations revealed: sodium 145 mmol/L, potassium 2.8 mmol/L, bicarbonate 35 mmol/L, chloride 80 mmol/L, magnesium 0.6 mmol/L (normal range > 0.8 mmol/L), urea 5 mmol/L, glucose 5.2 mmol/L, urinary sodium excretion of 60 mmol and potassium excretion of 60 mmol/day.

Question

(a) What is the likely diagnosis?

Answer

(a) This patient has classic Gitelman's syndrome. It is similar to Bartter's but hypomagnesaemia favours Gitelman's syndrome.

Case 12.6

A 36-year-old woman with a past medical history of peptic ulceration presented with a history of 3 days of vomiting. She looked unwell and investigations revealed: haemoglobin 16.3 mmol/L, sodium 138 mmol/L, potassium 2.8 mmol/L, urea 14.3 mmol/L, pH 7.52, bicarbonate 36 mmol/L, chloride 75 mmol/L.

Questions

(a) What is the likely metabolic abnormality?
(b) What is the likely diagnosis?
(c) What is the pH of the patient's urine?

Answers

(a) This patient suffers from hypochloraemic metabolic alkalosis.
(b) The underlying cause is gastric outflow obstruction.
(c) The patient's urine is paradoxically acid, despite alkalosis.

Case 12.7

A 72-year-old man was admitted with a 3-week history of feeling unwell, poor appetite and diarrhoea. On examination, he was clearly dehydrated and had acidotic breathing. His blood pressure was 90/70; the postural drop to 60/30. He was frail. The rest of the general and system examination was unremarkable. The initial biochemistry revealed: sodium 121 mmol/L, potassium 1.9 mmol/L, chloride 83 mmol/L, bicarbonate 4 mmol/L, urea 90 mmol/L, creatinine 960 µmol/L, pH 7.1, P_aO_2 15.7 kPa, P_aCO_2 2.2 kPa, serum osmolality 334 mOsm/kg, urine osmolality 404 mOsm/kg, urinary sodium 2 mmol/L and potassium 28 mmol/L. He continued to pass between 50 and 80 mL of urine per hour.

Questions

(a) How would you describe the metabolic abnormality?
(b) What was the likely cause?
(c) Why did this patient remain polyuric in the face of severe dehydration?

Answers

(a) This patient suffers from volume depletion syndrome characterized by dehydration, hypokalaemia, and hypochloraemic metabolic acidosis with high ionic gap. He has severe acute prerenal failure with normal urine output and dilute urine.
(b) The only single diagnosis which can explain this abnormality is a colorectal secretory villous adenoma.
(c) His polyuria in the face of severe dehydration is due to nephrogenic diabetes insipidus secondary to chronic hypokalaemia. Hypokalaemia downregulates aquaporin II, which is essential for ADH-dependent water absorption from the collecting duct.

ESSENTIAL ANATOMY, PHYSIOLOGY AND EMBRYOLOGY OF THE HEART

Introduction

Myocardial cells constitute 75% of the heart mass but only about 25% of the cell number. They are designed to perform two fundamental functions: initiation and conduction of electrical impulses and contraction. Although most myocardial cells are able to perform both these functions, the vast majority are predominantly contractile cells (myocytes) and a small number are specifically designed as electrical cells. The latter, collectively known as the conducting system of the heart, are not nervous tissue but modified myocytes lacking in myofibril components. They have the ability to generate electrical impulses which are then conducted to the myocytes, leading to contraction by a process known as excitation–contraction coupling. The rate of electrical impulse generation and the force of myocardial contraction are modified by numerous factors including autonomic input and stretch.

Three epicardial coronary arteries supply blood to the myocardium, and a more complex network of veins is responsible for drainage. In the face of continuous arterial pressure fluctuations, blood vessels, especially in the cerebral circulation, maintain constant tissue perfusion by a process known as '*autoregulation*'; blood vessel control is, however, complex involving additional local and central mechanisms.

The conduction system of the heart

The sinus node

The sinus node is a complex spindle-shaped structure that lies in the lateral and epicardial aspects of the junction between the superior vena cava and the right atrium (Fig. 13.1). Physiologically, it generates impulses automatically by spontaneous depolarization of its membrane at a rate quicker than any other cardiac cell type. It is therefore the natural pacemaker of the heart.

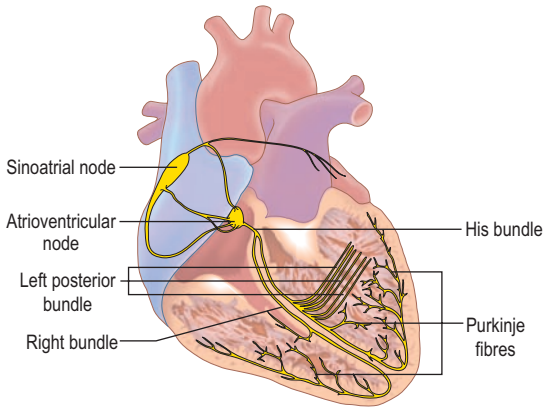

Fig. 13.1 **The conducting system of the heart.**

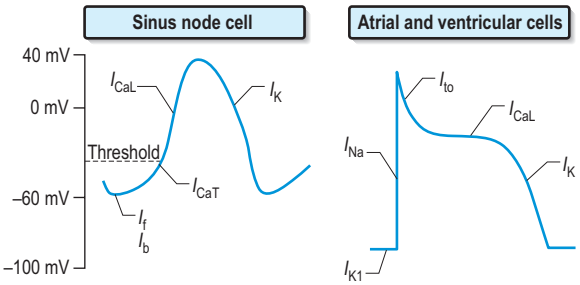

Fig. 13.2 **Myocardial action potentials.** I_b, background inward sodium current; I_f, 'funny' current; I_{CaT}, transient (or 'T' type) and I_{CaL}, long-lasting (or 'L' type) calcium channels; I_{Na}, inward sodium current; I_{to}, transient outward potassium current; I_{K1}, inwards rectifier current; I_K delayed rectifier potassium current.

A number of factors are responsible for the spontaneous decay of the sinus node cell membrane potential ('the pacemaker potential'), the most significant of which is a small influx of sodium ions into the cells. This small sodium current has two components: the background inward current (I_b) and the 'funny' (I_f) current (or pacemaker current) (Fig. 13.2). The term 'funny' current denotes ionic flow through channels activated in *hyperpolarized* cells (–60 mV or greater), unlike other time- and voltage-dependent channels activated by *depolarization*. The rate of depolarization of the sinus node membrane potential is modulated by autonomic tone (i.e. sympathetic and parasympathetic input), stretch, temperature, hypoxia, blood pH and in response to other hormonal influences (e.g. tri-iodothyronine and serotonin).

Atrial and ventricular myocyte action potentials

Action potentials in the sinus node trigger depolarization of the atrial and subsequently the ventricular myocytes. These cells have a different action potential from that of sinus node cells (see Fig. 13.2). Their resting membrane potential is a consequence of a small flow of potassium ions into the cells through open 'inward rectifier' channels; at this stage sodium and calcium channels are closed. The arrival of adjacent action potentials triggers the opening of voltage-gated, fast, self-inactivating sodium channels, resulting in a sharp depolarization spike. This is followed by a partial repolarization of the membrane due to activation of 'transient outward' potassium channels.

The plateau phase which follows is unique to myocytes and results from a small, but sustained inward calcium current through L-type calcium channels lasting 200–400 ms. This calcium influx is caused by a combined increase in permeability of the cell, especially the sarcolemmal membranes to calcium (Fig. 13.3). This plateau (or refractory) phase in myocyte action potential prevents early reactivation of the myocytes and directly determines the strength of contraction. The gradual inactivation of the calcium channels activates delayed rectifier potassium channels repolarizing the membrane. Atrial tissue is activated like a 'forest fire', but the activation peters out when the insulating layer between the atrium and the ventricle – the annulus fibrosus – is reached. Controversy still exists about whether impulses from the sinoatrial (SA) node travel over specialized conducting 'pathways' or over ordinary atrial myocardium.

The atrioventricular node, His bundle and Purkinje fibres

The depolarization continues to conduct slowly through the atrioventricular (AV) node. This is a small, bean-shaped structure that lies beneath the right atrial endocardium within the lower interatrial septum. The AV node continues as the His bundle, which penetrates the annulus fibrosus and conducts the cardiac impulse rapidly towards the ventricle. The His bundle reaches the crest of the interventricular septum and divides into the right bundle branch and the main left bundle branch.

The *right bundle branch* continues down the right side of the interventricular septum to the apex, from where it radiates and divides to form the Purkinje network, which spreads throughout the subendocardial surface of the right ventricle. The *main left bundle branch* is a short structure, which fans out into many strands on the left side of the interventricular septum. These strands can be grouped into an anterior superior division (the anterior hemi-bundle) and a posterior inferior division (the posterior hemi-bundle). The anterior hemi-bundle supplies the subendocardial Purkinje network of the anterior and superior surfaces of the left ventricle, and the inferior hemi-bundle supplies the inferior and posterior surfaces. Impulse conduction through the AV node is slow and depends on action potentials largely produced by slow transmembrane calcium flux. In the atria, ventricles and His–Purkinje system, conduction is rapid and is due to action potentials generated by rapid transmembrane sodium diffusion.

The cellular basis of myocardial contraction – excitation–contraction coupling

Each myocyte, approximately 100 μm long, branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction to adjacent cells. Myocytes contain bundles of parallel myofibrils. Each myofibril is made up of a series of sarcomeres (Fig. 13.4). A sarcomere (which is the basic unit of contraction) is bound by two transverse Z lines, to each of which is attached a perpendicular filament of the protein actin. The actin filaments from each of the two Z bands overlap with thicker parallel protein filaments known as myosin. Actin and myosin filaments are attached to each other by cross-bridges that contain ATPase, which breaks down adenosine triphosphate (ATP) to provide the energy for contraction.

Two chains of actin molecules form a helical structure, with another molecule, tropomyosin, in the grooves of the

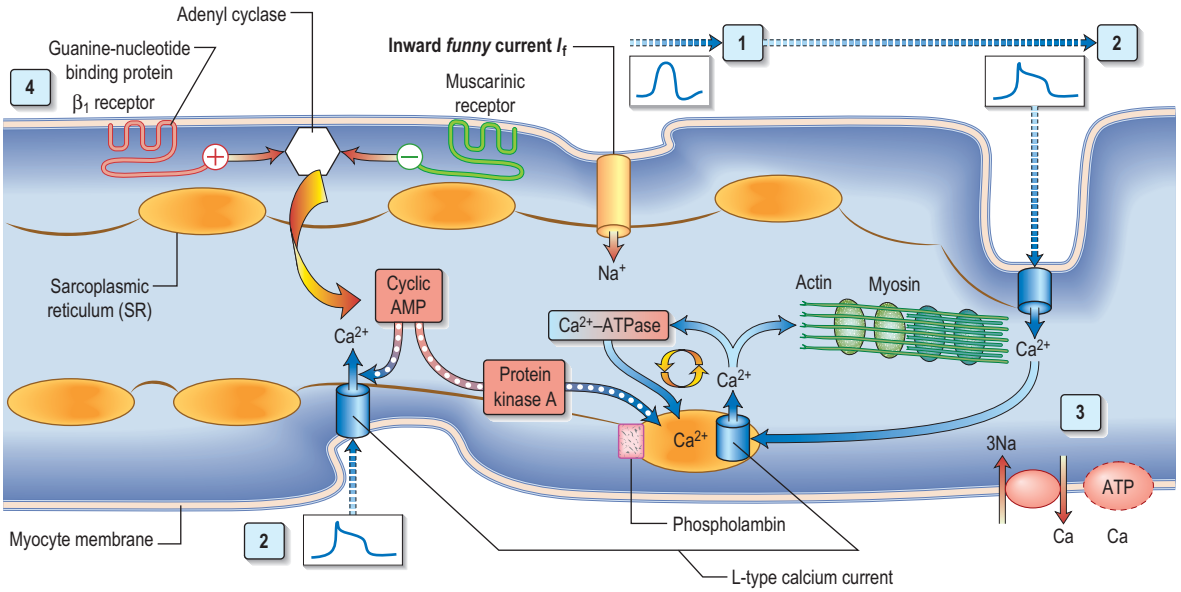

Fig. 13.3 **The 'complete' cardiac cell. 1.** Spontaneous depolarization in sinus node cells due to sodium (Na) influx through the 'funny' current generates the 'pacemaker' potential. **2.** This activates other atrial and ventricular myocytes, triggering action potentials and activating L-type calcium (Ca) channels in the surface and transverse tubule membranes (at top and bottom of figure). **3.** The resulting Ca influx acts on Ca-induced Ca release channels (RyR2) on the sarcoplasmic reticulum (SR), resulting in release of stored Ca, which acts on actin and myosin fibrils, resulting in contraction. Ca reuptake pumps in the SR, regulated by phospholamban, replenish the stores; various exchange pumps also expel Ca from the cell. **4.** Autonomic input has either a positive chronotropic/inotropic effect (β_1 receptors) or a negative chronotropic/inotropic effect (muscarinic receptors).

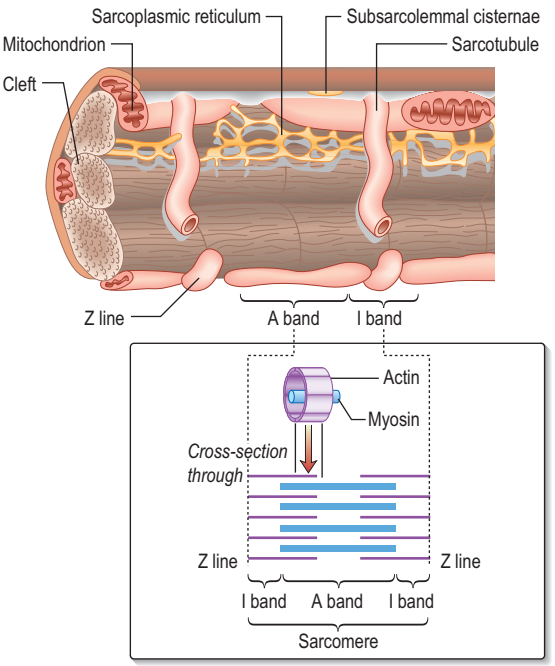

Fig. 13.4 **Schematic diagram showing the structure of a myofibril within a myocyte.** The myofibrils are made up of a series of sarcomeres joined at the Z line.

actin helix, and a further molecule, troponin, is attached to every seven actin molecules. During cardiac contraction the length of the actin and myosin monofilaments does not change. Rather, the actin filaments slide between the myosin filaments when ATPase splits a high-energy bond of ATP. To supply the ATP, the myocyte (which cannot stop for a rest) has a very high mitochondrial density (35% of the cell volume). As calcium ions bind to troponin C, the activity of troponin I is inhibited, which induces a conformational change in tropomyosin. This event unlocks the active site between actin and myosin, enabling contraction to proceed.

Calcium is made available during the plateau phase of the action potential by calcium ions entering the cell and by being mobilized from the sarcoplasmic reticulum through the ryanodine receptor (RyR2) calcium-release channel. RyR2 activity is regulated by the protein calstabin 2 (see p. 791) and nitric oxide. The force of cardiac muscle contraction ('inotropic state') is thus regulated by the influx of calcium ions into the cell through calcium channels (Fig. 13.3). T (transient) calcium channels open when the muscle is more depolarized, whereas L (long-lasting) calcium channels require less depolarization. The extent to which the sarcomere can shorten determines the stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or severe exercise.

Starling's law of the heart

The contractile function of an isolated strip of cardiac tissue can be described by the relationship between the velocity of muscle contraction, the load that may be moved by the contracting muscle, and the extent to which the muscle is stretched before contracting. As with all other types of muscle, the velocity of contraction of myocardial tissue is reduced by increasing the load against which the tissue must contract. However, in the non-failing heart, pre-stretching of cardiac muscle improves the relationship between the force and velocity of contraction (Fig. 13.5).

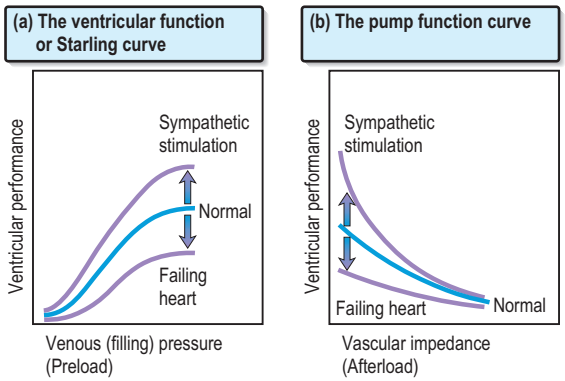

Fig. 13.5 **The Frank–Starling mechanism,** showing the effect on ventricular contraction of alteration in filling pressures and outflow impedance in the normal, failing and sympathetically stimulated ventricle.

This phenomenon was described in the intact heart as an increase of stroke volume (ventricular performance) with an enlargement of the diastolic volume (preload), and is known as 'Starling's law of the heart' or the 'Frank–Starling relationship'. It has been transcribed into more clinically relevant indices. Thus, stroke work (aortic pressure × stroke volume) is increased as ventricular end-diastolic volume is raised. Alternatively, within certain limits, cardiac output rises as pulmonary capillary wedge pressure increases. This clinical relationship is described by the ventricular function curve (Fig. 13.5), which also shows the effect of sympathetic stimulation.

Nerve supply of the myocardium

Adrenergic nerves supply atrial and ventricular muscle fibres as well as the conduction system. β_1-Receptors predominate in the heart with both epinephrine (adrenaline) and norepinephrine (noradrenaline) having positive inotropic and chronotropic effects. Cholinergic nerves from the vagus supply mainly the SA and AV nodes via M_2 muscarinic receptors. The ventricular myocardium is sparsely innervated by the vagus. Under basal conditions, vagal inhibitory effects predominate over the sympathetic excitatory effects, resulting in a slow heart rate.

Adrenergic stimulation and cellular signalling

β_1-Adrenergic stimulation enhances Ca^{2+} flux in the myocyte and thereby strengthens the force of contraction (Fig. 13.3). Binding of catecholamines, e.g. norepinephrine (noradrenaline), to the myocyte β_1-adrenergic receptor stimulates membrane-bound adenylate kinases. These enzymes enhance production of cyclic adenosine monophosphate (cAMP) that activates intracellular protein kinases, which in turn phosphorylate cellular proteins, including L-type calcium channels within the cell membrane. β_1-Adrenergic stimulation of the myocyte also enhances myocyte relaxation.

The return of calcium from the cytosol to the sarcoplasmic reticulum (SR) is regulated by phospholamban (PL), a low-molecular-weight protein in the SR membrane. In its dephosphorylated state, PL inhibits Ca^{2+} uptake by the SR ATPase pump (Fig. 13.3). However, β_1-adrenergic activation of protein kinase phosphorylates PL, and blunts its inhibitory effect. The subsequently greater uptake of Ca^{2+} ions by the SR hastens Ca^{2+} removal from the cytosol and promotes myocyte relaxation.

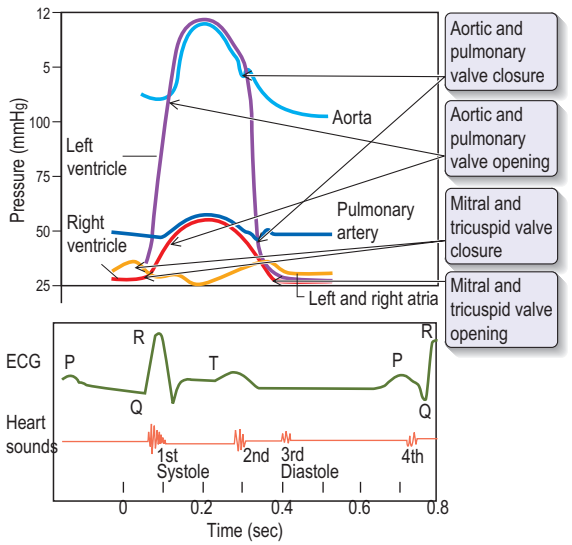

Fig. 13.6 **The cardiac cycle.**

The increased cAMP activity also results in phosphorylation of troponin I, an action that inhibits actin–myosin interaction, and further enhances myocyte relaxation.

The cardiac cycle

The cardiac cycle (Fig. 13.6) consists of precisely timed rhythmic electrical and mechanical events that propel blood into the systemic and pulmonary circulations. The first event in the cardiac cycle is atrial depolarization (a P wave on the surface ECG) followed by right atrial and then left atrial contraction. Ventricular activation (the QRS complex on the ECG) follows after a short interval (the PR interval). Left ventricular contraction starts and shortly thereafter right ventricular contraction begins. The increased ventricular pressures exceed the atrial pressures, and close first the mitral and then the tricuspid valves.

Until the aortic and pulmonary valves open, the ventricles contract with no change of volume (isovolumetric contraction). When ventricular pressures rise above the aortic and pulmonary artery pressures, the pulmonary valve and then the aortic valve open and ventricular ejection occurs. As the ventricles begin to relax, their pressures fall below the aortic and pulmonary arterial pressures, and aortic valve closure is followed by pulmonary valve closure. Isovolumetric relaxation then occurs. After the ventricular pressures have fallen below the right atrial and left atrial pressures, the tricuspid and mitral valves open. The cardiac cycle can be graphically depicted as the relationship between the pressure and volume of the ventricle. This is shown in Figure 13.7, which illustrates the changing pressure–volume relationships in response to increased contractility and to exercise.

The coronary circulation

The coronary arterial system (Fig. 13.8) consists of the right and left coronary arteries. These arteries branch from the aorta, arising immediately above two cusps of the aortic valve. These arteries are unique in that they fill during diastole, when not occluded by valve cusps and when not squeezed by myocardial contraction. The right coronary artery arises from the right coronary sinus and courses through the right side of the AV groove, giving off vessels

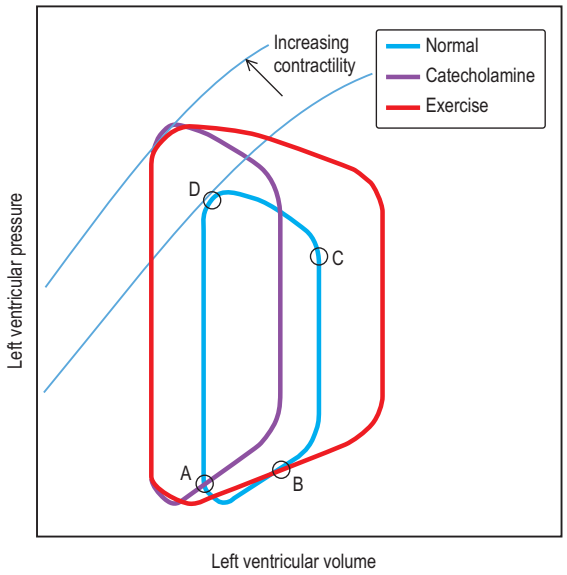

Fig. 13.7 **Pressure–volume loop.** AB, diastole – ventricular filling; BC systole – isovolumetric ventricular contraction; CD, systole – ventricular emptying; DA, diastole – isovolumetric ventricular relaxation.

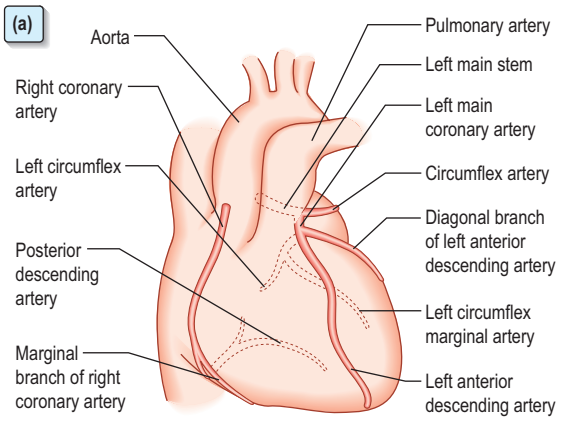
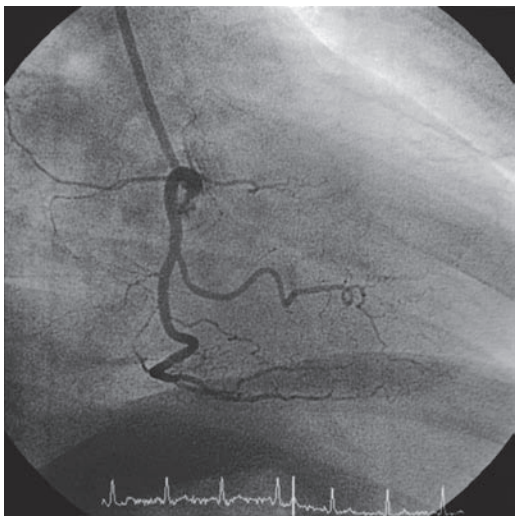
that supply the right atrium and the right ventricle. The vessel usually continues as the posterior descending coronary artery, which runs in the posterior interventricular groove and supplies the posterior part of the interventricular septum and the posterior left ventricular wall.



Within 2.5 cm of its origin from the left coronary sinus, the left main coronary divides into the left anterior descending artery and the circumflex artery. The left anterior descending artery runs in the anterior interventricular groove and supplies the anterior septum and the anterior left ventricular wall. The left circumflex artery travels along the left AV groove and gives off branches to the left atrium and the left ventricle (marginal branches).



The sinus node and the AV node are supplied by the right coronary artery in about 60% and 90% of people, respectively. Therefore, disease in this artery may cause sinus bradycardia and AV nodal block. The majority of the left ventricle is supplied by the left coronary artery, so that stenosis in the left main artery is extremely dangerous; total obstruction of this vessel is rarely compatible with life.

Some blood from the capillary beds in the wall of the heart drains directly into the cavities of the heart by tiny veins, but the majority returns by veins which accompany the arteries, to empty into the right atrium via the coronary sinus. An extensive lymphatic system drains into vessels that travel along the coronary vessels and then into the thoracic duct.

Blood vessel control and functions of the vascular endothelium

In functional terms, the tunica intima with the vascular endothelium and the smooth-muscle-cell-containing tunica media are the main constituents of blood vessels. These two structures are closely interlinked by a variety of mechanisms to regulate vascular tone. The central control of blood vessels is achieved via the neuroendocrine system. Sympathetic vasoconstrictor and parasympathetic vasodilator nerves regulate vascular tone in response to daily activity. Where

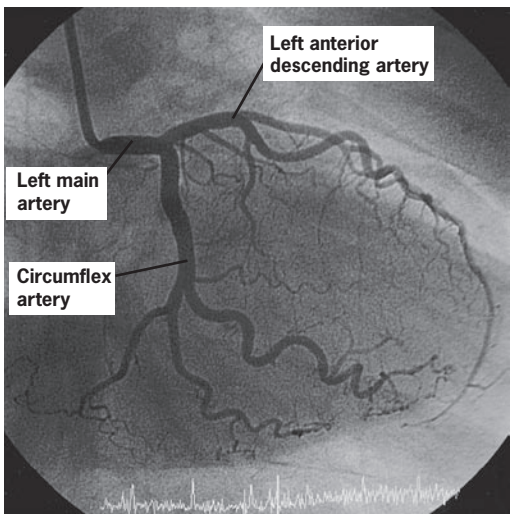


Fig. 13.8 **(a) Diagram of the normal coronary arterial anatomy. (b) Angiogram of non-dominant right coronary system. (c) Angiogram of dominant left coronary system from the same patient.** Right anterior oblique projection.

neural control is impaired, or in various pathological states, e.g. haemorrhage, endocrine control of blood vessels mediated through epinephrine (adrenaline), angiotensin and vasopressin takes over.

At a local level, tissue perfusion is maintained automatically and by the effect of various factors synthesized and/or

released in the immediate vicinity. In the face of fluctuating arterial pressures, blood vessels vasoconstrict independently of nervous input when blood pressure drops and vice versa. This process of *autoregulation* is a consequence of:

- the *Bayliss myogenic* response – the ability of blood vessels to constrict when distended
- the *vasodilator washout* effect – the vasoconstriction triggered by a decrease in the concentration of tissue metabolites.

The vascular endothelium is a cardiovascular endocrine organ, which occupies a strategic interface between blood and other tissues. It produces various compounds (e.g. nitrous oxide (NO), prostacyclin (PGI_2), endothelin, endothelial-derived hyperpolarizing factor (ERHF), adhesion molecules, vascular endothelial growth factor (VEGF)) and has enzymes located on the surface controlling the levels of circulating compounds such as angiotensin, bradykinin and serotonin. It has many regulatory roles:

Vasomotor control

NO is a diffusible gas with a very short half-life, produced in endothelial cells from the amino acid L-arginine via the action of the enzyme NO synthase (NOS), which is controlled by cytoplasmic calcium/calmodulin (Fig. 13.9). It is produced in response to various stimuli (Table. 13.1), triggering vascular smooth muscle relaxation through activation of guanylate cyclase, leading to an increase in the intracellular levels of cyclic 3,5-guanine monophosphate (cGMP). Its cardiovascular effects protect against atherosclerosis, high blood

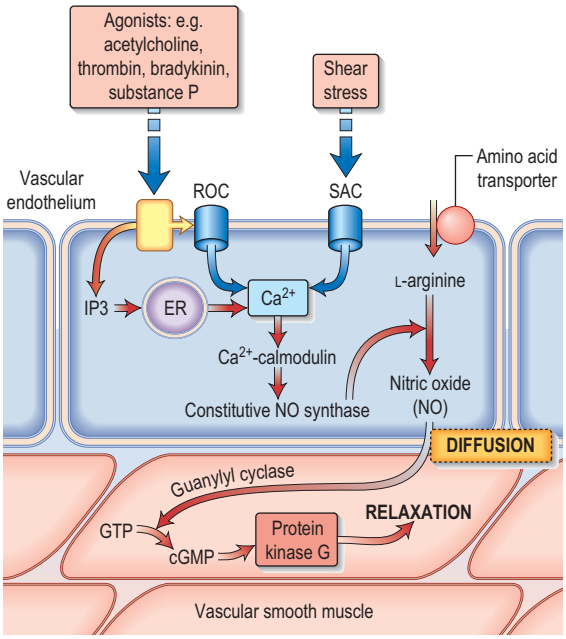

Fig. 13.9 **Nitric oxide (NO): the stimulus for production and function of NO.** Various stimuli lead to the production of NO via cytoplasmic calcium/calmodulin. NO triggers smooth muscle relaxation via the activation of guanylyl cyclase. ROC, receptor-operated Ca^{2+} channel; SAC, stretch-activated Ca^{2+} channel; IP3, inositol triphosphate; ER, endoplasmic reticulum; GTP, guanine triphosphate; cGMP, cyclic guanine monophosphate.

Table 13.1 Some of the products and functions of the vascular endothelium

Endothelial product	Function(s)	Stimulus
Nitrous oxide	Vasodilation Inhibits platelet aggregation Inhibits transcription of adhesion molecules Inhibits vascular smooth muscle proliferation	Shear stress, e.g. induced by exercise Agonists: thrombin, acetylcholine, endothelin, bradykinin, serotonin, substance P Inflammation/endotoxin shock
Prostacyclin (PGI_2)	Vasodilation Inhibits platelet aggregation	Agonist: thrombin Inflammation
Prostanoids	Vasoconstriction	Hypoxia
Endothelin	Vasoconstriction	Thrombin, angiotensin II, vasopressin Hypoxia N.B.: Inhibited by shear stress
Endothelial-derived hyperpolarizing factor	Vasodilation	Agonists: bradykinin, acetylcholine
Angiotensin-converting enzyme	Vasoconstriction	Expressed naturally
von Willebrand factor	Promotes platelet aggregation Stabilizes factor VIII	Agonists: thrombin, epinephrine (adrenaline)
Adhesion molecules		
P, L, E selectins ICAM, VCAM, PECAM	Margination of while blood cells (WBCs) Binding and diapedesis of WBCs into vessel wall	Inflammatory mediators: histamine, thrombin, TNF, IL-6
Vascular endothelial growth factor (VEGF)	Angiogenesis Vasodilation Increased vascular permeability	Pregnancy Hypoxia Inflammation: rheumatoid arthritis, trauma, tumours

ICAM, intracellular adhesion molecule; VCAM, vascular cell adhesion molecule, PECAM, platelet/endothelial cell adhesion molecule; TNF, tumour necrosis factor; IL, interleukin.

pressure, heart failure and thrombosis. NO is also the neurotransmitter in various 'nitrergic' nerves in the central and peripheral nervous systems and may play a role in the central regulation of vascular tone. The new class of drugs used to treat erectile dysfunction, the phosphodiesterase (PDE_5) inhibitors, prevent the breakdown of cGMP and promote vasodilatation.

PGI_2 is synergistic to NO and also plays a role in the local regulation of vasomotor tone.

Endothelin is a 21-amino-acid peptide that counteracts the effects of NO. Its production is inhibited by shear stress, i.e. the stress exerted on the vessel wall by the flowing blood, and it causes profound vasoconstriction and vascular smooth muscle hypertrophy. It is thought to play a role in the genesis of hypertension and atheroma.

Angiotensin-converting enzyme located on the endothelial cell membrane converts circulating angiotensin I (synthesized by the action of renin on angiotensinogen) to angiotensin II which has vasoconstrictor properties and leads to aldosterone release (Fig. 18.27). Aldosterone promotes sodium absorption from the kidney and together with the angiotensin-induced vasoconstriction provides haemodynamic stability.

Other factors which influence vasomotor tone include histamine (released by mast cells), bradykinin (synthesized from kininogen by the action of coagulation factor XIIa) and serotonin released by platelets.

Anti- and pro-thrombotic mechanisms

PGI_2, produced from arachidonic acid in the endothelial cell membrane by the action of the enzyme cyclo-oxygenase (Fig. 14.32), inhibits platelet aggregation. Low-dose aspirin prevents activation of the cyclo-oxygenase pathway in platelets but only to a degree that does not affect PGI_2 synthesis, unlike higher doses. Other antithrombotic agents such as clopidogrel (ADP receptor antagonist) and glycoprotein IIb/IIIa inhibitors achieve their effects by acting directly on platelet receptors. The antithrombotic effect of PGI_2 is aided by NO, affecting platelets via activation of guanylate cyclase. The endothelial cell membrane also produces other anticoagulant molecules such as thrombomodulin, heparin sulphate and various fibrinolytic factors. Clinically used, fast-acting, heparin preparations are identical to this naturally occurring molecule.

In addition to their ability to prevent clotting, endothelial cells also aid thrombosis. They are responsible for the production of von Willebrand factor through a unique organelle called the Weibel–Palade body, which not only acts as a carrier for factor VIII but also promotes platelet adhesion by binding to exposed collagen (p. 432).

Modulation of immune responses

In response to various inflammatory mediators, the vascular endothelium expresses various so-called 'adhesion molecules' which promote leucocyte attraction, adhesion and infiltration into the blood vessel wall (p. 67).

Regulation of vascular cell growth

The endothelial cells are also responsible for the development of new blood vessels ('angiogenesis') in the placenta, wound healing, tissue repair and tumour growth. This process is facilitated by VEGF.

Fetal circulation

In utero, the pulmonary circulation is largely unnecessary because fetal blood is oxygenated by placental blood flow, a parallel and integral element in the systemic circulation. In the fetus, systemic venous blood returning to the right atrium is partly deflected through the foramen ovale to the left atrium. Blood that passes through the right ventricle is diverted from the pulmonary artery to the aorta through the ductus arteriosus (Fig. 13.10a). Thus, the systemic

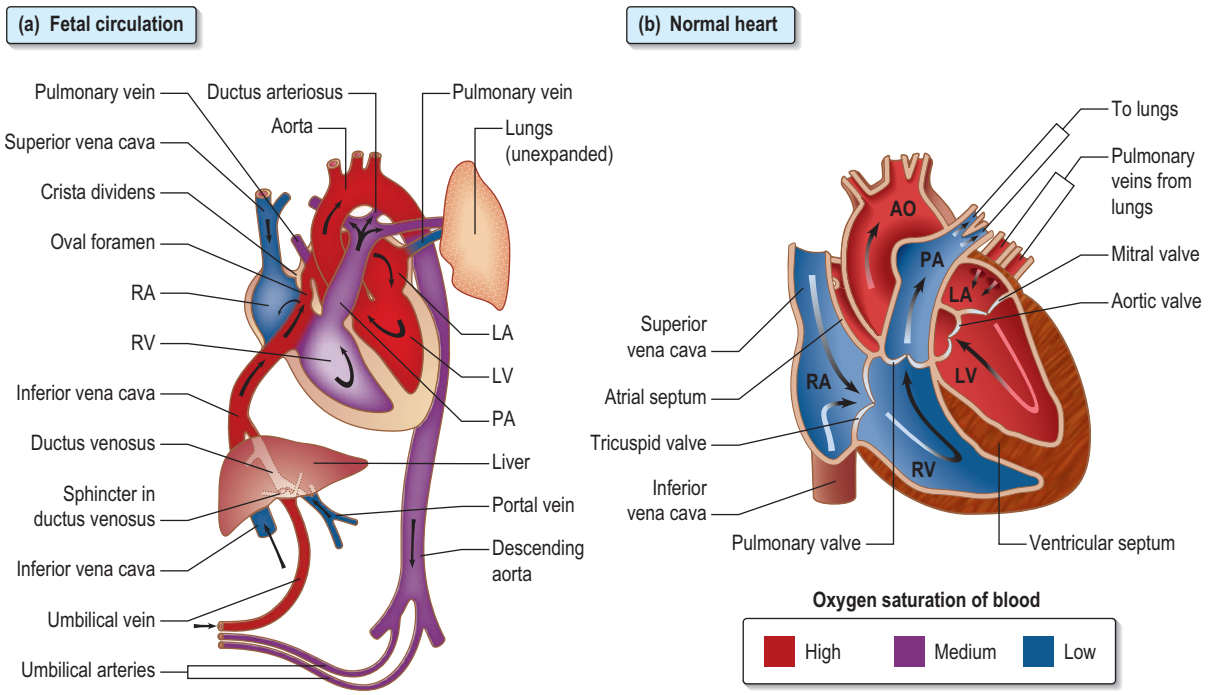

Fig. 13.10 **Anatomy showing circulation: (a) fetal; (b) after birth (normal heart).** AO, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

venous return, which is a mixture of oxygenated and deoxygenated blood, is mostly returned to the systemic arterial system.

At birth, inspiration dilates the pulmonary arterioles, resulting in a dramatic reduction of pulmonary vascular resistance. Blood therefore flows through the pulmonary circulation. The increased oxygen tension and reduced levels of prostaglandins trigger closure of the ductus arteriosus, and the reduced right atrial pressure and increasing left atrial pressure tend to close the foramen ovale. Thus, the circulation is divided into two separate circuits connected in series (Fig. 13.10b).

In the fetus the left and right heart both propel blood from the systemic veins to the systemic arteries; thus, severe abnormalities of the heart may not compromise fetal blood flow.

SYMPTOMS OF HEART DISEASE

The following symptoms occur with heart disease:

- chest pain
- dyspnoea
- palpitations
- syncope
- fatigue
- peripheral oedema.

The severity of cardiac symptoms or fatigue may be classified according to the New York Heart Association (NYHA) grading of 'cardiac status' (Table 13.2). The differential diagnosis of chest pain is given in Table 13.3.

Central chest pain

This is the most common symptom associated with heart disease. The pain of angina pectoris and myocardial infarction is due to myocardial hypoxia. Types of pain include:

- retrosternal heavy or gripping sensation with radiation to the left arm or neck that is provoked by exertion and eased with rest or nitrates – *angina* (p. 748)
- similar pain at rest – *acute coronary syndrome* (p. 752)
- severe tearing chest pain radiating through to the back – *aortic dissection* (p. 808)
- sharp central chest pain that is worse with movement or respiration but relieved with sitting forward – *pericarditis pain* (p. 795)
- sharp stabbing left submammary pain associated with anxiety – *Da Costa's syndrome*.

Table 13.2 The New York Heart Association grading of 'cardiac status' (modified)

Grade 1	Uncompromised (no breathlessness)
Grade 2	Slightly compromised (on severe exertion)
Grade 3	Moderately compromised (on mild exertion)
Grade 4	Severely compromised (breathless at rest)

Dyspnoea

Left ventricular failure causes dyspnoea due to oedema of the pulmonary interstitium and alveoli. This makes the lungs stiff (less compliant), thus increasing the respiratory effort required to ventilate the lungs. *Tachypnoea* (increased respiratory rate) is often present owing to stimulation of pulmonary stretch receptors.

Orthopnoea refers to breathlessness on lying flat. Blood is redistributed from the legs to the torso, leading to an increase in central and pulmonary blood volume. The patient uses an increasing number of pillows to sleep.

Paroxysmal nocturnal dyspnoea (PND) is when a patient is woken from sleep fighting for breath. It is due to the same mechanisms as orthopnoea. However, as sensory awareness is reduced whilst asleep, the pulmonary oedema can become quite severe before the patient is awoken.

Hyperventilation with alternating episodes of apnoea (*Cheyne–Stokes respiration*) occurs in severe heart failure.

Central sleep apnoea syndrome (CSAS). If hypopnoea occurs rather than apnoea, the phenomenon is termed 'periodic breathing', but the two variations are known together as CSAS. This occurs due to malfunctioning of the respiratory centre in the brain, caused by poor cardiac output with concurrent cerebrovascular disease.The symptoms of CSAS, such as daytime somnolence and fatigue, are similar to those of obstructive sleep apnoea syndrome (OSAS, p. 842) and there is considerable overlap with the symptoms of heart failure. CSAS is believed to lead to myocardial hypertrophy and fibrosis, deterioration in cardiac function and complex arrhythmias, including non-sustained ventricular tachycardia, hypertension and stroke. Patients with CSAS have a worse prognosis compared to similar patients without CSAS.

Palpitations

These represent an increased awareness of the normal heart beat or the sensation of slow, rapid or irregular heart rhythms.

Table 13.3 Differential diagnosis of chest pain

Central	Lateral/peripheral
Cardiac	**Pulmonary**
Ischaemic heart disease (infarction or angina)	Infarction
Coronary artery spasm	Pneumonia
Pericarditis/myocarditis	Pneumothorax
Mitral valve prolapse	Lung cancer
Aortic aneurysm/dissection	Mesothelioma
Non-cardiac	**Non-pulmonary**
Pulmonary embolism	Bornholm disease (epidemic myalgia)
Oesophageal disease (see Box 6.2)	Herpes zoster
Mediastinitis	Trauma (ribs/muscular)
Costochondritis (Tietze's disease)	
Trauma (soft tissue, rib)	

The most common arrhythmias felt as palpitations are premature ectopic beats and paroxysmal tachycardias. A useful trick is to ask patients to tap out the rate and rhythm of their palpitations, as the different arrhythmias have different characteristics:

- *Premature beats* are felt by the patient as a pause followed by a forceful beat. This is because premature beats are usually followed by a pause before the next normal beat, as the heart resets itself. The next beat is more forceful as the heart has had a longer diastolic period and therefore is filled with more blood before this beat.
- *Paroxysmal tachycardias* (see p. 722) are felt as a sudden racing heart beat.
- *Bradycardias* (p. 717) may be appreciated as slow, regular, heavy or forceful beats. Most often, however, they are simply not sensed. All palpitations may be graded by the NYHA cardiac status (Table 13.2).

Syncope

This is a transient loss of consciousness due to inadequate cerebral blood flow. The cardiovascular causes are listed in Table 13.4.

Vascular:

- A *vasovagal attack* (p. 1144) is a simple faint and is the most common cause of syncope. The mechanism begins with peripheral vasodilatation and venous pooling of blood, leading to a reduction in the amount of blood returned to the heart. The near-empty heart responds by contracting vigorously, which in turn stimulates mechanoreceptors (stretch receptors) in the inferoposterior wall of the left ventricle. These in turn trigger reflexes via the central nervous system, which act to reduce ventricular stretch (i.e. further vasodilatation and sometimes profound bradycardia), but this causes a drop in blood pressure and therefore syncope. These episodes are usually associated with a prodrome of dizziness, nausea, sweating, tinnitus, yawning and a sinking feeling. Recovery occurs within a few seconds, especially if the patient lies down.
- *Postural (orthostatic) hypotension* is a drop in systolic blood pressure of 20 mmHg or more on standing from a sitting or lying position. Usually, reflex vasoconstriction prevents a drop in pressure but if this is absent or the patient is fluid depleted or on *vasodilating or diuretic drugs*, hypotension occurs.
- *Postprandial hypotension* is a drop in systolic blood pressure of 20 mmHg or more or the systolic blood pressure drops from above 100 mmHg to under 90 mmHg within 2 hours of eating. The mechanism is unknown but may be due to pooling of blood in the splanchnic vessels. In normal subjects, this elicits a homeostatic response via activation of baroreceptors and the sympathetic system, peripheral vasoconstriction and an increase in cardiac output.
- *Micturition syncope* refers to loss of consciousness whilst passing urine.
- *Carotid sinus syncope* occurs when there is an exaggerated vagal response to carotid sinus stimulation, provoked by wearing a tight collar, looking upwards or turning the head.

Obstructive. The obstructive cardiac causes listed in Table 13.4 all lead to syncope due to restriction of blood flow from the heart into the rest of the circulation, or between the different chambers of the heart.

Arrhythmias. Stokes–Adams attacks (p. 719) are a sudden loss of consciousness unrelated to posture and due to intermittent high-grade AV block, profound bradycardia or ventricular standstill. The patient falls to the ground without warning, is pale and deeply unconscious. The pulse is usually very slow or absent. After a few seconds the patient flushes brightly and recovers consciousness as the pulse quickens. Often there are no sequelae, but patients may injure themselves during falls. Occasionally a generalized convulsion may occur if the period of cerebral hypoxia is prolonged, leading to a misdiagnosis of epilepsy.

Table 13.4 Cardiovascular causes of syncope

Vascular
Neurocardiogenic (vasovagal)
Postural hypotension
Postprandial hypotension
Micturition syncope
Carotid sinus syncope
Obstructive
Aortic stenosis
Hypertrophic cardiomyopathy
Pulmonary stenosis
Tetralogy of Fallot
Pulmonary hypertension/embolism
Atrial myxoma/thrombus
Defective prosthetic valve
Arrhythmias
Rapid tachycardias
Profound bradycardias (Stokes–Adams)
Significant pauses (in rhythm)
Artificial pacemaker failure

Fatigue

Fatigue may be a symptom of inadequate systemic perfusion in heart failure. It is due to poor sleep, a direct side-effect of medication, particularly beta-blockers, electrolyte imbalance due to diuretic therapy and as a systemic manifestation of infection such as endocarditis.

Peripheral oedema

Heart failure results in salt and water retention due to renal underperfusion and consequent activation of the renin–angiotensin–aldosterone system (p. 1023). This leads to dependent pitting oedema.

EXAMINATION OF THE CARDIOVASCULAR SYSTEM

GENERAL EXAMINATION

General features of the patient's well-being should be noted as well as the presence of conjunctival pallor, obesity, jaundice and cachexia.

- **Clubbing** (p. 820) is seen in congenital cyanotic heart disease, particularly Fallot's tetralogy and also in 10% of patients with subacute infective endocarditis.
- **Splinter haemorrhages.** These small, subungual linear haemorrhages are frequently due to trauma, but are also seen in infective endocarditis.
- **Cyanosis** is a dusky blue discoloration of the skin (particularly at the extremities) or of the mucous membranes when the capillary oxygen saturation is less than 85%. *Central cyanosis* (p. 820) is seen with shunting of deoxygenated venous blood into the systemic circulation, as in the presence of a right-to-left heart shunt. *Peripheral cyanosis* is seen in the hands and feet, which are cold. It occurs in conditions associated with peripheral vasoconstriction and stasis of blood in the extremities leading to increased peripheral oxygen extraction. Such conditions include congestive heart failure, circulatory shock, exposure to cold temperatures and abnormalities of the peripheral circulation.

THE ARTERIAL PULSE

The first pulse to be examined is the right radial pulse. A delayed femoral pulsation occurs because of a proximal stenosis, particularly of the aorta (coarctation).

Pulse rate

The pulse rate should be between 60 and 80 beats per minute (b.p.m.) when an adult patient is lying quietly in bed.

Rhythm

The rhythm is regular except for a slight quickening in early inspiration and a slowing in expiration (sinus arrhythmia).

Premature beats occur as occasional or repeated irregularities superimposed on a regular pulse rhythm. Similarly, intermittent heart block is revealed by occasional beats dropped from an otherwise regular rhythm.

Atrial fibrillation produces an irregularly irregular pulse. This irregular pattern persists when the pulse quickens in response to exercise, in contrast to pulse irregularity due to ectopic beats, which usually disappears on exercise.

Character of pulse (Fig. 13.11)

Carotid pulsations are not normally apparent on inspection of the neck but may be visible (Corrigan's sign) in conditions associated with a large-volume pulse, including high output states (such as thyrotoxicosis, anaemia or fever) and in aortic regurgitation.

A *'collapsing'* or *'water hammer'* pulse is a large-volume pulse characterized by a short duration with a brisk rise and fall. This is best appreciated by palpating the radial artery with the palmer aspect of four fingers whilst elevating the patient's arm above the level of the heart. A collapsing pulse is characteristic of aortic valvular regurgitation or a persistent ductus arteriosus.

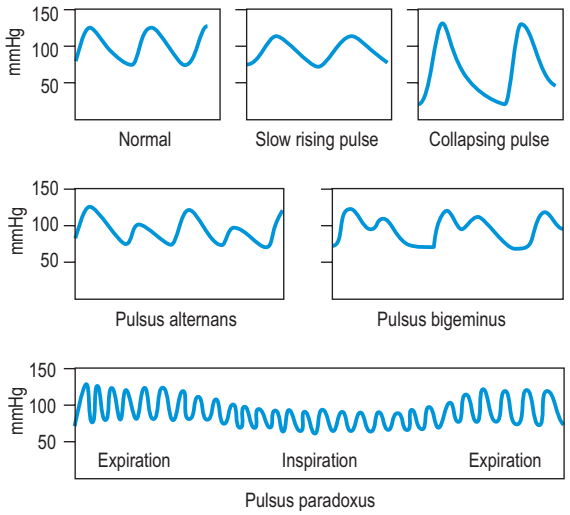

Fig. 13.11 **Arterial waveforms.**

A *small-volume pulse* is seen in cardiac failure, shock and obstructive valvular or vascular disease. It may also be present during tachyarrhythmias.

A *plateau pulse* is small in volume and slow in rising to a peak due to aortic stenosis (Fig. 13.11).

Paradoxical pulse

Paradoxical pulse is a misnomer, as it is actually an exaggeration of the normal pattern (Fig. 13.11). In normal subjects, the systolic pressure and the pulse pressure (the difference between the systolic and diastolic blood pressures) fall during inspiration. The normal fall of systolic pressure is less than 10 mmHg, and this can be measured using a sphygmomanometer. It is due to increased pulmonary intravascular volume during inspiration. In severe airflow limitation (especially severe asthma) there is an increased negative intrathoracic pressure on inspiration which enhances the normal fall in blood pressure. In patients with cardiac tamponade, the fluid in the pericardium increases the intrapericardial pressure, thereby impeding diastolic filling of the heart. The normal inspiratory increase in venous return to the right ventricle is at the expense of the left ventricle, as both ventricles are confined by the accumulated pericardial fluid within the pericardial space. Paradox can occur through a similar mechanism in constrictive pericarditis but is less common.

Alternating pulse (pulsus alternans)

This is characterized by regular alternate beats that are weak and strong. It is a feature of severe myocardial failure and is due to the prolonged recovery time of damaged myocardium; it indicates a very poor prognosis. It is easily noticed when taking the blood pressure because the systolic pressure may vary from beat to beat by as much as 50 mmHg (Fig. 13.11).

Bigeminal pulse (pulsus bigeminus)

This is due to a premature ectopic beat following every sinus beat. The rhythm is not regular (Fig. 13.11) because every weak pulse is premature.

Ask the authors
www.studentconsult.com

Practical Box 13.1 Taking the blood pressure

Use a properly calibrated machine.

1. The blood pressure is taken in the (right) arm with the patient relaxed and comfortable.
2. The sphygmomanometer cuff is wrapped around the upper arm with the inflation bag placed over the brachial artery.
3. The cuff is inflated until the pressure exceeds the arterial pressure – when the radial pulse is no longer palpable.
4. The diaphragm of the stethoscope is positioned over the brachial artery just below the cuff.
5. The cuff pressure is slowly reduced until sounds (Korotkoff sounds) can be heard (*phase 1*). This is the **systolic pressure**.
6. The pressure is allowed to fall further until the Korotkoff sounds become suddenly muffled (*phase 4*).
7. The pressure is allowed to fall still further until they disappear (*phase 5*).

The **diastolic pressure** is usually taken as *phase 5* because this phase is more reproducible and nearer to the intravascular diastolic pressure. The Korotkoff sounds may disappear (*phase 2*) and reappear (*phase 3*) between the systolic and diastolic pressures. Do not mistake *phase 2* for the diastolic pressure or *phase 3* for the systolic pressure.

Pulsus bisferiens

This is a pulse that is found in hypertrophic cardiomyopathy and in mixed aortic valve disease (regurgitation combined with stenosis). The first systolic wave is the 'percussion' wave produced by the transmission of the left ventricular pressure in early systole. The second peak is the 'tidal' wave caused by recoil of the vascular bed. This normally happens in diastole (the dicrotic wave), but when the left ventricle empties slowly or is obstructed from emptying completely, the tidal wave occurs in late systole. The result is a palpable double pulse (Fig. 13.11).

THE BLOOD PRESSURE

The peak systemic arterial blood pressure is produced by transmission of left ventricular systolic pressure. Vascular tone and an intact aortic valve maintain the diastolic blood pressure. How to take the blood pressure is outlined in Practical box 13.1.

JUGULAR VENOUS PRESSURE

There are no valves between the internal jugular vein and the right atrium. Observation of the column of blood in the internal jugular system is therefore a good measure of right atrial pressure. The external jugular cannot be relied upon because of its valves and because it may be obstructed by the fascial and muscular layers through which it passes; it can only be used if typical venous pulsation is seen, indicating no obstruction to flow.

Measurement of jugular venous pressure (JVP) (Practical box 13.2)

Elevation of the jugular venous pressure occurs in *heart failure*. It is also produced by an elevated jugular venous pressure which occurs in constrictive pericarditis and cardiac tamponade (increases in inspiration – *Kussmaul's sign*), renal disease with salt and water retention, overtransfusion or excessive infusion of fluids, congestive cardiac failure and superior vena cava obstruction. A reduced jugular venous pressure occurs in hypovolaemia.

Practical Box 13.2 Measurement of jugular venous pressure

The patient is positioned at about 45° to the horizontal (between 30° and 60°), wherever the top of the venous pulsation can be seen in a good light.

The jugular venous pressure is measured as the vertical distance between the manubriosternal angle and the top of the venous column.

The normal jugular venous pressure is usually less than 3 cmH_2O, which is equivalent to a right atrial pressure of 8 cmH_2O when measured with reference to a point midway between the anterior and posterior surfaces of the chest.

The venous pulsations are not usually palpable (except for the forceful venous distension associated with tricuspid regurgitation).

Compression of the right upper abdomen causes a temporary increase in venous pressure and makes the JVP more visible (hepatojugular reflux).

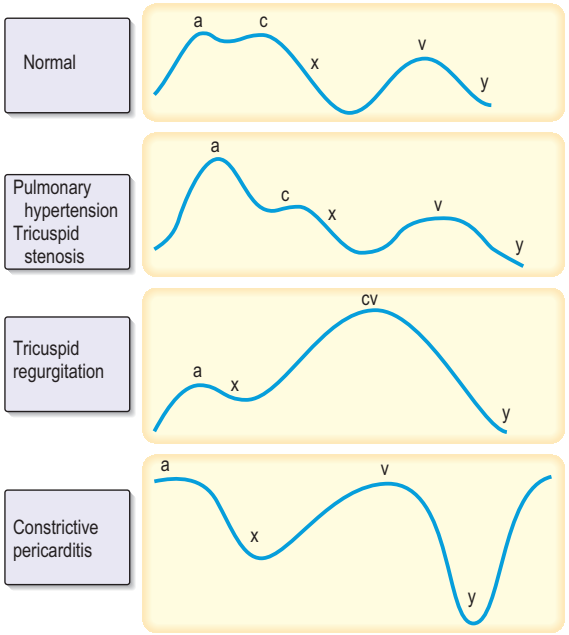

Fig. 13.12 **Jugular venous waveforms.**

The jugular venous pressure wave

This consists of three peaks and two troughs (Fig. 13.12). The peaks are described as *a*, *c* and *v* waves and the troughs are known as *x* and *y* descents:

- The ***a* wave** is produced by atrial systole and is increased with right ventricular hypertrophy secondary to pulmonary hypertension or pulmonary stenosis. Giant cannon waves occur in complete heart block and ventricular tachycardia.
- The ***x* descent** occurs when atrial contraction finishes.
- The ***c* wave** occurs during the *x* descent and is due to transmission of right ventricular systolic pressure before the tricuspid valve closes.
- The ***v* wave** occurs with venous return filling the right atrium. Giant *v* waves occur in tricuspid regurgitation.

- The ***y* descent** follows the *v* wave when the tricuspid valve opens. A steep *y* descent is seen in constrictive pericarditis and tricuspid incompetence.

EXAMINATION OF THE PRECORDIUM

- With the patient at 45°, the cardiac apex is located in the 5th intercostal space mid-clavicular line. Left ventricular dilatation will displace the apex downwards and laterally. It may be impalpable in patients with emphysema, obesity, pericardial or pleural effusions.
- A *tapping apex* is a palpable first sound and occurs in mitral stenosis.
- A *vigorous apex* may be present in diseases with volume overload, e.g. aortic regurgitation. A *heaving apex* may occur with left ventricular hypertrophy – aortic stenosis, systemic hypertension and hypertrophic cardiomyopathy.
- A *double pulsation* may occur in hypertrophic cardiomyopathy.
- A *sustained left parasternal heave* occurs with right ventricular hypertrophy or left atrial enlargement.
- A *palpable thrill* may be felt overlying an abnormal cardiac valve, e.g. systolic thrill with aortic stenosis.

Auscultation

The *bell* of the stethoscope is used for low-pitched sounds (heart sounds and mid-diastolic murmur in mitral stenosis).

The *diaphragm* is used for high-pitched sounds (systolic murmurs, aortic regurgitation, ejection clicks and opening snaps).

First heart sound (S1)

This is due to mitral and tricuspid valve closure. A loud S1 occurs in thin people, hyperdynamic circulation, tachycardias and mild–moderate mitral stenosis. A soft S1 occurs in obesity, emphysema, pericardial effusion, severe calcific mitral stenosis, mitral or tricuspid regurgitation, heart failure, shock, bradycardias and first-degree block.

Second heart sound (S2)

This is due to aortic and pulmonary valve closure. Physiological splitting of S2 occurs during inspiration in children and young adults.

Third and fourth heart sounds

These are pathological.

- A *third heart sound* is due to rapid ventricular filling and is present in heart failure.
- A *fourth heart sound* occurs in late diastole and is associated with atrial contraction.

Either, singly or together, will produce a gallop rhythm.

Heart murmurs

These are due to turbulent blood flow and occur in hyperdynamic states or with abnormal valves. Innocent or flow murmurs are soft, early systolic, short and non-radiating. They are heard frequently in children and young adults. The individual murmurs are discussed under valve disease, p. 760.

- aortic area is the 2nd intercostal space right sternal edge
- pulmonary area is the 2nd intercostal space left sternal edge
- tricuspid area is the 3rd–5th intercostal space left sternal edge
- mitral area is the 5th intercostals space mid-clavicular line.

CARDIAC INVESTIGATIONS

Chest X-ray

Ideally, this is taken in the postero-anterior (PA) direction at maximum inspiration with the heart close to the X-ray film to minimize magnification with respect to the thorax. A lateral may give additional information if the PA is abnormal. The cardiac structures and great vessels that can be seen on these X-rays are indicated in Figure 13.13. An antero-posterior (AP) view is only taken in an emergency.

Heart size

Heart size can be reliably assessed only from the PA chest film. The maximum transverse diameter of the heart is compared with the maximum transverse diameter of the thorax measured from the inside of the ribs (the cardiothoracic ratio).

The cardiothoracic ratio (CTR) is usually less than 50%, except in neonates, infants, athletes and patients with skeletal abnormalities such as scoliosis and funnel chest. A transverse cardiac diameter of more than 15.5 cm is abnormal. Pericardial effusion or cardiac dilatation causes an increase in the ratio.

A *pericardial effusion* produces a globular, sharp-edged shadow (Fig. 13.120, p. 796). This enlargement may occur quite suddenly and, unlike in heart failure, there is no associated change in the pulmonary vasculature. The echocardiogram is more specific (p. 704).

Certain patterns of specific chamber enlargement may be seen on the chest X-ray:

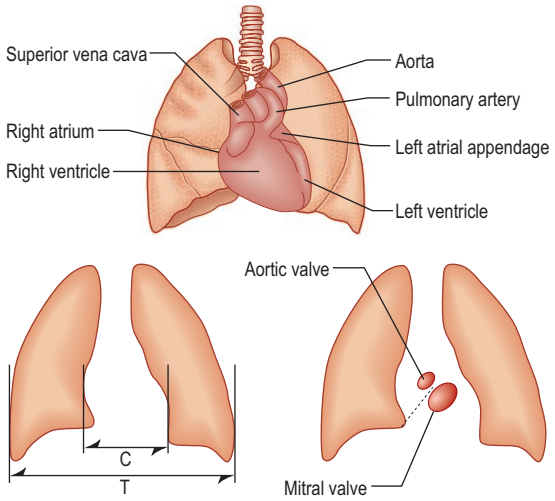

Fig. 13.13 **Diagrams to show the heart silhouette on the chest X-ray,** measurements of the cardiothoracic ratio (CTR) and the location of the cardiac valves. The dotted line is an arbitrary line from the left hilum to the right cardiophrenic angle: a calcified aortic valve is seen above this line. CTR = (C/T) × 100%; normal CTR <50%.

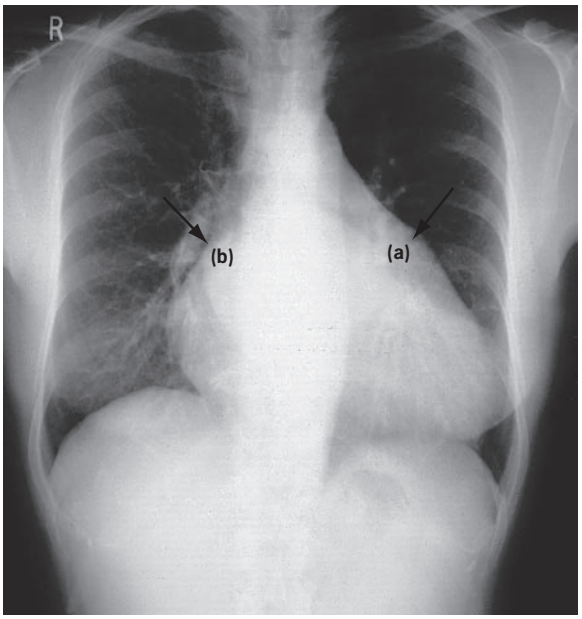

Fig. 13.14 **Plain PA chest X-ray of a patient with mixed mitral valve disease.** The left atrium is markedly enlarged (arrow a). Note the large bulge on the left heart border (left atrium) and the 'double shadow' (border of the right and left atria) (arrow b) on the right side of the heart. There is cardiac (left ventricular) enlargement due to mitral regurgitation.

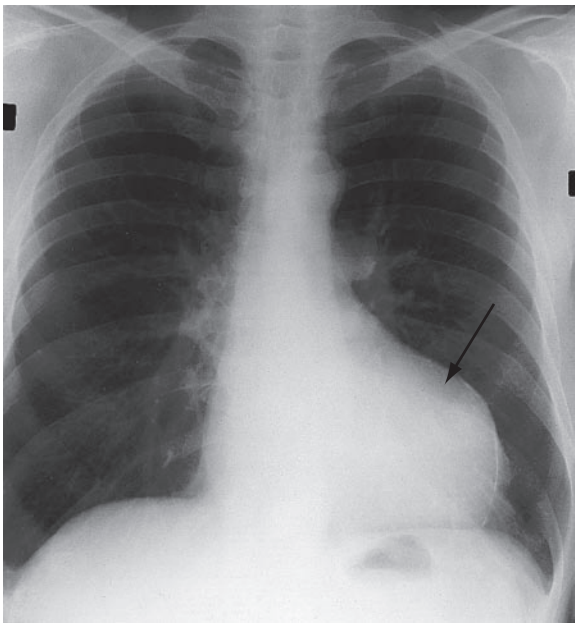

Fig. 13.15 **Left ventricular aneurysm: plain PA chest X-ray demonstrating a cardiac silhouette with a 'bulge' (arrow) on the left lateral border.** This bulge is due to aneurysm formation of many years following a myocardial infarction. A thin line of calcification can be seen along the edge of this bulge.

Left atrial dilatation. This results in prominence of the left atrial appendage and a straightening or convex bulging of the upper left heart border, a double atrial shadow to the right of the sternum, and splaying of the carina because a large left atrium elevates the left main bronchus (Fig. 13.14). On a lateral chest X-ray an enlarged left atrium bulges backwards, impinging on the oesophagus.

Left ventricular enlargement. This results in an increase in the CTR and a smooth elongation and increased convexity of the left heart border. A left ventricular aneurysm may produce a distinct bulge or distortion of the left heart border (Fig. 13.15).

Right atrial enlargement. This results in the right border of the heart projecting into the right lower lung field.

Right ventricular enlargement. This results in an increase of the CTR and an upward displacement of the apex of the heart because the enlarging right ventricle pushes the left ventricle leftwards, upwards and eventually backwards. Differentiation of left from right ventricular enlargement may be difficult from the shape of the left heart border alone, but the lateral view shows enlargement anteriorly for the right ventricle and posteriorly for the left ventricle.

Ascending aortic dilatation or enlargement. This is seen as a prominence of the aortic shadow to the right of the mediastinum between the right atrium and superior vena cava.

Dissection of the ascending aorta. This is seen as a widening of the mediastinum on chest X-ray but an ultrasound/magnetic resonance imaging (MRI) should be performed.

Enlargement of the pulmonary artery. Enlargement of the pulmonary artery in pulmonary hypertension, pulmonary artery stenosis and left-to-right shunts produces a prominent bulge on the left-hand border of the mediastinum below the aortic knuckle.

Calcification

Calcification in the cardiovascular system occurs because of tissue degeneration. Calcification is visible on a lateral or a penetrated PA film, but is best studied with computed tomography (CT) scanning. Various types of calcification can occur.

Pericardial calcification is plaque-like opacities over the surface of the heart (particularly concentrated in the atrioventricular groove) often result from tuberculous pericarditis and can cause pericardial constriction (see Fig. 13.121, p. 797).

Valvular calcification results from long-standing rheumatic or bicuspid aortic valve disease.

Myocardial calcification occurs after myocardial infarction, especially in association with a left ventricular aneurysm (Fig. 13.15).

Calcification of the aorta is a common, normal finding in patients over the age of 40 years and appears as a curvilinear opacity around the circumference of the aortic knuckle. Calcification in the ascending aorta usually denotes syphilitic aortitis, whereas in the descending aorta it is due to atheroma or, in the younger patient, to non-specific aortitis.

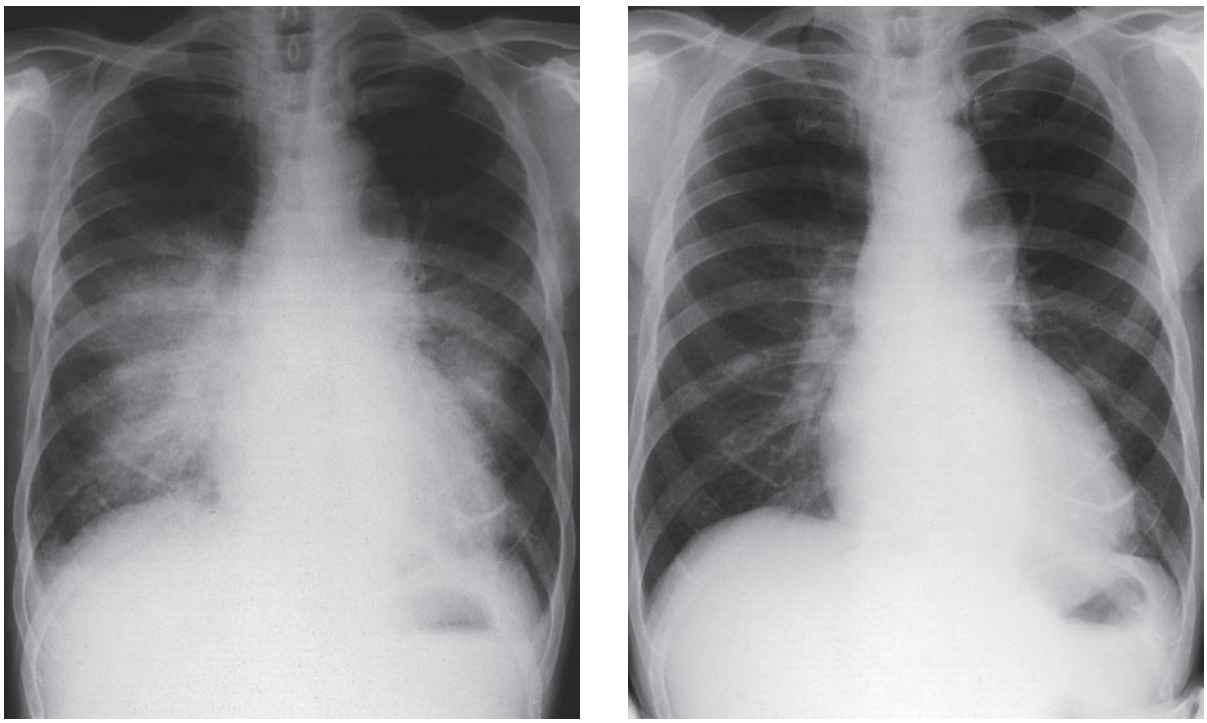
Coronary arterial calcification, especially of the proximal left coronary artery, is associated with coronary atheroma and is best seen on CT with multidetector CT (MDCT) scanners (see p. 705).

Lung fields

Pulmonary plethora results from left-to-right shunts (e.g. atrial or ventricular septal defects). It is seen as a general increase in the vascularity of the lung fields and as an

increase in the size of hilar vessels (e.g. in the right lower lobe artery), which normally should not exceed 16 mm diameter.

Pulmonary oligaemia is a paucity of vascular markings and a reduction in the width of the arteries. It occurs in situations where there is reduced pulmonary blood flow, such as pulmonary embolism, severe pulmonary stenosis and Fallot's tetralogy.



Pulmonary arterial hypertension may result from pulmonary embolism, chronic lung disease or chronic left heart disease, such as shunts due to a ventricular septal defect or mitral valve stenosis. In addition to X-ray features of these conditions, the pulmonary arteries are prominent close to the hila but are reduced in size (pruned) in the peripheral lung fields. This pattern is usually symmetrical.

Pulmonary venous hypertension occurs in left ventricular failure or mitral valve disease. Normal pulmonary venous pressure is 5–14 mmHg at rest. Mild pulmonary venous hypertension (15–20 mmHg) produces isolated dilatation of the upper zone vessels. Interstitial oedema occurs when the pressure is between 21 and 30 mmHg. This manifests as fluid collections in the interlobar fissures, interlobular septa (Kerley B lines) and pleural spaces. This gives rise to indistinctness of the hilar regions and haziness of the lung fields. Alveolar oedema occurs when the pressure exceeds 30 mmHg, appearing as areas of consolidation and mottling of the lung fields (Fig. 13.16) and pleural effusions. Patients with long-standing elevation of the pulmonary venous pressure have reactive thickening of the pulmonary arteriolar intima, which protects the alveoli from pulmonary oedema. Thus, in these patients the pulmonary venous pressure may increase to well above 30 mmHg before frank pulmonary oedema develops.

Electrocardiography

The electrocardiogram (ECG) is a recording of the electrical activity of the heart. It is the vector sum of the depolarization and repolarization potentials of all myocardial cells (see Fig. 13.2, p. 682). At the body surface these generate potential differences of about 1 mV, and the fluctuations of these potentials create the familiar P-QRS-T pattern. At rest the intracellular voltage of the myocardium is polarized at –90 mV compared with that of the extracellular space. This diastolic voltage difference occurs because of the high intracellular potassium concentration, which is maintained by the sodium potassium pump despite the free membrane permeability to potassium. Depolarization of cardiac cells occurs when there is a sudden increase in the permeability of the membrane to sodium. Sodium rushes into the cell and the negative resting voltage is lost (phase 0 in Fig. 13.42, p. 716). The depolarization of a myocardial cell causes the depolarization of adjacent cells and, in the healthy heart, the entire myocardium is depolarized in a coordinated fashion. During repolarization, cellular electrolyte balance is slowly restored (phases 1, 2 and 3). Slow diastolic depolarization (phase 4) follows until the threshold potential is reached. Another action potential then follows.

The ECG is recorded from two or more simultaneous points of skin contact (electrodes). When cardiac activation proceeds towards the positive contact, an upward deflection is produced on the ECG. Correct representation of a three-

(a) (b)

Fig. 13.16 **Acute pulmonary oedema.** This pair of chest X-rays were taken from a patient before **(a)** and after **(b)** treatment of acute pulmonary oedema. The X-ray taken when the oedema was present demonstrates hilar haziness, Kerley B lines, upper lobe venous engorgement and fluid in the right horizontal interlobar fissure. These abnormalities are resolved on the film taken after successful treatment.

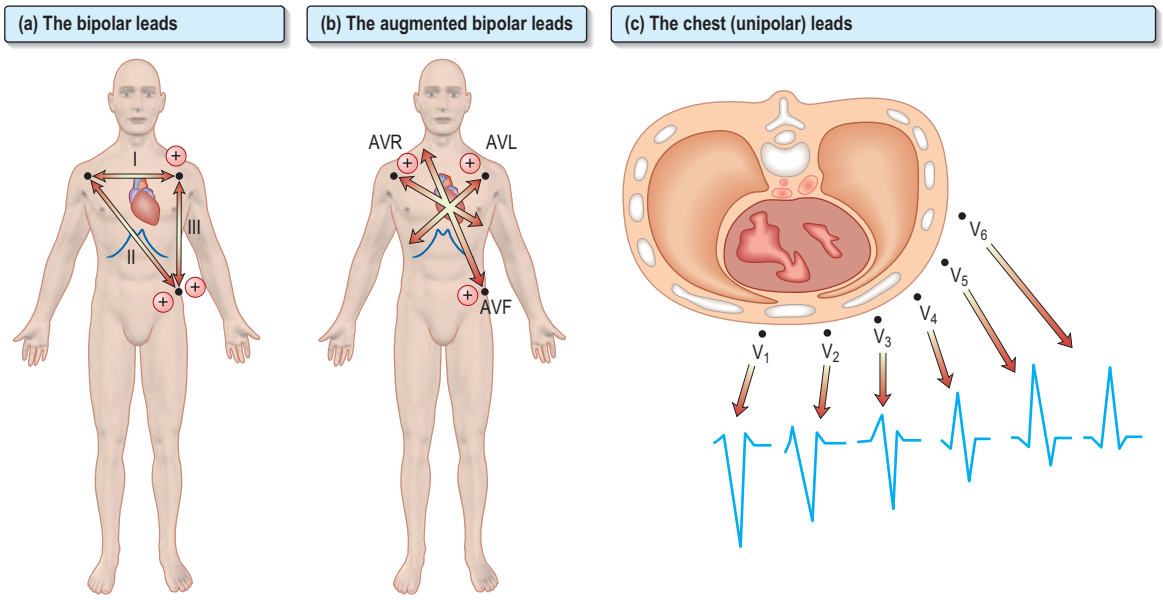


Fig. 13.17 **The connections or directions that comprise the 12-lead electrocardiogram.**

dimensional spatial vector requires recordings from three mutually perpendicular (orthogonal) axes. The shape of the human torso does not make this easy, so the practical ECG records 12 projections of the vector, called 'leads' (Fig. 13.17).

Six of the leads are obtained by recording voltages from the limbs (I, II, III, AVR, AVL and AVF). The other six leads record potentials between points on the chest surface and an average of the three limbs: RA, LA and LL. These are designated V_1–V_6 and aim to select activity from the right ventricle (V_1–V_2), interventricular septum (V_3–V_4) and left ventricle (V_5–V_6). Note that leads AVR and V_1 are oriented towards the cavity of the heart, leads II, III and AVF face the inferior surface, and leads I, AVL and V_6 face the lateral wall of the left ventricle. A V_4 on the right side of the chest (V_4R) is occasionally useful (e.g. for the diagnosis of right ventricular infarction).

Most ECG machines are simultaneous three-channel recorders with output either as a continuous strip or with automatic channel switching. Many ECG machines also analyse the recordings and print the analysis on the record. Usually the machine interpretation is correct, but many arrhythmias still defy automatic analysis.

The ECG waveform

The shape of the normal ECG waveform (Fig. 13.18) has similarities, whatever the orientation. The first deflection is caused by atrial depolarization, and it is a low-amplitude slow deflection called a *P wave*. The *QRS complex* reflects ventricular activation or depolarization and is sharper and larger in amplitude than the P wave. An initial downward deflection is called the *Q wave*. An initial upward deflection is called an *R wave*. The *S wave* is the last part of ventricular activation. The *T wave* is another slow and low-amplitude deflection that results from ventricular repolarization.

The *PR interval* is the length of time from the start of the P wave to the start of the QRS complex. It is the time taken for activation to pass from the sinus node, through the atrium, AV node and His–Purkinje system to the ventricle.

The *QT interval* extends from the start of the QRS complex to the end of the T wave. This interval represents the time

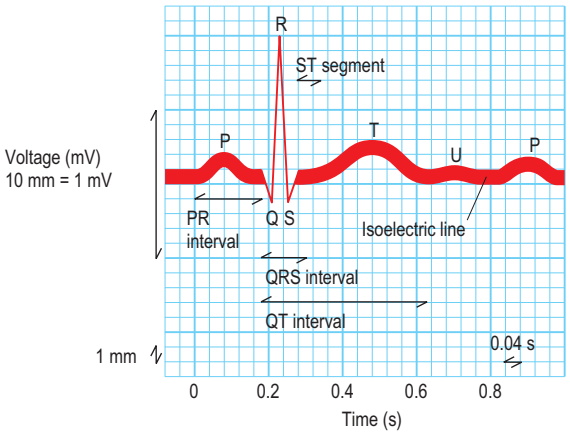

Fig. 13.18 **The waves and elaboration of the normal electrocardiogram.** From Goldman MJ. *Principles of Clinical Electrocardiography*, 9th edn. Los Altos: Lange, 1976.

Table 13.5 Normal ECG intervals

P wave duration	≤0.12 s
PR interval	0.12–0.22 s
QRS complex duration	≤0.10 s
Corrected QT (QT_c)	≤0.44 s in males ≤0.46 s in female
$QT_{cB} = QT/\sqrt{(R-R)}$	Bazett's square root formula
$QT_{cF} = QT/\sqrt[3]{(R-R)}$	Fridericia's cube root formula

taken to depolarize and repolarize the ventricular myocardium. The QT interval varies greatly with heart rate and is often represented as a corrected QT interval (or QTc) for a given heart rate. There are a number of formulae for derivation of QTc, but the most widely accepted are Bazett's formula and Fridericia's correction (Table 13.5).

An abnormally prolonged QTc can predispose to a risk of dangerous ventricular arrhythmias. Prolongation of QT

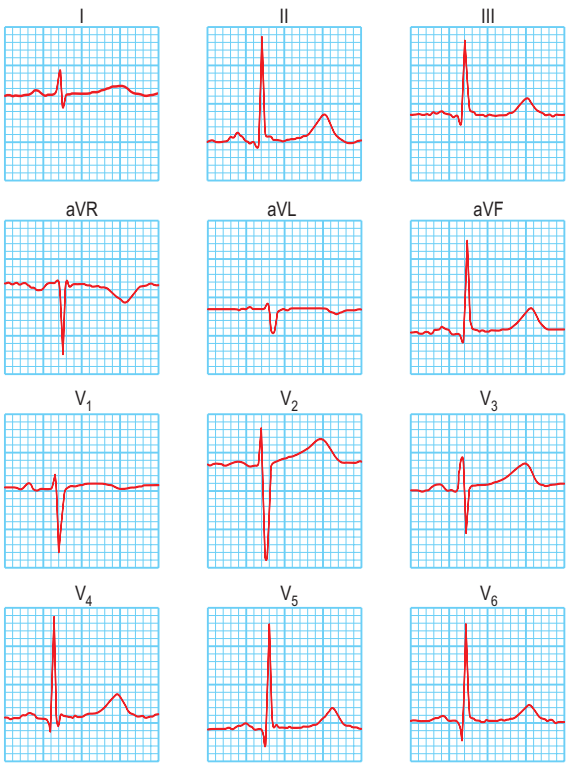

Fig. 13.19 **A normal 12-lead electrocardiogram.**

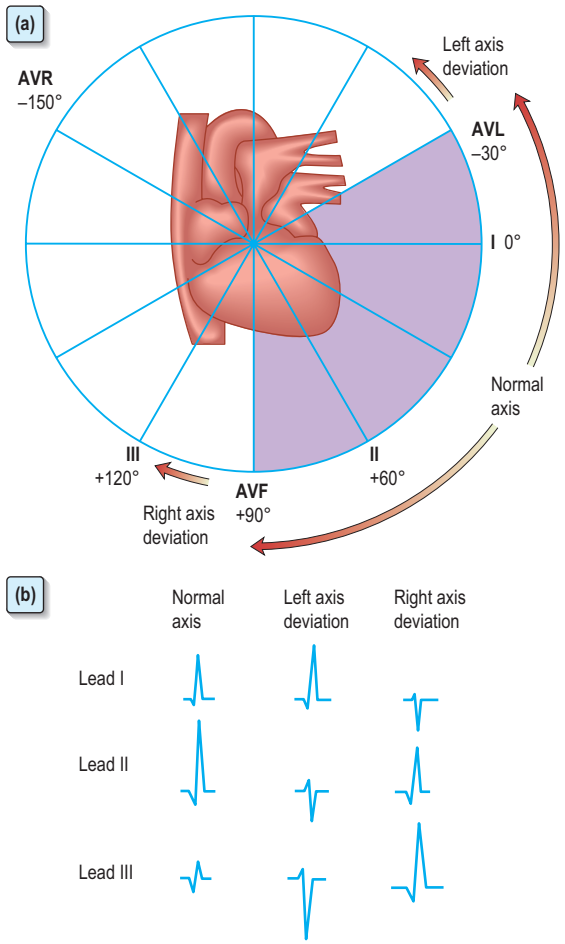

Fig. 13.20 **Cardiac vectors. (a) The hexaxial reference system,** illustrating the six leads in the frontal plane, e.g. lead I is 0°, lead II is +60°, lead III is +120°. **(b) Calculating the direction of the cardiac vector.** In the first column the QRS complex with zero net amplitude (i.e. when the positive and negative deflections are equal) is seen in lead III. The mean QRS vector is therefore perpendicular to lead III and is either –150° or +30°. Lead I is positive, so the axis must be +30°, which is normal. In left axis deviation (second column) the main deflection is positive (R wave) in lead I and negative (S wave) in lead III. In right axis deviation (third column) the main deflection is negative (S wave) in lead I and positive (R wave) in lead III. The frontal plane QRS axis is normal only if the QRS complexes in leads I and II are predominantly positive.

interval may be congenital or can occur in many acquired conditions (see Table 13.14, p. 727).

The *ST segment* is the period between the end of the QRS complex and the start of the T wave. In the normal heart, all cells are depolarized by this phase of the ECG, i.e. the ST segment represents ventricular repolarization.

A normal ECG is shown in Figure 13.19, and the normal values for the electrocardiographic intervals are indicated in Table 13.5. Leads that face the lateral wall of the left ventricle have predominantly positive deflections, and leads looking into the ventricular cavity are usually negative. Detailed patterns depend on the size, shape and rhythm of the heart and the characteristics of the torso.

Cardiac vectors

At any point in time during depolarization and repolarization, electrical potentials are being propagated in different directions. Most of these cancel each other out and only the net force is recorded. This net force in the frontal plane is known as the cardiac vector.

The mean QRS vector can be calculated from the six standard leads (Fig. 13.20):

- normal between –30° and +90°
- left axis deviation between –30° and –90°
- right axis deviation between +90° and +150°.

Calculation of this vector is useful in the diagnosis of some cardiac disorders.

Exercise electrocardiography

The ECG is recorded whilst the patient walks or runs on a motorized treadmill. The test is based upon the principle that exercise increases myocardial demand on coronary blood supply, which may be inadequate during exercise, and at peak stress can result in relative myocardial ischaemia. Most exercise tests are performed according to a standardized method, e.g. the Bruce protocol. Recording an ECG after exercise is not an adequate form of stress test. Normally there is little change in the T wave or ST segment during exercise.

The patient's exercise capacity (the total time achieved) will depend on many factors; however, patients who can only exercise for less than 6 minutes generally have a poorer prognosis.

Myocardial ischaemia provoked by exertion results in ST segment depression (>1 mm) in leads facing the affected area. The form of ST segment depression provoked by ischaemia is characteristic: it is either planar or shows down-sloping depression (Fig. 13.21). Up-sloping depression is a non-specific finding. The degree of ST segment

Fig. 13.21 **Electrocardiographic changes during exercise test.** Upper trace – significant horizontal ST segment depression during exercise. Lower trace – ST elevation during exercise.

depression is positively correlated to the degree of myocardial ischaemia.

ST segment elevation during an exercise test is induced much less frequently than ST depression. When it occurs, it reflects transmural ischaemia caused by coronary spasm or critical stenosis.

Although most abnormalities are detected in leads V_5 (anterior and lateral ischaemia) or AVF (inferior ischaemia), it is best to record a full 12-lead ECG. During an exercise test the blood pressure and rhythm responses to exercise are also assessed. Exercise normally causes an increase in heart rate and blood pressure. A sustained fall in blood pressure usually indicates severe coronary artery disease. A slow recovery of the heart rate to basal levels has also been reported to be a predictor of mortality.

Frequent premature ventricular depolarizations during the test are associated with a long-term increase in the risk of death from cardiovascular causes and further testing is required in these patients. Use of the exercise test in angina is described on page 749.

24-Hour ambulatory taped electrocardiography

This records transient changes such as a brief paroxysm of tachycardia, an occasional pause in the rhythm, or intermittent ST segment shifts (Fig. 13.22). A conventional 12-lead ECG is recorded in less than a minute and usually samples less than 20 complexes. In a 24-hour period over 100 000 complexes are recorded. Such a large amount of data must be analysed by automatic or semi-automatic methods. This technique is called 'Holter' electrocardiography after its inventor.

Event recording is another technique that is used to record less frequent arrhythmias. The patient is provided with a pocket-sized device that can record and store a short segment of the ECG. The device may be kept for several days or weeks until the arrhythmia is recorded. Most units of this kind will also allow transtelephonic ECG transmission so that the physician can determine the need for treatment or the continued need for monitoring.

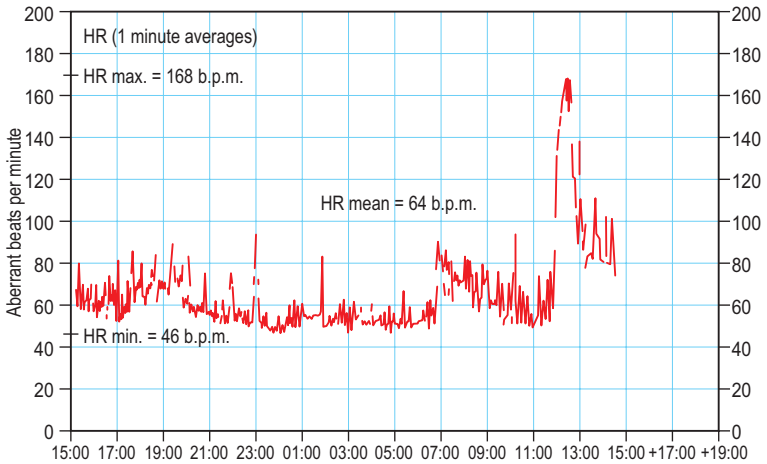
A very small event recorder, known as an implantable loop recorder (ILR), can also be implanted subcutaneously, triggered by events or a magnet, and interrogated by the physician.

Other tests

Non-invasive methods that make use of digitalized Holter recordings to identify increased risk of ventricular arrhythmias include assessment of heart rate variability, signal averaged ECG (SAECG) and T wave alternans.

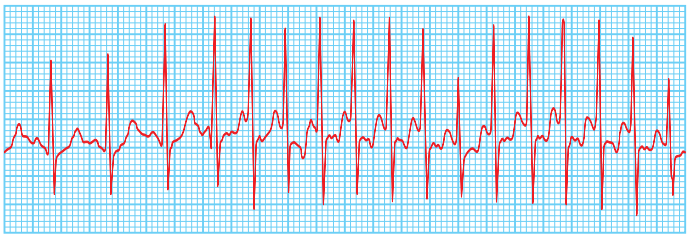
Heart rate variability (HRV) can be assessed from a 24-hour ECG. HRV is decreased in some patients following myocardial infarction and represents an abnormality of autonomic tone or cardiac responsiveness. Low HRV is a major risk factor for sudden death and ventricular arrhythmias in patients discharged from hospital following myocardial infarction.

Signal-averaged ECG (SAECG) is a technique that requires amplification and averaging of abnormal low-amplitude signals which occur beyond the end of the QRS complex and extend well into the ST segment. These signals are therefore also known as late potentials and are too small to be detected on a surface ECG. They arise in areas of slow conduction in the myocardium, such as the border zone of an infarct, where re-entrant ventricular arrhythmias can originate.



T wave alternans (TWA) is a valuable technique used as a non-invasive marker of susceptibility to ventricular arrhythmias and sudden cardiac death. TWA represents microvolt level changes in the morphology of the T waves in every other beat and can be detected during acute myocardial ischaemia using amplification techniques. Visible TWA on an ordinary surface ECG is quite a rare phenomenon, except in patients with long QT syndromes, particularly during emotion or exercise.

Tilt testing



Patients with suspected neurocardiogenic (vasovagal) syncope should be investigated by upright tilt testing. The patient is secured to a table which is tilted to + 60° to the vertical for 45 minutes or more. The ECG and blood pressure are monitored throughout. If neither symptoms nor signs develop, isoprenaline may be slowly infused or glyceryl trinitrate inhaled and the tilt repeated. A positive test results in hypotension, sometimes bradycardia (Fig. 13.23) and pre-syncope/syncope, and supports the diagnosis of neurocardiogenic syncope. If symptoms and signs appear, placing the patient flat can quickly reverse them. The effect of treatment can be evaluated by repeating the tilt test, but it is not always reproducible. The overall sensitivity is low.

Carotid sinus massage

Carotid sinus massage (see p. 698, Practical Box 13.3) may lead to asystole (>3 s) and/or a fall of systolic blood pressure (>50 mmHg). This hypersensitive response occurs in many of the normal (especially elderly) population, but may also be responsible for loss of consciousness in some patients with carotid sinus syndrome (p. 689). In one-third of cases carotid sinus massage is only positive when the patient is standing. Atherosclerosis can cause narrowing and stenosis of carotid arteries. Carotid sinus massage should thus be avoided in patients with carotid bruits.

(b) Ambulatory ECG record of the same patient, revealing supraventricular tachycardia. (c) Ambulatory ECG showing ST depression in a patient with silent myocardial ischaemia.

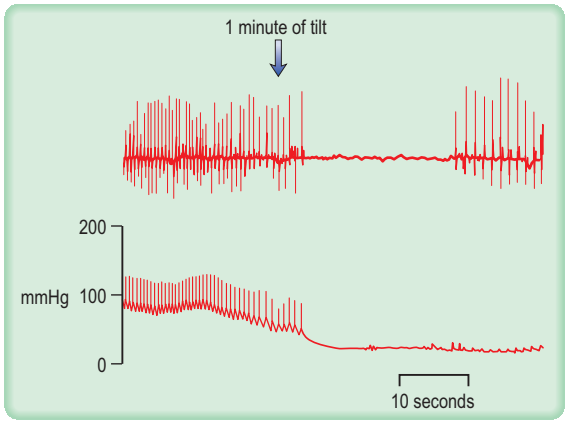

Fig. 13.23 **Tilt test.** The ECG (top trace) and arterial blood pressure (bottom trace) recorded during a tilt test. After 1 minute of tilt, hypotension, bradycardia and syncope occur.

Practical Box 13.3 Carotid sinus massage

- Ensure there is no significant carotid artery disease (carotid bruits).
- Provide continuous electrocardiographic monitoring.
- Patient is in supine position with the head slightly extended.
- Start with right carotid sinus massage.
- Apply firm rotary pressure to the carotid artery at the level of the third cervical vertebra for 5 seconds.
- Alternatively, steady pressure can be applied.
- If no response, massage left carotid sinus.
- Generally, right carotid sinus massage decreases the sinus node discharge, and left carotid sinus massage slows atrioventricular conduction.
- Do not massage both carotid sinuses at the same time.
- Single application of carotid sinus pressure may be effective in about 20–30% of patients with paroxysmal supraventricular tachycardias; multiple applications can terminate tachycardia in about 50% of patients.
- Asystole is a potential but rare complication.

Echocardiography

Echocardiography is a non-invasive diagnostic technique that is widely used in clinical cardiology. It involves the use of ultrasound (either alone or with contrast agent) to assess cardiac structure and function.

Physics

Echocardiography uses transmitted ultrasound wavelengths of 1 mm or less, which correspond to frequencies of approximately 2 MHz (2 million cycles per second) or more. At such high frequencies, the ultrasound waves can be focused into a 'beam' and aimed at a particular region of the heart. The waves are generated in very short bursts or pulses a few microseconds long by a crystal transducer, which also detects returning echoes and converts them into electrical signals.

When the handheld crystal transducer is placed on the body surface the emitted ultrasound pulses encounter interfaces between various body tissues as they pass through the body. In crossing each interface, some of the wave energy is reflected, and if the beam path is approximately at right angles to the plane of the interface, the reflected waves return to the transducer as an echo. Since the velocity of sound in body tissues is almost constant (1550 m/s), the time delay for the echo to return measures the distance of the reflecting interface. Thus, if a single ultrasound pulse is transmitted, a series of echoes return, the first of which is from the closest interface.

Echocardiographic modalities

M mode

M-mode echocardiography is a technique that details the changing motion of structures along the ultrasound beam with time. Thus the motion of the interventricular septum during the cardiac cycle (either towards or away from the transducer placed on the chest wall) can be assessed and quantified. Stationary structures thus generate horizontal straight lines, the distances of which from the top of the screen indicate their depths, and movements, such as those of heart valves, are indicated by zigzag lines (Fig. 13.24c).

Two-dimensional echocardiography

Alternatively, a series of views from different positions can be obtained in the form of a two-dimensional image (cross-sectional 2-D echocardiography) (Fig. 13.24a, b, d). This method is useful for delineating anatomical structures and for quantifying volumes of cardiac chambers. It is conventional for different imaging planes to be used to create standard 2-D views.

Three-dimensional echocardiography

Three-dimensional echocardiography is a novel development in cardiac imaging in which a volumetric dataset is acquired using a multiplane probe rotating around a fixed axis. Current clinical uses include accurate volumetric assessment of ventricular function and mass, assessment of mitral and aortic valve disease and assessment of adult congenital heart disease (Fig. 13.25).

Doppler echocardiography

Echocardiography imaging utilizes echoes from tissue interfaces. Using high amplification, it is also possible to detect weak echoes scattered by small targets, including those from red blood cells. Blood velocity in the heart chambers is typically much more rapid (>1 m/s) than the movement of myocardial tissue. If the blood is moving in the same direction as the direction of the ultrasound beam, the frequency of the returning echoes will be changed according to the Doppler phenomenon. The Doppler shift frequency is directly proportional to the blood velocity. Blood velocity data can be acquired and displayed in several ways.

Pulsed-wave (PW) Doppler extracts velocity data from the pulse echoes used to form a 2-D image and gives useful qualitative information. PW echoes can be specified from locations within an image identified by a sample volume cursor placed on the screen. Such information from the left ventricular outflow tract (LVOT) and right ventricular outflow tract provides the stroke distance, and is used to estimate cardiac output (CO) and also to quantify intracardiac shunts.

Cardiac output can then be derived using the formula: CO = stroke volume × heart rate. Stroke volume is the stroke distance multiplied by the area of the LVOT, which can also be measured echocardiographically. PW Doppler of the flow across the mitral valve and into the left atrium through the pulmonary veins can be used as part of the estimation of left ventricular filling pressure.

Colour flow Doppler. Doppler colour flow imaging uses one colour for blood flowing towards the transducer and another colour for blood flowing away. This technique allows the direction, velocity and timing of the flow to be measured with a simultaneous view of cardiac structure and function. Colour flow Doppler is used to help assess valvular regurgitation (Fig. 13.26) and may be useful in the assessment of coronary blood flow.

Continuous-wave (CW) Doppler collects all the velocity data from the path of the beam and analyses it to generate a spectral display. This is unlike PW Doppler, which provides information from a particular sample volume at one location along a line. Thus, CW Doppler does not provide any depth information.

The outline of the envelope of the spectral display is used to estimate the value of peak velocity throughout the cardiac cycle. CW Doppler is used typically to assess valvular obstruction, which then causes increased velocities. For example, normal flow velocities are of the order of 1 m/s across the normal aortic valve, but if there is a severe obstructive lesion, such as a severely stenotic aortic valve, velocities of 4 m/s or more can occur (Fig. 13.27a, b). These velocities are generated by the pressure gradient that exists across the lesion.

According to the Bernoulli equation, the pressure difference between two chambers is calculated as: 4 multiplied by the square of the CW Doppler velocity between chambers. Thus a velocity of 5 m/s across the aortic valve suggests a peak gradient of $4 \times 5 \times 5 = 100$ mmHg between the ascending aorta and the left ventricle. This equation has been validated in a wide variety of clinical situations, including valve stenoses, ventricular septal defects and intraventricular obstruction (as in hypertrophic cardiomyopathy). It is often

Fig. 13.24 **Echocardiograms. Fig. 13.26 **Colour Doppler** shows blood flowing away from the echocardiography probe as a blue signal and towards the probe as a red signal. In this patient with tricuspid regurgitation, blood leaks from the right ventrical to the right atrium during cardiac systole.

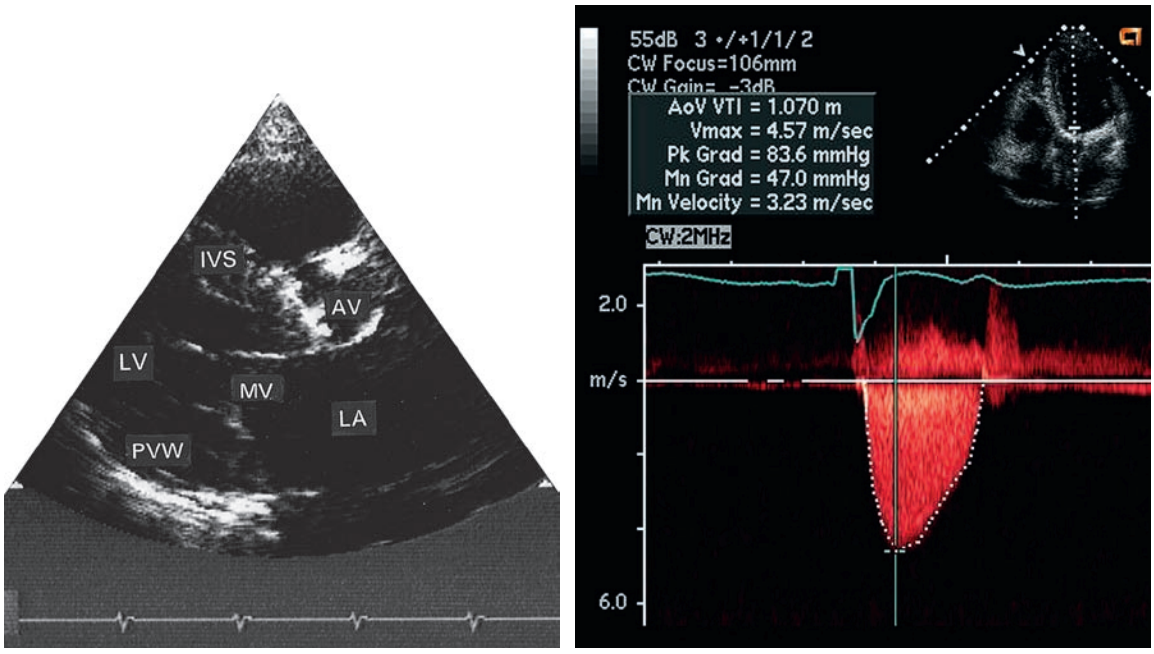
clinically unnecessary to resort to invasive methods such as cardiac catheterization to measure intracardiac pressure gradients.

Similarly, pulmonary artery (PA) systolic pressure and right ventricular diastolic pressure can be calculated using the Bernoulli equation. In this case, CW Doppler tracing of the tricuspid regurgitant jet is used to estimate the pressure gradient between the right ventricle and the right atrium. The PA systolic pressure is then calculated by adding the estimated right atrial pressure to the pressure gradient between the right ventricle and the right atrium.

Tissue Doppler is similar to PW Doppler. It measures myocardial tissue velocities within a particular sample volume placed on the image. Such velocities are of the order of 1 cm/s. Currently, tissue Doppler of the mitral annulus is used as part of the estimation of left ventricular filling pressure.

Other ultrasound modalities. Harmonic power Doppler, pulse inversion Doppler and ultraharmonics are used to detect and amplify microsphere-specific signals as part of the echocardiographic assessment of myocardial perfusion.

The echocardiographic examination



Transthoracic echocardiography is a 'non-invasive' procedure that causes the patient no discomfort and is harmless. A physician or technician performs the studies and a comprehensive examination takes 15–45 minutes. The ultrasound machines are either mobile on wheels, or are handheld.

The technical issue associated with echocardiography is that the lungs and rib cage obstruct the passage of ultrasound to the heart in the adult subject. Small 'windows' can usually be found in the third and fourth left intercostal spaces (termed left parasternal); just below the xiphoid process of the sternum (subcostal); and, with the subject turned to the left and exhaling, from the point where the apical beat is palpated (apical). By positioning the transducer successively over these sites and angling and rotating it to line up with the scan plane, a series of standard sectional views is obtained. In children, and some adults, the aortic arch can be visualized from a suprasternal position.

The standard nomenclature for 2-D echocardiographic images is shown in Figure 13.24a. The parasternal position of the transducer gives access to the long-axis and short-axis planes. The apical approach gives a second view of the long-axis plane, but with the apex in the foreground, and also shows the four-chamber plane (Fig. 13.24e). A three-chamber apical view is sometimes also obtained. The convention adopted in most adult cardiology units of showing the transducer position at the top of the image results in the apical views being 'upside-down' compared to the anatomical position of the heart. M-mode recordings are obtained from the parasternal position to document motion patterns of the aorta, aortic valve and left atrium, the mitral valve, and the left and right ventricles (Fig. 13.24c).

Quantification in echocardiography

Quantification is helpful because of the relative inaccuracy of *subjective* assessment of chamber size and cardiac function. M mode is used to assess lengths in a single plane. The 1 cm calibration markers on M-mode recordings permit

(a) (b)

Fig. 13.27 **Cardiac echograms. (a) 2-D Echocardiogram (long-axis view) in a patient with calcific aortic stenosis.** The calcium in the valve generates abnormally intense echoes. There is some evidence of the associated left ventricular hypertrophy. **(b) Continuous-wave (CW) Doppler signals** obtained from the right upper parasternal edge, where the high-velocity jet from the stenotic valve is coming towards the transducer. AV, aortic valve; LA, left atrium; MV, mitral valve; LV, left ventricle; IVS, interventricular septum; PVW, posterior ventricular wall.

measurement of cardiac dimensions at any point in the cardiac cycle with a typical accuracy of ± 2–3 mm. M mode can be used to estimate LV systolic function by comparing end-diastolic and end-systolic dimensions. For example, the percentage reduction in the left ventricular cavity size ('shortening fraction' – SF) is given by:

$$SF = \frac{LVDD - LVSD}{LVDD} \times 100\%$$

where LVDD is left ventricular diastolic diameter and LVSD is left ventricular systolic diameter, at the base of the heart. The normal range is 30–45%.

This method is easy to perform, but is an inaccurate measure of ejection fraction (EF) because it does not take account of reduced regional function of the mid or apical myocardium, due to infarction for example. For this reason, estimation of EF based upon the difference in LV volumes from systole to diastole, derived from planimetered measurements of LV area in at least two planes, is more accurate. A normal EF is >55%. This method is helpful in assessing the response of the patient with heart failure to therapy. It also permits estimation of LV mass.

Transoesophageal echocardiography (TOE)

This involves placing the transducer mounted on a flexible tube into the oesophagus. This involves the use of local anaesthesia and sometimes intravenous sedation. High-resolution images can be obtained because of the close proximity of the heart to the transducer in the oesophagus, and also because of the higher frequencies that are used relative to transthoracic imaging. TOE is most commonly used in the assessment of valve structure and function (to assess for reparability of mitral valve prolapse), for features and complications of infective endocarditis, to assess the aorta for aortic dissection and to assess for a cardiac source of embolus.

Wall motion stress echocardiography

Echocardiography can be used clinically to evaluate the patient for the presence of myocardial scars and of reversible ischaemia. Since ultrasound cannot directly detect red blood cells in capillaries, myocardial wall motion is used as a surrogate for perfusion. Myocardial segments that demonstrate a change in function (defined as a change or reduction in thickening) from rest to stress can be assumed to be supplied by a flow-limiting stenosis in the epicardial artery or graft.

Stress for this indication needs to be inotropic to induce true ischaemia. Physiological stress includes treadmill exercise, which is complicated by the difficulty in obtaining reliable images rapidly as the patient comes off the treadmill, before heart rate reduces back to sub-maximal levels. Alternatively, pharmacological stress can be induced with dobutamine at graded doses. This is relatively safe but complications such as ventricular arrhythmia have been reported.

This technique can also be used to assess for viability of the myocardium and for hibernating or stunned myocardium (p. 740).

Myocardial perfusion echocardiography

In order to assess myocardial perfusion by echocardiography (MPE), microspheres of similar size to red blood cells are used as an intravenous contrast agent. Microsphere-specific ultrasound modes such as harmonic power Doppler can be used for detection. MPE involves the use of intravenous infusion of contrast to fill the myocardium. A pulse of ultrasound destroys microspheres within the capillaries (and not the LV

cavity), and the time taken to replenish the capillaries is a measure of myocardial blood flow. The time taken to fill should be significantly shorter at stress than at rest.

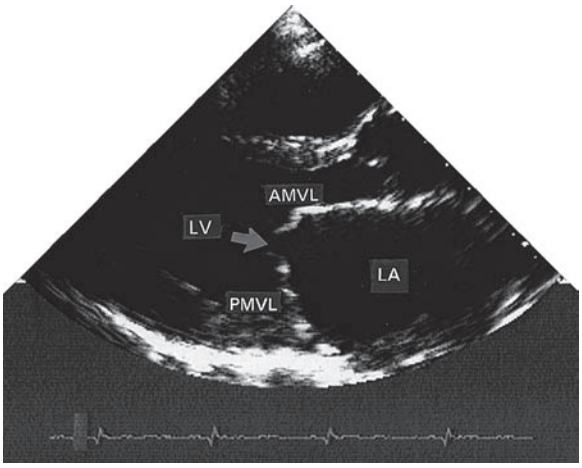
Clinical use of echocardiography

The echocardiographic findings in particular conditions are discussed in relevant sections, but a brief overview is given below.

Valve stenosis

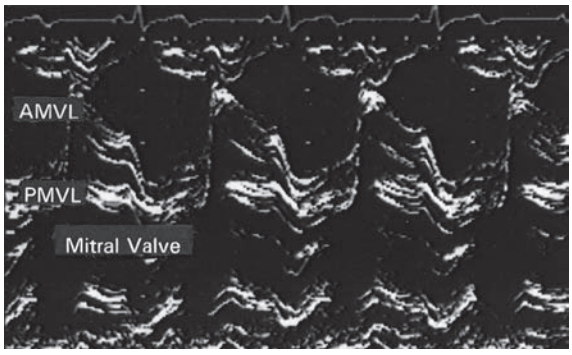
Congenitally abnormal aortic or pulmonary valves show a characteristic 'dome' shape in systole because the cusps cannot separate fully and a bicuspid configuration may be demonstrated. The presence of calcium in a valve gives rise to intense echoes that generate multiple, parallel lines on M-mode recordings. CW Doppler (p. 699) directed from the apex measures velocity of the jet crossing the diseased valve, from which the pressure gradient can be calculated (Fig. 13.27b).

Mitral stenosis



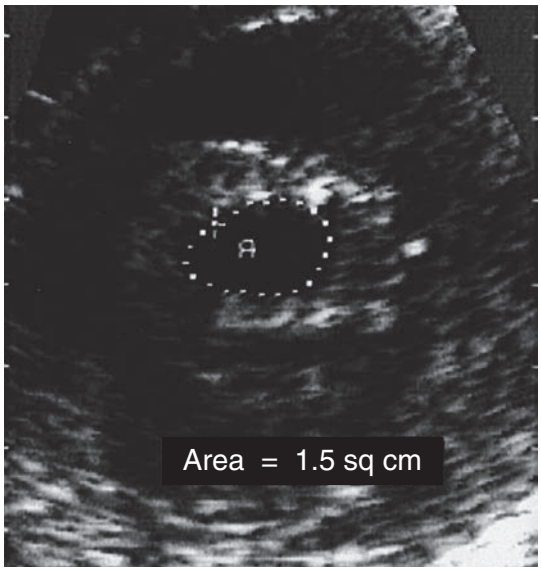
The M-mode shows restriction and reversal of direction of the posterior leaflet motion (Fig. 13.28c). A short-axis view shows the shape of the mitral orifice in diastole, and its area can be measured directly from the image. Peak, mean and end-diastolic pressure gradients can be obtained from CW Doppler. Additional imaging views indicate the size of the left atrium, and may show the presence of left atrial thrombus.

Valve regurgitation



Doppler is extremely sensitive for detecting valve regurgitation and care must be taken not to overestimate severity of regurgitation. Transthoracic echocardiography is as accurate as angiography in the evaluation of valvular regurgitation, provided appropriate algorithms for interpretation are used. Echocardiography can determine the underlying cause such as rheumatic disease or mitral valve prolapse.

Aortic aneurysms and dissections



Dilatation of the aortic root can be measured accurately and the presence of a reflecting structure within the lumen of the aorta is strongly suggestive of an intimal flap associated with dissection. Transoesophageal views are particularly suitable for detecting pathology in the ascending and descending aorta. In some hospitals this is the investigation of first choice

(a) 2-D Long-axis view** showing enlarged left atrium and 'hooked' appearance of the mitral valve leaflets resulting from commissural fusion. **(b) Magnified short-axis view** showing the mitral valve orifice as seen from the direction of the arrow in (a). The orifice area can be planimetered to assess the severity; in this case it is 1.5 cm^2, indicating moderately severe disease. **(c) M-mode recording** of the mitral valve showing restricted motion of the thickened leaflets. **(d) Continuous-wave (CW) Doppler** recording showing slow rate of decay of flow velocity from the left atrium to the left ventricle during diastole. It is also possible to derive the valve orifice area from the velocity decay rate. LA, left atrium; LV, left ventricle; AMVL, PMVL, anterior and posterior mitral valve leaflets.

when aortic dissection is suspected although MRI is increasingly used.

Prosthetic heart valves

Each type of mechanical heart valve prosthesis has characteristic echocardiographic features. Irregularity or restriction of movement can be shown. Bioprostheses can also be assessed echocardiographically. The presence of stenosis or regurgitation may be documented by colour flow and CW Doppler. Prosthetic valves imaged transthoracically cast acoustic shadows that obscure the area behind the valve. For this reason a transoesophageal approach is often used to inspect a prosthetic mitral valve for evidence of endocarditis or thrombosis.

Infective endocarditis

Vegetations >2 mm can be detected (Fig. 13.87a, p. 772). Complications of endocarditis such as valvar regurgitation and abscess can be identified.

Cardiac failure

Left ventricular function and response to treatment is readily assessed and should be performed in all patients with known or suspected heart failure. Left- and right-sided heart cardiac output and filling pressures can also be estimated.

Cardiomyopathies

Dilated cardiomyopathy is characterized by an enlarged, globular shaped, thin-walled left ventricle with poor function and low stroke output shown by reduced movements of the valves (Fig. 13.114, p. 793).

Hypertrophic cardiomyopathy (HCM) (Fig. 13.107, p. 790) shows that the left ventricle is typically small and hypertrophied, with a thickened, interventricular septum (asymmetric septal hypertrophy – ASH). There is a characteristic, displacement of the mitral valve apparatus towards the septum in systole (systolic anterior motion – SAM). Some patients have outflow tract or other LV obstruction and others have regional hypertrophy of other segments.

Restrictive cardiomyopathy shows the typical appearances of conditions such as amyloid, and LV diastolic function can be evaluated.

Pericardial effusion

Fluid in the pericardial cavity shows as an echo-free region between the myocardium and the intense echo of the parietal pericardium (Fig. 13.29). The most severe manifestation of pericardial effusion is tamponade, which is a clinical and not an echocardiographic diagnosis. The size of a pericardial effusion alone does not indicate tamponade. Echocardiographic features of haemodynamically significant effusions include marked (>25%) respiratory variation of tricuspid, aortic or mitral Doppler tracings. If the inferior vena cava is small and collapses with respiration, it is unlikely that the patient is in tamponade.

Masses within the heart

Echocardiography is a sensitive method for detecting masses within the heart (Fig. 13.104, p. 787), and their haemodynamic significance.

Ischaemic disease

Coronary arteries cannot be imaged adequately using echo techniques, but images may be useful for the diagnosis of complications related to myocardial infarction, such as mitral papillary muscle rupture, tamponade or ventricular septal rupture. The use of stress echocardiography to identify chronic coronary artery disease is discussed above (p. 702).

In the post-infarction period, echocardiography and Doppler are used to diagnose left ventricular aneurysm, left ventricular thrombus, mitral regurgitation and pericardial effusion as well as to assess left ventricular function (ejection fraction).

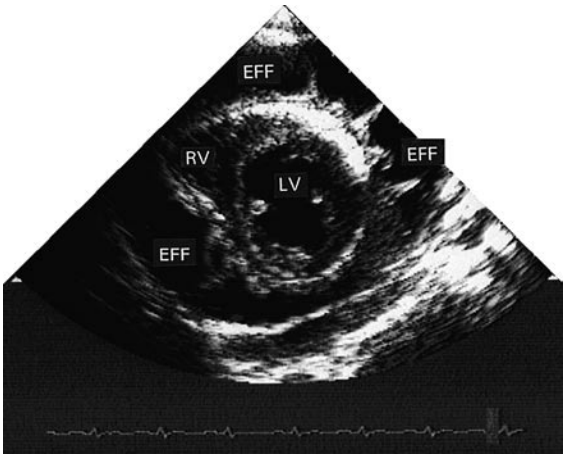

Fig. 13.29 **2-D Echocardiogram (short-axis view) from a patient with a large pericardial effusion** associated with pulmonary tuberculosis. The exudate is seen between the visceral and parietal layers of the pericardium and would give a false impression of cardiomegaly on a chest X-ray. Note the multiple fibrous strands within the effusion, showing that it is consolidating and will probably lead to constriction of cardiac function. LV, left ventricle; RV, right ventricle; EFF, effusion.

Congenital heart disease

Echocardiography has largely replaced cardiac catheterization and angiography. The aim of the examination is first to establish the sequence of blood flow through the heart, and to define anatomical abnormalities as well to evaluate the postoperative status of the operated congenital heart patients.

Contrast echo for LV opacification

Intravenous contrast agents opacify the left ventricle and can define the endocardial border. Their clinical utility has reduced with the advent of harmonic imaging, which has improved image quality in previously 'difficult to image' patients.

Intravascular (coronary) ultrasound

Intravascular (coronary) ultrasound probes can be used to image proximal coronary arteries as part of a percutaneous transluminal coronary angioplasty (PTCA) procedure, e.g. to assess for adequacy of deployment of intracoronary stents.

Nuclear imaging

Nuclear imaging is used to detect myocardial infarction or to measure myocardial function, perfusion or viability, depending on the radiopharmaceutical used and the technique of imaging. These data are particularly valuable when used in combination.

Image type

Gamma cameras produce a planar image in which structures are superimposed as in a standard radiograph. Single-photon-emission computed tomography (SPECT) imaging uses similar raw data to construct tomographic images, just as a CT image is reconstructed from X-rays. This gives finer anatomical resolution, but is technically demanding. These methods may be used with any of the radiopharmaceuticals.

Myocardial perfusion and viability

Thallium-201 is rapidly taken up by the myocardium, so an image taken immediately after injection reflects the distribution of blood flow to the myocardium. Areas of ischaemia or infarction receive less ^{201}Tl and appear dark. Between 2 and 24 hours after injection, ^{201}Tl is redistributed so that all cardiac myocytes contain a comparable concentration. Images at this time show dark areas where the myocardium has infarcted, but normal density in ischaemic areas. Comparison of the early and late images is one method of predicting whether an ischaemic area of myocardium contains enough viable tissue to justify coronary bypass or angioplasty.

Technetium-99-labelled tetrofosmin (Fig. 13.30) is also taken up rapidly by cardiac myocytes, but does not undergo redistribution. When this substance is injected during exercise, its distribution in the myocardium reflects the distribution of blood at the time of the exercise, even if the image is taken several hours later. This is a sensitive method of detecting myocardial viability. Images produced following injection of [^{99m}Tc]tetrofosmin during exercise can be compared to images produced following injection at rest to decide which areas of ischaemia are reversible (p. 740). In patients unable to exercise, the heart can be stressed with drugs, e.g. dipyridamole or dobutamine.

Infarct imaging

Perfusion images produced using compounds labelled with ^{201}Tl or [^{99m}Tc]sestamibi show a myocardial infarction as a perfusion defect or 'cold spot'. These methods are sensitive for detecting and localizing the infarct, but give no information about its age. [^{99m}Tc]Pyrophosphate is preferentially taken up by myocardium which has undergone infarction within the previous few days. Images are difficult to interpret because the isotope is also concentrated by bone and cartilage.

Cardiac computed tomography

Computed tomography is useful for the assessment of the thoracic aorta and mediastinum. The development of 64-slice multidetector CT (MDCT) scanners has enabled accurate non-invasive imaging of the coronary arteries.

Coronary artery calcification

Calcium is absent in normal coronary arteries but is present in atherosclerosis and increases with age. Studies have

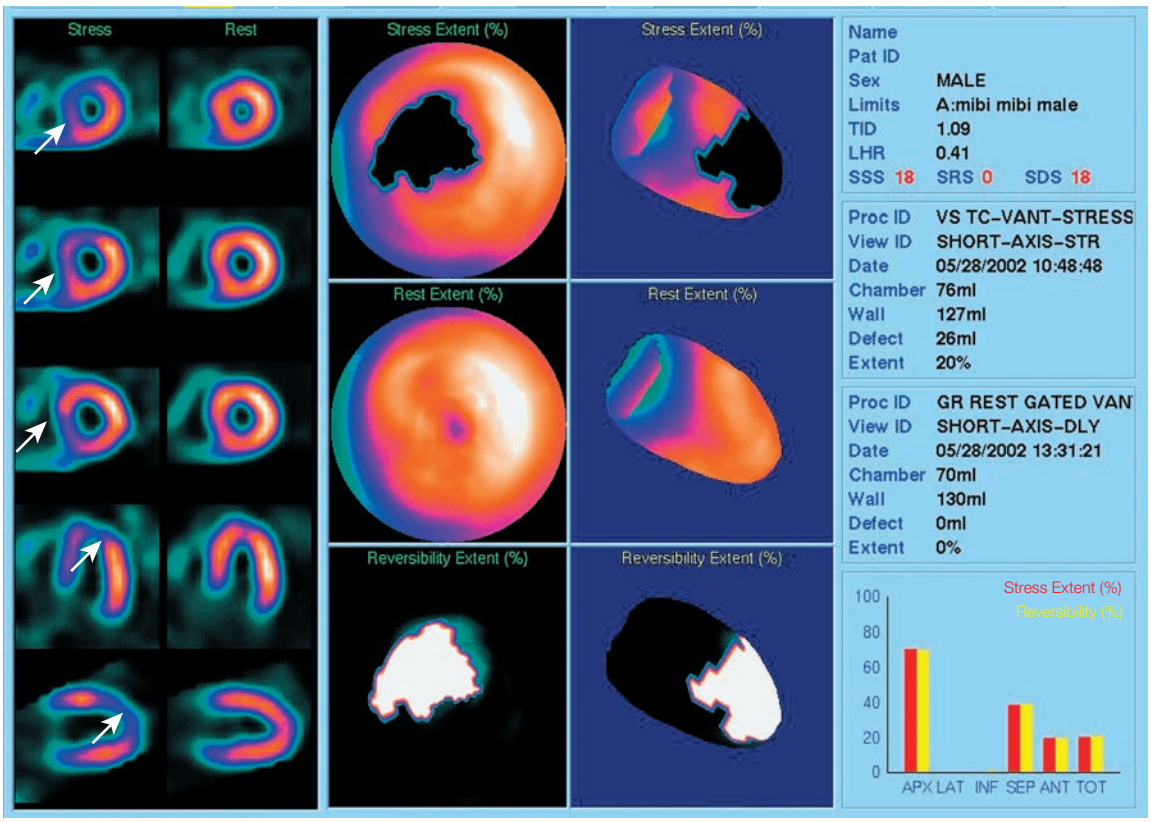

Fig. 13.30 **Myocardial SPECT study acquired with [^{99}Tc]tetrofosmin tracer.** Left panel – three short axis slices, a horizontal and a vertical axis plane of the left ventricle after stress and following a resting re-injection of tracer. The **rest** images demonstrate normal tracer uptake (orange signal) in the whole of the left ventricle. The **stress** images demonstrate reduced tracer uptake (arrows; purple–blue signal) in the anterior and septal walls consistent with a significant stenosis in the left anterior descending artery. Middle panel – polar maps of the whole myocardium can localize the ischaemic territory. Right panel – quantitative analysis can help define the extent and reversibility of the ischaemia.

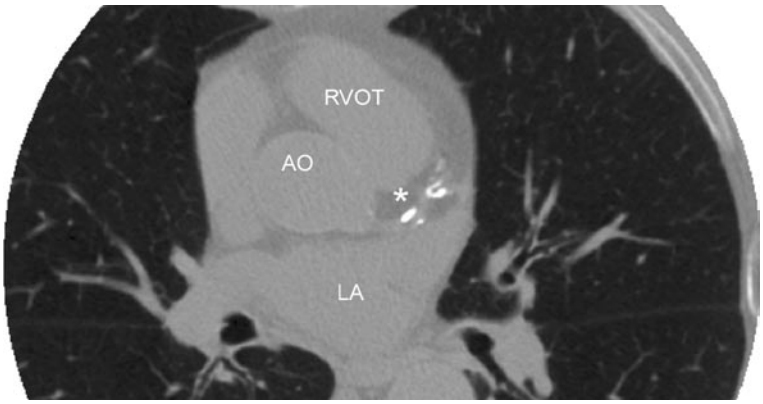

Fig. 13.31 **Multi-slice CT showing calcium deposits (*)** in the left main stem and left anterior descending coronary arteries. AO, aorta; LA, left atrium; RVOT, right ventricular outflow tract.

demonstrated a positive correlation between calcification and the presence of coronary artery stenoses, although the relationship is non-linear. Electron beam CT (EBT) and MDCT scanners are used to obtain multiple thin axial slices through the heart (Fig. 13.31) and then the calcium score is calculated. The calcium score is based on the X-ray attenuation coefficient or CT number measured in Hounsfield units. Meta-analyses have demonstrated that a higher calcium score is associated with higher event rate and higher relative risk ratios, although currently no study has shown a net effect on health outcomes of calcium scoring.

CT coronary angiography

CT coronary angiography (CTCA) is performed with a supine patient connected to a 3-lead ECG for cardiac synchronization. Sixty-four-slice MDCT scanners have a temporal resolution of 165–210 ms and image quality is optimal with a slow and steady heart rate (<65–70 b.p.m.), which can be obtained with the use of oral or intravenous beta-blockers. Sublingual nitroglycerin (0.4–0.8 mg dose) may improve visualization of the coronary artery lumen. A volume dataset containing the whole heart is acquired during a single breath-hold with the injection of 60–80 ml of iodinated contrast agent at 4–6 ml/s. The radiation dose during the scan is 11–22 mSv but this can be reduced to 7–11 mSv with ECG-controlled dose modulation; this compares to 2.5–5.0 mSv for diagnostic coronary angiography and 15–20 mSv for SPECT. The volume dataset is then analysed with multiplanar reformatting for the presence of coronary artery stenoses (Fig. 13.32). Recent studies have reported high sensitivity (>85%) and specificity (>90%) for the detection of coronary artery disease with a very high negative predictive value (>95%). CTCA may become part of an acute chest pain service in the emergency medicine department to exclude aortic dissection, pulmonary embolism and coronary artery disease.

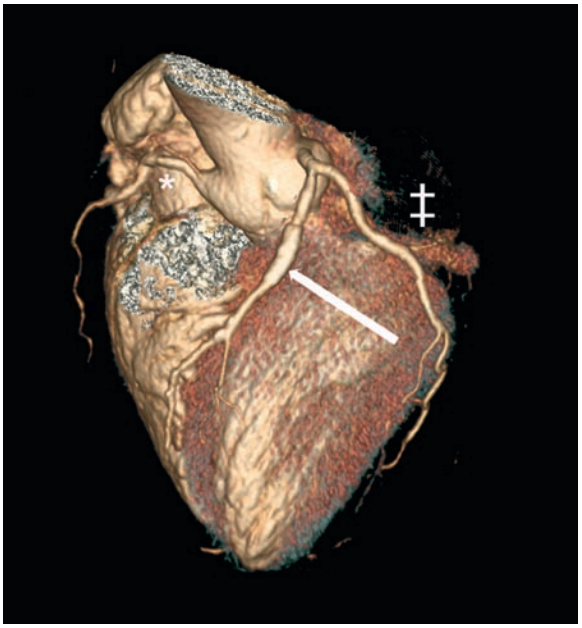

Fig. 13.32 **Multi-slice CT – volume rendered image in a patient with coronary artery stent insertion** (arrow) demonstrating a patent left anterior descending coronary artery with mild stenosis before the stent. The right (*) and the circumflex (++) coronary arteries are free from significant stenoses.

Cardiovascular magnetic resonance

Cardiovascular magnetic resonance (CMR), a non-invasive imaging technique that does not involve harmful radiation, is increasingly used in the investigation of patients with cardiovascular disease.

CMR is usually performed with multiple breath-holds to minimize respiratory motion artefacts and cardiac gating to reduce blurring during the cardiac cycle. Several different sequences are used to provide anatomical and functional information. Most sequences do not require a contrast agent but intravenous gadolinium may be required for magnetic resonance angiography, myocardial perfusion, infarct and fibrosis imaging. The major contraindications are permanent pacemaker or defibrillator, intracerebral clips and significant claustrophobia. Patients with coronary stents and prosthetic valves can be safely scanned.

Clinical use of CMR

The current indications for CMR are summarized in Table 13.6.

Congenital heart disease

CMR provides additional and complementary information to echocardiography in patients with congenital heart disease.

www.studentconsult.com
Ask the authors

Ciné imaging can accurately assess systemic and non-systemic ventricular function and mass. Extra-cardiac conduits, anomalous pulmonary venous return and aortic coarctations pre- and post-repair can be studied by CMR and the studies repeated for long-term follow-up without the risk of ionizing radiation.

Cardiomyopathies, pericardial disease and cardiac masses

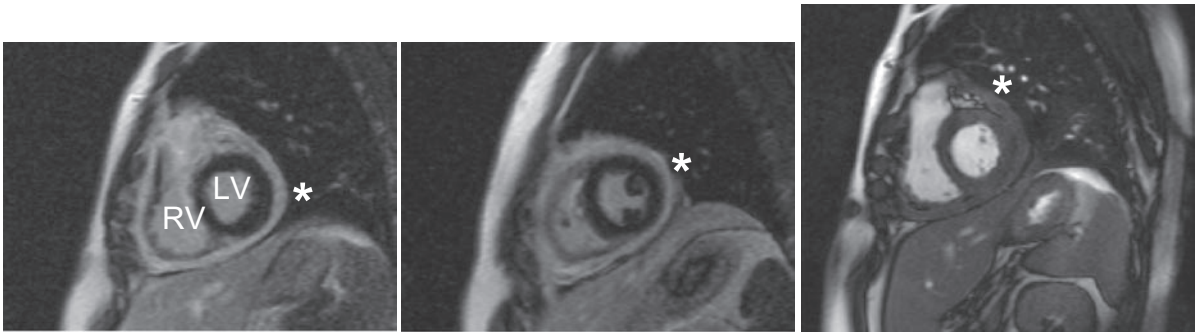
In hypertrophic cardiomyopathy CMR accurately defines the extent and distribution of myocardial hypertrophy and can be used in patients with sub-optimal echocardiograms. Intravenous gadolinium can be used to demonstrate regional myocardial fibrosis which is associated with an adverse prognosis. In patients with suspected arrhythmogenic right ventricular cardiomyopathy, CMR is the imaging investigation of choice to detect global and regional wall motion abnormalities of the right ventricle and right ventricular outflow tract, and to detect fatty or fibro-fatty infiltration of the right and left ventricles. In constrictive pericarditis and restrictive cardiomyopathy CMR can demonstrate the effects of the impaired ventricular filling common to both conditions (dilated right atrium and inferior vena cava), but can also determine the thickness of the pericardium (usually 4 mm in normal individuals) (Fig. 13.33). In patients with dilated cardiomyopathy CMR can accurately quantify bi-ventricular function and with gadolinium can demonstrate myocardial fibrosis. In inflammatory and infiltrative conditions of the myocardium, such as myocarditis, sarcoidosis and amyloidosis, CMR is increasingly used as a diagnostic investigation due to different patterns of signal enhancement seen with gadolinium. In patients with thalassaemia, CMR can detect iron deposition within the myocardium and guide chelation therapy. CMR can be useful in patients with cardiac masses to differentiate benign from malignant tumours and to identify thrombus not visualized on echocardiography.

Table 13.6 Cardiovascular magnetic resonance (CMR)

Indications

1. Congenital heart disease (CHD):
   - anatomical assessment following echocardiography, particularly in patients with complex CHD or following surgical intervention
   - follow-up/surveillance studies
   - anomalous pulmonary or systemic venous return
   - assessment of right or left ventricular function/dilatation
2. Cardiomyopathies/cardiac infiltration/pericardial disease
3. Disease of the aorta, including aortic dissection, aneurysm, coarctation
4. Valvular heart disease:
   - quantification of stenosis and regurgitation
   - accurate ventricular dimensions/function
   - planimetry of valvular stenosis
5. Coronary artery disease:
   - left and right ventricular function
   - wall motion assessment during dobutamine stress
   - myocardial perfusion during adenosine stress
   - coronary artery and coronary artery bypass graft imaging
   - myocardial infarct imaging and viability assessment with dobutamine CMR or delayed enhancement
6. Pulmonary vessels

Diseases of the aorta



CMR is an excellent technique for assessing patients with aortic dissection and can detect the clinical features of an aortic dissection; the intimal flap, thrombosis in a false lumen, aortic regurgitation, pericardial effusion and aortic dilatation. As it does not involve radiation or need contrast, CMR is an ideal method of surveillance of patients with dilated thoracic aortas or repaired coarctation.

Valvular heart disease

Valvular stenosis produces signal void on gradient-echo CMR. CMR can quantify the velocity across a stenosed valve using phase-contrast velocity mapping. Valvular regurgitation can be accurately quantified using phase-contrast velocity mapping across the valve, or by calculating the stroke volumes of the left and right ventricle which are equal in the absence of significant regurgitation. However, in most patients, transthoracic and transoesophageal echocardiography should provide sufficient information.

Coronary artery disease

CMR can be used to assess coronary artery anatomy, left ventricular function, myocardial perfusion and viability in a 'one-stop' approach to the assessment of patients with coronary artery disease. Coronary artery anatomy and

(a) (b) (c)

Fig. 13.33 **Short-axis cardiac magnetic resonance (CMR) in a patient with constrictive pericarditis.** The pericardium is thickened (*) and on **ciné imaging (c)** there is septal bounce. LV, left ventricle; RV, right ventricle.

stenoses can be identified with ultra-fast breath-hold or respiratory-gated sequences with high accuracies. Global left ventricular function and wall motion abnormalities can be detected with ciné imaging performed at rest and during dobutamine stress. Myocardial perfusion can be assessed with gadolinium and first-pass imaging; ischaemia can be demonstrated with adenosine for coronary vasodilatation. Myocardial viability can be determined using gadolinium and 'delayed enhancement' images. With these techniques CMR is increasingly used both for the assessment of ischaemia in patients with suspected coronary disease and to assess myocardial viability prior to revascularization in patients with impaired cardiac function (Figs 13.34 and 13.35).

Pulmonary vessels

Magnetic resonance angiography with gadolinium can provide high quality images of the pulmonary veins which can be fused with electrical data during pulmonary vein isolation for the treatment of atrial fibrillation.

Positron emission tomography (PET)

This is a technique based on detection of high-energy emissions caused by annihilation of positrons released from unstable isotopes. There are several advantages of PET over other techniques, e.g. improved spatial resolution, accurate quantification, the use of biological isotopes of carbon, nitrogen and oxygen. However, PET is expensive and requires a cyclotron to produce the short-lived tracers. PET has become a useful investigation in the detection of viable myocardium in patients who are suitable for revascularization.

Myocardial perfusion and ischaemia can be determined using PET with ^{13}N-ammonia or oxygen-15 with greater sensitivity than SPECT. Myocardial metabolism and viability can be detected with the use of ^{18}F-fluorodeoxyglucose (FDG), which the cardiac myocyte utilizes for energy production in the presence of reduced oxygen supply and blood flow. There may be reduced perfusion to infarcted or fibrotic myocardium, but also reduced FDG uptake. In hibernating myocardium, with viable but dysfunctional myocardium, PET can demonstrate reduced myocardial perfusion but with preserved or increased FDG uptake.

Cardiac catheterization

Cardiac catheterization is the introduction of a thin radio-opaque tube (catheter) into the circulation. The right heart is catheterized by introducing the catheter into a peripheral vein (usually the right femoral or internal jugular vein) and advancing it through the right atrium and ventricle into the pulmonary artery. The pressures in the right heart chambers, and pulmonary artery can be measured directly. An indirect measure of left atrial pressure can be obtained by 'wedging' a catheter into the distal pulmonary artery (p. 902). In this position the pressure from the right ventricle is obstructed by the catheter and only the pulmonary venous and left atrial pressures are recorded.

Left heart catheterization is usually performed via the right femoral artery, although the brachial and radial arteries are sometimes used in patients with significant peripheral vascular disease. A pigtail catheter is advanced up the aorta and manipulated through the aortic valve into the left ventricle. Pressure tracings are taken from the left ventricular cavity. The end-diastolic pressure is invariably elevated in patients with left ventricular dysfunction. A power injection of radio-opaque contrast material is used to opacify the left ventricular cavity (left ventriculography) and thereby assesses left ventricular systolic function. The catheter is then withdrawn across the aortic valve into the aorta and the 'pullback' gradient across the valve is measured.

Aortography (a power injection into the aortic root) can be performed to assess the aortic root and the presence and severity of aortic regurgitation.

Specially designed catheters are then used to selectively engage the left and right coronary arteries, and contrast ciné-angiograms are taken in order to define the coronary circulation and identify the presence and severity of any coronary artery disease. Coronary angiography is described further on page 749.

During cardiac catheterization, blood samples may be withdrawn to measure the concentration of ischaemic metabolites (e.g. lactate) and the oxygen content. These estimations are used to gauge ischaemia, quantify intracardiac shunts and measure cardiac output.

Digital subtraction angiography

This technique permits the injection of small volumes of radio-contrast agents during cardiac catheterization with the production of computer-analysed high-quality angiograms.

Unfortunately, peripheral injection of contrast does not give adequate visualization of the coronary arteries, but aortic lesions can be visualized.

THERAPEUTIC PROCEDURES

Cardiac resuscitation

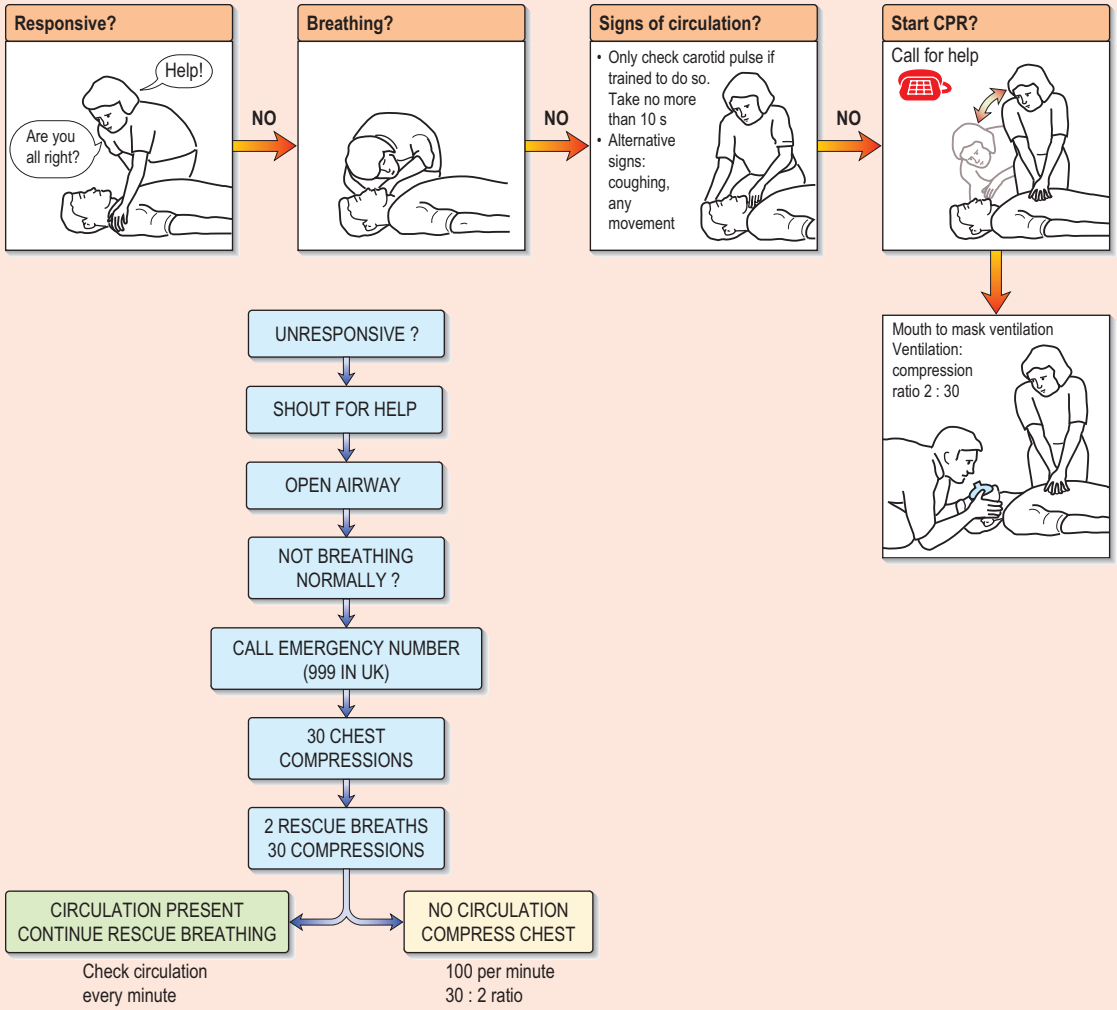
When cardiac arrest occurs, basic life support must be started immediately. The longer the period of respiratory and circulatory arrest, the lower is the chance of restoring healthy life. After 3 minutes, irreversible anoxic cerebral damage occurs.

All healthcare professionals should be familiar with basic procedures. Organization and teamwork are essential to a successful outcome. Cardiac massage alone by bystanders is the preferable approach to resuscitation for adult patients with witnessed out-of-hospital cardiac arrest.

Basic life support (BLS)

The first step is to ensure the safety of the victim and rescuer. The next is to ascertain that the victim is unresponsive by shaking him/her and shouting into one ear. If no response is obtained, help should be sought immediately prior to commencement of basic life support. If the likely cause of the unconsciousness is due to a breathing problem (e.g. trauma, drowning, choking, drug/alcohol intoxication or if the victim is an infant or child) then the rescuer should perform resuscitation for about 1 minute before going for help. Basic life support is easily remembered as A (airway), B (breathing) and C (circulation) (Emergency box 13.1).

Airway



Debris (e.g. blood and mucus) in the mouth and pharynx should be removed. Loose or ill-fitting dentures should be removed. The airway should be opened gently by flexing the neck and extending the head ('sniffing the morning air' position). This manoeuvre is not recommended if a cervical spine injury is suspected. Any obstruction deep in the oral cavity or upper respiratory tract may require abdominal and/or chest thrusts (Heimlich manoeuvre, p. 834).

Breathing

Once a clear airway has been established the victim's breathing should be assessed by the 'look, listen and feel' method. By placing a cheek close to the victim's mouth, breath can be felt and breath sounds can be heard, and

Emergency Box 13.1

Basic life support

Send or go for help as soon as possible according to guidelines

the rise and fall of the chest and abdomen observed. If there is no evidence of breathing, expired air ventilation should be commenced.

With the head of the victim tilted backwards (*head tilt*), the chin pulled forward (*chin lift*) or (*jaw thrust*) and the nostrils pinched firmly, the rescuer takes a deep breath and seals his/her lips around the mouth of the victim. Two effective breaths are given over 1 second each. Expired air respiration is the only method of artificial respiration that successfully ventilates the patient. If resistance to these puffs is experienced, the airway needs to be reassessed and/or the head tilt and jaw lift corrected.

If the rescuer feels reluctant to give mouth-to-mouth resuscitation because of safety concerns (e.g. potentially infective material such as blood or vomitus in the oropharynx) it is acceptable to perform chest compressions alone, or to use a mouth piece if available.

Circulation

Cardiac arrest is accompanied by circulatory collapse. Absence of the carotid pulse confirms this and should be assessed for at least 10 seconds by someone trained to do so. The carotid pulse lies lateral and posterior to the thyroid cartilage and medial to the medial border of sternocleidomastoid: it can sometimes be difficult to palpate.

If absent, the circulation is best re-established by external chest compression. The heel of one hand is placed over the centre of the chest and the heel of the second hand is placed over the first with the fingers interlocked. The arms are kept straight and the sternum is rhythmically depressed by 2–5 cm at a rate of approximately 100 per minute. Chest compressions do not massage the heart. The thorax acts as a pump and the heart provides a system of one-way valves to ensure forward circulation. Respiratory and circulatory support is continued by providing two effective breaths for

every 30 cardiac compressions (30:2 for one or two persons).

It is better to give compressions without interruption. This maintains adequate cerebral and coronary perfusion pressures. There is evidence to suggest that if the person performing compressions tires, the quality of resuscitation deteriorates.

Advanced cardiac life support

By the time effective life support has been established, more help should have arrived and advanced cardiac life support can begin. This consists of ECG monitoring, endotracheal intubation and setting up an intravenous infusion in a large peripheral or central vein. Immediate therapy includes defibrillation, oxygen and cardioactive drugs. It is not possible to recommend an exact sequence of management because it will depend on the arrival of skilled personnel and equipment, and the nature of the cardiac arrest.

As soon as possible the cardiac rhythm should be established. At first this is easily achieved by monitoring the ECG through the paddles of a defibrillator. Later, ECG monitoring can be set up. If the ECG shows ventricular fibrillation or if there is any doubt as to the nature of the rhythm (e.g. 'fine' ventricular fibrillation may be confused with asystole), no time should be lost before defibrillating the patient (<2 minutes in hospital). If initial defibrillation attempts are unsuccessful, time can then be spent intubating the patient and setting up an intravenous infusion whilst the circulation is supported by external chest compression.

If there is any difficulty in intubating the patient, ventilation should be continued by means of an airway, a ventilating bag and oxygen. Intravenous epinephrine (adrenaline) results in vasoconstriction and increases the proportion of the cardiac output delivered to the brain.

Causes of unexpected cardiac arrest

Each year in the UK there are approximately 100 000 unexpected deaths occurring within 24 hours of the development of cardiac symptoms. About half of these deaths are almost instantaneous. There are several causes (Table 13.7).

Most deaths are due to ventricular fibrillation or rapid ventricular tachycardia, and a small proportion are due to severe bradyarrhythmias. Coronary artery disease accounts for approximately 80% of sudden cardiac deaths in western society. Transient ischaemia is suspected as the major trigger factor; however, only a small proportion of survivors have clinical evidence of acute myocardial infarction.

There are two mechanisms of sudden unexpected cardiac arrest:

- ventricular fibrillation or pulseless ventricular tachycardia (VF/VT)
- non-VF/VT (asystole and pulseless electrical activity also known as electromechanical dissociation).

Table 13.7 Causes of unexpected cardiac arrest

Cardiac arrhythmias (e.g. ventricular fibrillation)
Sudden pump failure (e.g. acute myocardial infarction)
Acute circulatory obstruction (e.g. pulmonary embolism)
Cardiovascular rupture (e.g. aortic dissection, myocardial rupture)
Vasomotor collapse (e.g. in pulmonary hypertension)

The principal difference in the management of these two groups of arrhythmias is the need for attempted defibrillation in those patients with VF/VT (Fig. 13.36).

Three-quarters of arrests are due to ventricular fibrillation or rapid ventricular tachycardia. Only a very small proportion are due to pulseless electrical activity. The remainder are due to asystole. An agonal rhythm is characterized by an inexorable slowing and widening of the QRS complexes associated with falling blood pressure and cardiac output. This type of arrhythmia is very difficult to reverse and usually no attempt should be made because it is the result rather than the cause of death.

Arrests are treated in the following ways:

- Ventricular fibrillation or pulseless ventricular tachycardia is readily treated with IMMEDIATE defibrillation, cardiopulmonary resuscitation (CPR) and drugs. Intravenous amiodarone is the first-line drug in refractory VF/pulseless VT.
- Asystole is more difficult to treat but the heart may respond to atropine or epinephrine (adrenaline). More recently vasopressin has been shown to be successful. If there is any sign of slow electromechanical activity (e.g. bradycardia with a weak pulse), emergency pacing should be used.
- Pulseless electrical activity: several potentially reversible causes are listed in the universal algorithm (Fig. 13.36). It carries a very poor prognosis. Effective treatment involves addressing the underlying cause.

Figure 13.36 shows the treatments recommended by the European Resuscitation Council and the Resuscitation Council UK.

Defibrillation

This technique is used to convert ventricular fibrillation to sinus rhythm. When the defibrillator is discharged, a high-voltage field envelopes the heart which depolarizes the myocardium and allows an organized heart rhythm to emerge. Electrical energy is discharged through two paddles placed on the chest wall.

The paddles are placed in one of two positions:

- One paddle is placed to the right of the upper sternum and the other over the cardiac apex.
- One paddle is placed under the tip of the left scapula and the other is placed over the anterior wall of the left chest.

Electrode jelly or electrolyte gel pads should be used to ensure good contact between the electrode paddles and the skin. Jelly smeared carelessly across the chest may cause short-circuits and arcing of the charge. All personnel should stand clear of the patient. The person performing defibrillation has the responsibility for ensuring the safety of the patient and other people present.

Conventional defibrillators employ a damped monophasic waveform. Biphasic defibrillators which require less energy are increasingly common. Automated external defibrillators (AEDs) which recognize ventricular fibrillation automatically deliver a shock if indicated. These are available in some public places. It is the responsibility of all healthcare practitioners to be familiar with the range of defibrillators they may be called on to use in their workplace.

Post resuscitation – therapeutic hypothermia

Recent studies have supported the use of therapeutic hypothermia in unconscious adult patients with spontaneous circulation after an out-of-hospital cardiac arrest due to ventricular fibrillation. These patients should be cooled with careful temperature monitoring to 32–34°C for 12–24 hours. External cooling methods include the use of cooling blankets; ice packs to the groin, axillae and neck; wet towels; and a cooling helmet. Invasive methods include intravenous infusions and peritoneal and pleural lavage. Shivering should be prevented by the use of a neuromuscular blocker and sedation to reduce oxygen consumption.

DC-cardioversion (DCC)

Tachyarrhythmias that do not respond to medical treatment or that are associated with haemodynamic compromise (e.g. hypotension, worsening heart failure) may be converted to sinus rhythm by the use of a transthoracic electric shock. A short-acting general anaesthetic is used. Muscle relaxants are not usually given.

When the arrhythmia has definite QRS complexes, the delivery of the shock should be timed to occur with the downstroke of the QRS complex (synchronization) (Fig. 13.37). The machine being used to perform the cardioversion

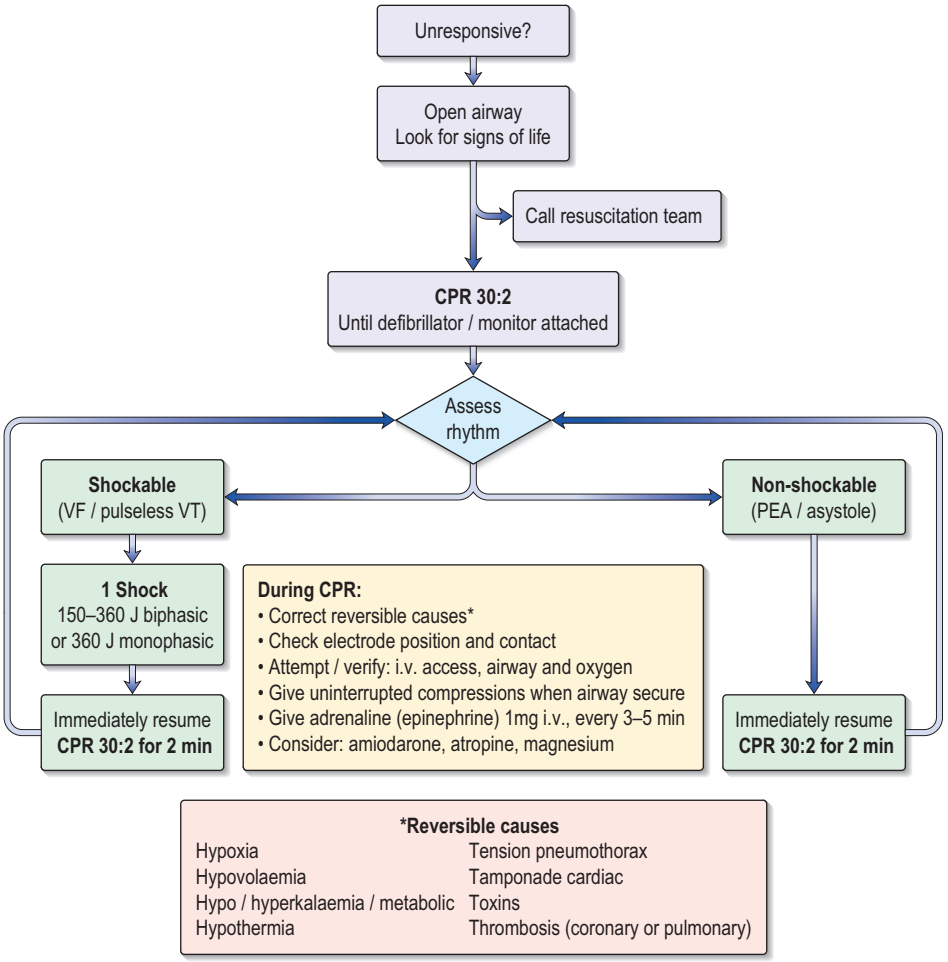


Fig. 13.36 **Adult advanced life support algorithm**. CPR, cardiopulmonary resuscitation; PEA, pulseless electrical activity; VF, ventricular fibrillation. Reproduced with permission from the Resuscitation Council http://www.resus.org.uk/siteindex.htm

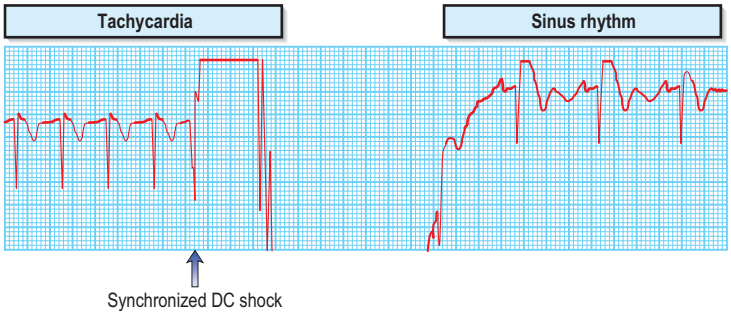

Fig. 13.37 **DC-cardioversion of a supraventricular tachycardia to sinus rhythm**. The direct current shock is delivered synchronously with the QRS complex.

will do this automatically if the appropriate button is pressed. There is a crucial difference between defibrillation and cardioversion: a non-synchronized shock is used to defibrillate. Accidental defibrillation of a patient who does not require it may itself precipitate ventricular fibrillation.

Typical indications for DCC include:

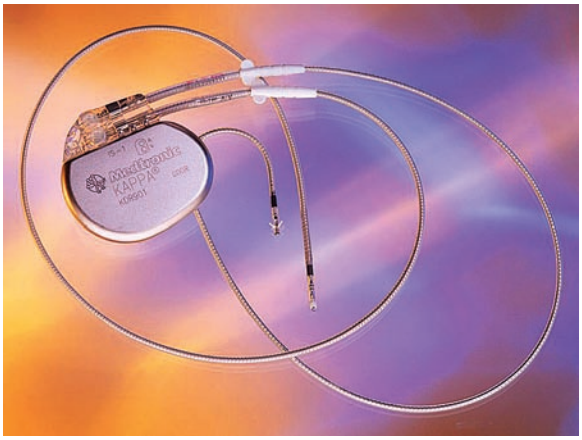
- atrial fibrillation
- atrial flutter
- sustained ventricular tachycardia
- junctional tachyarrhythmias.

If atrial fibrillation or flutter has been present for more than a few days, it is necessary to anticoagulate the patient adequately for 3 weeks before elective cardioversion to reduce the risk of embolization. The duration of anticoagulation after successful cardioversion for atrial fibrillation is a complex issue and depends on a number of factors: it should be for at least 4 weeks after the procedure and may well be for much longer.

Digoxin toxicity may lead to ventricular arrhythmias or asystole following cardioversion. Therapeutic digitalization does not increase the risks of cardioversion, but it is conventional to omit digoxin several days prior to elective cardioversion in order to be sure that toxicity is not present.

Cardiac enzyme levels may rise after a cardioversion.

Temporary pacing



Therapeutic cardiac pacing is employed in any patient with sustained symptomatic or haemodynamically compromising bradycardia. Bradycardias may be due to either a slow intrinsic heart rate (e.g. sinus node dysfunction) or atrioventricular block. Prophylactic cardiac pacing is employed in asymptomatic patients with either bradycardia or conduction abnormalities in whom the risk of progression to symptomatic bradycardia justifies such a strategy.

Transvenous pacing is the preferred method in patients with symptomatic bradycardias. In summary, a thin (French gauge 5 or 6), bipolar pacing electrode wire is inserted via an internal jugular vein, a femoral vein or a subclavian vein and is positioned at the right ventricular apex using cardiac fluoroscopy. The energy needed for successful pacing (the pacing threshold) is assessed by reducing the energy until the pacemaker fails to stimulate the tissue (loss of capture). The output energy is then set at three times the threshold value to prevent inadvertent loss of capture. If the threshold increases above 5 V, the pacemaker wire should be resited. A temporary pacemaker unit (Fig. 13.38a) is almost always set to work 'on demand' – to fire only when a spontaneous beat has not occurred. The rate of temporary pacing is usually 60–80 per minute.

Transcutaneous pacing is the preferred method in selected patients with asymptomatic bradycardia or conduction abnormalities and may be life-saving for patients in whom a cardiac arrest is precipitated by bradycardia. In this method the myocardium is depolarized by current flow between two large adhesive electrodes positioned anteriorly and posteriorly on the chest wall. Transcutaneous pacing is uncomfortable for the conscious patient. However, it can usually be tolerated until a temporary transvenous pacemaker is inserted.

(a)

(b)

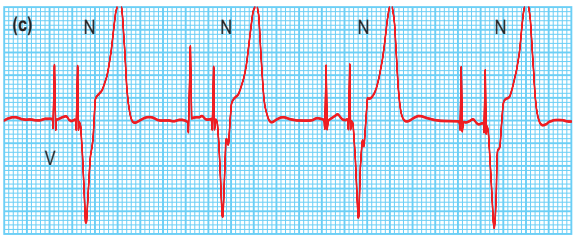


Fig. 13.38 **Pacemakers. (a)** A temporary pacemaker unit. **(b)** A permanent pacemaker with atrial (placed in the right atrium, usually in its high lateral wall) and ventricular (placed in the right ventricular apex) leads. **(c)** An electrocardiogram showing dual (atrial and ventricular) chamber pacing. A wide QRS complex results from abnormal activation of the ventricles from the right ventricular apex.

Permanent pacing

Permanent pacemakers are fully implanted in the body and connected to the heart by one or two electrode leads (Fig. 13.38b). The pacemaker is powered by solid-state lithium batteries, which usually last 5–10 years. Pacemakers are 'programmable' in that their operating characteristics (e.g. the pacing rate) can be changed by a programmer that transmits specific electromagnetic signals through the skin. The pacemaker leads are passed transvenously to the right heart chambers.

Pacemakers are designed to both pace and sense either the ventricles or the atria or more commonly both chambers. A single chamber ventricular pacemaker is described as a 'VVI' unit because it paces the ventricle (V), senses the ventricle (V) and is inhibited (I) by a spontaneous ventricular signal. Occasionally (e.g. in symptomatic sinus bradycardia), an atrial pacemaker (AAI) may be implanted. Pacemakers that are connected to both the right atrium and ventricle ('dual chamber' pacemakers) are used to simulate the natural pacemaker and activation sequence of the heart. This form of pacemaker is called DDD because it paces the two (dual) chambers, senses both (D) and reacts in two (D) ways – pacing in the same chamber is inhibited by spontaneous atrial and ventricular signals, and ventricular pacing is triggered by spontaneous atrial events (Fig. 13.38c).

In addition, pacemakers may be 'rate responsive' (R). A rate-responsive pacemaker detects motion (level of vibration or acceleration), respiration, or changes in QT interval, and by employing one or more biosensors, changes its rate of pacing so that it is appropriate to the level of exertion.

The choice of pacemaker mostly depends on the underlying rhythm abnormality and the general condition of the patient. For example, complete heart block in patients with sinus rhythm should be treated with a dual-chamber device in order to maintain AV synchrony, whereas inactive or infirm patients may not benefit from the most sophisticated units. Specialized biventricular pacemakers are used for the treatment of severe heart failure.

Permanent pacemakers are inserted under local anaesthetic using fluoroscopy to guide the insertion of the electrode leads via the cephalic or subclavian veins. Perioperative prophylactic antibiotics are routinely prescribed. The pacemaker is usually positioned subcutaneously in front of the pectoral muscle. Following surgery, which usually takes 60–90 minutes, the patient rests in bed for 6–12 hours before being discharged. Patients may not drive for at least 1 week after implantation, and must inform the licensing authorities and their motor insurers.

Complications are few but can prove to be very difficult to manage, and patients should be referred to the pacemaker clinic. They include the following:

- infection
- erosion
- pocket haematoma
- lead displacement
- electromagnetic interference.

Pericardiocentesis (Fig. 13.39)

A pericardial effusion is an accumulation of fluid between the parietal and visceral layers of pericardium. Fluid is removed to relieve symptoms that are due to haemodynamic embarrassment or for diagnostic purposes. This can be a technically difficult procedure, particularly in the acute setting. In an emergency it can be performed at the bedside.

Pericardial aspiration or pericardiocentesis is performed by inserting a needle into the pericardial space, usually via a subxiphisternal route under ultrasound guidance. Certain effusions, particularly posterior ones, require surgical drainage under a general anaesthetic. If a large volume of fluid is to be removed, a wide-bore needle and cannula are inserted. The needle may be removed and the cannula left in situ to drain the fluid. Fluid that is removed is sent for chemical analysis, microscopy, including cytology, Gram-stain and culture. If a reaccumulation of pericardial fluid is anticipated, the cannula may be left in place for several days, or an operation can be performed to cut a window in the parietal pericardium (fenestration) or to remove a large section of the pericardium.

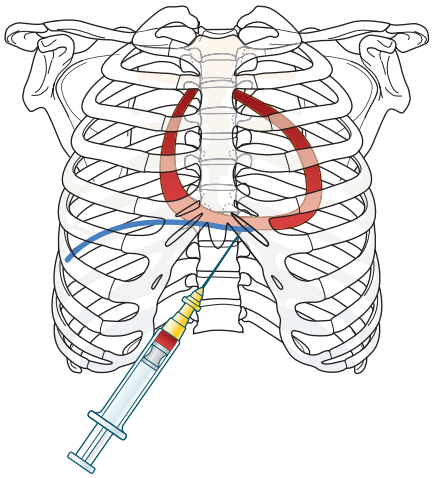

Fig. 13.39 **Schematic diagram of pericardiocentesis showing the site for insertion of the needle.**

Right-heart bedside catheterization (Fig. 15.18)

Bedside catheterization of the pulmonary artery with a pulmonary artery balloon flotation catheter (Swann–Ganz catheter) is performed in patients with:

- cardiac failure
- cardiogenic shock
- doubtful fluid status.

Intra-aortic balloon pumping

This is a technique used to assist temporarily the failing left ventricle. A catheter with a long sausage-shaped balloon at its tip is introduced percutaneously into the femoral artery and manipulated under X-ray control so that the balloon lies in the descending aorta just below the aortic arch (Fig. 13.40). The balloon is rhythmically deflated and inflated with carbon dioxide gas. Using the ECG or intra-aortic pressure changes, the inflation is timed to occur during ventricular diastole to increase diastolic aortic pressure and consequently to improve coronary and cerebral blood flow. During systole the balloon is deflated, resulting in a reduction in the resistance to left ventricular emptying. Intra-aortic balloon pumping is used for circulatory support in the following acute situations:

- *Acute heart failure.* Balloon pumping is used to improve cardiac output when there is a transient or reversible depression of left ventricular function, such as in a patient with severe mitral valve regurgitation who is awaiting surgical replacement of the mitral valve, or in a patient with a ventricular septal defect that is due to septal infarction. It may also be used to support patients awaiting heart transplantation.
- *Unstable angina pectoris.* Balloon pumping is used to treat unstable angina pectoris by improving coronary

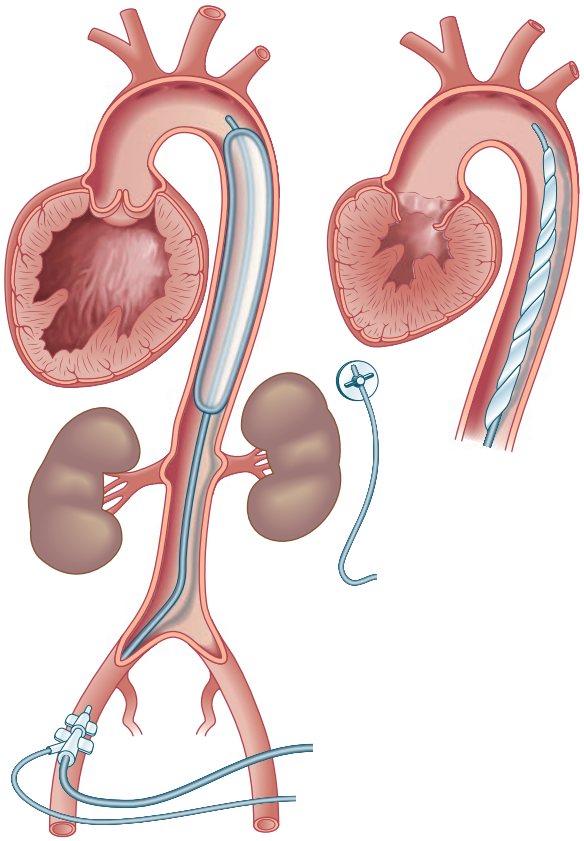

Fig. 13.40 **Intra-aortic balloon pump** – inflated in aorta on the left and deflated on the right.

flow and decreasing myocardial oxygen consumption by reducing the 'afterload'. This technique may be successful, even when medical therapy has failed. It is followed by early angiography and appropriate definitive therapy such as surgery or coronary angioplasty.

Balloon pumping should not be used when there is no remediable cause of cardiac dysfunction. It is also unsuitable in patients with severe aortic regurgitation, aortic dissection and severe peripheral vascular disease.

Complications of balloon pumping occur in about 20% of patients and include aortic dissection, leg ischaemia, emboli from the balloon and balloon rupture. Embolic complications are reduced by anticoagulation with heparin.

CARDIAC ARRHYTHMIAS

An abnormality of the cardiac rhythm is called a cardiac arrhythmia. Arrhythmias may cause sudden death, syncope, heart failure, chest pain, dizziness, palpitations or no symptoms at all. There are two main types of arrhythmia:

- bradycardia: the heart rate is slow (<60 b.p.m.)
- tachycardia: the heart rate is fast (>100 b.p.m.).

Tachycardias are more symptomatic when the arrhythmia is fast and sustained. Tachycardias are subdivided into supraventricular tachycardias, which arise from the atrium or the atrioventricular junction, and ventricular tachycardias, which arise from the ventricles.

Some arrhythmias occur in patients with apparently normal hearts, and in others arrhythmias originate from diseased tissue, such as scar, as a result of underlying structural heart disease. When myocardial function is poor, arrhythmias are more symptomatic and are potentially life-threatening.

SINUS NODE FUNCTION

The normal cardiac pacemaker is the sinus node (p. 681) and, like most cardiac tissue, it depolarizes spontaneously.

The rate of sinus node discharge is modulated by the autonomic nervous system. Normally the parasympathetic system predominates, resulting in slowing of the spontaneous discharge rate from approximately 100 to 70 b.p.m. A reduction of parasympathetic tone or an increase in sympathetic stimulation leads to tachycardia; conversely, increased parasympathetic tone and decreased sympathetic stimulation produces bradycardia. The sinus rate in women is slightly faster than in men. Normal sinus rhythm is characterized by P waves that are upright in leads I, and II of the ECG (Fig. 13.19, p. 696), but inverted in the cavity leads AVR and V1 (Fig. 13.41a).

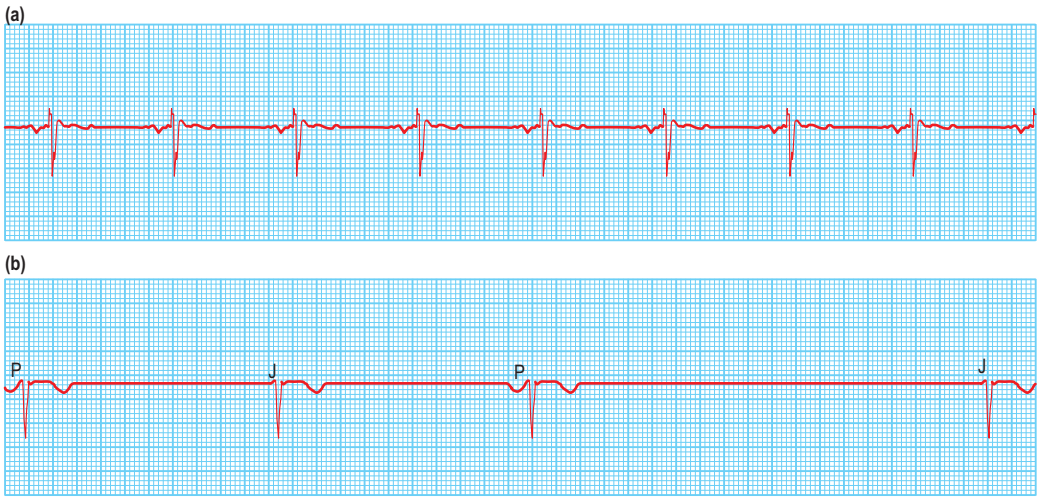

Fig. 13.41 **(a) An ECG showing normal sinus rhythm** (PR interval <0.2 s). P wave preceding each QRS complex. **(b) A patient with sick sinus syndrome**. This shows sinus arrest (only occasional sinus P waves) and junctional escape beats (J). P waves are inverted in the cavity leads that are shown here.

Sinus arrhythmia

Fluctuations of autonomic tone result in phasic changes of the sinus discharge rate. During inspiration, parasympathetic tone falls and the heart rate quickens, and on expiration the heart rate falls. This variation is normal, particularly in children and young adults. Typically sinus arrhythmia results in predictable irregularities of the pulse.

Sinus bradycardia

A sinus rate of less than 60 b.p.m. during the day or less than 50 b.p.m. at night is known as sinus bradycardia.

It is usually asymptomatic unless the rate is very slow. It is normal in athletes owing to increased vagal tone. Other causes may be divided into systemic or cardiac and are discussed below in the section entitled 'Bradycardias and heart block' (see p. 717).

Sinus tachycardia

Sinus rate acceleration to more than 100 b.p.m. is known as sinus tachycardia. Again, causes may be divided into systemic or cardiac and are discussed below in the section entitled 'Supraventricular tachycardias' (p. 720).

Mechanisms of arrhythmia production

Abnormalities of automaticity, which could arise from a single cell, and abnormalities of conduction, which require abnormal interaction between cells, account for both bradycardia and tachycardia. Sinus bradycardia is a result of abnormally slow automaticity while bradycardia due to AV block is caused by abnormal conduction within the AV node or the intraventricular conduction system. The mechanisms generating tachycardia are shown in Figure 13.42.

Accelerated automaticity (Fig. 13.42a)

The normal mechanism of spontaneous cardiac rhythmicity is slow depolarization of the transmembrane voltage during diastole until the threshold potential is reached and the action potential of the pacemaker cells takes off. This mechanism may be accelerated by increasing the rate of diastolic depolarization or changing the threshold potential. For example, sympathetic stimulation releases epinephrine (adrenaline), which enhances automaticity. Abnormal automaticity can occur in virtually all cardiac tissues and may initiate arrhythmias. Such changes are thought to produce sinus tachycardia, escape rhythms and accelerated AV nodal (junctional) rhythms.

Triggered activity (Fig. 13.42b)

Myocardial damage can result in oscillations of the transmembrane potential at the end of the action potential. These oscillations, which are called 'after depolarizations', may reach threshold potential and produce an arrhythmia. If they occur before the transmembrane potential reaches its threshold (at the end of phase 3 of the action potential), they are called 'early after depolarizations' (E in Fig. 13.42b). When they develop after the transmembrane potential is completed, they are called 'delayed after depolarizations' (D in the figure).

The abnormal oscillations can be exaggerated by pacing, catecholamines, electrolyte disturbances, hypoxia, acidosis and some medications, which may then trigger arrhythmia. The atrial tachycardias produced by digoxin toxicity are due to triggered activity. The initiation of ventricular arrhythmia in the long QT syndrome (p. 727) may be caused by this mechanism.

Re-entry (or circus movements) (Fig. 13.42c)

The mechanism of re-entry occurs when a 'ring' of cardiac tissue surrounds an inexcitable core (e.g. in a region of scarred myocardium). Tachycardia is initiated if an ectopic beat finds one limb refractory (α), resulting in unidirectional block, and the other limb excitable. Provided conduction through the excitable limb (β) is slow enough, the other limb (α) will have recovered and will allow retrograde activation to complete the re-entry loop. If the time to conduct around the ring is longer than the recovery times (refractory periods) of the tissue within the ring, circus movement will be main-

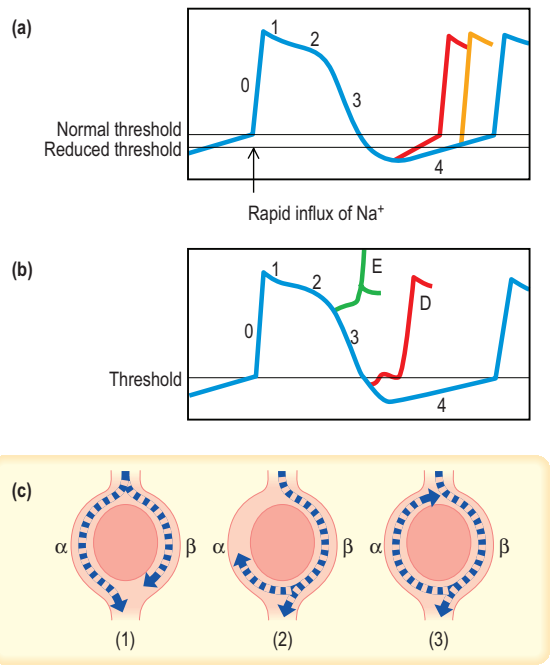

Fig. 13.42 **Mechanisms of arrhythmogenesis. (a and b) Action potentials** (i.e. the potential difference between intracellular and extracellular fluid) of ventricular myocardium after stimulation. **(a) Increased (accelerated) automaticity** due to reduced threshold potential or an increased slope of phase 4 depolarization (see p. 694). **(b) Triggered activity** due to early (E) or delayed (D) 'after depolarizations' reaching threshold potential. **(c) Mechanism of circus movement or re-entry.** In panel (1) the impulse passes down both limbs of the potential tachycardia circuit. In panel (2) the impulse is blocked in one pathway (α) but proceeds slowly down pathway β, returning along pathway α until it collides with refractory tissue. In panel (3) the impulse travels so slowly along pathway β that it can return along pathway α and complete the re-entry circuit, producing a circus movement tachycardia.

tained, producing a run of tachycardia. The majority of regular paroxysmal tachycardias are produced by this mechanism.

BRADYCARDIAS AND HEART BLOCK

Bradycardias may be due to failure of impulse formation (sinus bradycardia) or failure of impulse conduction from the atria to the ventricles (atrioventricular block).

Bradycardia

Sinus bradycardia

Sinus bradycardia is due to extrinsic factors influencing a relatively normal sinus node or due to intrinsic sinus node disease. The mechanism can be acute and reversible or chronic and degenerative. Common causes of sinus bradycardia include:

Extrinsic causes

- hypothermia, hypothyroidism, cholestatic jaundice and raised intracranial pressure
- drug therapy with beta-blockers, digitalis and other antiarrhythmic drugs
- neurally mediated syndromes (see below).

Intrinsic causes

- acute ischaemia and infarction of the sinus node (as a complication of acute myocardial infarction)
- chronic degenerative changes such as fibrosis of the atrium and sinus node (sick sinus syndrome).

Sick sinus syndrome or *sinoatrial disease* is usually caused by idiopathic fibrosis of the sinus node. Other causes of fibrosis such as ischaemic heart disease, cardiomyopathy or myocarditis can also cause the syndrome. Patients develop episodes of sinus bradycardia or sinus arrest (Fig. 13.41b) and commonly, owing to diffuse atrial disease, experience paroxysmal atrial tachyarrhythmias (tachy-brady syndrome).

Neurally mediated syndromes

Neurally mediated syndromes are due to a reflex (called Bezold–Jarisch) that may result in both bradycardia (sinus bradycardia, sinus arrest and AV block) and reflex peripheral vasodilatation. These syndromes usually present as syncope or pre-syncope (dizzy spells).

Carotid sinus syndrome occurs in the elderly and mainly results in bradycardia. Syncope occurs (see p. 689).

Neurocardiogenic (*vasovagal*) *syncope* (*syndrome*) usually presents in young adults but may present for the first time in elderly patients. It results from a variety of situations (physical and emotional) that affect the autonomic nervous system. The efferent output may be predominantly bradycardic, predominantly vasodilatory or mixed.

Postural orthostatic tachycardia syndrome (*POTS*) is a sudden and significant increase in heart rate associated with normal or mildly reduced blood pressure produced by standing. The underlying mechanism is a failure of the peripheral vasculature to appropriately constrict in response to orthostatic stress, which is compensated by an excessive increase in heart rate.

Many medications, such as antihypertensives, tricyclic antidepressants and neuroleptics can be the cause of syncope, particularly in the elderly. Careful dose titration and avoidance of combining two agents with potential to cause syncope help to prevent iatrogenic syncope.

Treatment

The management of sinus bradycardia is first to identify and if possible remove any extrinsic causes. Temporary pacing may be employed in patients with reversible causes until a normal sinus rate is restored and in patients with chronic degenerative conditions until a permanent pacemaker is implanted.

Chronic symptomatic sick sinus syndrome requires permanent pacing (DDD), with additional antiarrhythmic drugs (or ablation therapy) to manage any tachycardia element. Thromboembolism is common in tachy-brady syndrome and patients should be anticoagulated unless there is a contraindication.

Patients with carotid sinus hypersensitivity (asystole >3 s), especially if symptoms are reproduced by carotid sinus massage, and in whom life-threatening causes of syncope have been excluded, benefit from pacemaker implantation.

Treatment options in vasovagal attacks include avoidance, if possible, of situations known to cause syncope in a particular patient. Increased salt intake, compression of the lower legs with hose and drugs such as beta-blockers, alpha-agonists or myocardial negative inotropes (such as disopyramide) may be helpful. In selected patients with 'malignant' neurocardiogenic syncope (syncope associated with injuries) permanent pacemaker therapy is helpful. These patients benefit from dual chamber pacemakers with a feature called 'rate drop response' which, once activated, paces the heart at a fast rate for a set period of time in order to prevent syncope.

Heart block

Heart block or conduction block may occur at any level in the conducting system. Block in either the AV node or the His bundle results in AV block, whereas block lower in the conduction system produces bundle branch block.

Atrioventricular block

There are three forms:

First-degree AV block

This is simple prolongation of the PR interval to more than 0.22 s. Every atrial depolarization is followed by conduction to the ventricles but with delay (Fig. 13.43).

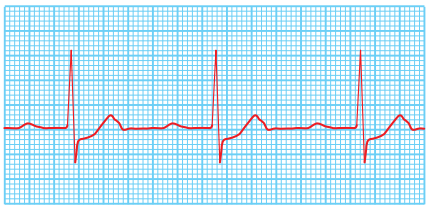

Fig. 13.43 **An ECG showing first-degree atrioventricular block** with a prolonged PR interval. In this trace coincidental ST depression is also present.

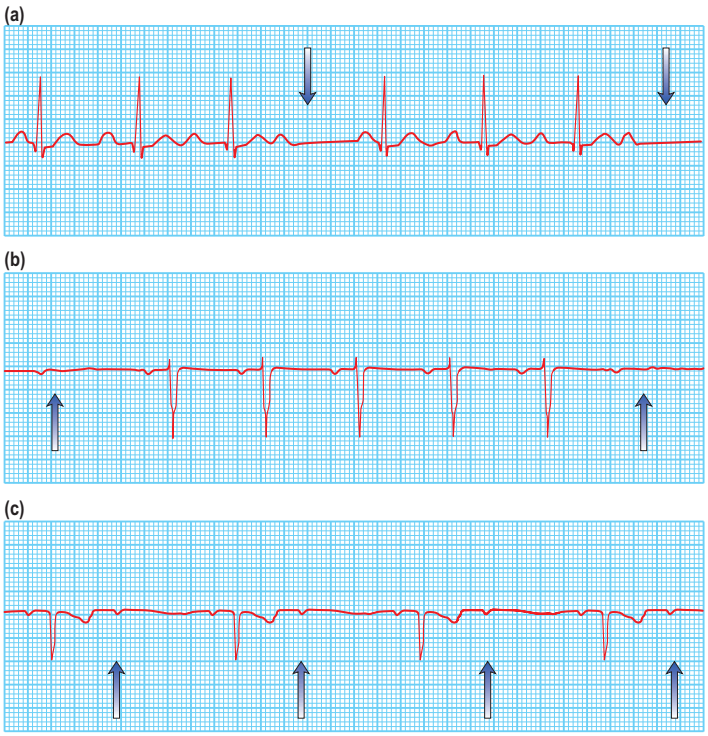

Fig. 13.44 **Three varieties of second-degree atrioventricular (AV) block. (a) Wenckebach (Mobitz type I) AV block.** The PR interval gradually prolongs until the P wave does not conduct to the ventricles (arrows). **(b) Mobitz type II AV block.** The P waves that do not conduct to the ventricles (arrows) are not preceded by gradual PR interval prolongation. **(c) Two P waves to each QRS complex.** The PR interval prior to the dropped P wave is always the same. It is not possible to define this type of AV block as type I or type II Mobitz block and it is, therefore, a third variety of second-degree AV block (arrows show P waves).

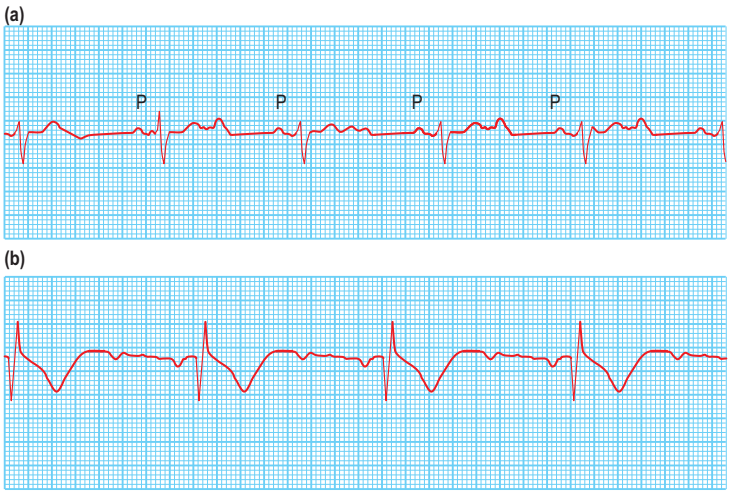

Fig. 13.45 **Two examples of complete heart block. (a) Congenital complete heart block.** The QRS complex is narrow (0.08 s) and the QRS rate is relatively rapid (52 b.p.m.). **(b) Acquired complete heart block.** The QRS complex is broad (0.13 s) and the QRS rate is relatively slow (38 b.p.m.).

Second-degree AV block

This occurs when some P waves conduct and others do not. There are several forms (Fig. 13.44):

- *Mobitz I block* (Wenckebach block phenomenon) is progressive PR interval prolongation until a P wave fails to conduct. The PR interval before the blocked P wave is much longer than the PR interval after the blocked P wave.
- *Mobitz II block* occurs when a dropped QRS complex is not preceded by progressive PR interval prolongation. Usually the QRS complex is wide (>0.12 s). Usually the QRS complex is wide (>0.12 s).
- *2:1 or 3:1* (*advanced*) *block* occurs when every second or third P wave conducts to the ventricles. This form of second-degree block is neither Mobitz I nor II.

Wenckebach AV block in general is due to block in the AV node, whereas Mobitz II block signifies block at an infra-nodal level such as the His bundle. The risk of progression to complete heart block is greater and the reliability of the resultant escape rhythm is less with Mobitz II block. Therefore pacing is usually indicated in Mobitz II block, whereas patients with Wenckebach AV block are usually monitored.

Acute myocardial infarction may produce *second-degree heart block*. In inferior myocardial infarction, close monitoring and transcutaneous temporary back-up pacing are all that is required. In anterior myocardial infarction, second-degree heart block is associated with a high risk of progression to complete heart block, and temporary pacing followed by permanent pacemaker implantation is usually indicated. 2:1 Heart block may either be due to block in the AV node or at an infra-nodal level. Management depends on the clinical setting in which it occurs.

Third-degree (complete) AV block

Complete heart block occurs when all atrial activity fails to conduct to the ventricles (Fig. 13.45). In patients with complete heart block the aetiology needs to be established

Table 13.8 Aetiology of complete heart block

Congenital
Autoimmune (e.g. maternal SLE)
Structural heart disease (e.g. transposition of the great vessels)

Idiopathic fibrosis
Lev's disease (progressive fibrosis of distal His–Purkinje system in elderly patients)
Lenegre's disease (proximal His–Purkinje fibrosis in younger patients)

Ischaemic heart disease
Acute myocardial infarct
Ischaemic cardiomyopathy

Non-ischaemic heart disease
Calcific aortic stenosis
Idiopathic dilated cardiomyopathy
Infiltrations (e.g. amyloidosis, sarcoidosis, neoplasia)

Cardiac surgery
e.g. following aortic valve replacement, CABG, VSD repair

Iatrogenic
Radiofrequency AV node ablation and pacemaker implantation

Drug-induced
e.g. digoxin, beta-blockers, non-dihydropyridine calcium-channel blockers, amiodarone

Infections
Endocarditis
Lyme disease
Chagas' disease

Rheumatic autoimmune disease
e.g. SLE, rheumatoid arthritis

Neuromuscular diseases
e.g. Duchenne muscular dystrophy

SLE, systemic lupus erythematosus; CABG, coronary artery bypass graft surgery; VSD, ventricular septal defect; AV, atrioventricular.

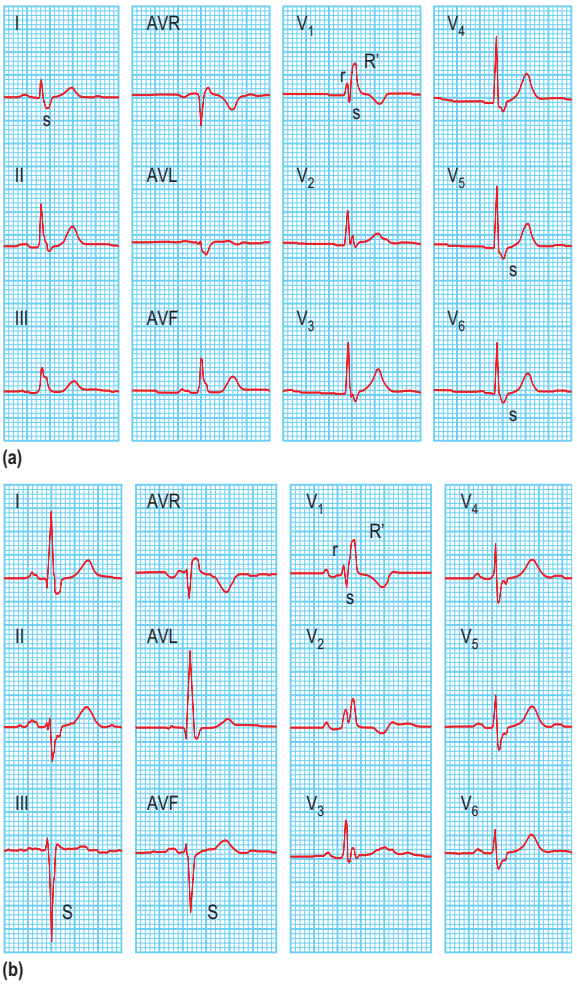

Fig. 13.46 **Right bundle branch block versus bifascicular block. (a) A 12-lead ECG showing right bundle branch block.** Note an rsR pattern with the tall R in lead V_1–V_2 and the broad S waves in leads I and V_5–V_6. **(b) Compare with an ECG showing bifascicular block.** In addition to right bundle branch block, note left axis deviation and deep S waves in leads III and AVF typical for left anterior hemiblock.

(Table 13.8). In this situation life is maintained by a spontaneous escape rhythm.

Narrow complex escape rhythm (<0.12 s QRS complex) implies that it originates in the His bundle and therefore that the region of block lies more proximally in the AV node. The escape rhythm occurs with an adequate rate (50–60 b.p.m.) and is relatively reliable.

Treatment depends on the aetiology. Recent-onset narrow-complex AV block due to transient causes may respond to intravenous atropine, but temporary pacing facilities should be available for the management of these patients. Chronic narrow-complex AV block requires permanent pacing (dual chamber, p. 714) if it is symptomatic or associated with heart disease. Pacing is also advocated for isolated, congenital AV block, even if asymptomatic.

Broad complex escape rhythm (>0.12 s) implies that the escape rhythm originates below the His bundle and therefore that the region of block lies more distally in the His–Purkinje system.

The resulting rhythm is slow (15–40 b.p.m.) and relatively unreliable. Dizziness and blackouts (*Stokes–Adams attacks*) often occur. In the elderly, it is usually caused by degenerative fibrosis and calcification of the distal conduction system (*Lev's disease*). In younger individuals, a proximal progressive cardiac conduction disease due to the inflammatory process is known as *Lenegre's syndrome*. Sodium channel abnormalities have been identified in both syndromes. Broad-complex AV block may also be caused by ischaemic heart disease, myocarditis or cardiomyopathy. Permanent pacemaker implantation (p. 713) is indicated, as pacing considerably reduces the mortality. Because ventricular arrhythmias are not uncommon, an implantable cardioverter–defibrillator (ICD) may be indicated in those with severe left ventricular dysfunction (>0.30 s).

Bundle branch block

The His bundle gives rise to the right and left bundle branches. The left bundle subdivides into the anterior and posterior divisions of the left bundle. Various conduction disturbances can occur.

Bundle branch conduction delay

This produces slight widening of the QRS complex (up to 0.11 s). It is known as incomplete bundle branch block.

Complete block of a bundle branch

This is associated with a wider QRS complex (0.12 s or more). The shape of the QRS depends on whether the right or the left bundle is blocked.

Right bundle branch block (Fig. 13.46a) produces late activation of the right ventricle. This is seen as deep S waves in

leads I and V_6 and as a tall late R wave in lead V_1 (late activation moving towards right- and away from left-sided leads).

Left bundle branch block (Fig. 13.47) produces the opposite – a deep S wave in lead V_1 and a tall late R wave in leads I and V_6. Because left bundle branch conduction is normally responsible for the initial ventricular activation, left bundle branch block also produces abnormal Q waves.

Hemiblock

Delay or block in the divisions of the left bundle branch produces a swing in the direction of depolarization (electrical axis) of the heart. When the anterior division is blocked (left anterior hemiblock), the left ventricle is activated from inferior to superior. This produces a superior and leftwards movement of the axis (left axis deviation). Delay or block in the postero-inferior division swings the QRS axis inferiorly to the right (right axis deviation).

Bifascicular block (Fig. 13.46b)

This is a combination of a block of any two of the following: the right bundle branch, the left antero-superior division and the left postero-inferior division. Block of the remaining fascicle will result in complete AV block.

Clinical features of heart blocks

Bundle branch blocks are usually asymptomatic. Right bundle branch block causes wide but physiological splitting of the second heart sound. Left bundle branch block may cause reverse splitting of the second sound. Patients with intraventricular conduction disturbances may complain of syncope. This is due to intermittent complete heart block or to ventricular tachyarrhythmias. ECG monitoring and electrophysiological studies are needed to determine the cause of syncope in these patients.

Causes

Right bundle branch block occurs as an isolated congenital anomaly or is associated with cardiac or pulmonary conditions (Table 13.9). Right bundle branch block alone does not alter the electrical axis of the heart. Axis deviations signify right ventricular hypertrophy (RV overload) or coexistent fascicular block. The combination of right bundle branch block with left axis deviation is associated with ostium primum atrial septal defects. Complete left bundle branch block is often associated with extensive left ventricular disease. The most common causes are listed in Table 13.10 and are similar to those of complete heart block.

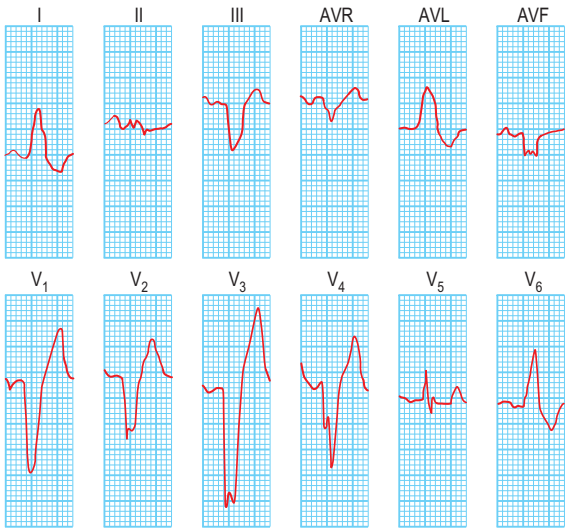

Fig. 13.47 **A 12-lead ECG showing left bundle branch block**. The QRS duration is greater than 0.12 s. Note the broad notched R waves with ST depression in leads I, AVL and V_6, and the broad QS waves in V_1–V_3.

SUPRAVENTRICULAR TACHYCARDIAS

Supraventricular tachycardias (SVTs) arise from the atrium or the atrioventricular junction. Conduction is via the His–Purkinje system; therefore the QRS shape during tachycardia is usually similar to that seen in the same patient during baseline rhythm. A classification of supraventricular tachycardia is listed in Table 13.11. Some of these are discussed in more detail below.

Inappropriate sinus tachycardia

Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated to or out of proportion with the level of physical or emotional stress. It is found predominantly in young women and is not uncommon in health professionals. Sinus tachycardia due to intrinsic sinus node abnormalities such as enhanced automaticity, or abnormal autonomic regulation of the heart with excess sympathetic and reduced parasympathetic input, is extremely rare.

In general, sinus tachycardia is a secondary phenomenon and the underlying causes need to be actively investigated. Depending on the clinical setting, acute causes include exercise, emotion, pain, fever, infection, acute heart failure, acute

Table 13.11 Causes of supraventricular tachycardia (SVT)

Tachycardia	ECG features	Comment
Sinus tachycardia	P wave morphology similar to sinus rhythm preceding QRS	Need to determine underlying cause
AV nodal re-entry tachycardia (AVNRT)	No visible P wave, or inverted P wave immediately before or after QRS complex	Commonest cause of palpitations in patients with normal hearts
AV reciprocating tachycardia (AVRT) complexes	P wave visible between QRS and T wave	Due to an accessory pathway. If pathway conducts in both directions, ECG during sinus rhythm may be pre-excited
Atrial fibrillation	Irregularly irregular RR intervals and absence of organized atrial activity	Commonest tachycardia in patients over 65 years
Atrial flutter	Visible flutter waves at 300/min (saw-tooth appearance) usually with a 2:1 AV conduction	Suspect in any patient with regular SVT at 150/min
Atrial tachycardia	Organized atrial activity with P wave morphology different from sinus rhythm preceding QRS	Usually occurs in patients with structural heart disease
Multifocal atrial tachycardia	Multiple P wave morphologies (≥3) and irregular RR intervals	Rare arrhythmia; most commonly associated with significant chronic lung disease
Accelerated junctional tachycardia	ECG similar to AVNRT	Rare in adults

pulmonary embolism and hypovolaemia. Chronic causes include pregnancy, anaemia, hyperthyroidism and catecholamine excess. The underlying cause should be found and treated, rather than treating the compensatory physiological response. If necessary, beta-blockers may be used to slow the sinus rate, e.g. in hyperthyroidism (p. 987).

Atrioventricular junctional tachycardias

AV nodal re-entry and AV re-entry tachycardias are usually referred to as paroxysmal SVTs and are often seen in young patients with no or little structural heart disease, although congenital heart abnormalities (e.g. Ebstein's anomaly, atrial septal defect, Fallot's tetralogy) can coexist in a small proportion of patients with these arrhythmias. The first presentation is commonly between ages 12 and 30, and the prevalence is approximately 2.5 per 1000.

In these tachycardias the AV node is an essential component of the re-entry circuit.

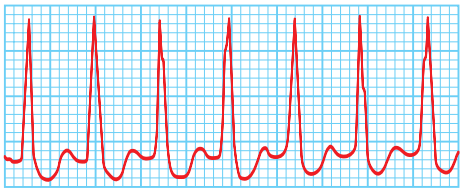
Atrioventricular nodal re-entry tachycardia (AVNRT)

This tachycardia is twice as common in women. Clinically, the tachycardia often strikes suddenly without obvious provocation, but exertion, coffee, tea and alcohol may aggravate or induce the arrhythmia. An attack may stop spontaneously or may continue indefinitely until medical intervention.

In AVNRT, there are two functionally and anatomically different pathways predominantly within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and conducts faster. In sinus rhythm, the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g. an atrial premature beat) occurs early when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles. It then travels back through the fast pathway which has already recovered its excitability, thus initiating the most common 'slow–fast', or typical, AVNRT.

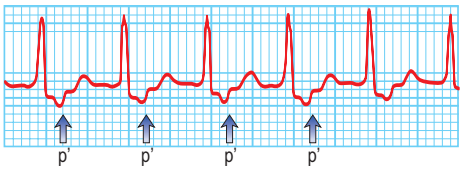
The rhythm is recognized on ECG by normal regular QRS complexes, usually at a rate of 140–240 per minute (Fig. 13.48a). Sometimes the QRS complexes will show typical bundle branch block. P waves are either not visible or are seen immediately before or after the QRS complex because of simultaneous atrial and ventricular activation. Less commonly observed (5–10%) is tachycardia when the atrial impulse conducts anterogradely through the fast pathway and returns through the slow pathway, producing a long RP′ interval ('fast–slow', or long RP′ tachycardia).

Atrioventricular reciprocating tachycardia (AVRT)



In AVRT there is a large circuit comprising the AV node, the His bundle, the ventricle and an abnormal connection from the ventricle back to the atrium. This abnormal connection consists of myocardial fibres that span the AV groove; it is called an accessory pathway or bypass tract. Bypass tracts result from incomplete separation of the atria and the ventricles during fetal development.

In contrast to AVNRT, this tachycardia is due to a macro-reentry circuit and each part of the circuit is activated sequentially. As a result atrial activation occurs after ventricular activation and the P wave is usually clearly seen between the QRS and T wave (Fig. 13.48b).



Accessory pathways are most commonly situated on the left but may occur anywhere around the AV groove. The most common accessory pathways, known as *Kent bundles*, are in the free wall or septum. In about 10% of cases multiple pathways occur. *Mahaim fibres* are atrio-fascicular or nodo-fascicular fibres entering the ventricular myocardium in the region of the right bundle branch. Accessory pathways that conduct from the ventricles to the atria only are not visible on the surface ECG during sinus rhythm and are therefore 'concealed'. Accessory pathways that conduct bidirectionally usually are manifest on the surface ECG. If the accessory pathway conducts from the atrium to the ventricle during sinus rhythm, the electrical impulse can conduct quickly over this abnormal connection to depolarize part of the ventricles abnormally (pre-excitation). A pre-excited ECG is

(a) *Atrioventricular nodal re-entry* tachycardia. The QRS complexes are narrow and the P waves cannot be seen.

(b) *Atrioventricular re-entry* tachycardia (Wolff–Parkinson–White syndrome). The tachycardia P waves (arrows) are clearly seen after narrow QRS complexes.

(c) An electrocardiogram taken in a patient with *Wolff–Parkinson–White (WPW) syndrome* during sinus rhythm. Note the short PR interval and the δ wave (arrow).

(d) *Atrial fibrillation in the WPW syndrome*. Note tachycardia with broad QRS complexes with fast and irregular ventricular rate.

characterized by a short PR interval and a wide QRS complex that begins as a slurred part known as the δ wave (Fig. 13.48c). Patients with a history of palpitations and a pre-excited ECG have a syndrome known as Wolff–Parkinson–White (WPW) syndrome.

During AVRT the AV node and ventricles are activated normally (orthodromically), resulting usually in a narrow QRS complex. Less commonly, the tachycardia circuit can be reversed, with activation of the ventricles via the accessory pathway and atrial activation via retrograde conduction through the AV node (antidromic AVRT). This results in a broad complex tachycardia. These patients are also prone to atrial fibrillation.

During atrial fibrillation, the ventricles may be depolarized by impulses travelling over both the abnormal and the normal pathways. This results in pre-excited atrial fibrillation, a characteristic tachycardia that is characterized by irregularly irregular broad QRS complexes (Fig. 13.48d). If an accessory pathway has a short antegrade effective refractory period (<250 ms), it may conduct to the ventricles at an extremely high rate and may cause ventricular fibrillation. The incidence of sudden death is 0.15–0.39% per patient-year and it may be a first manifestation of the disease in younger individuals. Verapamil and digoxin may allow a higher rate of conduction over the abnormal pathway and precipitate ventricular fibrillation. Therefore, neither verapamil nor digoxin should be used to treat atrial fibrillation associated with the WPW syndrome.

Symptoms

The leading symptom of most SVTs, in particular AV node re-entry and AV re-entry tachycardias, is rapid regular palpitations, usually with abrupt onset and sudden termination, which can occur spontaneously or be precipitated by simple movements. A common feature is termination by Valsalva manoeuvres. In younger individuals with no structural heart disease, the rapid heart rate can be the main pathological finding.

Irregular palpitations may be due to atrial premature beats, atrial flutter with varying AV conduction block, atrial fibrillation or multifocal atrial tachycardia. In patients with depressed ventricular function, uncontrolled atrial fibrillation can reduce cardiac output and cause hypotension and congestive heart failure.

Other symptoms may include anxiety, dizziness, dyspnoea, neck pulsation, central chest pain and weakness. Polyuria may occur because of release of atrial natriuretic peptide in response to increased atrial pressures during the tachycardia, especially during AVNRT and atrial fibrillation. Prominent jugular venous pulsations due to atrial contractions against closed atrioventricular valves may be observed during AVNRT.

Syncope has been reported in 10–15% of patients, usually just after initiation of the arrhythmia or in association with a prolonged pause following its termination. It is more common if the patient is standing. However, in older patients with concomitant heart disease, such as aortic stenosis, hypertrophic cardiomyopathy and cerebrovascular disease, significant hypotension and syncope may result from moderately fast ventricular rates.

Acute management

In an emergency, distinguishing between AVNRT and AVRT may be difficult, but it is usually not critical as both tachycardias respond to the same treatment. Patients presenting with SVTs and haemodynamic instability (e.g. hypotension, pulmonary oedema) require emergency cardioversion. If the patient is haemodynamically stable, vagal manoeuvres, including right carotid massage (Practical box 13.3), Valsalva manoeuvre (Practical box 13.4) and facial immersion in cold water can be successfully employed.

Of these techniques, the Valsalva manoeuvre is the best and is often easier for the patient to perform successfully. It should be undertaken when the patient is resting in the supine position (thus avoiding elevated background sympathetic tone). Several seconds after the release of strain, the resulting intense vagal effect may terminate AVNRT or AVRT or may produce sufficient AV block to reveal an underlying atrial tachyarrhythmia.

If physical manoeuvres have not been successful, intravenous adenosine (initially 6 mg by i.v. push, followed by 12 mg if needed) should be tried. This is a very short-acting (half-life <10 s) naturally occurring purine nucleoside that causes complete heart block for a fraction of a second fol-

Practical Box 13.4 Valsalva manoeuvre

- Valsalva manoeuvre is an abrupt voluntary increase in intrathoracic and intra-abdominal pressures by straining.
- Provide continuous electrocardiographic monitoring.
- Patient is in supine position.
- Patient should not take deep inspiration before straining.
- Ideally, the patient blows into the mouthpiece of a manometer against a pressure of 30–40 mmHg for 15 seconds.
- Alternatively, the patient strains for 15 seconds while breath-holding.
- Transient acceleration of tachycardia usually occurs during the strain phase as a result of sympathetic excess.
- On release of strain, the rate of tachycardia slows because of the compensatory increase in vagal tone (baroreceptor reflex), and it may be terminated in about 50% of patients.
- Termination of tachycardia may be followed by pauses and transient ventricular ectopics.

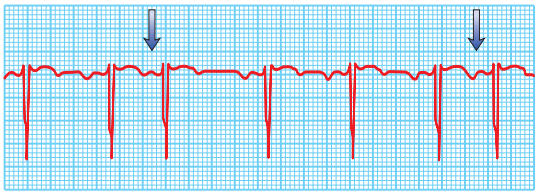
lowing i.v. administration. It is highly effective at terminating AVNRT and AVRT or unmasking underlying atrial activity. It rarely affects ventricular tachycardia. The side-effects of adenosine are very brief but include:

- bronchospasm
- flushing
- chest pain
- heaviness of the limbs
- sense of impending doom.

It is contraindicated in patients with a history of asthma. In some patients, adenosine can induce atrial fibrillation.

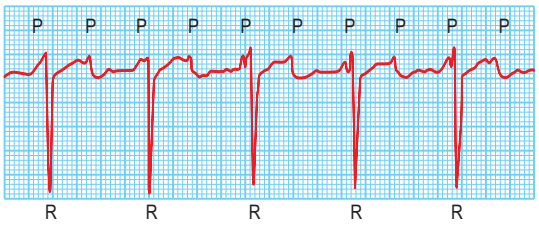
An alternative treatment is verapamil 5–10 mg i.v. over 5–10 minutes, i.v. diltiazem, or beta-blockers (esmolol, propranolol, metoprolol). Verapamil (or diltiazem) must not be given after beta-blockers *or* if the tachycardia presents with broad (>0.12 s) QRS complexes.

Long-term management



Patients with suspected cardiac arrhythmias should always be referred to the cardiologist for electrophysiological evaluation and long-term management, as both pharmacological and non-pharmacological alternatives, including ablation of an accessory pathway, are readily available. Verapamil, diltiazem and beta-blockers have proven efficacy in 60–80% of patients. Sodium-channel blockers (flecainide and propafenone), potassium repolarization current blockers (sotalol, dofetilide, azimilide), and the multichannel blocker amiodarone may also prevent the occurrence of tachycardia.

Refinement of catheter ablation techniques has rendered many AV junctional tachycardias entirely curable. Modification of the slow pathway is successful in 96% of patients with AVNRT, although a 1% risk of AV block is present. In AVRT, the target for catheter ablation is the accessory pathway(s). The success rate for ablation of a single accessory pathway is approximately 95%, with a recurrence rate of 5%, requiring a repeat procedure.



Atrial tachyarrhythmias

Atrial tachyarrhythmias including atrial fibrillation, atrial flutter, atrial tachycardia and atrial ectopic beats all arise from the atrial myocardium (Fig. 13.49a–d). They share common aetiologies, which are listed in Table 13.12.

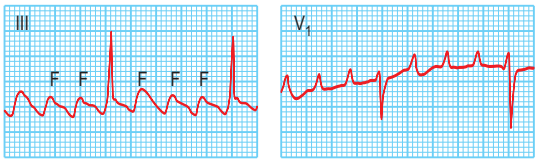


Fig. 13.49 **ECGs of a variety of atrial arrhythmias.**

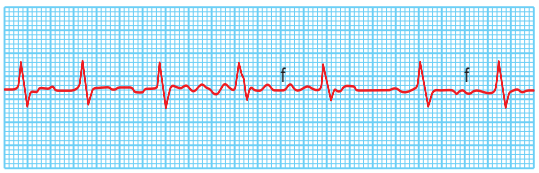

(a) Atrial premature beats (arrows). The premature P wave is different from the sinus P wave and conducts to the ventricle with a slightly prolonged PR interval.

(b) Atrial tachycardia with second-degree atrioventricular block. Note the fast atrial (P wave) rate of 150/min and the slower ventricular (R wave) rate of 75/min.

(c) Atrial flutter. Some flutter waves are marked with an F. In this case the flutter frequency is 240/min. Every fourth flutter wave is transmitted to the ventricles and the ventricular rate is therefore 60/min.

(d) Atrial fibrillation. Note absolute rhythm irregularity and baseline undulations (f waves).

Table 13.12 Causes of atrial tachyarrhythmias

Cardiac	Non-cardiac
Hypertension	Thyrotoxicosis
Congestive heart failure	Phaeochromocytoma
Coronary artery disease and myocardial infarction	Acute and chronic pulmonary disease (pneumonia, chronic obstructive pulmonary disease)
Valvular heart disease	Pulmonary vascular disease (pulmonary embolism)
Cardiomyopathy: dilated, hypertrophic	Electrolyte disturbances (hypokalaemia)
Myocarditis and pericarditis	Increased sympathetic tone (exercise, adrenergically mediated arrhythmia)
Wolff–Parkinson–White syndrome	Increased parasympathetic tone (vagally induced and postprandial arrhythmia)
Sick sinus syndrome	Alcohol abuse ('holiday heart' and long-term use)
Cardiac tumours	Caffeine, smoking, recreational drug use, e.g. cannabis
Cardiac surgery	Myotonic dystrophy type 1
Familial tachyarrhythmia (e.g. lone atrial fibrillation)	Chagas' disease
Genetic predisposition	

Atrial fibrillation

This is a common arrhythmia, occurring in 5–10% of patients over 65 years of age. It also occurs, particularly in a paroxysmal form, in younger patients. Any condition resulting in raised atrial pressure, increased atrial muscle mass, atrial fibrosis, or inflammation and infiltration of the atrium, may cause atrial fibrillation. There are also many systemic causes of atrial fibrillation (Table 13.12).

Although rheumatic heart disease, alcohol intoxication and thyrotoxicosis are the 'classic' causes of atrial fibrillation, hypertension and heart failure are the most common causes. Hyperthyroidism may provoke atrial fibrillation, sometimes as virtually the only feature of the disease, and thyroid function tests are mandatory in any patient with unaccounted atrial fibrillation. Atrial fibrillation occurs in one-third of patients after coronary bypass surgery and in more than half of those undergoing valvular surgery. It usually manifests during the first 4 days and is associated with increased morbidity and mortality, largely due to stroke and circulatory failure, and longer hospital stay.

In some patients no cause can be found, and this group is labelled as 'lone' atrial fibrillation. The pathogenesis of 'lone', or 'idiopathic', atrial fibrillation is unknown but genetic predisposition or even specific genetically predetermined forms of the arrhythmia have been proposed. Thirty to 40% of those with AF, especially those who present at a young age, have at least one parent with AF and genes associated with the sodium channel, the potassium channel and gap junction proteins have been implicated. Gene defects linked to chromosomes 10, 6, 5 and 4 have been associated with familial AF.

Atrial fibrillation is maintained by continuous, rapid (300–600 per minute) activation of the atria by multiple meandering re-entry wavelets, often driven by rapidly depolarizing automatic foci, located predominantly within the pulmonary veins. The atria respond electrically at this rate but there is no coordinated mechanical action and only a proportion of the impulses are conducted to the ventricles. The ventricular response depends on the rate and regularity of atrial activity, particularly at the entry to the AV node, the refractory properties of the AV node itself, and the balance between sympathetic and parasympathetic tone.

Symptoms and signs

Symptoms attributable to atrial fibrillation are highly variable. In some patients (about 30%) it is an incidental finding, whilst others attend hospital as an emergency following the onset of atrial fibrillation. Most patients experience some deterioration of exercise capacity or well-being, but this may only be appreciated once sinus rhythm is restored. When caused by rheumatic mitral stenosis, the onset of atrial fibrillation results in considerable worsening of cardiac failure.

The patient has a very irregular pulse, as opposed to a basically regular pulse with an occasional irregularity (e.g. extrasystoles) or recurring irregular patterns (e.g. Wenckebach block). The irregular nature of the pulse in atrial fibrillation is maintained during exercise.

The ECG shows fine oscillations of the baseline (so-called fibrillation or f waves) and no clear P waves. The QRS rhythm is rapid and irregular. Untreated, the ventricular rate is usually 120–180 per minute, but it slows with treatment.

The clinical classification of atrial fibrillation includes first detected, paroxysmal, persistent, and permanent forms of the arrhythmia and is essential for the decision-making between rhythm restoration and rate control. For example, atrial fibrillation may be asymptomatic and the 'first detected episode' should not be regarded as necessarily the true onset.

Management

When atrial fibrillation is due to an acute precipitating event such as alcohol toxicity, chest infection or hyperthyroidism, the provoking cause should be treated. Strategies for the acute management of AF are ventricular rate control or cardioversion (± anticoagulation). Ventricular rate control is achieved by drugs which block the AV node (see below), while cardioversion may be achieved electrically by DC shock (p. 712) or medically either by intravenous infusion of an antiarrhythmic drug such as a class Ic or a class III agent or by taking an oral agent previously tested in hospital and found to be safe in a particular patient ('pill-in-pocket' approach).

The choice depends upon:

- how well the arrhythmia is tolerated (is cardioversion urgent?)
- whether anticoagulation is required before considering elective cardioversion
- whether spontaneous cardioversion is likely (previous history? reversible cause?).

Conversion to sinus rhythm can be achieved by electrical DC cardioversion (p. 712) in about 80% of patients. Biphasic waveform defibrillation is more effective than conventional (monophasic) defibrillation, and biphasic defibrillators are becoming standard. To minimize the risk of thromboembolism associated with cardioversion patients are fully anticoagulated (INR 2.0–3.0) with warfarin for 3 weeks before cardioversion (unless atrial fibrillation is of less than 1–2 days' duration) and at least 4 weeks after the procedure. The patient is then assessed for the necessity for long-term anticoagulation. If cardioversion is urgent, transoesophageal echocardiography may be used to document the presence or absence of atrial thrombus as a guide to possibly avoiding pre-cardioversion anticoagulation.

Two strategies are available for the long-term management of atrial fibrillation:

- 'rate control' (AV nodal slowing agents *plus warfarin*)
- 'rhythm control' (antiarrhythmic drugs plus DC cardioversion *plus warfarin*).

Major randomized studies in patients predominantly over the age of 65 years (AFFIRM) or in patients with heart failure (AF-CHF) have shown that there is no net mortality or symptom benefit to be gained from one strategy compared with the other. Which strategy to adopt needs to be assessed for each individual patient. Factors to consider include the likelihood of maintaining sinus rhythm and the safety/tolerability of antiarrhythmic drugs in a particular patient.

Rhythm control is advocated for younger, symptomatic and physically active patients. Recurrent paroxysms may be prevented by oral medication. In general, class Ic agents are employed in patients with no significant heart disease and class III agents are preferred in patients with significant structural heart disease. Catheter ablation techniques such as pulmonary vein isolation can be used in patients who do not respond to antiarrhythmic drugs.

Rate control as a primary strategy is appropriate in patients who:

- have the permanent form of the arrhythmia associated with symptoms which can be further improved by slowing heart rate or are older than 65 years with recurrent atrial tachyarrhythmias (primary 'accepted' atrial fibrillation)
- have persistent tachyarrhythmias and have failed cardioversion(s) and serial prophylactic antiarrhythmic drug therapy and in whom the risk/benefit ratio from using specific antiarrhythmic agents is shifted towards increased risk.

Rate control is usually achieved by a combination of *digoxin, beta-blockers* or *calcium-channel blockers* (*verapamil* or *diltiazem*). Digoxin monotherapy may be sufficient for elderly non-ambulant patients. In younger patients the effect of catecholamines easily overwhelms the vagotonic effect of digoxin and additional AV nodal slowing agents are needed. The ventricular rate response is generally considered controlled if the heart rate is between 60 and 80 b.p.m at rest and 90 and 115 b.p.m. during moderate exercise. To assess the adequacy of rate control, an ECG rhythm strip may be sufficient in an elderly patient but ambulatory 24-hour Holter monitoring and an exercise stress test (treadmill) are needed in younger individuals. Older patients with poor rate control despite optimal medical therapy should be considered for AV node ablation and pacemaker implantation (*'ablate and pace' strategy*). These patients usually experience a marked symptomatic improvement but because of the ongoing risk of thromboembolism require life-long *anticoagulation*.

Anticoagulation (target INR 2.0–3.0)

This is indicated in patients with atrial fibrillation and one of the following major or two of the following moderate risk factors:

Major risk factors

- prosthetic heart valve
- rheumatic mitral valve disease
- prior history of CVA/TIA.

Moderate risk factors

- age ≥ 75 years
- congestive heart failure
- hypertension
- diabetes mellitus.

In addition, anticoagulation with warfarin can be used for other less well validated features and include: age 65–74 years, coronary artery disease, history of thyrotoxicosis, female gender and echocardiographic evidence of left atrial enlargement, LV dysfunction of any cause, atrial thrombus or a reduced atrial appendage emptying velocity.

Aspirin is also sometimes required depending on the scoring system used.

A popular scoring system known as CHADS2 is often used to determine the need for anticoagulation. CHADS is an acronym standing for Congestive heart failure, Hypertension, Age ≥ 75, Diabetes mellitus and previous Stroke or TIA. Each factor scores 1 except previous stroke or TIA which scores 2. A total score of 0 implies no need for anticoagulation and with a score of 2 warfarin is needed. For a score of 1 warfarin or aspirin may be used depending on patient preference and the presence or absence of the additional less validated risk factors (see above).

For young patients (<65 years) with no significant heart disease (lone atrial fibrillation) aspirin 75–300 mg daily is generally prescribed. New oral anticoagulants, such as dabigatran, apixaban and rivaroxaban, which are easier to use than warfarin, are currently under trial.

Atrial flutter

Atrial flutter is often associated with atrial fibrillation and often requires a similar initial therapeutic approach. Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 b.p.m. Typical, or isthmus-dependent, atrial flutter involves a macro re-entrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the Eustachian ridge between the tricuspid annulus and the inferior vena cava, and up the interatrial septum, giving rise to the most frequent pattern, referred to as counter-clockwise flutter. Re-entry can also occur in the opposite direction (clockwise or reverse flutter).

The ECG shows regular sawtooth-like atrial flutter waves (F waves) between QRS complexes (Fig. 13.49c). In typical counter-clockwise atrial flutter, the F waves are negative in the inferior leads and positive in leads V_1 and V_2. In clockwise atrial flutter, the deflection of the F waves is the opposite. If F waves are not clearly visible, it is worth trying to reveal them by slowing AV conduction by carotid sinus massage or by the administration of AV nodal blocking drugs such as adenosine or verapamil.

Symptoms are largely related to the degree of AV block. Most often, every second flutter beat conducts, giving a ventricular rate of 150 b.p.m. Occasionally, every beat conducts, producing a heart rate of 300 b.p.m. More often, especially when patients are receiving treatment, AV conduction block reduces the heart rate to approximately 75 b.p.m.

Management

Treatment of a symptomatic acute paroxysm is electrical *cardioversion*. Patients who have been in atrial flutter more than 1–2 days should be treated in a similar manner to patients with atrial fibrillation and *anticoagulated* for 3 weeks prior to cardioversion.

Recurrent paroxysms may be prevented by oral medication. In general, *class Ic* agents are employed in patients with no significant heart disease and *class III* agents are preferred in patients with significant structural heart disease. *AV nodal blocking agents* may be used to control the ventricular rate if the arrhythmia persists. However, the treatment of choice for patients with recurrent atrial flutter is radiofrequency catheter *ablation* (p. 731), which permanently interrupts re-entry by creating a line of conduction block within the isthmus between the inferior vena cava and the tricuspid valve ring. This technique offers patients whose only arrhythmia is typical atrial flutter an almost certain chance of a cure.

Atrial tachycardia

This is an uncommon arrhythmia. Its prevalence is believed to be less than 1% in patients with arrhythmias. It is usually associated with structural heart disease but in many cases it is referred to as idiopathic. Macro re-entrant tachycardia often occurs after surgery for congenital heart disease.

Atrial tachycardia with block is often a result of digitalis poisoning.

The mechanisms of atrial tachycardia are attributed to enhanced automaticity, triggered activity or intra-atrial re-entry. Atrial re-entry tachycardia is usually relatively slow (125–150 b.p.m.) and can be initiated and terminated by atrial premature beats. The P′P′ intervals are regular. The PR interval depends on the rate of tachycardia and is longer than in sinus rhythm at the same rate.

Automatic tachycardia usually presents with higher rates (125–250 b.p.m.) and is often characterized by a progressive increase in the atrial rate with onset of the tachycardia ('warm-up') and progressive decrease prior to termination ('cool-down'). Atrial tachycardia is typically caused by a focus which is frequently located along the crista terminalis in the right atrium, adjacent to a pulmonary vein in the left atrium, or around one of the atrial appendages. Automatic atrial tachycardia may also present as an incessant variety leading to tachycardia-induced cardiomyopathy. Short runs of atrial tachycardia may provoke more sustained episodes of atrial fibrillation.

Figure 13.49b demonstrates an atrial tachycardia at an atrial rate of 150 per minute. The P waves are abnormally shaped and occur in front of the QRS complexes. Carotid sinus massage may increase AV block during tachycardia, thereby facilitating the diagnosis, but does not usually terminate the arrhythmia. Treatment options include *cardioversion*, *antiarrhythmic drug therapy* to maintain sinus rhythm, *AV nodal slowing agents* to control rate and, in selected cases, radiofrequency catheter *ablation*.

Atrial ectopic beats

These often cause no symptoms, although they may be sensed as an irregularity or heaviness of the heart beat. On the ECG they appear as early and abnormal P waves, and are usually, but not always, followed by normal QRS complexes (Fig. 13.49a). Treatment is not normally required unless the ectopic beats provoke more significant arrhythmias, when *beta-blockers* may be effective.

VENTRICULAR TACHYARRHYTHMIAS

Ventricular tachyarrhythmias can be considered under the following headings:

- life-threatening ventricular tachyarrhythmias
- torsades de pointes
- normal heart ventricular tachycardia
- non-sustained ventricular tachycardia
- ventricular premature beats.

Life-threatening ventricular tachyarrhythmias

Sustained ventricular tachycardia and ventricular fibrillation with haemodynamic instability (e.g. syncope, hypotension) are life-threatening ventricular tachyarrhythmias.

Sustained ventricular tachycardia

Sustained ventricular tachycardia (>30 s) often results in *pre-syncope* (dizziness), *syncope*, *hypotension* and *cardiac arrest*, although it may be remarkably well tolerated in some patients. Examination reveals a pulse rate typically between 120 and 220 b.p.m. Usually there are clinical signs of atrioventricular dissociation (i.e. intermittent cannon 'a' waves in the neck, p. 691) and variable intensity of the first heart sound).

The ECG shows a rapid ventricular rhythm with broad (often 0.14 s or more), abnormal QRS complexes. AV dissociation may result in visible P waves which appear to march through the tachycardia, capture beats (intermittent narrow QRS complex owing to normal ventricular activation via the AV node and conducting system) and fusion beats (intermediate between ventricular tachycardia beat and capture beat).

Supraventricular tachycardia with bundle branch block may resemble ventricular tachycardia on the ECG. However, if a broad complex tachycardia is due to SVT with either right or left bundle branch block, then the QRS morphology should resemble a typical RBBB or LBBB pattern (Figs 13.46a and 13.47). Other ECG criteria to differentiate VT from SVT with aberrancy are indicated in Table 13.13. Eighty per cent of all broad complex tachycardias are due to ventricular tachycardia, and the proportion is even higher in patients with structural heart disease. Therefore, in all cases of doubt, ventricular tachycardia should be diagnosed.

Treatment may be urgent, depending on the haemodynamic situation. If the patient is haemodynamically compromised (e.g. hypotensive or pulmonary oedema), emergency DC cardioversion may be required. On the other hand, if the blood pressure and cardiac output are well maintained, intravenous therapy with class I drugs or amiodarone is usually used. First-line drug treatment consists of lidocaine (50–100 mg i.v. over 5 minutes) followed by a lidocaine infusion (2–4 mg i.v. per minute). Amiodarone is given as a dilute intravenous infusion (5 mg/kg over 1 hour (loading dose)) followed by a maintenance infusion of 1200 mg over 24 hours. DC cardioversion is necessary if medical therapy is unsuccessful.

Ventricular fibrillation

This is very rapid and irregular ventricular activation with no mechanical effect. The patient is pulseless and becomes rapidly unconscious, and respiration ceases (cardiac arrest). The ECG shows shapeless, rapid oscillations and there is no hint of organized complexes (Fig. 13.50). It is usually provoked by a ventricular ectopic beat. Ventricular fibrillation rarely reverses spontaneously. The only effective treatment is electrical defibrillation. Basic and advanced cardiac life support is needed (p. 709).

If the attack of ventricular fibrillation occurs during the first day or two of an acute myocardial infarction, it is probable that prophylactic therapy will be unnecessary. If the

Table 13.13 ECG distinction between supraventricular tachycardia (SVT) with bundle branch block and ventricular tachycardia (VT)

VT is more likely than SVT with bundle branch block where there is:

- a very broad QRS (>0.14 s)
- atrioventricular dissociation
- a bifid, upright QRS with a taller first peak in V_1
- a deep S wave in V_6
- a concordant (same polarity) QRS direction in all chest leads (V_1–V_6)

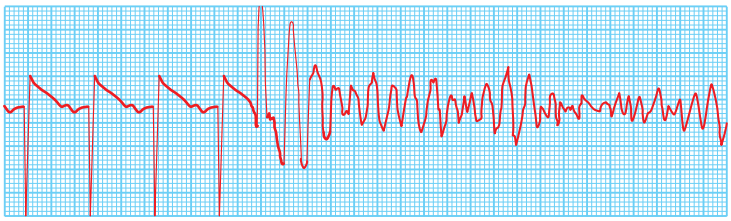

Fig. 13.50 **Ventricular fibrillation.** Four beats of sinus rhythm followed by a ventricular ectopic beat that initiates ventricular fibrillation. The ST segment during sinus rhythm is elevated owing to acute myocardial infarction in this case.

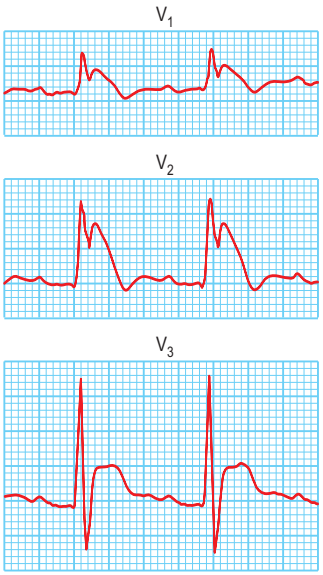

Fig. 13.51 **The Brugada ECG.** ST elevation in V_1–V_3 with right bundle branch block.

ventricular fibrillation was not related to an acute infarction, the long-term risk of recurrent cardiac arrest and sudden death is high.

Survivors of these ventricular tachyarrhythmias are, in the absence of an identifiable reversible cause (e.g. acute myocardial infarction, severe metabolic disturbance), at high risk of sudden death. Implantable cardioverter–defibrillators (ICDs) are first-line therapy in the management of these patients (p. 732).

The Brugada syndrome

This inheritable condition accounts for part of a group of patients with idiopathic ventricular fibrillation who have no evidence of causative structural cardiac disease. It is more common in young male adults and in South East Asia. The diagnosis is made by identifying the classic ECG changes that may be present spontaneously or be provoked by the administration of a class I antiarrhythmic (flecainide or ajmaline): right bundle branch block with coved ST elevation in leads V_1–V_3 (Fig. 13.51).

In 20% of cases it is a monogenic inheritable condition associated with loss of sodium channel function due to a mutation in the *SCN5A gene*. Recently other mutations in the glycerol-3-phosphate dehydrogenase-1-like gene (*GPD1LL*-type) and genes related to calcium channel subunits (*CACNA1C* and *CACNB2*) have also been implicated in the genesis of this syndrome. It can present with sudden death during sleep, resuscitated cardiac arrest and syncope, or the patient may be asymptomatic and diagnosed incidentally or during familial assessment. There is a high risk of sudden death, particularly in the symptomatic patient or those with spontaneous ECG changes. The only successful treatment is an ICD. Beta-blockade is not helpful and may be harmful in this syndrome.

Table 13.14 Causes of long QT syndrome

Long QT syndrome

This describes an ECG where the ventricular repolarization (QT interval) is greatly prolonged. The causes of long QT syndrome are listed in Table 13.14.

Congenital long QT syndrome

Two major syndromes have been described, which may (Jervell and Lange–Nielsen syndrome) or may not (Romano–Ward syndrome) be associated with congenital deafness.

The molecular biology of the congenital long QT syndromes has been shown to be heterogeneous. It is usually a monogenic disorder and has been associated with mutations in cardiac potassium and sodium channel genes (Table 13.15). The different genes involved appear to correlate with different phenotypes (Fig. 13.52b) that can exhibit such variable penetrance that carriers may have completely normal ECGs. There are three major sub-types: LQT1 in which the arrhythmia is usually provoked by exercise, particularly swimming; LQT2 with provocation associated with emotion and acoustic stimuli; and LQT3 where the arrhythmias occur during rest or when asleep. It is likely that identification of the mutation involved will not only improve diagnostic accuracy but also guide future therapy for the congenital long QT syndrome.

FURTHER READING

Morita H, Wu J, Zipes DP. The QT syndromes: long and short. *Lancet* 2008; **372**: 750–763.

In *acquired long QT syndrome*, QT prolongation and torsades de pointes are usually provoked by bradycardia.

Clinical features

Patients with a long QT develop syncope and palpitations as a result of polymorphic ventricular tachycardia (torsade de pointes). They usually terminate spontaneously but may degenerate to ventricular fibrillation, resulting in sudden death.

Torsades de pointes is characterized on the ECG by rapid, irregular, sharp complexes that continuously change from an upright to an inverted position (Fig. 13.52a).

Between spells of tachycardia or immediately preceding the onset of tachycardia the ECG shows a prolonged QT interval; the corrected QT (Table 13.5, p. 695) is usually greater than 0.50 s.

Table 13.15 Single gene mutations responsible for congenital long QT syndrome

Subtype	Chromosome	Gene	Channel
LQT1	11p15.5	KCNQ1	I_{ks} α subunit
LQT2	7q35–36	KCNH2	I_{kr} α subunit
LQT3	3p21–24	SCN5A	I_{Na} α subunit
LQT4	4q24–27	ANK2	Na, K, Ca

LQT9	3p25.3	CAV3	
LQT10	11q23.3	SCN4B	

Management

Acute (acquired):

- any electrolyte disturbance is corrected
- causative drugs are stopped
- the heart rate is maintained with atrial or ventricular pacing
- magnesium sulphate 8 mmol (Mg^{2+}) over 10–15 minutes for acquired long QT
- intravenous isoprenaline may be effective when QT prolongation is acquired (isoprenaline is contraindicated for congenital long QT syndrome).

Long-term, congenital long QT syndrome is generally treated by beta-blockade, left cardiac sympathetic denervation and pacemaker therapy. LQT1 patients seem to respond well to beta-blockade and LQT3 patients are better treated with sodium channel blockers. All LQT patients should avoid drugs known to prolong the QT interval. Patients who remain symptomatic despite conventional therapy and those with a strong family history of sudden death usually need ICD therapy.

Short QT syndrome

Five types have been described caused by genetic abnormalities leading to faster repolarization. Ventricular arrhythmias and sudden death may occur and an ICD is the best treatment.

Normal heart ventricular tachycardia

Monomorphic ventricular tachycardia in patients with structurally normal hearts (idiopathic VT) is usually a benign condition with an excellent long-term prognosis. Occasionally, it

Fig. 13.52 **Prolonged QT. (a)** An ECG demonstrating a supraventricular rhythm with a long QT (LQT) interval giving way to atypical ventricular tachycardia (torsades de pointes). The tachycardia is short-lived and is followed by a brief period of idioventricular rhythm. **(b)** Further three examples of a prolonged QT interval corresponding to three different types of LQT.

is incessant (so called Galavardin's tachycardia) and if untreated may lead to cardiomyopathy.

Normal heart VT either arises from a focus in the right ventricular outflow tract or in the left ventricular septum. Treatment of symptoms is usually with beta-blockers. There is a special form of verapamil-sensitive tachycardia that responds well to non-dihydropyridine calcium antagonists. In symptomatic patients, radiofrequency catheter ablation is highly effective, resulting in a cure in >90% cases. It is sometimes difficult to distinguish ARVC (p. 791) from this seemingly benign disorder.

Non-sustained ventricular tachycardia

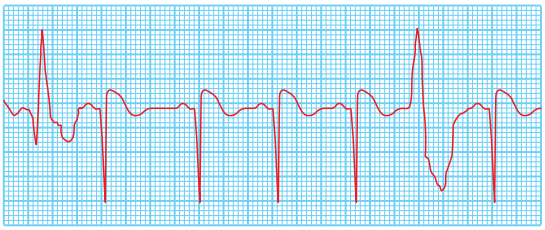
Non-sustained ventricular tachycardia (NSVT) is defined as ventricular tachycardia that is ≥5 consecutive beats but lasts <30 s (Fig. 13.53d). NSVT can be found in 6% of patients with normal hearts and usually does not require treatment. NSVT is documented in up to 60–80% of patients with heart disease. There is insufficient evidence on prognosis, but an ICD has been shown to improve survival of patients with particularly poor left ventricular function (ejection fraction 30% or less) by preventing arrhythmic death. Antiarrhythmic suppression of NSVT is not usually advocated but beta-blockers may improve quality of life in symptomatic individuals.

Ventricular premature beats

These may be uncomfortable, especially when frequent. The patient complains of extra beats, missed beats or heavy beats because it may be the premature beat, the post-ectopic pause or the next sinus beat that is noticed by the patient. The pulse is irregular owing to the premature beats. Some early beats may not be felt at the wrist. When a premature beat occurs regularly after every normal beat, 'pulsus bigeminus' may occur. If premature ventricular beats are highly symptomatic, treatment with beta-blockade may be helpful. If the ectopics stem from a single focus, especially when in the right ventricle, catheter ablation can be very effective.

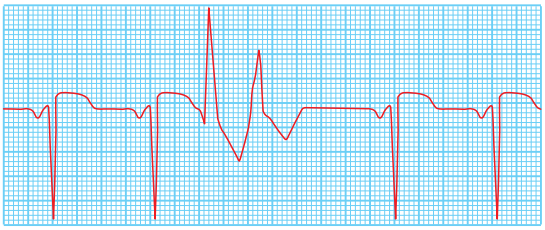
These premature beats (Fig. 13.53a-c) have a broad (>0.12 s) and bizarre QRS complex because they arise from an abnormal (ectopic) site in the ventricular myocardium. Following a premature beat there is usually a complete compensatory pause because the AV node or ventricle is refractory to the next sinus impulse. Early 'R-on-T' ventricular premature beats (occurring simultaneously with the upstroke or peak of the T wave of the previous beat) may induce ventricular fibrillation in patients with heart disease, particularly in patients following myocardial infarction.

Ventricular premature beats are usually treated only if symptomatic. Usually simple measures such as reassurance and beta-blocker therapy are all that is required.



LONG-TERM MANAGEMENT OF CARDIAC TACHYARRHYTHMIAS

Options for the long-term management of cardiac tachyarrhythmias include:



- antiarrhythmic drug therapy
- ablation therapy
- device therapy.

To determine the optimal strategy for a given patient the following questions must be addressed:

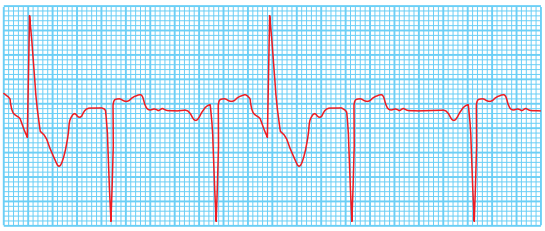


Fig. 13.53 **Varieties of ventricular ectopic activity.**

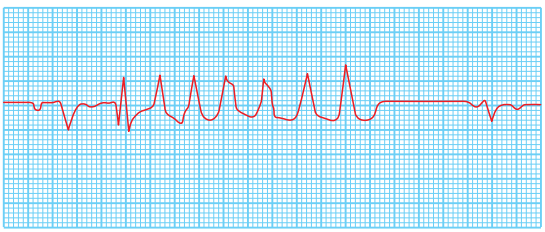

(a) Two ventricular ectopic beats of different morphology (multimorphological).

(b) Two ventricular premature beats (VPBs) occurring one after the other (a pair or couplet of VPBs).

(c) Frequently repetitive ventricular ectopic activity of a single morphology.

(d) Brief run of ventricular tachycardia (non-sustained ventricular tachycardia) that follows previous ectopic activity.

- Is the principal aim of treatment symptom relief or prevention of sudden death?
- Is maintaining sinus rhythm or controlling ventricular rates the treatment goal?

Commonly employed treatment strategies for the management of specific tachyarrhythmias are outlined in Table 13.16.

Antiarrhythmic drugs

Drugs that modify the rhythm and conduction of the heart are used to treat cardiac arrhythmias. Antiarrhythmic drugs may aggravate or produce arrhythmias (proarrhythmia) and they may also depress ventricular contractility and must therefore be used with caution. They are classified according to their effect on the action potential (Vaughan Williams' classification; Table 13.17 and Fig. 13.54).

Table 13.16 Long-term management of tachyarrythmias

Tachycardia	Management aims	Management strategies
AV node re-entry tachycardia (AVNRT)	Relieve symptoms	AV-node-blocking agents Class Ic or class III Catheter ablation
AV reciprocating tachycardia (AVRT)	Relieve symptoms	AV-node-blocking agents Class Ic or class III Catheter ablation
Wolff–Parkinson–White (WPW) syndrome	Relieve symptoms Prevent sudden death (esp. if documented pre-excited atrial fibrillation)	Class Ic or class III Catheter ablation
Atrial fibrillation	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Maintenance of sinus rhythm: class Ic or class III ± cardioversion catheter ablation of ectopic focus Rate control: AV-node-slowing agents AV node ablation plus plus pacemaker Anticoagulation
Atrial flutter	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Class Ic or class III Catheter ablation AV-node-blocking agents Anticoagulation
Atrial tachycardia	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Class Ic or class III Catheter ablation AV-node-blocking agents Anticoagulation
Life-threatening ventricular tachyarrhythmias	Prevent sudden death	Implantable cardioverter–defibrillator (ICD) Beta-blockers
Congenital long QT	Prevent sudden death	Beta-blockers ± pacemaker ICD Correct bradycardia Correct electrolytes
Acquired long QT	Prevent sudden death	Avoidance of all QT-prolonging drugs
Normal heart ventricular tachycardias	Relieve symptoms	Beta-blockers, calcium channel blockers Catheter ablation
Non-sustained VT (NSVT)	Relieve symptoms Prevent sudden death in certain situations	Beta-blockers Class Ic and class III ICD in clearly defined subgroups

Class I drugs

These are membrane-depressant drugs that reduce the rate of entry of sodium into the cell (sodium-channel blockers). They may slow conduction, delay recovery or reduce the spontaneous discharge rate of myocardial cells. Class Ia drugs (e.g. disopyramide) lengthen the action potential, class Ib drugs (e.g. lidocaine) shorten the action potential, and class Ic (flecainide, propafenone) do not affect the duration of the action potential. Class I agents have been found to increase mortality compared to placebo in post-myocardial infarction patients with ventricular ectopy (Cardiac Arrhythmia Suppression Trial (CAST) trials – class Ic agents) and in patients treated for atrial fibrillation (class Ia agent, quinidine). In view of this, class Ic agents such as flecainide and all other class I drugs should be reserved for patients who do not have significant coronary artery disease, left ventricular dysfunction, or other forms of significant structural heart disease.

Class II drugs

These antisympathetic drugs prevent the effects of catecholamines on the action potential. Most are β-adrenoceptor antagonists. Cardioselective beta-blockers (β_1) include metoprolol, bisoprolol, atenolol and acebutalol. Beta-blockers suppress AV node conduction, which may be effective in preventing attacks of junctional tachycardia, and may help to control the ventricular rate during paroxysms of other forms of SVT (e.g. atrial fibrillation). In general beta-blockers are anti-ischaemic and anti-adrenergic, and have proven beneficial effects in patients post-myocardial infarction (by preventing ventricular fibrillation) and in patients with congestive heart failure. It is therefore advisable to use beta-blocker therapy either alone or in combination with other antiarrhythmic drugs in patients with symptomatic tachyarrhythmias, particularly in patients with coronary artery disease.

Class III drugs

These prolong the action potential, usually by blocking the rapid component of the delayed rectifier potassium current (I_{Kr}) and do not affect sodium transport through the membrane. The drugs in this class are amiodarone and sotalol. Sotalol is also a beta-blocker.

Some drugs, such as ibutilide and dofetilide, are only available in some countries. Sotalol may result in acquired long QT syndrome and torsades de pointes. The risk of torsades is increased in the setting of hypokalaemia, and particular care should be taken in patients taking diuretic therapy. Amiodarone therapy in contrast to most other antiarrhythmic drugs carries a low risk of proarrhythmia in patients with significant structural heart disease. Because it has many toxic and potentially serious side-effects, patients need to be counselled prior to commencing amiodarone and

monitored at regular follow-up intervals. Dofetilide has been used to treat atrial fibrillation and flutter in patients with recent myocardial infarction and poor LV function.

Class IV drugs

The non-dihydropyridine calcium channel blockers that reduce the plateau phase of the action potential are particularly effective at slowing conduction in nodal tissue. Verapamil and diltiazem are two drugs in this group. These drugs can prevent attacks of junctional tachycardia (AVNRT and AVRT) and may help to control ventricular rates during paroxysms of other forms of SVT (e.g. atrial fibrillation).

Table 13.17 Vaughan Williams' classification of antiarrhythmic drugs

Class I	Membrane-depressant drugs (sodium-channel blockers)
Ia	Disopyramide
Ib	Lidocaine, mexiletine
Ic	Flecainide, propafenone
Class II	β-Adrenoceptor blocking drugs, e.g. atenolol, propranolol, esmolol
Class III	Prolong action potential, e.g. amiodarone, sotalol
Class IV	Calcium-channel blockers, e.g. verapamil, diltiazem
(Other	Adenosine, digoxin)

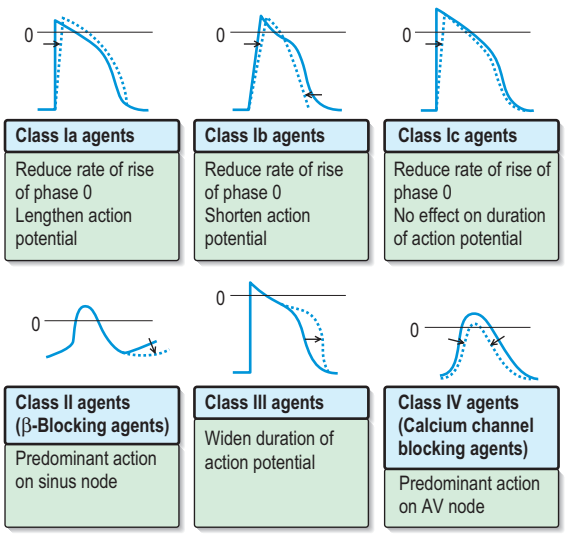

Fig. 13.54 **Vaughan Williams' classification of antiarrhythmic drugs** based on their effect on cardiac action potentials. 0, = 0 mV. The dotted curves indicate the effects of the drugs.

Drug therapy is commonly used for symptomatic relief in patients who do not have life-threatening tachyarrhythmias. Patient safety is the main factor determining the choice of antiarrhythmic therapy and proarrhythmic risks need to be carefully assessed prior to initiating therapy. As a generalization, class Ic agents are employed in patients with structurally normal hearts and class III agents are used in patients with structural heart disease.

In order to administer antiarrhythmic agents as safely as possible it is helpful to be familiar with the different proarrhythmia mechanisms and their main predisposing risk factors (Table 13.18).

Patients with structurally normal hearts and normal QT intervals, or with implantable defibrillators, are either at very low risk of proarrhythmia or are protected from any life-threatening consequences, and in these patients it is possible to persevere with drug therapy until an efficacious, well-tolerated agent is identified.

Catheter ablation

Radiofrequency catheter ablation is frequently employed in the management of symptomatic tachyarrhythmias. Ablations are performed by placing three or four electrode catheters into the heart chambers in order to record and pace from various sites. Pacing the atria or the ventricles is used to trigger the tachycardia and to study the tachycardia mechanism. Successful ablation depends on accurate identification of either the site of origin of a focal tachycardia or of a critical component of a macro-reentry tachycardia. The following tachyarrhythmias can be readily ablated:

- AV node re-entry tachycardia (AVNRT)
- AV re-entry tachycardia (AVRT) with an accessory pathway, including WPW syndrome
- normal heart VT
- atrial flutter
- atrial tachycardia
- atrial fibrillation.

Symptomatic patients with a pre-excited ECG because of accessory pathway conduction (WPW syndrome) are advised to undergo catheter ablation as first-line therapy, owing to the risk of sudden death associated with this condition. This is especially the case in patients with pre-excited atrial fibrillation. Patients with accessory pathways that only

Table 13.18 Proarrhythmia mechanisms and the predisposing risk factors

Proarrhythmia mechanism	Drug	Predisposing risk factors
Torsades de pointes	Class I (disopyramide, procainamide, quinidine) Sotalol 'Pure' class III (ibutilide)	Baseline QT prolongation Female gender Hypokalaemia/diuretic use Clinical heart failure Advanced structural heart disease Conversion of AF to sinus rhythm
Atrial flutter with 1:1 AV conduction and wide QRS complexes	Class 1_a (disopyramide, quinidine) Class I_c (flecainide, propafenone)	Risk reduced by adding an AV-nodal-slowing agent
'Late' sudden death (arrhythmic mechanism not clearly defined)	Class I_c (flecainide) Quinidine	Myocardial ischaemia

conduct retrogradely from the ventricles to the atrium are not at increased risk of sudden death but experience symptoms due to AVRT. These patients are commonly offered an ablation procedure if simple measures such as AV nodal slowing agents fail to suppress tachycardia. Asymptomatic patients with the WPW ECG pattern are now frequently offered an ablation procedure for prophylactic reasons. The main risk associated with accessory pathway ablation is thromboembolism in patients with left-sided accessory pathways. The success rate for catheter ablation of AVNRT and accessory pathways is greater than 95%.

Patients with normal hearts and documented ventricular tachycardia should be referred for specialist evaluation. Unlike VT in patients with structural heart disease, normal heart VT is not associated with increased risk of sudden death and is easily cured by catheter ablation.

Catheter ablation is recommended in patients with atrial flutter that is not easily managed medically. Ablation of typical flutter is effective in 90–95% cases. In the direct comparison of catheter ablation and antiarrhythmic therapy, the rate of recurrence was significantly lower following ablation. Atrial tachycardia, especially in patients with structurally normal hearts, may also be cured by catheter ablation. In atrial fibrillation, adequate control of ventricular rates is sometimes not possible despite optimal medical therapy. These patients experience a marked symptomatic improvement following AV node ablation and pacemaker implantation. Unlike other forms of catheter ablation this does not cure the arrhythmia; atrial fibrillation continues and anticoagulation is still required following ablation.

In *younger patients* with structurally normal hearts, atrial ectopic beats, which commonly arise from a focus situated in the pulmonary veins, may trigger atrial fibrillation. Catheter ablation of this ectopic focus includes the application of radiofrequency energy in or around the pulmonary veins in order to abolish the connection between the sleeves of arrhythmogenic atrial myocardium surrounding or extending into the veins from the remaining atrium (pulmonary vein isolation). The trigger is therefore eliminated and the arrhythmia does not recur. These techniques appear to be highly effective, especially in young patients with paroxysmal atrial fibrillation, normal atrial size and no underlying heart disease (70–80% long-term success), but are presently time-consuming procedures (4 hours or more) and are associated with some serious complications such as stroke, pericardial haemorrhage, pulmonary vein stenosis and atrio-oesophageal fistula in a small minority of patients (<2% in all).

Implantable cardioverter–defibrillator (ICD)

Life-threatening ventricular arrhythmias (ventricular fibrillation or rapid ventricular tachycardia with hypotension) result in death in up to 40% within 1 year of diagnosis. Large multicentre prospective trials such as the Antiarrhythmics (amiodarone) Versus Implantable Defibrillator (AVID) trial have proven that implantable defibrillators improve overall survival in patients who have experienced an episode of life-threatening ventricular tachyarrhythmia (Fig. 13.55).

The ICD recognizes ventricular tachycardia or fibrillation and automatically delivers pacing or a shock to the heart to cause cardioversion to sinus rhythm. Modern ICDs are only

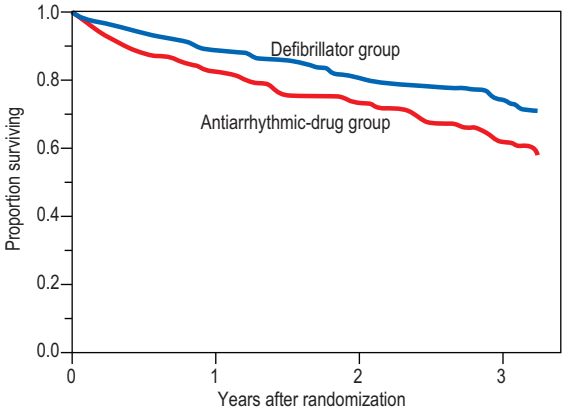

Fig. 13.55 **Survival curves of the Multicentre Automatic Defibrillator Implantation Trial (MADIT)** following myocardial infarction. Patients with left ventricular ejection fractions of ≤0.35 and documented asymptomatic non-sustained ventricular tachycardia and inducible ventricular tachycardia were randomized to receive an ICD or conventional therapy.

a little larger than a pacemaker and are implanted in a pectoral position (Fig. 13.56). The device may have leads to sense and pace both the right atrium and ventricle, and the lithium batteries employed are able to provide energy for over 100 shocks each of around 30 J. ICD discharges are painful if the patient is conscious. However, ventricular tachycardia may often be terminated by overdrive pacing the heart, which is painless. The ICD is superior to all other treatment options at preventing sudden cardiac death. The use of this device has cut the sudden death rate in patients with a history of serious ventricular arrhythmias to approximately 2% per year. However, the majority of these patients have significant structural heart disease and overall cardiac mortality due to progressive heart failure remains high. As a result the ICD is now first-line therapy in the secondary prevention of sudden death.

Implantable cardioverter–defibrillators are also employed in the primary prevention of sudden cardiac death. The chances of surviving an out-of-hospital cardiac arrest are as low as 10%. Therefore selected patients who have never experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia but who are assessed to be at high risk of sudden death are advised to undergo ICD implantation. In two large primary prevention ICD trials, Multicenter Automated Defibrillator Implantation Trial (MADIT II) and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), therapy with an ICD reduced mortality by 23–31% on top of conventional treatment, which included revascularization, beta-blockers and angiotensin-converting enzyme inhibitors.

The following groups of patients may merit prophylactic ICD placement:

- Patients with coronary artery disease; significant impairment of left ventricular function (LVEF ≤35–40%), spontaneous non-sustained ventricular tachycardia in whom sustained ventricular tachycardia was induced by pacing the heart during an electrophysiological study.

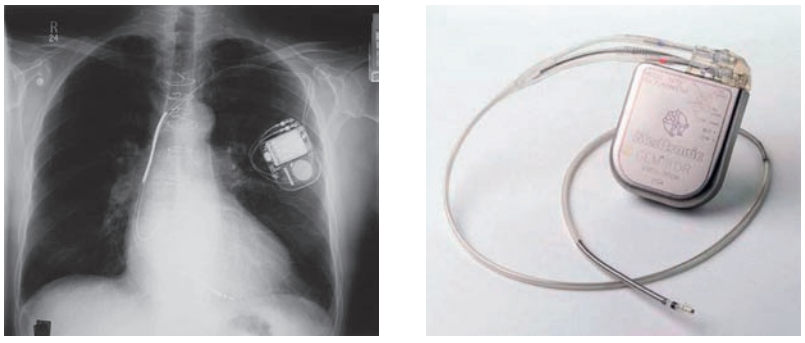

Fig. 13.56 **Implantable cardioverter–defibrillator. (a) X-ray of a 'dual-chamber' ICD** in a left pectoral position with atrial and ventricular leads. **(b) Termination of ventricular fibrillation** by the direct current shock at 20 J. Electrogram recorded internally from the ventricular lead of an ICD reveals chaotic ventricular activity consistent with ventricular fibrillation. This is confirmed by an electrocardiogram (lead V_2). The marker channel demonstrates that the device detects ventricular fibrillation correctly (FS, fibrillation sensing, lower line) and delivers an appropriate shock (CD) that terminates the arrhythmia and restores normal sinus rhythm (VS, ventricular sensing, lower line). Incidentally, atrial fibrillation is also detected before shock delivery (upper line on the marker channel).

- Patients with very poor LV function post-MI (LVEF ≤35%).
- Patients with dilated and particularly hypertrophic cardiomyopathy, long QT syndrome and Brugada syndrome or other channelopathies who have a strong family history of sudden cardiac death.

HEART FAILURE

Heart failure is a complex syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the heart to function as a pump to support a physiological circulation.

World-wide the incidence of heart failure is variable but increases with advancing age. For example, in Scotland the prevalence of heart failure is high at 7.1 in 1000, increasing with age to 90.1 in 1000 among patients over 85 years. In the UK overall incidence is about 2 in 1000. Approximately 23 million people world-wide have heart failure.

The prognosis of heart failure has improved over the past 10 years, but the mortality rate is still high with approximately 50% of patients dead at 5 years. Heart failure accounts for 5% of admissions to hospital medical wards. The cost of managing heart failure in the UK exceeds £1 billion per year. Coronary artery disease is the commonest cause of heart failure in western countries.

The causes of heart failure are shown in Table 13.19.

PATHOPHYSIOLOGY

When the heart fails, considerable changes occur to the heart and peripheral vascular system in response to the haemodynamic changes associated with heart failure (Table 13.20). These physiological changes are compensatory and maintain cardiac output and peripheral perfusion. However, as heart failure progresses, these mechanisms are overwhelmed and become pathophysiological. The development of pathological peripheral vasoconstriction and sodium retention in heart failure by activation of the renin–angiotensin–aldosterone system are a loss of beneficial compensatory mechanisms and represent cardiac decompensation. Factors involved are venous return, outflow resistance, contractility of the myocardium, and salt and water retention.

Table 13.19 Causes of heart failure

Main causes

Ischaemic heart disease (35–40%)

Cardiomyopathy (dilated) (30–34%)

Hypertension (15–20%)

Other causes

Cardiomyopathy (undilated): hypertrophic/obstructive, restrictive (amyloidosis, sarcoidosis)

Valvular heart disease (mitral, aortic, tricuspid)

Congenital heart disease (ASD, VSD)

Alcohol and drugs (chemotherapy – trastuzamab, imatinib)

Hyperdynamic circulation (anaemia, thyrotoxicosis, haemochromatosis, Paget's disease)

Right heart failure (RV infarct, pulmonary hypertension, pulmonary embolism, cor pulmonale (COPD))

Tricuspid incompetence

Arrhythmias (atrial fibrillation, bradycardia (complete heart block, the sick sinus syndrome))

Pericardial disease (constrictive pericarditis, pericardial effusion)

Infections (Chagas' disease)

Table 13.20 Pathophysiological changes in heart failure

Ventricular dilatation

Myocyte hypertrophy

Increased collagen synthesis

Altered myosin gene expression

Altered sarcoplasmic Ca^{2+}-ATPase density

Increased ANP secretion

Salt and water retention

Sympathetic stimulation

Peripheral vasoconstriction

Venous return (preload)

In the intact heart, myocardial failure leads to a reduction of the volume of blood ejected with each heart beat and an increase in the volume of blood remaining after systole. This increased diastolic volume stretches the myocardial fibres and, as Starling's law of the heart (p. 684) would suggest, myocardial contraction is restored. However, the failing myocardium results in depression of the ventricular function curve (cardiac output plotted against the ventricular diastolic volume) (Fig. 13.5, p. 684).

Mild myocardial depression is not associated with a reduction in cardiac output because it is maintained by an increase in venous pressure (and hence diastolic volume). However, the proportion of blood ejected with each heart beat (ejection fraction) is reduced early in heart failure. Sinus tachycardia also ensures that any reduction of stroke volume is compensated for by the increase in heart rate; cardiac output (stroke volume × heart rate) is therefore maintained.

When there is more severe myocardial dysfunction, cardiac output can be maintained only by a large increase in venous pressure and/or marked sinus tachycardia. The increased venous pressure contributes to the development of dyspnoea, owing to the accumulation of interstitial and alveolar fluid, and to the occurrence of hepatic enlargement, ascites and dependent oedema, due to increased systemic venous pressure. However, the cardiac output at rest may not be much depressed, but myocardial and haemodynamic reserve is so compromised that a normal increase in cardiac output cannot be produced by exercise.

In very severe heart failure the cardiac output at rest is depressed, despite high venous pressures. The inadequate cardiac output is redistributed to maintain perfusion of vital organs, such as the heart, brain and kidneys, at the expense of the skin and muscle.

Outflow resistance (afterload) (see Fig. 15.4)

This is the load or resistance against which the ventricle contracts. It is formed by:

- pulmonary and systemic resistance
- physical characteristics of the vessel walls
- the volume of blood that is ejected.

An increase in afterload decreases the cardiac output. This results in a further increase of end-diastolic volume and dilatation of the ventricle itself, which further exacerbates the problem of afterload. This is expressed by Laplace's law: the tension of the myocardium (T) is proportional to the intraventricular pressure (P) multiplied by the radius of the ventricular chamber (R): i.e. $T \propto PR$.

Myocardial contractility (inotropic state)

The state of the myocardium also influences performance. The sympathetic nervous system is activated in heart failure via baroreceptors as an early compensatory mechanism, which provides inotropic support and maintains cardiac output. Chronic sympathetic activation, however, has deleterious effects by further increasing neurohormonal activation and myocyte apoptosis. This is compensated by a down-regulation of β-receptors. Increased contractility (positive inotropism) can result from increased sympathetic drive, and this is a normal part of the Frank–Starling relationship (Fig. 13.5, p. 684). Conversely, myocardial depressants (e.g. hypoxia) decrease myocardial contractility (negative inotropism).

Neurohormonal and sympathetic system activation: salt and water retention

The increase in venous pressure that occurs when the ventricles fail leads to retention of salt and water and their accumulation in the interstitium, producing many of the physical signs of heart failure. Reduced cardiac output also leads to diminished renal perfusion, activating the renin–angiotensin system and enhancing salt and water retention (Fig. 12.3, p. 651), which further increases venous pressure (Fig. 13.57). The retention of sodium is in part compensated by the action of circulating atrial natriuretic peptides and antidiuretic hormone (see p. 653 and below).

The interaction of haemodynamic and neurohumoral factors in the progression of heart failure remains unclear. Increased ventricular wall stress promotes ventricular dilatation and further worsens contractile efficiency. In addition, prolonged activation of the sympathetic nervous and renin-angiotensin-aldosterone systems exerts direct toxic effects on myocardial cells.

Myocardial remodelling in heart failure

Left ventricular remodelling is a process of progressive alteration of ventricular size, shape and function owing to the influence of mechanical, neurohormonal and possibly genetic factors in several clinical conditions, including myocardial

infarction, cardiomyopathy, hypertension and valvular heart disease. Its hallmarks include hypertrophy, loss of myocytes and increased interstitial fibrosis. Remodelling continues for months after the initial insult, and the eventual change in the shape of the ventricle becomes responsible for significant impairment of overall function of the heart as a pump (Fig. 13.58a). In cardiomyopathy, the process of progressive ventricular dilatation or hypertrophy occurs without ischaemic myocardial injury or infarction (Fig. 13.58b).

Changes in myocardial gene expression

Haemodynamic overload of the ventricle stimulates changes in cardiac contractile protein gene expression. The overall effect is to increase protein synthesis, but many proteins also switch to fetal and neonatal isoforms. Human myosin is composed of a pair of heavy chains and two pairs of light chains. Myosin heavy chains (MHC) exist in two isoforms, α and β, that have different contractile properties and ATPase activity. αα-MHC predominates in the atria and ββ-MHC in the ventricles. In animal models, pressure overload results in a shift from αα- to ββ-MHC in the atria, in parallel with atrial size. This results in reduction in atrial contractility but reduced energy demands. This shift is less significant in the human ventricle, as the ββ-MHC isoform already predominates. Other genes affected in heart failure include those encoding Na^+/K^+-ATPase, Ca^{2+}-ATPase and β_1-adrenoceptors.

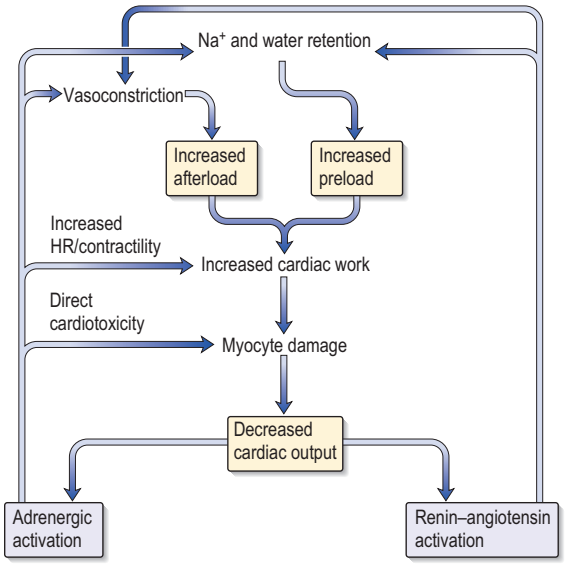

Fig. 13.57 **The compensatory physiological response to heart failure**. Chronic activation of the renin–angiotensin and adrenergic systems results in a 'vicious cycle' of cardiac deterioration that further exacerbates the physiological response.

Abnormal calcium homeostasis

Calcium ion flux within myocytes plays a pivotal role in the regulation of contractile function. Excitation of the myocyte cell membrane causes the rapid entry of calcium into myocytes from the extracellular space via calcium channels. This triggers the release of intracellular calcium from the sarcoplasmic reticulum and initiates contraction (see Fig. 13.3, p. 683). Relaxation results from the uptake and storage of calcium by the sarcoplasmic reticulum (see Fig. 13.9, p. 686) controlled by changes in nitric oxide. In heart failure, there is a prolongation of the calcium current in association with prolongation of contraction and relaxation.

Apoptosis (see also p. 27)

Apoptosis (or 'programmed cell death') of myocytes has been demonstrated in animal models of ischaemic reperfusion, rapid ventricular pacing, mechanical stretch and pressure overload. Apoptosis is associated with irreversible congestive heart failure, and the spiral of ventricular dysfunction, characteristic of heart failure, results from the initiation of apoptosis by cytokines, free radicals and other triggers.

Natriuretic peptides (ANP, BNP and C-type)

Atrial natriuretic peptide (ANP) is released from atrial myocytes in response to stretch. ANP induces diuresis, natriuresis, vasodilatation and suppression of the renin–angiotensin

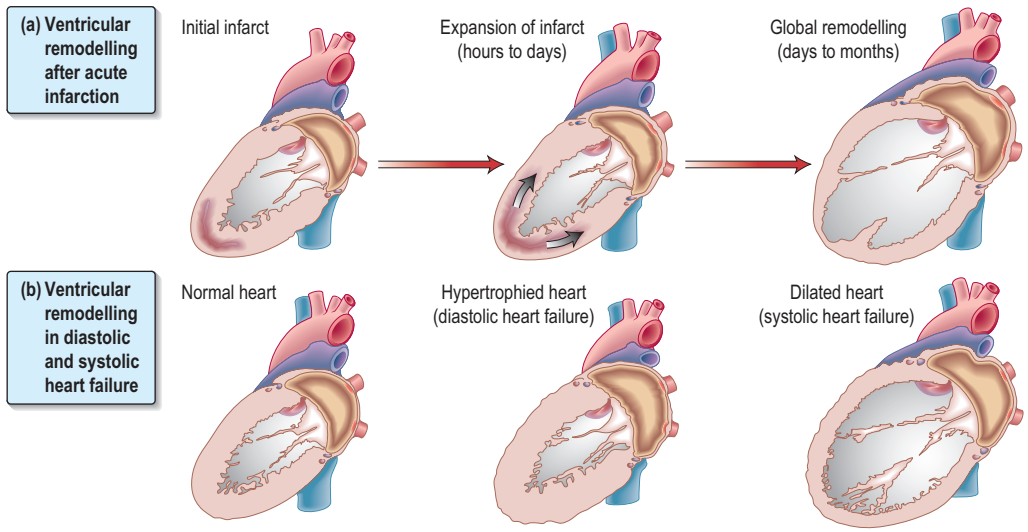

Fig. 13.58 **Ventricular remodelling in (a) ischaemic (MI) and (b) non-ischaemic heart failure**, e.g. in cardiomyopathy. From Jessop M, Brozana S. *New England Journal of Medicine* 2003; **348**: 2011, with permission. Copyright © 2003 Massachusetts Medical Society. All rights reserved.

Ask the authors
www.studentconsult.com

system. Levels of circulating ANP are increased in congestive cardiac failure and correlate with functional class, prognosis and haemodynamic state. The renal response to ANP is attenuated in heart failure, probably secondarily to reduced renal perfusion, receptor downregulation, increased peptide breakdown, renal sympathetic activation and excessive renin–angiotensin activity. Brain natriuretic peptide (BNP) (so called because it was first discovered in brain) is predominantly secreted by the ventricles, and has an action similar to that of ANP but greater diagnostic and prognostic value (p. 1023). *C-type peptide*, which is limited to vascular endothelium and the central nervous system, has similar effects to those of ANP and BNP.

The therapeutic benefits of the natriuretic peptides have been investigated in two ways. The administration of *synthetic BNP* (Nesritide) produces beneficial haemodynamic effects in acute heart failure (reducing pulmonary capillary wedge pressure and peripheral vascular resistance) but has been associated with an increased risk of death.

Neutral endopeptidase (NEP) is a metalloendopeptidase involved in the degradation of a variety of vasoactive peptides (including ANP, BNP, CNP and bradykinin). In animal studies NEP inhibitors can produce diuresis and natriuresis. Omapatrilat is a combined ACE-I and NEP-I that is an effective antihypertensive agent, but it has not received FDA approval because of an increased risk of severe angio-oedema.

Endothelial function in heart failure

The endothelium has a central role in the regulation of vasomotor tone. In patients with heart failure, endothelium-dependent vasodilatation in peripheral blood vessels is impaired and may be one mechanism of exercise limitation. The cause of abnormal endothelial responsiveness relates to abnormal release of both nitric oxide and vasoconstrictor substances, such as endothelin (ET). The activity of nitric oxide, a potent vasodilator, is blunted in heart failure. ET secretion from a variety of tissues is stimulated by many factors, including hypoxia, catecholamines and angiotensin II. The plasma concentration of ET is elevated in patients with heart failure, and levels correlate with the severity of haemodynamic disturbance. The major source of circulating ET in heart failure is the pulmonary vascular bed.

ET has many actions that potentially contribute to the pathophysiology of heart failure: vasoconstriction, sympathetic stimulation, renin–angiotensin system activation and left ventricular hypertrophy. Acute intravenous administration of endothelin antagonists improves haemodynamic abnormalities in patients with congestive cardiac failure, and oral endothelin antagonists are being developed. Plasma concentrations of some cytokines, in particular TNF, are increased in patients with heart failure.

Antidiuretic hormone (vasopressin)

Antidiuretic hormone (ADH) is raised in severe chronic heart failure, particularly in patients on diuretic treatment. High ADH concentration precipitates hyponatraemia which is an ominous prognostic indicator.

CLINICAL SYNDROMES OF HEART FAILURE

There are many causes of heart failure (see Table 13.19) that can present suddenly with acute heart failure (AHF) or more insidiously with chronic heart failure (CHF).

Left ventricular systolic dysfunction (LVSD) is commonly caused by ischaemic heart disease but can also occur with valvular heart disease and hypertension.

Right ventricular systolic dysfunction (RVSD) may be secondary to chronic LVSD but can occur with primary and secondary pulmonary hypertension, right ventricular infarction, arrhythmogenic right ventricular cardiomyopathy and adult congenital heart disease.

Diastolic heart failure is a syndrome consisting of symptoms and signs of heart failure with preserved left ventricular ejection fraction above 45–50% and abnormal left ventricular relaxation assessed by echocardiography. There is increased stiffness in the ventricular wall and decreased left ventricular compliance, leading to impairment of diastolic ventricular filling and hence decreased cardiac output. Diastolic heart failure is more common in elderly hypertensive patients but may occur with primary cardiomyopathies (hypertrophic, restrictive, infiltrative).

The symptoms and signs of heart failure are:

Symptoms:

- exertional dyspnoea
- orthopnoea
- paroxysmal nocturnal dyspnoea
- fatigue.

Signs:

- cardiomegaly
- third and fourth heart sounds
- elevated JVP
- tachycardia
- hypotension
- bi-basal crackles
- pleural effusion
- ankle oedema
- ascites
- tender hepatomegaly.

The New York Heart Association classification of heart failure (Table 13.21) can be used to describe the symptoms of heart failure and limitation of exercise capacity, and are useful to assess response to therapy. They do not include left ventricular ejection fraction to determine severity of heart failure.

Diagnosis of heart failure

The diagnosis of heart failure should not be based on history and clinical findings; it requires evidence of cardiac dysfunction with appropriate investigation using objective measures of left ventricular structure and function (usually echocardiography). Similarly, the underlying cause of heart failure

Table 13.21 New York Heart Association (NYHA) Classification of heart failure

Class I	No limitation. Normal physical exercise does not cause fatigue, dyspnoea or palpitations
Class II	Mild limitation. Comfortable at rest but normal physical activity produces fatigue, dyspnoea or palpitations
Class III	Marked limitation. Comfortable at rest but less gentle physical activity produces marked symptoms of heart failure
Class IV	Symptoms of heart failure occur at rest and are exacerbated by any physical activity

Table 13.22 Diagnosis of heart failure (European Society of Cardiology guidelines)

Essential features (criteria 1 and 2)

1. Symptoms and signs of heart failure (e.g. breathlessness, fatigue, ankle swelling)
2. Objective evidence of cardiac dysfunction (at rest)

Non-essential features

3. Response to treatment directed towards heart failure (in cases where the diagnosis is in doubt)

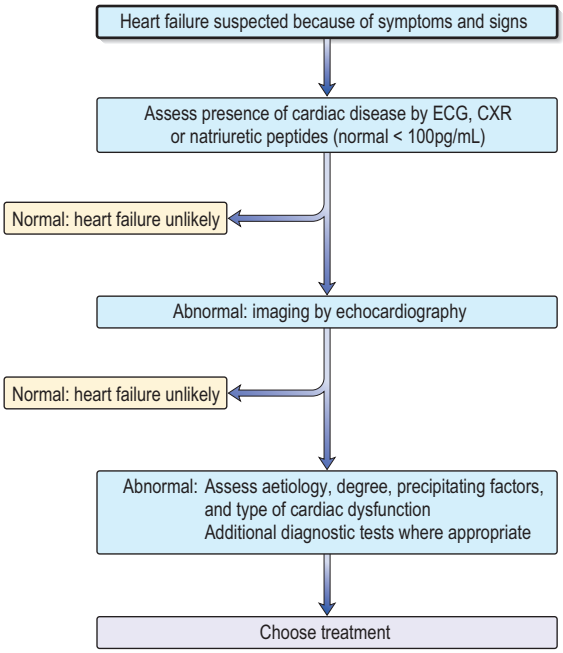

Fig. 13.59 **Algorithm for the diagnosis of heart failure.** Based on the European Society of Cardiology and NICE guidelines.

should be established in all patients (Table 13.22 and Fig. 13.59).

INVESTIGATIONS IN HEART FAILURE

- **Blood tests.** Full blood count, liver biochemistry, urea and electrolytes, cardiac enzymes in acute heart failure, BNP or N-terminal portion of proBNF (NPproBNP), thyroid function.
- **Chest X-ray.** Look for cardiomegaly, pulmonary congestion with upper lobe diversion, fluid in fissures, Kerley B lines, and pulmonary oedema.
- **Electrocardiogram** for ischaemia, hypertension or arrhythmia.
- **Echocardiography.** Cardiac chamber dimension, systolic and diastolic function, regional wall motion abnormalities, valvular heart disease, cardiomyopathies.
- **Stress echocardiography.** Assessment of viability in dysfunctional myocardium – dobutamine identifies contractile reserve in stunned or hibernating myocardium.
- **Nuclear cardiology.** Radionucleotide angiography (RNA) can quantify ventricular ejection fraction, single-photon-emission computed tomography (SPECT) or positron emission tomography (PET) can demonstrate myocardial ischaemia and viability in dysfunctional myocardium.
- **CMR (cardiac MRI).** Assessment of viability in dysfunctional myocardium with the use of dobutamine for contractile reserve or with gadolinium for delayed enhancement ('infarct imaging').
- **Cardiac catheterization.** Diagnosis of ischaemic heart failure (and suitability for revascularization), measurement of pulmonary artery pressure, left atrial (wedge) pressure, left ventricular end-diastolic pressure.
- **Cardiac biopsy.** Diagnosis of cardiomyopathies, e.g. amyloid, follow-up of transplanted patients to assess rejection.
- **Cardiopulmonary exercise testing.** Peak oxygen consumption (VO_2) is predictive of hospital admission and death in heart failure. A 6-minute exercise walk is an alternative.
- **Ambulatory 24-hour ECG monitoring (Holter).** In patients with suspected arrhythmia. May be used in patients with severe heart failure or inherited cardiomyopathy to determine if a defibrillator is appropriate (non-sustained ventricular tachycardia).

TREATMENT OF HEART FAILURE

Treatment is aimed at relieving symptoms, prevention and control of disease leading to cardiac dysfunction and heart failure, retarding disease progression and improving quality and length of life.

Measures to prevent heart failure include cessation of smoking, alcohol and illicit drugs, effective treatment of hypertension, diabetes and hypercholesterolaemia, and pharmacological therapy following myocardial infarction.

The management of heart failure requires that any factor aggravating the failure should be identified and treated. Similarly, the cause of heart failure must be elucidated and where possible corrected. Community nursing programmes to help with drug compliance and to detect early deterioration may prevent acute hospitalization.

General lifestyle advice

Education

Effective counselling of patients and family, emphasizing weight monitoring and dose adjustment of diuretics, may prevent hospitalization.

Obesity control

Maintain desired weight and body mass index.

Dietary modification

Large meals should be avoided and, if necessary, weight reduction instituted. Salt restriction is necessary and foods rich in salt or added salt in cooking and at the table should be avoided. A low-sodium diet is unpalatable and of questionable value. In severe heart failure fluid restriction is necessary. Alcohol has a negative inotropic effect and heart failure patients should moderate consumption.

A recent study has shown that omega-3 polyunsaturated fatty acids reduce mortality and admission to hospital.

Smoking

Smoking should be stopped, with help from antismoking clinics (p. 830) if necessary.

Physical activity, exercise training and rehabilitation

For patients with exacerbations of congestive cardiac failure, bed rest reduces the demands on the heart and is useful for a few days. Migration of fluid from the interstitium promotes a diuresis, reducing heart failure. Prolonged bed rest may lead to development of deep vein thrombosis; this can be avoided by daily leg exercises, low-dose subcutaneous heparin and elastic support stockings. Low-level endurance exercise (e.g. 20–30 minutes walking three or five times per week, or 20 minutes cycling at 70–80% of peak heart rate five times per week) is actively encouraged in patients with compensated heart failure in order to reverse 'deconditioning' of peripheral muscle metabolism. Strenuous isometric activity should be avoided.

Vaccination

While prospective clinical trials are lacking, it is recommended that patients with heart failure be vaccinated against pneumococcal disease and influenza.

Air travel

This is possible for most patients, subject to clinical circumstances. Check with the airline – most have guidelines on who should travel.

Sexual activity

Tell patients on nitrates not to take phosphodiesterase type 5 inhibitors (e.g. sildenafil) as it may induce profound hypotension.

Driving

Driving motor cars and motorcycles may continue provided there are no symptoms that distract the driver's attention. The DVLA in the UK does not need to be notified. Symptomatic heart failure disqualifies patients from driving large lorries and buses. Re/licensing may be permitted provided that the LV ejection fraction is good (i.e. LVEF is >0.4), the exercise test requirements can be met and there is no other disqualifying condition.

Monitoring of heart failure patients

The clinical condition of a person with heart failure fluctuates, and repeated admissions to hospital is common. Monitoring of clinical status is necessary and this responsibility should be shared between primary and secondary care health professionals.

Essential monitoring includes assessment of:

- functional capacity (e.g. VO_2 max, exercise tolerance test, echocardiography)
- fluid status (bodyweight, U&Es, clinical)
- cardiac rhythm (ECG, 24-hour tape).

Multidisciplinary team approach

Heart failure care should be delivered by a multidisciplinary team with an integrated approach across the healthcare community. The use of multiple biomarkers, e.g. troponins and CRP, is of prognostic value. The multidisciplinary team should involve specialist healthcare professionals: heart failure nurse, dietitian, pharmacist, occupational therapist, physiotherapist and palliative care adviser.

Understanding the information needs of patients and carers is vital. Good communication is essential for best clinical management, which should include advice on anxiety, depression and 'end of life' issues.

Drug management (Table 13.23)

The recommendations for pharmacological treatment of heart failure are based on consensus guidelines produced by the European Society of Cardiology and NICE (UK) (Figs 13.60 and 13.61).

Diuretics (p. 657)

These act by promoting the renal excretion of salt and water by blocking tubular reabsorption of sodium and chloride. Loop diuretics (e.g. furosemide and bumetanide) and thiazide diuretics (e.g. bendroflumethiazide, hydrochlorothiazide) should be given in patients with fluid overload. Although diuretics provide symptomatic relief of dyspnoea and improve exercise tolerance, there is limited evidence that they affect survival. In severe heart failure patients the combination of a loop and thiazide diuretic may be required. Serum electrolytes and renal function must be monitored regularly (risk of hypokalaemia and hypomagnesaemia).

Angiotensin-converting enzyme inhibitors ACEI

(Fig. 18.27, p. 1023)

Trials have shown that in addition to producing considerable symptomatic improvement in patients with symptomatic heart failure, prognosis is markedly improved and development of heart failure is slowed. ACEI also benefit patients with asymptomatic heart failure following myocardial infarction. Thus ACEI improve survival in patients in all functional classes (NYHA I–IV) and are recommended in all patients at risk of developing heart failure. The main adverse effects of ACE inhibitors are cough, hypotension, hyperkalaemia and renal dysfunction. The contraindications to their use include renal artery stenosis, pregnancy and previous angioedema. In patients with heart failure ACEI should be introduced gradually with a low initial dose and gradual titration with regular blood pressure monitoring. Serum creatinine should be measured concomitantly; potassium-sparing diuretics should be discontinued.

Angiotensin II receptor antagonists (ARA)

The angiotensin II receptor antagonists (ARA) (candesartan and valsartan) are indicated as second-line therapy in patients intolerant of ACEI. Unlike ACEI they do not affect bradykinin metabolism and do not produce a cough. The CHARM Alternative Trial showed that candesartan reduced the risk of heart failure hospitalization compared to placebo in patients intolerant to ACEI. Other trials (Val HeFT and ELITE II) have assessed other ARA.

Beta-blockers

Beta-blockers have been shown to improve functional status and reduce cardiovascular morbidity and mortality in patients with heart failure. Several trials (CIBIS, CIBIS II, MERIT-HF, COMET, SENOIRS) have assessed the effects of beta-blockers in varying degrees of heart failure. Bisoprolol and carvedilol reduce mortality in any grade of heart failure.

Nebivolol is used in the treatment of stable mild–moderate heart failure in patients over 70 years old.

In patients with heart failure, only evidence-based beta-blockers from successful trials should be used. In patients

Table 13.23 Drugs used in heart failure

Drug	Dose (initial/target)	Precautions
ACE inhibitors/angiotensin II receptor antagonists		Monitor renal function and avoid if baseline serum creatinine >250 μmol/L or baseline BP < 90 mmHg
Captopril	6.25 mg × 3 daily/25–50 mg × 3 daily	
Enalapril	2.5 mg daily/10 mg × 2 daily	
Ramipril	1.25–2.5 mg daily/2.5–5 mg × 2 daily	
Candesartan	4 mg daily/32 mg daily	
Valsartan	80 mg daily/320 mg daily	
Losartan	50 mg daily/100 mg daily	
Beta-blockers		Caution in obstructive airways disease, bradyarrhythmias
Bisoprolol	1.25 mg daily/10 mg daily	Avoid in acute heart failure until cardiovascularly stable
Carvedilol	3.125 mg daily/50 mg daily	
Nebivolol	1.25 mg daily/10 mg daily	
Diuretics		Monitor renal function and check for hypokalaemia and hypomagnesaemia
Furosemide	20–40 mg daily/max. 250–500 mg daily	
Bumetanide	0.5–1.0 mg daily/max. 5–10 mg daily	
Bendroflumethiazide	2.5 mg daily/max. 10 mg daily	
Metolazone	2.5 mg daily/max. 10 mg daily	For severe heart failure
Aldosterone antagonists		Monitor renal function, check for hyperkalaemia, gynaecomastia with spironolactone
Spironolactone	12.5–25 mg daily/max. 50–200 mg daily (lower if on ACE inhibitor)	
Eplerenone	25 mg daily/50 mg daily	
Cardiac glycosides		
Digoxin	0.125–0.25 mg daily (reduce dose in elderly or if renal impairment)	Caution in renal impairment, conduction disease and if on amiodarone
Vasodilators		
Isosorbide dinitrate	20–40 mg × 3 daily	
Hydralazine	37.5–75 mg × 3 daily	

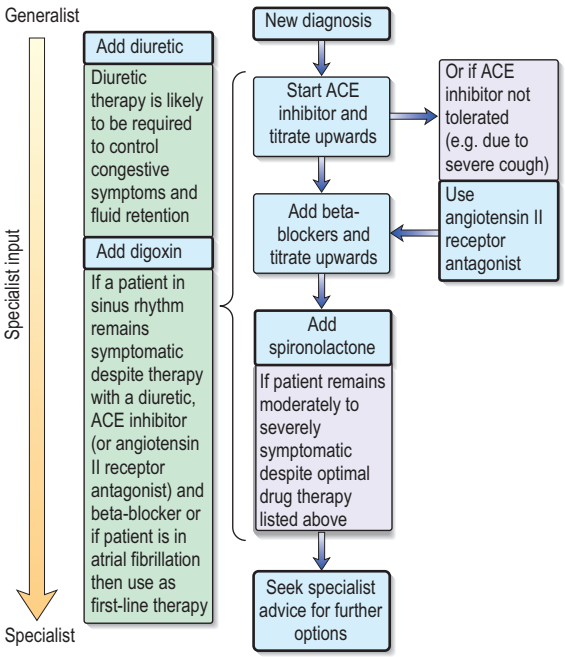

Fig. 13.60 Heart failure treatment guidelines. From NICE. 'Algorithm for the pharmacological treatment of symptomatic heart failure due to left ventricular systolic dysfunction' in CG5 chronic heart failure: management of chronic heart failure in adults in primary and secondary care. London: NICE, 2003. Available from www.nice.org.uk/CG005. Reproduced with permission.

with significant heart failure, beta-blockers are started at a low dose and gradually increased.

Aldosterone antagonists

The aldosterone antagonists spironolactone and eplerenone have been shown to improve survival in patients with heart failure. In RALES, spironolactone reduced total mortality by 30% in patients with severe heart failure. However, gynaecomastia or breast pain occurred in 1 in 10 men taking spironolactone. In EPHESUS, eplerenone given to patients with an acute myocardial infarction and heart failure reduced total mortality by 15% and sudden cardiac death by 21%, with no gynaecomastia.

Cardiac glycosides

Digoxin is a cardiac glycoside that is indicated in patients in atrial fibrillation with heart failure. It is used as add-on therapy in symptomatic heart failure patients already receiving ACEI and beta-blockers. The DIG study demonstrated that digoxin reduced hospital admissions in patients with heart failure.

Vasodilators and nitrates

The combination of hydralazine and nitrates reduces afterload and pre-load and is used in patients intolerant of ACEI or ARA. The Veterans Administration Cooperative Study demonstrated that the combination of hydralazine (with nitrates) improved survival in patients with chronic heart failure. The A-HeFT trial showed that the same combination reduced mortality and hospitalization for heart failure in black patients with heart failure.

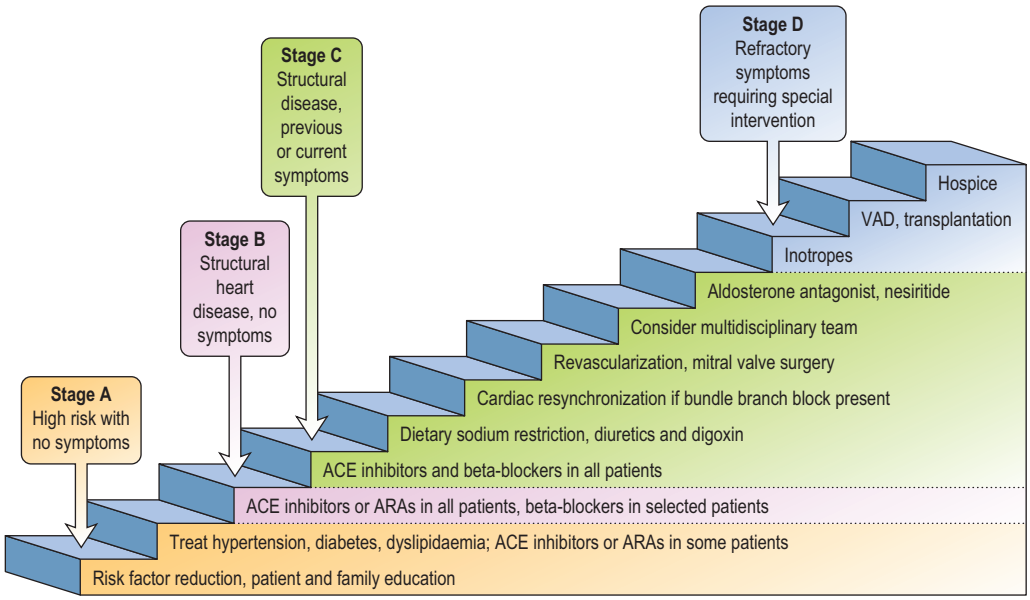

Fig. 13.61 **Stages of heart failure and treatment options for systolic heart failure**. ARA, angiotensin II receptor antagonist; ACE, angiotensin-converting enzyme; VAD, ventricular assisted device. From Jessop M, Brozana S. *New England Journal of Medicine* 2003; **348**: 2013, with permission. Copyright © 2003 Massachusetts Medical Society. All rights reserved.

Inotropic and vasopressor agents

Intravenous inotropes and vasopressor agents (see Table 13.23) are used in patients with chronic heart failure who are not responding to oral medication. Although they produce haemodynamic improvements they have not been shown to improve long-term mortality when compared with placebo.

Other medications

In hospital all patients require prophylactic anticoagulation. Heart failure is associated with a four-fold increase in the risk of a stroke. Oral anticoagulants are recommended in patients with atrial fibrillation and in patients with sinus rhythm with a history of thromboembolism, left ventricular thrombus or aneurysm. In patients with known ischaemic heart disease antiplatelet therapy (aspirin, clopidogrel) and statin therapy should be continued. Arrhythmias are frequent in heart failure and are implicated in sudden death. Although treatment of complex ventricular arrhythmias might be expected to improve survival, there is no evidence to support this and it may increase mortality. In the Sudden Cardiac Death Heart Failure Trial (SCD-HeFT), amiodarone showed no benefit compared to placebo in patients with impaired left ventricular function and mild–moderate heart failure (whereas an ICD reduced mortality by 23% compared to placebo). Patients with heart failure and symptomatic ventricular arrhythmias should be assessed for suitability for an ICD.

Ivabradine, which inhibits the I_f channels in the sincatrial node, slows the heart rate and this may be beneficial in heart failure.

Non-pharmacological treatment of heart failure

Revascularization

While coronary artery disease is the most common cause of heart failure, the role of revascularization in patients with heart failure is unclear. Patients with angina and left ventricular dysfunction have a higher mortality from surgery (10–20%), but have the most to gain in terms of improved symptoms and prognosis. Factors that must be considered before recommending surgery include age, symptoms and evidence for reversible myocardial ischaemia.

Hibernating myocardium and myocardial stunning

'Hibernating' myocardium can be defined as reversible left ventricular dysfunction due to chronic coronary artery disease that responds positively to inotropic stress and indicates the presence of viable heart muscle that may recover after revascularization. It is due to reduced myocardial perfusion, which is just sufficient to maintain viability of the heart muscle. Myocardial hibernation results from repetitive episodes of cardiac stunning that occur, for example, with repeated exercise in a patient with coronary artery disease.

Myocardial stunning is reversible ventricular dysfunction that persists following an episode of ischaemia when the blood flow has returned to normal, i.e. there is a mismatch between flow and function.

The prevalence of hibernating myocardium in patients with coronary artery disease can be estimated from the frequency of improvement in regional abnormalities in wall motion after revascularization and is estimated to be 33% of such patients. Techniques to try to identify hibernating myocardium include stress echocardiography, nuclear imaging techniques, cardiovascular magnetic resonance and positron emission tomography.

The clinical relevance of the hibernating and stunned myocardium is that ventricular dysfunction due to these mechanisms may be wrongly ascribed to myocardial necrosis and scarring which seems untreatable, whereas reversible hibernating and stunning respond to coronary revascularization.

Biventricular pacemaker or implantable cardioverter–defibrillator (p. 732) (Fig. 13.62)

Pacemakers are indicated in patients with sinoatrial disease and atrioventricular conduction block. Pacemakers are also valuable in patients without AV block but with prolonged PR intervals, left bundle branch block and severe mitral regurgitation. In patients with heart failure and left bundle branch block and NYHA 3 heart failure (MUSTIC study) biventricular pacing is more beneficial than conventional right ventricular pacing. The results showed an improvement in symptoms and exercise tolerance. The effect on prognosis is being addressed by an ongoing trial (CARE HF).

Biventricular pacing can also be used in patients not responding to therapy in the following situations:

- systolic heart failure
- non-reversible cause
- highly symptomatic (New York Heart Association grade 3/4)
- on optimal medical therapy
- ventricular dys-synchrony: left bundle branch block (QRS >120 ms)
- sinus rhythm, and possibly atrial fibrillation
- significant mitral regurgitation.

New guidelines recommend advanced pacing technologies should be used for cardiac resynchronization therapy (CRT) in selected patients with heart failure. Atrio-biventricular pacing has been shown to improve symptoms and reduce admission to hospital in patients with left bundle branch block and heart failure with poor LV function. The use of combined implantable defibrillators and atrio-biventricular pacemakers for patients with heart failure is likely to increase. One large trial (COMPANION) shows 21% reduction in all-cause mortality and all-cause admissions to hospital in the groups receiving biventricular pacing. ICD therapy in patients with NYHA (Grades 1 and 2, see Table 13.2, p. 688) has shown a reduction in mortality compared with placebo and amiodarone.

Cardiac transplantation

Cardiac transplantation has become the treatment of choice for younger patients with severe intractable heart failure, whose life-expectancy is less than 6 months. With careful recipient selection, the expected 1-year survival for patients following transplantation is over 90%, and is 75% at 5 years.

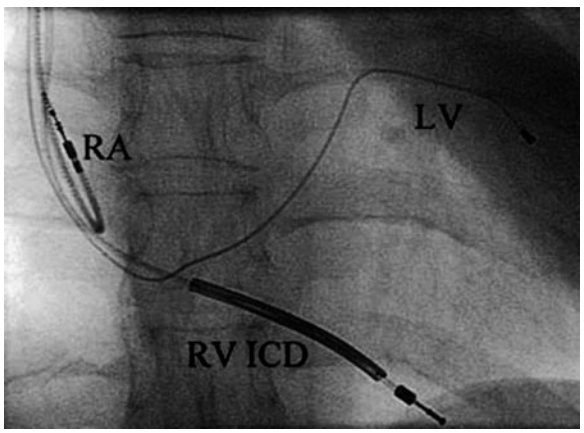

Fig. 13.62 Implanted biventricular pacing with ICD device.

Irrespective of survival, quality of life is dramatically improved for the majority of patients. The availability of heart transplantation is limited.

Heart allografts do not function normally. Cardiac denervation results in a high resting heart rate, loss of diurnal blood pressure variation and impaired renin–angiotensin–aldosterone regulation. Some patients develop 'stiff heart' syndrome, caused by rejection, denervation and ischaemic injury during organ harvest and implantation. Transplantation of an inappropriately small donor heart can also result in elevated right and left heart pressure.

The complications of heart transplantation are summarized in Table 13.24. Many (infection, malignancy, hypertension and hyperlipidaemia) are related to immunosuppression. Allograft coronary atherosclerosis is the major cause of long-term graft failure and is present in 30–50% of patients at 5 years. It is due to a 'vascular' rejection process in conjunction with hypertension and hyperlipidaemia.

There are specific contraindications to cardiac transplantation (Table 13.25); notably, high pulmonary vascular resistance is an absolute contraindication. Several options to transplantation are available: cardiomyoplasty (augmentation of left ventricular contraction by wrapping a latissimus dorsi muscle flap around the ventricle) and the Batista procedure (surgical ventricular size reduction and remodelling the geometry of the left ventricle). Both procedures have a high mortality and limited evidence of substantial benefit in the medium term.

Table 13.24 Complications of cardiac transplantation

Allograft rejection	**Allograft vascular disease**
'Humoral'	**Hypertension**
'Vascular'	**Hypercholesterolaemia**
'Cell-mediated'	**Malignancy**
Infections	
Early: nosocomial organisms – staphylococci, Gram-negative bacteria	
Late (2–6 months): opportunistic (toxoplasmosis, cytomegalovirus, fungi, *Pneumocystis*)	

Table 13.25 Contraindications for cardiac transplantation

Age > 60 years (some variations between centres)
Alcohol/drug abuse
Uncontrolled psychiatric illness
Uncontrolled infection
Severe renal/liver failure
High pulmonary vascular resistance
Systemic disease with multiorgan involvement
Treated cancer in remission but with <5 years' follow-up
Recent thromboembolism
Other disease with a poor prognosis

Acute heart failure

Acute heart failure (AHF) occurs with the rapid onset of symptoms and signs of heart failure secondary to abnormal cardiac function, causing elevated cardiac filling pressures. This causes severe dyspnoea and fluid accumulates in the interstition and alveolar spaces of the lung (pulmonary oedema). AHF has a poor prognosis with a 60-day mortality rate of nearly 10% and a rate of death or rehospitalization of 35% within 60 days. In patients with *acute pulmonary oedema* the in-hospital mortality rate is 12% and by 12 months this rises to 30%. Poor prognostic indicators include a high (>16 mmHg) pulmonary capillary wedge pressure (PCWP), low serum sodium concentration, increased left ventricular end-diastolic dimension on echo and low oxygen consumption.

The aetiology of AHF is similar to chronic heart failure:

- Patients with *ischaemic heart disease* present with an acute coronary syndrome or develop a complication of a myocardial infarct, e.g. papillary muscle rupture or ventricular septal defect requiring surgical intervention.
- Patients with *valvular heart disease* also present with AHF due to valvular regurgitation in endocarditis or prosthetic valve thrombosis. A thoracic aortic dissection may produce severe aortic regurgitation.
- Patients with *hypertension* present with episodes of 'flash' pulmonary oedema despite preserved left ventricular systolic function.
- In both *acute and chronic kidney disease* fluid overload and a reduced renal excretion will produce pulmonary oedema.
- *Atrial fibrillation* is frequently associated with AHF and may require emergency cardioversion.

Several clinical syndromes of AHF can be defined (Table 13.26). In a clinical environment both the Killip score (p. 758, based on a cardiorespiratory clinical assessment) and Forrester (based on right catheterization findings) classification are used to provide therapeutic and prognostic information.

Table 13.26 Clinical syndromes of acute heart failure (AHF)

Type	Clinical features
Acute decompensated heart failure	Mild features of heart failure, e.g. dyspnoea
Hypertensive AHF	High blood pressure, preserved left ventricular function, pulmonary oedema on CXR
Acute pulmonary oedema	Tachypnoea, orthopnoea, pulmonary crackles, oxygen saturation <90% on air, pulmonary oedema on CXR
Cardiogenic shock	Systolic blood pressure <90 mmHg, mean arterial pressure drop >30 mmHg, urine output <0.5 mL/kg/hour, heart rate >60 b.p.m.
High output heart failure	Warm peripheries, pulmonary congestion, blood pressure may be low, e.g. septic shock
Right heart failure	Low cardiac output, elevated jugular venous pressure, hepatomegaly, hypotension

Modified from the European Society of Cardiology.

Pathophysiology

The pathophyisology of AHF is similar to chronic heart failure with activation of the renin–angiotensin–aldosterone axis and sympathetic nervous system. In addition, prolonged ischaemia (e.g. in acute coronary syndromes) results in myocardial stunning (p. 740) that exacerbates myocardial dysfunction but may respond to inotropic support. If myocardial ischaemia persists the myocardium may exhibit hibernation (persistently impaired function due to reduced coronary blood flow) that may recover with successful revascularization.

Diagnosis

In a patient presenting with symptoms and signs of heart failure a structured assessment should result in the clinical diagnosis of AHF and direct initial treatment to stabilize the patient. Initial investigations performed in the emergency room should include:

- a *12-lead ECG* for acute coronary syndromes, left ventricular hypertrophy, atrial fibrillation, valvular heart disease, left bundle branch block
- a *chest X-ray* (cardiomegaly, pulmonary oedema, pleural effusion, non-cardiac disease)
- *blood investigations* (serum creatinine and electrolytes, full blood count, blood glucose, cardiac enzymes and troponin, CRP and D-dimer)
- *plasma BNP* or *NTproBNP* (BNP >100 pg/ml or NTproBNP >300 pg/ml) indicates heart failure
- transthoracic echocardiography should be performed without delay to confirm the diagnosis of heart failure (p. 704) and possibly identify the cause.

If the baseline investigations confirm AHF then treatment should be commenced.

Treatment

The goals of treatment in a patient with AHF include:

- immediate relief of symptoms and stabilization of haemodynamics (short-term benefits)
- reduction in length of hospital stay and hospital readmissions
- reduction in mortality from heart failure.

Patients with AHF should be managed in a high-care area with regular measurements of temperature, heart rate, blood pressure and cardiac monitoring. All patients require prophylactic anticoagulation with low molecular weigh heparin, e.g. enoxaparin 1 mg/kg s.c. daily.

Patients with haemodynamic compromise may require arterial lines (invasive blood pressure monitoring and arterial gases), central venous cannulation (intravenous medication, inotropic support, monitoring of central venous pressure) and pulmonary artery cannulation (calculation of cardiac output/index, peripheral vasoconstriction and pulmonary wedge pressure).

Initial therapy (Table 13.23) includes oxygen, diuretics (e.g. I.V. furosemide 50 mg) and vasodilator therapy (e.g. glyceryl trinitrate infusion 10–200 μg/min) if the blood pressure is maintained (systolic >85 mmHg). Inotropic support (see p. 907) with dobutamine, phosphodiesterase inhibitors or levosimendan can be added in patients who do not

respond to the initial therapy (Fig. 13.63). If blood pressure is low use noradrenaline (norepinephrine).

Patients with profound hypotension may require inotropes and vasopressors to improve the haemodynamic status and alleviate symptoms, but these have not been shown to improve mortality. Recently, non-invasive CPAP/NIPPV (see p. 916) has been shown to provide earlier improvement in dyspnoea and respiratory distress than standard oxygen via masks; mortality is however unaffected.

Mechanical assist devices

Mechanical assist devices can be used in patients who fail to respond to standard medical therapy but in whom there is either transient myocardial dysfunction with likelihood of recovery (e.g. post anterior myocardial infarction treated with coronary angioplasty) or a bridge is needed to cardiac surgery, including transplantation.

Ventricular assist devices (VAD) (Fig. 13.64). Ventricular assist devices are mechanical devices that replace or help the failing ventricles in delivering blood around the body. A

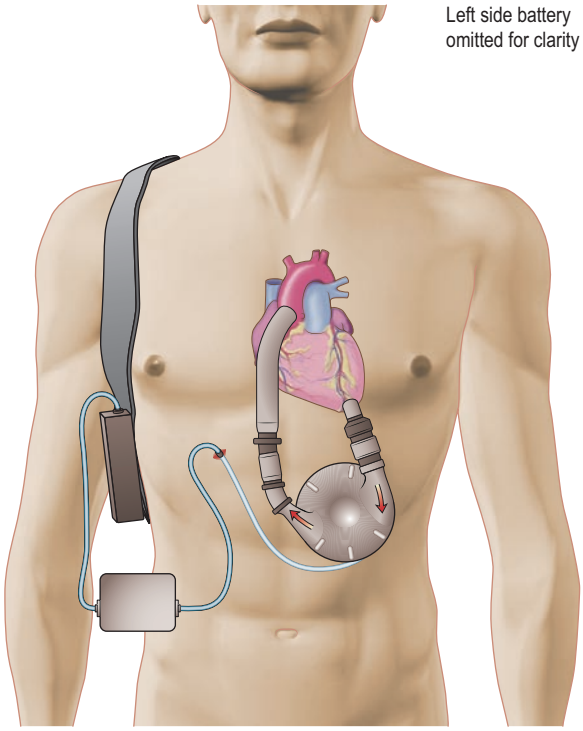

Fig. 13.64 **Left ventricular assist device.** From Moser DK, Riegel B. *Cardiac Nursing.* Philadelphia: Saunders, 2007: 981, with permission of Elsevier.

left ventricular assist device (LVAD) receives blood from the left ventricle and delivers it to the aorta; a right ventricular assist device (RVAD) receives blood from the right ventricle and delivers it to the pulmonary artery. The devices can be extracorporeal (suitable for short-term support) or intracorporeal (suitable for long-term support as a bridge to transplantation or as destination therapy in patients with end-stage heart failure not candidates for transplantation). The main problems with VADs include thromboembolism, bleeding, infection and device malfunction.

ISCHAEMIC HEART DISEASE

Myocardial ischaemia occurs when there is an imbalance between the supply of oxygen (and other essential myocardial nutrients) and the myocardial demand for these substances.

Coronary blood flow to a region of the myocardium may be reduced by a mechanical obstruction that is due to:

- atheroma
- thrombosis
- spasm
- embolus
- coronary ostial stenosis
- coronary arteritis (e.g. in SLE).

There can be a decrease in the flow of oxygenated blood to the myocardium that is due to:

- anaemia
- carboxyhaemoglobulinaemia

- hypotension causing decreased coronary perfusion pressure.

An increased demand for oxygen may occur owing to an increase in cardiac output (e.g. thyrotoxicosis) or myocardial hypertrophy (e.g. from aortic stenosis or hypertension).

Myocardial ischaemia most commonly occurs as a result of obstructive coronary artery disease (CAD) in the form of coronary atherosclerosis. In addition to this fixed obstruction, variations in the tone of smooth muscle in the wall of a coronary artery may add another element of dynamic or variable obstruction.

CAD is the largest single cause of death in the UK and many parts of the world. However, over the last decade, the mortality rate in the UK has fallen considerably. Each year there are approximately 60 deaths per 100 000 (giving a standardized mortality rate of about 200 per 100 000). It has been estimated that by 2010, 60% of the world's heart disease is expected to occur in India. Sudden cardiac death is a prominent feature of CAD. One in every six coronary attacks present with sudden death as the first, last and only symptom.

Process of coronary atherosclerosis

Coronary atherosclerosis is a complex inflammatory process characterized by the accumulation of lipid, macrophages and smooth muscle cells in intimal plaques in the large and medium-sized epicardial coronary arteries. The vascular endothelium plays a critical role in maintaining vascular integrity and homeostasis. Mechanical shear stresses (e.g. from morbid hypertension), biochemical abnormalities (e.g. elevated and modified LDL, diabetes mellitus, elevated plasma homocysteine), immunological factors (e.g. free radicals from smoking), inflammation (e.g. infection such as *Chlamydia pneumoniae* and *Helicobacter pylori*) and genetic alteration may contribute to the initial endothelial 'injury' or dysfunction, which is believed to trigger atherogenesis.

The *development of atherosclerosis* follows the endothelial dysfunction, with increased permeability to and accumulation of oxidized lipoproteins, which are taken up by macrophages at focal sites within the endothelium to produce lipid-laden foam cells. Macroscopically, these lesions are seen as flat yellow dots or lines on the endothelium of the artery and are known as '*fatty streaks*'. The 'fatty streak' progresses with the appearance of extracellular lipid within the endothelium ('*transitional plaque*'). Release of cytokines such as platelet-derived growth factor and transforming growth factor-β (TGF-β) by monocytes, macrophages or the damaged endothelium promotes further accumulation of macrophages as well as smooth muscle cell migration and proliferation. The proliferation of smooth muscle with the formation of a layer of cells covering the extracellular lipid separates it from the adaptive smooth muscle thickening in the endothelium. Collagen is produced in larger and larger quantities by the smooth muscle and the whole sequence of events cumulates as an '*advanced or raised fibrolipid plaque*'. The 'advanced plaque' may grow slowly and encroach on the lumen or become unstable, undergo thrombosis and produce an obstruction ('*complicated plaque*').

Two different mechanisms are responsible for thrombosis on the plaques (Fig. 13.65).

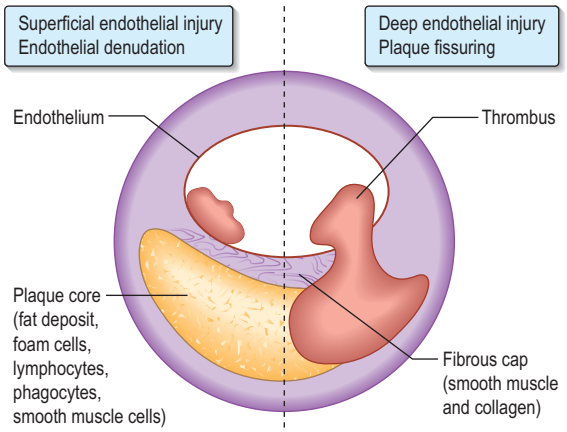

Fig. 13.65 **The mechanisms for the development of thrombosis on plaques.**

- The *first process* is superficial endothelial injury, which involves denudation of the endothelial covering over the plaque. Subendocardial connective tissue matrix is then exposed and platelet adhesion occurs because of reaction with collagen. The thrombus is adherent to the surface of the plaque.
- The *second process* is deep endothelial fissuring, which involves an advanced plaque with a lipid core. The plaque cap tears (ulcerates, fissures or ruptures), allowing blood from the lumen to enter the inside of the plaque itself. The core with lamellar lipid surfaces, tissue factor (which triggers platelet adhesion and activation) produced by macrophages and exposed collagen, is highly thrombogenic. Thrombus forms within the plaque, expanding its volume and distorting its shape. Thrombosis may then extend into the lumen.

A 50% reduction in luminal diameter (producing a reduction in luminal cross-sectional area of approximately 70%) causes a haemodynamically significant stenosis. At this point the smaller distal intramyocardial arteries and arterioles are maximally dilated (coronary flow reserve is near zero), and any increase in myocardial oxygen demand provokes ischaemia.

CAD gives rise to a wide variety of clinical presentations, ranging from relatively stable angina through to the acute coronary syndromes of unstable angina and myocardial infarction (Fig. 13.66). Figure 13.67 shows an actual plaque rupture.

Risk factors for coronary artery disease – primary and secondary prevention

CAD is an atherosclerotic disease that is multifactorial in origin, giving rise to the risk factor concept. Certain living habits promote atherogenic traits in genetically susceptible persons. A number of 'risk' factors are known to predispose to the condition (Table 13.27). Some of these, such as age, gender, race and family history, cannot be changed, whereas other major risk factors, such as serum cholesterol, smoking habits, diabetes and hypertension, can be modified.

Atherosclerotic disease manifest in one vascular bed is often advanced in other territories. Patients with intermittent

Obesity
Gout
Soft water
Drugs, e.g. contraceptive pill, nucleoside analogues, COX-2 inhibitors, rosiglitazone
Heavy alcohol consumption

claudication have a two- to four-fold increased risk of CAD, stroke, or heart failure. Following initial myocardial infarction (MI), there is a three- to six-fold increase in the risk of heart failure and stroke. After stroke, the risk of heart failure and MI is increased twofold.

The disease can be asymptomatic in its most severe form, with one in three myocardial infarctions going unrecognized. Thirty to 40% of individuals who present with an acute coronary syndrome have had no prior warning symptom to suggest the presence of underlying disease.

Primary prevention can be defined as the prevention of the atherosclerotic disease process and *secondary prevention* as the treatment of the atherosclerotic disease process (i.e. treatment of the disease or its complications). The objective of prevention is to reduce the incidence of first or recurrent clinical events due to CAD, ischaemic stroke and peripheral artery disease.

Traditional risk factors

Age

CAD rates increase with age. Atherosclerosis is rare in childhood, except in familial hyperlipidaemia, but is often detectable in young men between 20 and 30 years of age. It is almost universal in the elderly in the West. Atheromatous lesions in the elderly are often complicated by calcification.

Gender

Men have a higher incidence of coronary artery disease than premenopausal women. However, after the menopause, the incidence of atheroma in women approaches that in men. The reasons for this gender difference are not clearly understood, but probably relate to the loss of the protective effect of oestrogen.

Family history

CAD is often found in several members of the same family. Because the disease is so prevalent and because other risk factors are familial, it is uncertain whether family history, per se, is an independent risk factor. A positive family history is generally accepted to refer to those in whom a first-degree relative has developed ischaemic heart disease before the age of 50 years.

Smoking (see p. 829)

In men, the risk of developing CAD is directly related to the number of cigarettes smoked. It is estimated that about 20% of deaths from CAD in men and 17% of deaths from CAD in women are due to smoking. Evidence suggests that each

person stopping smoking will reduce his/her own risk by 25%. The risk from smoking declines to almost normal after 10 years of abstention.

Diet and obesity (see p. 228)

Diets high in fats are associated with ischaemic heart disease, as are those with low intakes of antioxidants (i.e. fruit and vegetables). Supplementation with antioxidants has been shown to be unhelpful in RCTs (p. 224).

It is estimated that up to 30% of deaths from CAD are due to unhealthy diets. The dietary changes which would help to reduce rates of CAD include a reduction in fat, particularly saturated fat intake, a reduction in salt intake and an increase in carbohydrate intake. The consumption of fruit and vegetables should be increased by 50% to about 400 g per day, which is equivalent to at least five daily portions (see Box 5.2).

There is overwhelming evidence from clinical trials that modification of the diet has a significant impact on the risk of CVD in both the primary and secondary prevention settings.

Weight. Patients who are overweight and those who are obese have an increased risk of CAD. It is estimated that about 5% of deaths from CAD in men and that 6% of such deaths in women are due to obesity (a body mass index (BMI) of greater than 30 kg/m^2).

The adverse effect of excess weight is more pronounced when the fat is concentrated mainly in the abdomen. This is known as central obesity (visceral fat) and can be identified by a high waist/hip ratio.

Exercise. Reduction in weight by diet and exercise not only lowers the incidence of CVD but also diabetes/insulin resistance. It is estimated that about 36% of deaths from CAD in men and 38% of deaths from CAD in women are due to lack of physical activity. To produce the maximum benefit the activity needs to be regular and aerobic. Aerobic activity involves using the large muscle groups in the arms, legs and back steadily and rhythmically so that breathing and heart rate are significantly increased.

It is recommended that adults should participate in a minimum of 30 minutes of at least moderate intensity activity (such as brisk walking, cycling or climbing the stairs) on 5 or more days of the week.

Hypertension

Both systolic and diastolic hypertension are associated with an increased risk of CAD. Both drug treatment and lifestyle changes – particularly weight loss, an increase in physical activity and a reduction in salt and alcohol intake – can effectively lower blood pressure.

It is estimated that 14% of deaths from CAD in men and 12% of deaths from CAD in women are due to a raised blood pressure (defined as a systolic blood pressure of 140 mmHg or over, or a diastolic blood pressure of 90 mmHg or over) and that 6% of deaths from CAD in the UK could be avoided if the numbers of people who have high blood pressure were to be reduced by 50%.

Hyperlipidaemia (see p. 1063)

High serum cholesterol, especially when associated with a low value of high-density lipoproteins (HDL), is strongly associated with coronary atheroma. There is increasing evidence that high serum triglyceride (TG) is also independently linked with coronary atheroma.

Familial hypercholesterolaemia combined with hypertriglyceridaemia and remnant hyperlipidaemia are also associated with increased risk of coronary atherosclerosis.

Measurement of the fasting lipid profile (total cholesterol, low- and high-density lipoproteins and triglycerides) should be performed on all people with an increased risk of cardiac disease.

The risk of CAD is directly related to serum cholesterol levels. Serum cholesterol levels can be reduced by drugs, physical activity and by dietary changes, in particular a reduction in the consumption of saturated fat. It is estimated that 45% of deaths from CAD in men and 47% of deaths from CAD in women are due to a raised serum cholesterol level (in this case >5.2 mmol/L) and that 10% of deaths from CAD in the UK could be avoided if everyone in the population had a serum cholesterol level of less than 6.5 mmol/L.

Different guidelines give slightly different advice for managing high levels of serum cholesterol (hyperlipidaemia). The National Service Framework for coronary heart disease in England includes guidelines on the prevention of CAD in clinical practice and suggests a cholesterol target of less than 5.0 mmol/L for both primary and secondary prevention.

High-density lipoprotein cholesterol (HDL-cholesterol) is the fraction of cholesterol that removes cholesterol (via the liver) from the blood. Low levels of HDL-cholesterol are associated with an increased risk of CAD and a worse prognosis after a heart attack. Guidelines on HDL-cholesterol generally recommend treatment for those with concentrations below 1.0 mmol/L. HDL increases with exercise, alcohol in moderation, not smoking and when TG is lowered.

A 1% reduction in cholesterol levels reduces risks of CAD by 2–3%. Hyperlipidaemia can be treated as follows:

- *Statins*: 24–30% reduction in mortality in primary and secondary prevention will be achieved if a statin (pravastatin or simvastatin) is given. Up to 50% reduction is achieved if the dose of statin (e.g. atorvastatin) is titrated to achieve a target LDL of <2.6 mmol/L.
- *Fibrates* result in a significant reduction in CAD events in diabetics and patients with high TG and low HDL.
- *Diet*: the so-called Mediterranean diet (p. 210) has resulted in a 75% reduction in CAD events in post-myocardial infarction patients.

Angiographic studies have shown that lowering the serum cholesterol can slow the progression of coronary atherosclerosis, and can cause regression of disease. Large clinical trials have shown that lipid lowering, usually with a statin, can decrease total mortality and new coronary events, and reduce the need for revascularization. Management of hypercholesterolaemia is described in detail on page 1065.

Diabetes mellitus

Diabetes, an abnormal glucose tolerance or raised fasting glucose is strongly associated with vascular disease.

Diabetes substantially increases the risk of CAD. Men with type 2 diabetes have a two- to four-fold greater annual risk of CAD, with an even higher (three- to five-fold) risk in women with type 2 diabetes.

Diabetes not only increases the risk of CAD but also magnifies the effect of other risk factors for CAD such as raised cholesterol levels, raised blood pressure, smoking and obesity.

Other risk factors

Although there is general agreement on established cardiovascular risk factors, epidemiological research continues to identify or evaluate additional risk factors that contribute to the occurrence of atherosclerotic CVD and warrant further clarification.

Sedentary lifestyle

Lack of exercise is an independent risk factor for CAD equal to hypertension, hyperlipidaemia and smoking. Regular exercise probably protects against its development (see above).

Psychosocial well-being

Four different types of psychosocial factors have been found to be most consistently associated with an increased risk of CAD: work stress, lack of social support, depression (including anxiety) and personality (particularly hostility).

Alcohol

Moderate alcohol consumption (one or two drinks per day) is associated with a reduced risk of CAD. At high levels of intake – particularly in 'binges' – the risk of CAD is increased. It is currently advised that 'regular consumption of between three and four units a day by men' and 'between two and three units a day by women of all ages will not lead to any significant health risk'.

Genetic factors

A number of genetic factors have been linked with coronary artery disease. The angiotensin-converting enzyme (ACE) gene contains an insertion/deletion (I/D) polymorphism, the DD genotype of which has been associated with a predisposition to CAD and myocardial infarction.

Lipoprotein (a)

High plasma Lp(a) concentrations are associated with CAD and, although probably not an independent risk factor, elevated plasma Lp(a) increases the CAD risk associated with more traditional risk factors.

Coagulation factors

Serum fibrinogen is strongly, consistently and independently related to CAD risk. The pathophysiological mechanism by which fibrinogen levels mediate coronary disease risk is related to its effect on the coagulation cascade, platelet aggregation, endothelial function and smooth muscle cell proliferation and migration.

High levels of *coagulation factor VII* are also a risk factor. Polymorphisms of the factor VII gene may increase the risk of myocardial infarction.

Homocysteine, an amino acid regulated by vitamins B_{12}, B_6 and folate, is another factor that has been associated with CAD and atherosclerosis (see p. 224). Homocysteinaemia is a major risk factor in the pathogenesis of CAD and a strong predictor of mortality in this group. Plasma levels of homocysteine are influenced by a variety of genetic and non-genetic factors. The mechanism associating hyperhomocysteinaemia with atherosclerosis is its adverse effect on vascular endothelium. Folic acid in low doses may ameliorate this process.

C-reactive protein (CRP)

CRP is linked with future risk of coronary events independently of the traditional risk factors but its use as a marker for subclinical atherosclerosis and cardiovascular risk has been questioned.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs that are specific inhibitors of cyclo-oxygenase-2 (COX-2) have been shown to increase cardiovascular risk and mortality. Rofecoxib has already been withdrawn.

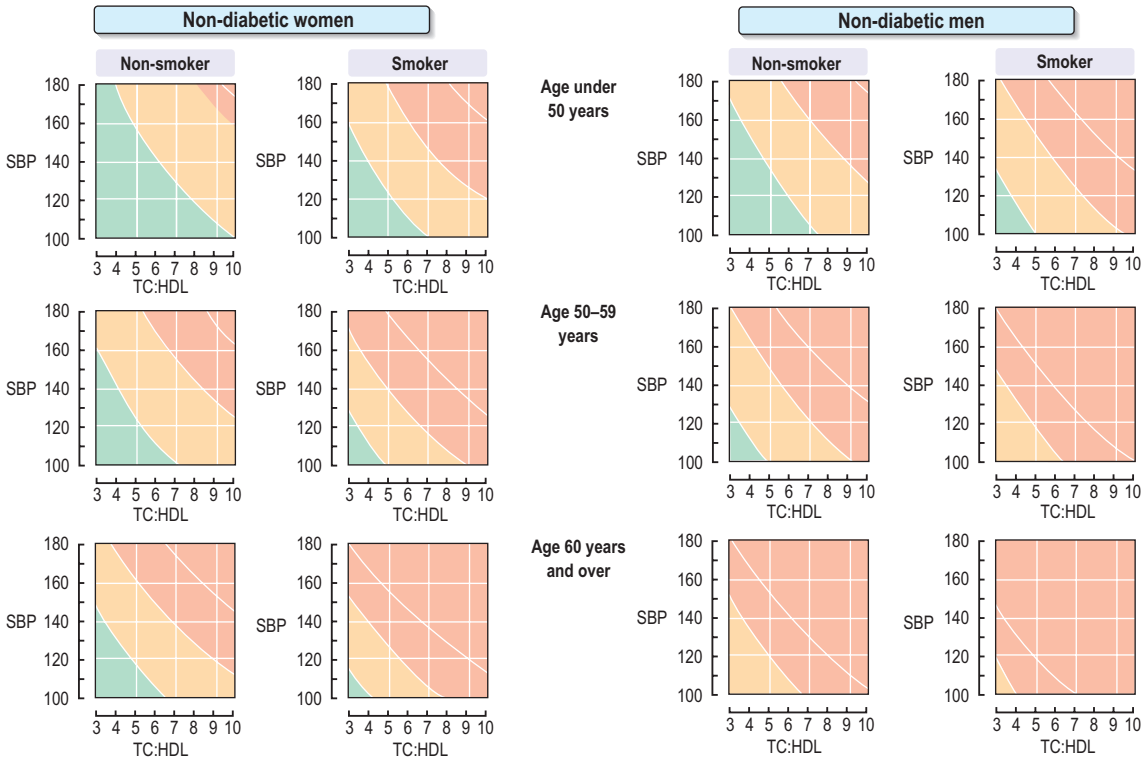
Prevention policy

The priorities for CVD prevention in clinical practice are:

- Patients with established CAD, PVD and cerebrovascular atherosclerotic disease.
- Asymptomatic individuals who are at high risk of developing atherosclerotic disease because of multiple risk factors resulting in a 10-year risk of >5% now (or if extrapolated to age 60) for developing a fatal event, i.e. those with markedly raised levels of single risk factors:
  - cholesterol >8 mmol/L
  - LDL cholesterol >6 mmol/L
  - BP >180/110 mmHg.
- All patients with diabetes.
- Close relatives of:
  - patients with early-onset atherosclerotic cardiovascular disease
  - asymptomatic individuals at a particular high risk.
- Other individuals encountered in routine clinical practice.

How to estimate total cardiovascular risk in asymptomatic people as a guide to prevention strategies

Patients with established CVD have declared themselves to be at high total risk of further vascular events. Therefore they require the most intense lifestyle intervention, and where appropriate drug therapies.



However, in the majority of asymptomatic, apparently healthy people, preventative actions should be guided in accordance with the total CVD risk level. Indeed, risk factor management decisions should usually not be based on considerations of a single modestly raised factor.

To evaluate candidates for the major cardiovascular events cost-effectively, multivariate risk profiles have been formulated; these facilitate targeting those at high risk for preventative measures.

The Joint British Societies, the European Society of Cardiology and the American Heart Association have emphasized the importance of these risk profiles for motivating as well as reassuring patients and in assisting in selecting therapy. They concluded that these scores direct healthcare professionals to look at the whole patient and to recognize the cumulative nature of risk factors (Fig. 13.68). However, not all practitioners agree with this approach (see pp. 748 and 1067).

National Service Framework (NSF)

Plans to reduce CAD-related death in the under-75-year age group by 40% by the year 2010 by the implementation of set standards have been published in the UK by the Department of Health. The NSF includes a nurse-led audited approach to reduce CAD by lowering saturated fat intake, increasing exercise and, most relevant, decreasing/stopping smoking. The hypertension treatment targets are 140/85 mmHg in patients at risk of or with established coronary artery disease

- To estimate an individual's absolute 10-year risk of developing CVD, choose the panel for the gender, smoking status and age. Within this, define the level of risk from the point where the co-ordinates for SBP and ratio of the total to HDL-cholesterol cross. If no HDL cholesterol result is available, assume it is 1.00 mmol/l and use the lipid scale as total serum cholesterol.
- Highest risk individuals (red areas) are those whose 10-year CVD risk exceeds 20%, which is approximately equivalent to a 10-year CHD risk of >15% (indicated by the 1998 charts). As a minimum, those with CVD risk >30% (shown by the line within the red area) should be targeted and treated now. When resources allow, others with a CVD risk >20% should be targeted progressively.
- The chart also assists in identification of individuals with a moderately high 10-year CVD risk — in the range of 10–20% (orange area) and those in whom it is lower than 10% (green area).
- Smoking status should reflect lifetime exposure to tobacco.

and 130/80 mmHg in diabetics. The cholesterol target is either total cholesterol of <5.0 mmol/L (LDL-cholesterol <3 mmol/L) or a reduction of 30% (whichever is greater).

ANGINA (see also p. 688)

The diagnosis of angina is largely based on the clinical history. The chest pain is generally described as 'heavy', 'tight' or 'gripping'. Typically, the pain is central/retrosternal and may radiate to the jaw and/or arms. Angina can range from a mild ache to a most severe pain that provokes sweating and fear. There may be associated breathlessness. CAD is common, fatal and largely preventable. More than 1.4 million people in the UK suffer from angina. CAD accounts for about 3% of all hospital admissions in England. The prevalence of angina is approximately 2% with an incidence of new cases each year of approximately 1 per 1000.

Classical or exertional angina pectoris is provoked by physical exertion, especially after meals and in cold, windy weather, and is commonly aggravated by anger or excitement. The pain fades quickly (usually within minutes) with rest. Occasionally it disappears with continued exertion ('walking through the pain'). Whilst in some patients the pain occurs predictably at a certain level of exertion, in most patients the threshold for developing pain is variable.

Decubitus angina is angina that occurs on lying down. It usually occurs in association with impaired left ventricular function, as a result of severe coronary artery disease.

Nocturnal angina occurs at night and may wake the patient from sleep. It can be provoked by vivid dreams. It tends to occur in patients with critical coronary artery disease and may be the result of vasospasm.

Variant (Prinzmetal's) angina refers to an angina that occurs without provocation, usually at rest, as a result of coronary artery spasm. It occurs more frequently in women. Characteristically, there is ST segment elevation on the ECG during the pain. Specialist investigation using provocation tests (e.g. hyperventilation, cold-pressor testing or ergometrine challenge) may be required to establish the diagnosis. Arrhythmias, both ventricular tachyarrhythmias and heart block, can occur during the ischaemic episode.

Cardiac syndrome X refers to those patients with a good history of angina, a positive exercise test and angiographically normal coronary arteries. They form a heterogeneous group, and the syndrome is much more common in women than in men. Whilst they have a good prognosis, they are often highly symptomatic and can be difficult to treat. In women with this syndrome the myocardium shows an abnormal metabolic response to stress, consistent with the suggestion that the myocardial ischaemia results from abnormal dilator responses of the coronary microvasculature to stress. The prognostic and therapeutic implications are not known.

Unstable angina refers to angina of recent onset (<1 month), worsening angina or angina at rest, and will be discussed below in more detail in the section entitled 'Acute coronary syndrome' (see p. 752).

Examination and diagnosis

There are usually no abnormal findings in angina, although occasionally a fourth heart sound may be heard. Signs to suggest anaemia, thyrotoxicosis or hyperlipidaemia (e.g. lipid arcus, xanthelasma, tendon xanthoma) should be sought. It is essential to exclude aortic stenosis (i.e. slow-rising carotid impulse and ejection systolic murmur radiating to the neck) as a possible cause for the angina. The blood pressure should be taken to identify coexistent hypertension.

Investigations for angina

Resting ECG

This is usually normal between attacks. Evidence of old myocardial infarction (e.g. pathological Q waves), left ventricular hypertrophy or left bundle branch block may be present. During an attack, transient ST depression, T wave inversion or other changes of the shape of the T wave may appear.

Exercise ECG

Exercise testing can be very useful both in confirming the diagnosis of angina and in giving some indication as to the severity of the CAD. ST segment depression of ≥1 mm suggests myocardial ischaemia, particularly if typical chest pain occurs at the same time (Fig. 13.21).

The test has a specificity of 80% and a sensitivity of about 70% for CAD. A strongly positive test (within 6 minutes of starting the Bruce protocol) suggests 'prognostic' disease and helps to identify patients who should be offered coronary intervention. Exercise testing, however, can be misleading:

- A normal test does not exclude CAD (so-called false-negative test) although these patients, as a group, have a good prognosis.
- Up to 20% of patients with positive exercise tests are subsequently found to have no evidence of coronary artery disease (so-called false-positive test).

Cardiac scintigraphy

Myocardial perfusion scans (see p. 705), both at rest and after stress (i.e. exercise or dobutamine), are helpful. Redistribution of the contrast agent is a sensitive indicator of ischaemia and can be particularly useful in deciding if a stenosis seen at angiography is giving rise to ischaemia. A normal perfusion scan makes significant CAD unlikely.

Echocardiography

This can be used to assess ventricular wall involvement and ventricular function. Regional wall motion abnormalities at rest reflect previous ventricular damage. Stress echocardiography, although technically difficult, is useful, especially in women with coronary artery disease.

CT coronary angiography (see p. 706)

This is increasingly being used to diagnose coronary artery disease and exclude other causes, e.g. pulmonary embolism.

Cardiovascular magnetic resonance (MR)

This is being increasingly used and provides excellent details of the coronary anatomy (see Fig. 13.34, p. 708).

Coronary angiography

This is occasionally useful in patients with chest pain where the diagnosis is unclear. More often, the test is performed to delineate the exact coronary anatomy in patients being considered for revascularization (i.e. coronary artery bypass grafting or coronary angioplasty). Coronary angiography should be performed only when the benefit in terms of diagnosis and potential treatment outweighs the small risk of the procedure (a mortality rate of <1 in 1000 cases).

Lesions with complex morphology (irregular borders, overhanging edges, thrombus or ulceration) appear to identify a subgroup of stenoses associated with disease progression and adverse clinical outcomes.

Treatment of angina

General management

Patients should be informed as to the nature of their condition and reassured that the prognosis is good (annual mortality <2%). Underlying problems, such as anaemia or hyperthyroidism, should be treated. Management of coexistent conditions, such as diabetes and hypertension, should be optimized. Risk factors should be evaluated and steps made to correct them where possible; for example, smoking must be stopped, hypercholesterolaemia should be identified and treated (see below), weight loss, where appropriate, and regular exercise should be encouraged.

Choosing between medical therapy and revascularization (coronary artery bypass grafting and angioplasty) can be difficult and will depend on a number of factors including symptoms, angiographic anatomy and patient/physician preference. The various treatment options are not mutually exclusive and should be considered as complementary.

Medical treatment

Prognostic therapies

Aspirin reduces the risk of coronary events in patients with coronary artery disease. All patients with angina, therefore, should take aspirin (75 mg daily is probably adequate) unless contraindicated.

Lipid-lowering therapy (see p. 1065) should be used in patients with total cholesterol above 4.8 mmol/L (particularly if the LDL is >3.3 mmol/L and the HDL is <1.0 mmol/L), despite a low fat diet. If the triglycerides (TGs) are under 3.5 mmol/L, then one of the statins (HMG-CoA reductase inhibitors) should be used. If the TGs are above 3.5 mmol/L, a fibrate is indicated. If simple therapy fails to reduce the LDL adequately, then the patient should be referred to a lipidologist. Lipid-lowering therapy can be expected to prevent 20–30 deaths or myocardial infarcts per 1000 patient-years.

Hormone replacement therapy (HRT) is of no value in prevention of CAD.

Symptomatic treatment

Glyceryl trinitrate (GTN) used sublingually, either as a tablet or as a spray, gives prompt relief (peak action 4–8 minutes and lasts 20–30 minutes). It can be used prior to performing activities that the patient knows will provoke angina. Transdermal GTN preparations last up to 24 hours.

All but the most mildly affected patients will probably require regular prophylactic therapy. The choice of drugs is between beta-blockers, nitrates and calcium-channel blockers. There is no commonly accepted algorithm and treatment needs to be tailored to the individual patient. Some patients will require combination therapy, but there is little evidence that adding a third drug is of benefit. Patients not controlled adequately on medical therapy should be considered for revascularization (see below).

Beta-blockers reduce the heart rate (negative chronotropic effect) and the force of ventricular contraction (negative inotropic effect), both of which reduce myocardial oxygen demand, especially on exertion. They are the drugs of choice in patients with previous myocardial infarction because of their proven benefit in secondary prevention. Atenolol, 50–100 mg daily, is the most commonly prescribed. Metoprolol, 25–50 mg twice daily, is often used if renal function is impaired. Beta-blockers may aggravate coronary artery spasm.

Long-acting nitrates (e.g. isosorbide mononitrate) are particularly useful in patients who gain relief from sublingual GTN. They reduce venous return and hence intracardiac diastolic pressures, reduce the impedance to the emptying of the left ventricle and relax the tone of the coronary arteries. Once-daily preparations are available which have a smooth pharmacokinetic profile and avoid the problem of tolerance. Nitrates should be given with care to patients on other hypotensive agents. Sildenafil (or other PDE5 inhibitors) should not be given to patients taking nitrates.

Calcium-channel blockers block calcium flux into the cell and the utilization of calcium within the cell. They relax coronary arteries, cause peripheral vasodilatation and reduce the force of left ventricular contraction, thereby reducing the oxygen demand of the myocardium. The non-dihydropyridine calcium antagonists (e.g. diltiazem and verapamil) also reduce the heart rate and are particularly useful antianginal agents, but should be used with caution in combination with beta-blockers. Short-acting dihydropyridines (e.g. nifedipine) can cause reflex tachycardia when used alone. Case-control studies have suggested that high-dose nifedipine is associated with adverse outcome. Slow-release formulations and the third-generation agents (e.g. amlodipine) can be used once daily and have a smooth profile of action with no significant effect on the heart rate and no significant negative inotropic effect.

Nicorandil is a potassium-channel activator with a nitrate component; it has both arterial and venous vasodilating properties. Whilst not used as a first-line drug, it is used when there are contraindications to the above agents and in refractory unstable angina.

Ranolazine is a novel agent that interacts with sodium channels and can improve exercise tolerance and reduce the frequency of angina attacks in patients with ischaemic heart disease. However, ranolazine causes QT interval prolongation and should be reserved for patients who do not respond to other antianginal drugs (long-acting nitrates, calcium-channel blockers and beta-blockers).

Ivabradine is a selective and specific inhibitor of the cardiac pacemaker I_f current (see p. 682) that controls the spontaneous diastolic depolarization in the sinus node and regulates heart rate. It has recently been licensed for the symptomatic treatment of chronic stable angina pectoris in patients with normal sinus rhythm who have a contraindication or intolerance to beta-blockers. It is particularly helpful in a subgroup with heart rates >70 beats/min.

Percutaneous coronary intervention

Percutaneous transluminal coronary angioplasty (PTCA) is the process of dilating a coronary artery stenosis using an inflatable balloon introduced into the arterial circulation via the femoral, radial or brachial artery (Fig. 13.69). PTCA is an effective treatment that can reduce angina symptoms, reduce the requirement for antianginal drug therapy and increase exercise capacity. Coronary artery anatomy determines the success of PTCA. A discrete, soft lesion in a straight vessel without involving a bifurcation has the best outcome. Unfavourable lesions are occluded vessels, stenoses that are calcified, tortuous, long, or involve a bifurcation. The risks of PTCA include acute myocardial infarction (2%) and death (1%). The benefits of PTCA were initially reduced by coronary restenosis, but with the introduction of metallic stents (Fig. 13.70) the effectiveness increased. The STRESS and BENESTENT studies demonstrated superiority of percutaneous coronary intervention (PCI) with stenting over PTCA alone, with reduced need for repeat revascularization. Peripheral vascular complications were more frequent after PCI because of the use of heparin and warfarin therapy post stent insertion. The bleeding complications were significantly reduced with the use of ticlopidine and then clopidogrel as alternative antithrombotic agents to formal anticoagulation. Further improvements to patient outcome post PCI have occurred with the addition of the antiplatelet GPIIb/IIIa antagonists (tirofiban, eptifibatide and abciximab) that inhibit platelet function and reduce acute stent thrombosis.

A further development in PCI was the introduction of coated stents which are lined with substances that reduce coronary artery restenosis and offer the prospect of long-term vessel patency post PCI, especially in narrow vessels with long stenoses. The *Cypher stent* contains sirolimus, which is an immunosuppressant agent that reduces cellular proliferation. Biolimus (a lipophilic sirolimus analogue) eluting stents are being trialled; the drug dissolves completely

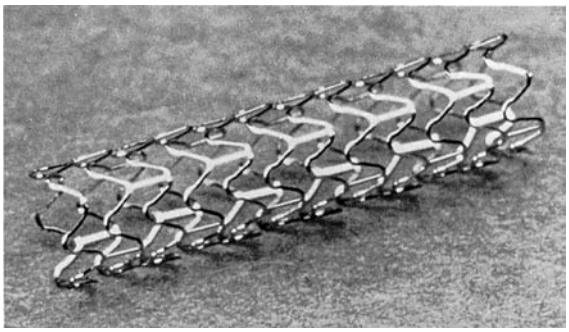

Fig. 13.70 **An intracoronary stent.**

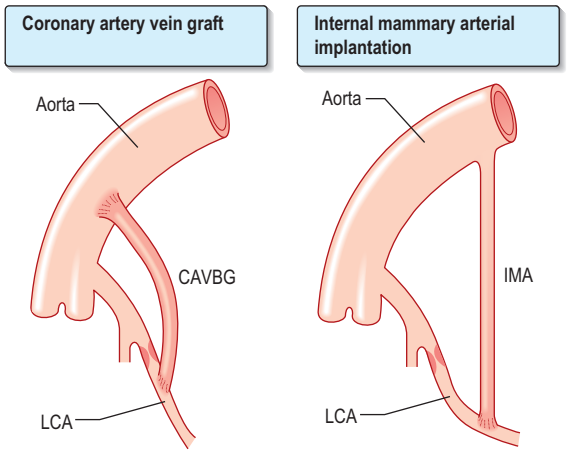

Fig. 13.71 **Relief of coronary obstruction by surgical techniques:** coronary artery vein bypass grafting (CAVBG) or internal mammary arterial implantation (IMA). In both of these examples, the graft bypasses a coronary obstruction in the left coronary artery (LCA).

leaving a bare-metal stent in 9 months. The *Taxus stent* contains paclitaxel which is a mitotic inhibitor drug that inhibits neointima formation. Both stents have demonstrated superiority over 'bare-metal' stenting in reducing coronary artery restenosis and the need for repeat revascularization at 6–12 months. However, recent reports have raised concerns about late-stent thrombosis (>6 months post insertion) in patients with drug-eluting stents leading to acute myocardial infarction and frequently death. It has been suggested that inadequate endothelialization of the stent leads to exposure of thrombus stimulating surface when the patient discontinues clopidogrel therapy, leading to recommendations that patients take prolonged dual therapy (aspirin and clopidogrel) and avoid discontinuing therapy within 6–12 months of implantation.

Coronary artery bypass grafting

With coronary artery bypass grafting (CABG) autologous veins or arteries are anastamosed to the ascending aorta and to the native coronary arteries distal to the area of stenosis (Fig. 13.71). Improved graft survival can be obtained with in-situ internal mammary and gastroepiploic arteries grafted onto the stenosed coronary artery. Three major randomized controlled trials compared CABG with medical therapy: the Coronary Artery Surgery Study (CASS), the Veterans Administration (VA) Co-operative Study and the European Coronary Surgery Study (ECSS). A meta-analysis has been performed that demonstrated that compared to medical therapy, CABG significantly improved angina symptoms, exercise capacity and reduced the need for antianginal therapy. In addition, CABG improves 10-year survival in patients with angina, and particularly patients with >50% left main stem stenosis and triple-vessel disease with impaired left ventricular function. Operative mortality is well below 1% in patients with normal left ventricular function. Perioperative strokes occur in up to 2% of cases, and more subtle neurological deficits are common. Off-pump coronary surgery is now performed; results show that it is as safe as on-pump surgery and causes less myocardial damage, but the graft patency rate is lower. Minimally invasive operative procedures for bypass grafting ('MIDCAB') are being developed, including laparoscopic approaches, and may be of use in certain subgroups of patients (e.g. previous CABG and those with coexistent medical conditions which would increase the operative risks of 'full' CABG).

CABG versus PCI

Comparative trials between CABG and PCI have now been performed. In the multicentre ERACI II study, PCI patients had lower major adverse events (death, myocardial infarction, repeat revascularization procedures and stroke) in the first 30 days compared with the CABG patients (3.6% versus 12.3%) with a long-term follow-up (mean 18 months), patient survival was 96.9% in the PCI group versus 92.5% in the CABG group. However, the need for repeat revascularization was significantly greater in the PCI group than in the CABG group (16.8% versus 4.8%).

In another multicentre study, SoS (Stent or Surgery), the incidence of death or Q-wave myocardial infarction was similar for both groups (PCI 9% versus 10% CABG) at follow-up at a median of 2 years. However, there were fewer deaths in the CABG group (2% versus 5%) and there was less need for repeat revascularization (6% versus 21%). The choice of CABG versus PCI is influenced by coronary artery anatomy, left ventricular function, diabetes and patient choice. In asymptomatic patients revascularization cannot improve symptoms but will improve prognosis.

Patients with intractable angina

Some patients remain symptomatic despite medication and are not suitable for (further) revascularization.

- *Transmyocardial laser revascularization* (TMR), whereby a laser is used to form channels in the myocardium to allow direct perfusion of the myocardium from blood within the ventricular cavity, has been used in some centres but in controlled trials it has not been beneficial.
- *Spinal cord stimulation* (SCS) is accomplished using a flexible electrode in the epidural space at the mid-thoracic level. Stimulation via a pacemaker-like generator reduces angina and has been shown to reduce indices of ischaemia.
- Similarly, *transcutaneous electrical nerve stimulation* has been shown to reduce angina and increase exercise capacity in selected patients.

ACUTE CORONARY SYNDROMES

Acute coronary syndromes (ACS) include ST-elevation myocardial infarction (STEMI), non-ST-elevation myocardial infarction (NSTEMI) and unstable angina. Myocardial infarction (MI) occurs when cardiac myocytes die due to myocardial ischaemia, and can be diagnosed on the basis of appropriate clinical history, 12-lead ECG and elevated biochemical markers – troponin I and T, CK-MB. STEMI will be covered in the next section (p. 755).

Eagle KA, Lim MJ, Dabbous OH, et al, for the GRACE investigators. A validated prediction model for all forms of acute coronary syndrome. Estimating the risk of 6-month post-discharge death in an international registry. *Journal of the American Medical Association* 2004; **291**: 2727–2733.

Pathophysiology

The common mechanism to all ACS is rupture or erosion of the fibrous cap of a coronary artery plaque. This leads to platelet aggregation and adhesion, localized thrombosis, vasoconstriction and distal thrombus embolization. The presence of a rich lipid pool within the plaque and a thin fibrous cap are associated with an increased risk of rupture. Thrombus formation and the vasoconstriction produced by platelet release of serotonin and thromboxane A_2, results in myocardial ischaemia due to reduction of coronary blood flow.

Diagnosis

Clinical presentation

Patients with an ACS may complain of a new onset of *chest pain*, chest pain at rest, or a deterioration of pre-existing angina. However, some patients present with atypical features including indigestion, pleuritic chest pain or dyspnoea. Physical examination can detect alternative diagnoses such as aortic dissection, pulmonary embolism or peptic ulceration. In addition it can also detect adverse clinical signs such as hypotension, basal crackles, fourth heart sounds and cardiac murmurs.

Electrocardiogram

Although the 12-lead ECG may be normal in patients with an ACS, ST depression and T wave inversion are highly suggestive for an ACS, particularly if associated with anginal chest pain. The ECG should be repeated when the patient is in pain, and continuous ST-segment monitoring is recommended. With a STEMI, complete occlusion of a coronary vessel will result in persistent ST-elevation or left bundle branch block pattern, although transient ST elevation is seen with coronary vasospasm or Prinzmetal's angina.

Biochemical markers

- The measurement of the ***creatinine-kinase-MB*** level was until recently the standard marker for myocyte death used in ACS. However, the presence of low levels of CK-MB in the serum of normal individuals and in patients with significant skeletal muscle damage, has limited its accuracy. It can be used to determine reinfarction as levels drop back to normal after 36–72 hours.
- The ***cardiac troponin*** complex is made up of three distinct proteins (I, T and C) that are situated with tropomyosin on the thin actin filament that forms the skeleton of the cardiac myofilament. Troponin T attaches the complex to tropomyosin, troponin-C binds calcium during excitation–contraction coupling, and troponin-I inhibits the myosin binding site on the actin.

  The cardiac troponins are not detectable in normal people and so monoclonal antibody tests to cardiac-specific troponin I and cardiac-specific troponin T are highly sensitive markers of myocyte necrosis. If the initial troponin assay is negative, then it should be repeated 9–12 hours after admission. The troponin assay has prognostic information that can determine mortality risk in ACS (Fig. 13.72) and define which patients may benefit from aggressive medical therapy and early coronary revascularization.
- ***Myoglobin*** may be useful for a rapid diagnosis of an ACS as the levels become elevated very early in the time course of an MI, but because of the presence of myoglobin in skeletal muscle the test has poor specificity for ACS.

Risk stratification

Initial risk in ACS is determined by complications of the acute thrombosis. This may produce recurrent myocardial ischaemia, marked ST depression, dynamic ST changes, a raised troponin level and be demonstrated with coronary angiography.

Long-term risk is defined by clinical risk factors; age, prior myocardial infarction or bypass surgery, diabetes or heart failure. Biological markers such as C-reactive protein, fibrinogen, brain natriuretic peptide, modified albumin and serum creatinine, can be used to further stratify patient risk. Left ventricular dysfunction and the presence of left main or triple vessel disease significantly increase the future cardiovascular risk. Both the Thrombolysis In Myocardial Infarction (TIMI) (Table 13.28) score and the Global Registry of Acute Coronary Events (GRACE) prediction score can be used in patients with ACS to define risk. TIMI is shown in Table 13.28. The GRACE score is based on age, heart rate, systolic blood pressure, serum creatinine and the Killip score.

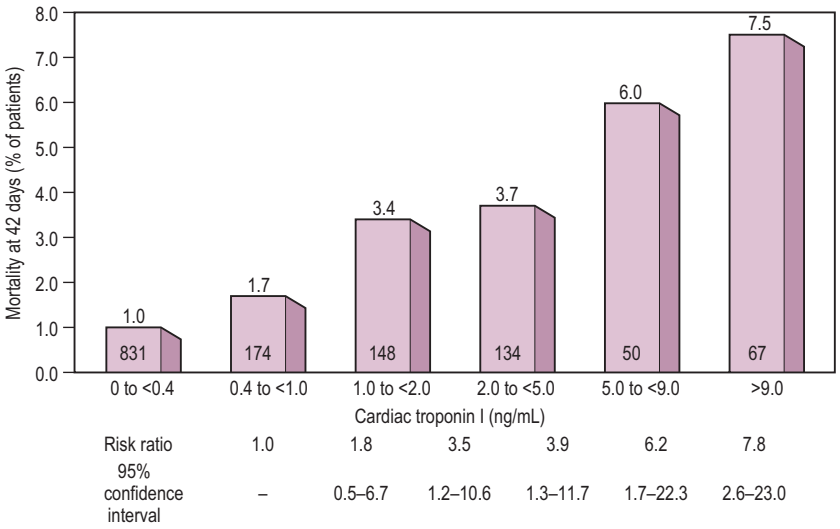

Fig. 13.72 **Relationship between cardiac troponin I levels and risk of death in patients with the acute coronary syndrome (ACS).** Numbers within histograms are the number of patients in each group. From Antman EM, Tanasijevic MJ, Thompson B et al. Cardiac-specific troponin I levels to predict the risk of mortality in patients with acute coronary syndromes. *New England Journal of Medicine* 1996; **335**: 1342–1349. Table 13.28 The TIMI risk score in acute coronary syndrome (NSTEMI/UA)

Risk factor	Score
Age >65	1
More than three coronary artery disease risk factors – hypertension, hyperlipidaemia, family history, diabetes, smoking	1
Known coronary artery disease (coronary angiography stenosis >50%)	1
Aspirin use in the last 7 days	1
Severe angina (more than two episodes of rest pain in 24 hours)	1
ST deviation on ECG (horizontal ST depression or transient ST elevation >1 mm)	1
Elevated cardiac markers (CK–MB or troponin)	1

Total score	Rate of death/MI in 14 days (%)	Rate of death /MI/urgent revascularization (%)
0–1	3	4.75
2	3	8.3
3	5	13.2
4	7	19.9
5	12	26.2
6–7	19	40.9

Investigation and treatment

All patients require immediate management of their chest pain as outlined on p. 755 and in Table 13.29.

High-risk patients for progression to myocardial infarction or death require urgent coronary angiography. These patients include those with persistent or recurrent angina with ST changes ≥2 mm or deep negative T wave changes, clinical signs of heart failure or haemodynamic instability, life-threatening arrhythmias (VF, VT).

Patients with *immediate or high-risk* TIMI or GRACE scores, elevated troponins, dynamic ST or T wave changes, diabetes mellitus, renal dysfunction, reduced left ventricular function, early post-infarction angina, previous myocardial infarction, PCI within 6 months, or previous CABG, should have early (<72 hours) coronary angiography and interventions.

Low-risk patients can be managed with oral aspirin, clopidogral, beta-blockers and nitrates. These include patients with no recurrence of chest pain during observation, no signs of heart failure, normal ECG or minor T wave changes on arrival and at 6–12 hours, normal troponins on the initial assays and at 6–12 hours post admission. An exercise test should be performed – a negative result has a good prognosis and an early positive test should direct the patient to an invasive strategy. If the patient is unable to exercise satisfactorily, or if the baseline ECG is abnormal (e.g. left ventricular hypertrophy or LBBB), then dobutamine stress echocardiography or myocardial perfusion scintigraphy are recommended.

Antiplatelet agents

The platelet is a key part of the thrombosis cascade involved in ACS. Rupture of the atheromatous plaque exposes the circulating platelets to ADP (adenosine diphosphate), thromboxane A_2 (TxA_2), epinephrine (adrenaline), thrombin and collagen tissue factor. This causes platelet activation, with thrombin as an especially potent stimulant of such activity. Platelet activation stimulates the expression of glycoprotein (GP) IIb/IIIa receptors on the platelet surface. These receptor bridge fibrinogen between adjacent platelets, causing platelet aggregates (Fig 8.41).

Aspirin blocks the formation of thromboxane A_2 and so prevents platelet aggregation. In ACS patients 75–150 mg aspirin reduced the relative risk of death or myocardial infarction by about 35–50%.

Ticlopidine and clopidogrel are thienopyridines that inhibit ADP-dependent activation of the GPIIb/IIIa complex that allows platelet aggregates to form. Both ticlopidine and clopidogrel can be used in patients allergic to aspirin, but ticlopidine causes more systemic side-effects including neutropenia or thrombocytopenia. In the CURE study of 12562 ACS patients, 9 months of 75 mg clopidogrel reduced the primary end-point of cardiovascular death, myocardial infarction, or stroke from 11.4% to 9.3% ($P<0.0001$), compared to placebo. Prasugrel is also being used with fewer thrombotic episodes but no change in mortality.

Activated GP (glycoprotein) IIb/IIIa receptors on platelets bind to fibrinogen initiating platelet aggregation. Receptor antagonists have been developed that are powerful inhibitors

Table 13.29 Pharmacological therapy in acute coronary syndrome

Drug	Dose	Notes
Myocardial oxygenation		
Oxygen	35–50%	Check ABG in severe COPD
Antiplatelet		
Aspirin	150–300 mg chewable or soluble aspirin, then 75–10 mg p.o. daily	Caution if active peptic ulceration
Clopidogrel	300 mg p.o. loading dose, then 75 mg p.o. daily	Caution: increased risk of bleeding, avoid if CABG planned
Antithrombin		
Heparin	5000 units i.v. bolus, then 0.25 units/kg/hour	Measure anticoagulant effect with APTT at 6 hours
Low-molecular-weight heparins		
e.g. Enoxaparin	1 mg/kg s.c. × 2 daily	
Bivalirudin	750 μg/kg i.v. bolus, then 0.75 mg/kg/hour	
Glycoprotein IIB/IIIA inhibitors		
Abciximab	0.25 mg/kg i.v. bolus, then 0.125 μg/kg/min up to 10 μg/min i.v. × 12 hours	Indicated if coronary intervention likely within 24 hours
Eptifibatide	180 μg/kg i.v. bolus, then 2 μg/kg/min × 72 hours	Indicated in high-risk patients managed without coronary intervention or during PCI
Tirofiban	0.4 μg/kg/min for 30 minutes, then 0.1 μg/kg/min × 48–108 hours	Indicated in high-risk patients managed without coronary intervention or during PCI
Analgesia		
Diamorphine or morphine	2.5–5.0 mg i.v.	Prescribe with antiemetic, e.g. metoclopramide 10 mg i.v.
Myocardial energy consumption		
Atenolol	5 mg i.v. repeated after 15 minutes, then 25–50 mg p.o. daily	Avoid in asthma, heart failure, hypotension, bradyarrhythmias
Metoprolol	5 mg i.v. repeated to a maximum of 15 mg, then 25–50 mg p.o. × 2 daily	Avoid in asthma, heart failure, hypotension, bradyarrhythmias
Coronary vasodilation		
Glyceryl trinitrate	2–10 mg/hour i.v./buccal/sublingual	Maintain systolic BP >90 mmHg
Plaque stabilization/ventricular remodelling		
HMG-CoA reductase inhibitors (statins)		Combine with dietary advice and modification
Simvastatin	20–40 mg p.o.	
Pravastatin	20–40 mg p.o.	
Atorvastatin	80 mg p.o.	
ACE inhibitors		Monitor renal function
Ramipril	2.5–10 mg p.o.	
Lisinopril	5–10 mg p.o.	

of platelet aggregation. Abciximab is a monoclonal antibody that binds tightly and has a long half-life. Eptifibatide is a cyclic peptide that selectively inhibits GPIIb/IIIa receptors, but has a short half-life and wears off in 2–4 hours. Tirofiban is a small non-peptide that rapidly blocks the GPIIb/IIIa receptors and is reversible in 4–6 hours.

In the GUSTO-IV ACS study of 7800 patients, abciximab was administered but coronary intervention discouraged. At 30 days 8.2 % of abciximab patients and 8.0 % of placebo patients had reached the composite end-point of death or myocardial infarction. In the PRISM study of 3232 patients with angina, tirofiban reduced the 30-day death or myocardial infarction rate from 7.1% with placebo to 5.8%. Troponin-positive patients with diabetes scheduled to have coronary intervention benefit most from GPIIb/IIIa receptor antagonists.

Antithrombins

In ACS patients off aspirin, *unfractionated heparin (UFH)* produces a lower rate of refractory angina/myocardial infarction and death than placebo, and when used with aspirin reduces death and myocardial infarction from 10.3% to 7.9%. However, because of poor bioavailability and variable effects, frequent monitoring of APTT is necessary to ensure therapeutic levels. *Low molecular weight heparins* and in particular enoxaparin appear superior to UFH and can be given subcutaneously twice daily. Bivalirudin is a direct thrombin inhibitor that reversibly binds to thrombin and inhibits clot-bound thrombin. In the ACUITY trial bivalirudin appeared as effective as heparin plus GPIIb/IIIa inhibitors in reducing ischaemic events in patients pretreated with a thienopyridine and undergoing diagnostic angiography or percutaneous intervention, but with less bleeding.

Anti-ischaemia agents

In patients with no contraindications (asthma, AV-block, acute pulmonary oedema), beta-blockers are administered intravenously or orally, to reduce myocardial ischaemia by blocking circulating catecholamines. This will reduce the heart rate and blood pressure, reducing myocardial oxygen consumption. The dose can be titrated to produce a resting heart rate of 50–60 b.p.m. In patients with ongoing angina, nitrates should be given either sublingually or intravenously. They effectively reduce preload and produce coronary vasodilation. However, tolerance can become a problem and patients should be weaned off intravenous administration should if symptoms resolve.

Plaque stabilization/remodelling

HMG-CoA reductase inhibitor drugs (statins) and ACE-inhibitors are routinely administered to patients with ACS. These agents may produce plaque stabilization, improve vascular and myocardial remodelling, and reduce future cardiovascular events. Starting the drugs whilst the patient is still in hospital increases the likelihood of patients receiving secondary drug therapy.

Coronary intervention

Coronary revascularization is recommended in high-risk patients with ACS. Coronary stenting may stabilize the disrupted coronary plaque; in the BENESTENT II trial it was demonstrated that stenting was superior to PTCA in reducing angiographic restenosis rates. Sub-group analysis of patients with unstable angina in the EPIC, EPILOG and CAPTURE trials, confirmed the benefit of GPIIb/IIIa inhibitors at reducing the complication rate during PCI. The PCI-CURE study demonstrated that pretreatment with clopidogrel reduces the rate of cardiovascular death and MI. The current rate of CABG in ACS is low (5.4%). The mortality rates with CABG are greater in the high risk group patients, particularly with a recent myocardial infarction. Single vessel lesions are usually treated with PCI, unless the anatomy is unfavourable. Conversely in patients with left main stem or triple vessel disease with impaired left ventricular function are best managed with surgery. Two studies have compared a conservative versus an invasive strategy in the modern era. In the FRISC-II study 2457 high-risk ACS patients were randomized to PTCA or CABG at 4 and 8 days, respectively, or a conservative approach with intervention only for severe angina. Revascularization within 10 days was performed in 71% of the invasive arm versus 9% of the conservative arm. After 1 year there was a significant reduction in total mortality (2.2% versus 3.9%) in the invasive arm, as well a significant reduction in MI (8.6% versus 11.6%). In addition, the rate of angina or readmission was reduced by 50%. In the TACTICS study of 2220 high-risk ACS patients, similar findings were obtained with the rate of death or MI reduced from 9.5% to 7.3% by an invasive strategy. Patients with a troponin T >0.01 ng/ml obtained benefit, but not those who were troponin T negative.

Post ACS

After the initial management of the ACS (diagnosis, treatment, investigation, revascularization) risk factor modification is achieved to reduce future cardiovascular events:

- Patients should stop cigarette smoking and if necessary be referred to a smoking cessation clinic. In addition, patients should maintain optimal weight, daily exercise and have a healthy diet.
- Hypertension should be treated to a level <130/85.
- In patients with diabetes, glycaemic control should be very tight.
- Low-fat diets should be combined with HMG-CoA reductase inhibitors to reduce LDL cholesterol.
- Medication on discharge should include aspirin, clopidogrel, beta-blocker and an ACE-inhibitor, with a GTN spray for symptomatic relief of angina.

ST ELEVATION MYOCARDIAL INFARCTION (STEMI)

Myocardial infarction occurs when cardiac myocytes die due to prolonged myocardial ischaemia. The diagnosis can be made in patients with an appropriate clinical history together with findings from repeated 12-lead ECGs and elevated biochemical markers – troponin I and T, CK-MB.

Pathophysiology

Rupture or erosion of a vulnerable coronary artery plaque can produce prolonged occlusion of a coronary artery leading to myocardial necrosis within 15–30 minutes. The subendocardial myocardium is initially affected but with continued ischaemia the infarct zone extends through to the subepicardial myocardium, producing a transmural Q-wave myocardial infarction. Early reperfusion may salvage regions of the myocardium, reducing future mortality and morbidity.

The 1-month mortality in patients with a myocardial infarction may be as high as 50% in the community, with 50% of deaths occurring in the first 2 hours of the event. In the pre-thrombolytic era the in-hospital mortality rate was nearly 20% but with modern therapy it may be as low as 6–7% at 1 month. Several risk factors can be identified that predict death rate at 30 days (TIMI STEMI score – Table 13.30).

Diagnosis

Symptoms and signs

Any patient presenting with severe chest pain lasting more than 20 minutes may be suffering from a myocardial infarction. The pain does not usually respond to sublingual GTN, and opiate analgesia is required. The pain may radiate to the left arm, neck or jaw. However, in some patients, particularly elderly or diabetic patients, the symptoms may be atypical and include dyspnoea, fatigue, pre-syncope or syncope. Autonomic symptoms are common and on examination the patient is pale and clammy, with marked sweating. In addition, the pulse is thready with significant hypotension, bradycardia or tachycardia.

Electrocardiography

An ECG in patients with chest pain should be performed on admission to A&E. The baseline ECG is rarely normal, but if so should be repeated every 15 minutes while the patient remains in pain. Continuous cardiac monitoring is required because of the high likelihood of significant cardiac arrhythmias. ECG changes (Table 13.31) are usually confined to the ECG leads that 'face' the infarction. The presence of new ST

Table 13.30 TIMI risk score in ST elevation myocardial infarction (STEMI)

Risk factor	Score
Age >65	2
Age >75	3
History of angina	1
History of hypertension	1
History of diabetes	1
Systolic BP <100	3
Heart rate >100	2
Killip II–IV	2
Weight >67 kg	1
Anterior MI or LBBB	1
Delay to treatment >4 hours	1

Total score	Risk of death at 30 days (%)
0	0.8
1	1.6
2	2.2
3	4.4
4	7.3
5	12.4
6	16.1
7	23.4
8	26.8
9–16	35.9

elevation (due to opening of the K^+ channels) ≥0.2 mV at the J-point in leads V_1–V_3, and ≥0.1 mV in other leads, suggests anterior MI (Fig. 13.73). An inferior wall MI is diagnosed when ST elevation is seen in leads II, III and AVF (Fig. 13.74). Lateral MI produces changes in leads I, AVL and V_5/V_6. In patients with a posterior MI, there may be ST depression in leads V_1–V_3 with a dominant R wave, and ST elevation in lead V_5/V_6. New LBBB or presumed new LBBB is compatible with coronary artery occlusion requiring urgent reperfusion therapy. The evolution of the ECG during the course of STEMI is illustrated in Figure 13.75.

Table 13.31 Typical ECG changes in myocardial infarction (STEMI)

Infarct site	Leads showing ST elevation
Anterior:	
Small	V_3–V_4
Extensive	V_2–V_5
Anteroseptal	V_1–V_3
Anterolateral	V_4–V_6, I, AVL
Lateral	I, AVL
Inferior	II, III, AVF
Posterior	V_1, V_2 (reciprocal)
Subendocardial	Any lead
Right ventricle	VR_4

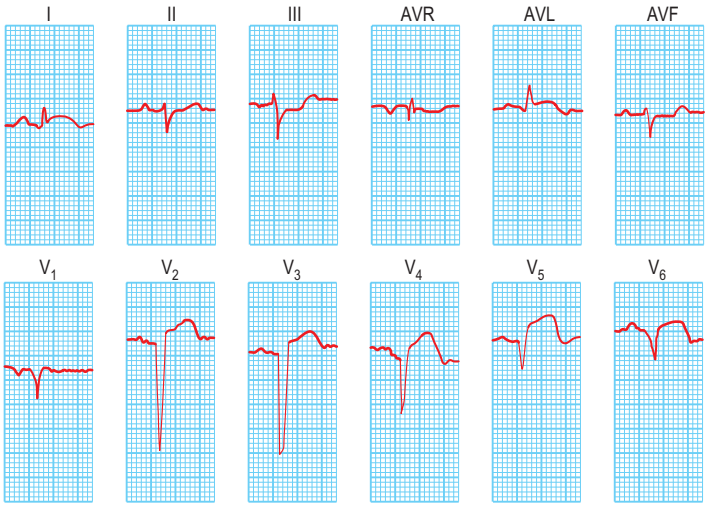

Fig. 13.73 **An acute anterolateral myocardial infarction** shown by a 12-lead ECG. Note the ST segment elevation in leads I, AVL and V_2–V_6. The T wave is inverted in leads I, AVL and V_3–V_6. Pathological Q waves are seen in leads V_2–V_6.

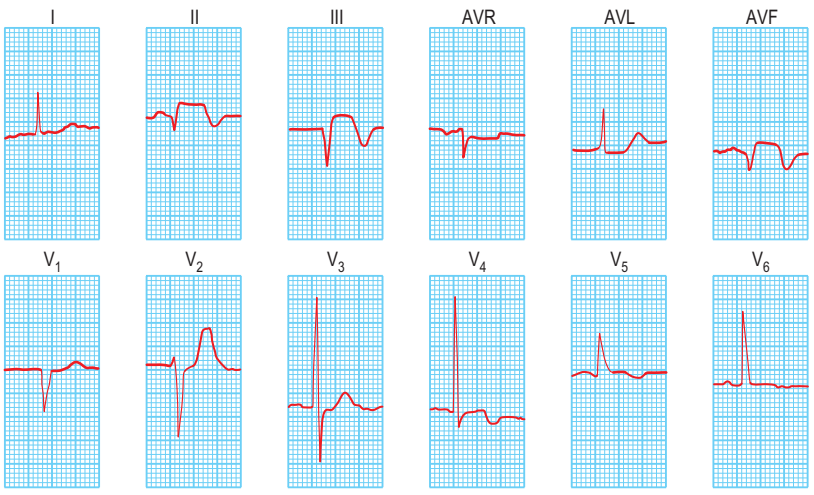

Fig. 13.74 **An acute inferior wall myocardial infarction** shown by a 12-lead ECG. Note the raised ST segment and Q waves in the inferior leads (II, III and AVF). The additional T wave inversion in V_4 and V_5 probably represents anterior wall ischaemia.

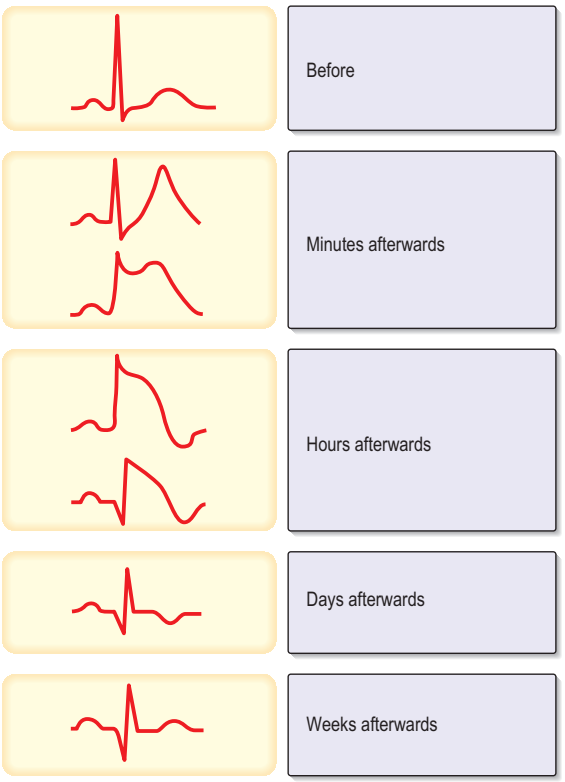

Fig. 13.75 **Electrocardiographic evolution of myocardial infarction (STEMI).** After the first few minutes the T waves become tall, pointed and upright and there is ST segment elevation. After the first few hours the T waves invert, the R wave voltage is decreased and Q waves develop. After a few days the ST segment returns to normal. After weeks or months the T wave may return to upright but the Q wave remains.

Investigations

Blood samples should be taken for cardiac troponin I or T levels or CK-MB level according to local hospital protocol, although treatment should not be deferred until the results are available. Full blood count, serum electrolytes, glucose and lipid profile should be obtained. Transthoracic echocardiography (TTE) may be helpful to confirm a myocardial infarction, as wall-motion abnormalities are detectable early in STEMI. TTE may detect alternative diagnoses such as aortic dissection, pericarditis or pulmonary embolism.

Early medical management

Accident and emergency

Rapid triage for chest pain (N.B. time is muscle):

- aspirin 150–300 mg chewed and clopidogrel 300 mg oral gel
- sublingual glyceryl trinitrate 0.3–1 mg. Repeat
- oxygen – nasal cannula 2–4 L/min (Fig. 15.21)
- brief history/risk factors. Examination
- intravenous access + blood for markers (plus FBC, biochemistry, lipids, glucose)
- 12-lead ECG
- intravenous opiate, e.g. diamorphine (or morphine) 2.5–5 mg + antiemetic, e.g. metoclopramide 10 mg
- beta-blocker (if no contraindication) for ongoing chest pain, hypertension, tachycardia
- if primary PCI available (see p. 750) give GP IIb/IIIa inhibitor. Alternatively give thrombolysis (see below).

Pre-hospital treatment, including thrombolysis, can be given by trained healthcare professionals under strict guidelines.

Fibrinolysis

Fibrinolytic agents enhance the breakdown of occlusive thromboses by the activation of plasminogen to form plasmin. The initial thrombolytic agent used in clinical trials was streptokinase. This agent is derived from bacteria, which can lead to the development of neutralizing antibodies that limit its repeated use. In the ISIS 2 study of acute myocardial infarction, patients were randomized to receive a 1-hour intravenous infusion of 1.5 million units of streptokinase, or 1 month of 160 mg/day enteric-coated aspirin, both active treatments, or neither. Both streptokinase and aspirin were significantly better than placebo in reducing vascular mortality at 5 weeks (9.2% versus 12.0%, and 9.4% versus 11.8%, respectively). The combination of streptokinase and aspirin was significantly better than either agent alone.

The GISSI 2 and ISIS 3 studies showed no significant difference in the effectiveness of streptokinase and tissue plasminogen activator (t-PA) or anistreplase. In addition there was no mortality benefit from subcutaneous unfractionated heparin versus no heparin.

In the GUSTO trial, accelerated t-PA over 90 minutes with intravenous heparin reduced death by 10 in every 1000 patients versus streptokinase, although there were three more strokes in the t-PA group versus streptokinase and subcutaneous heparin.

In the meta-analysis of fibrinolytics (FTT), fibrinolysis within 6 hours of STEMI or LBBB MI, prevented 30 deaths in every 1000 patients treated. Between 7 and 12 hours 20 in every 1000 deaths were prevented. After 12 hours the benefits are limited, and there is evidence to suggest less benefit for older patients, possibly because of the increased risk of strokes.

Prompt reperfusion therapy (door to needle time <30 minutes) will reduce the death rate following myocardial infarction. Double bolus r-PA (reteplase) and single bolus TNK-t-PA (tenecteplase) facilitate rapid administration of fibrinolytic therapy and can be used for pre-hospital thrombolysis. In patients who fail to reperfuse by 60–90 minutes as demonstrated by 50% resolution of the ST segment elevation, rethrombolysis or referral for rescue coronary angioplasty is recommended.

Aspirin therapy should be prescribed with fibrinolysis, but there is little additional benefit in combining clopidogrel or abciximab therapy in patients with STEMI/new LBBB. Heparin is recommended with t-PA or tenecteplase, but not with streptokinase. Enoxaparin (low molecular weight heparin) appears to be superior to unfractionated i.v. heparin in patients receiving TNK-t-PA, with less reocclusion and better late patency (ASSENT 3).

The contraindications to thrombolysis are provided in Table 13.32.

Percutaneous coronary intervention (PCI)

PCI performed within 90 minutes is the preferred reperfusion therapy in interventional cardiology centres that have the expertise available. In the PAMI (Primary Angioplasty in Myocardial Infarction) trial, patients with a myocardial infarction who presented within 12 hours of the onset of STEMI were

Table 13.32 Contraindications to thrombolysis

Absolute contraindications

Haemorrhagic stroke or stroke of unknown origin at any time

Ischaemic stroke in preceding 6 months

Central nervous system damage or neoplasms

Recent major trauma/surgery/head injury (within preceding 3 weeks)

Gastrointestinal bleeding within the last month

Known bleeding disorder

Aortic dissection

Relative contraindications

Transient ischaemic attack in preceding 6 months

Oral anticoagulant therapy

Pregnancy or within 1 week postpartum

Non-compressible punctures

Traumatic resuscitation

Refractory hypertension (systolic blood pressure > 180 mmHg)

Advanced liver disease

Infective endocarditis

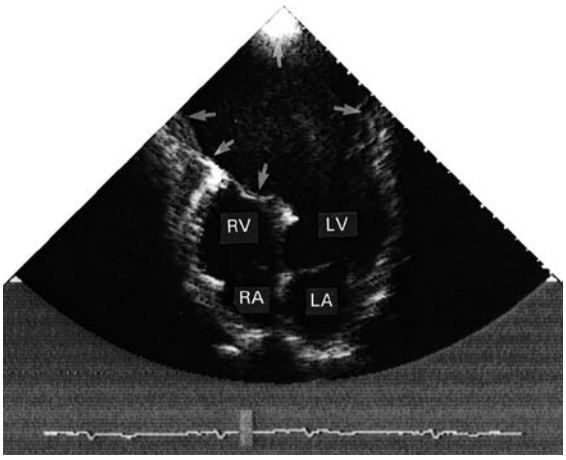

Fig. 13.76 **2-D Echocardiogram (apical four-chamber view) showing a very large apical left ventricular aneurysm** (arrows).The relatively static blood in the aneurysm produces a swirling 'smoke' effect. This aneurysm was successfully resected surgically. LV, left ventricle; LA, left atrium; RV, right ventricle; RA, right atrium.

randomized to primary PTCA or t-PA followed by conservative care. At 2-year follow-up the primary PTCA group had less recurrent ischaemia, lower re-intervention rates and reduced hospital readmission rates. Primary PTCA produced a combined end-point of death or re-infarction of 14.9% compared to 23% for t-PA. PCI with thrombus aspiration has recently been shown to result in better reperfusion and clinical outcomes.

The DANAMI 2 study investigated if rapid transfer of patients with STEMI for primary angioplasty in an interventional centre was superior to thrombolysis. Patients within 12 hours of a high-risk STEMI (>4 mm elevation) received front-loaded t-PA, primary angioplasty at a local centre, or primary angioplasty at an interventional centre after transfer. Primary PCI significantly reduced the death rate in both local and transferred patients as compared to thrombolytic therapy (8.0% versus 13.7%). The majority of the benefits with primary PCI are obtained by a reduction in recurrent myocardial infarction.

Coronary stenting in primary PCI reduces the need for repeat target vessel revascularization but did not appear to reduce mortality rates. However, one recent study using drug-eluting stents showed a decreased 2-year mortality rate.

The use of abciximab in STEMI patients undergoing primary angioplasty reduces immediate outcome (death, myocardial infarction, urgent revascularization), but this benefit is minimal by 6 months.

PCI following thrombolysis was discouraged but a recent trial suggests it is safe and improves the 1-year clinical outcome.

Recent randomized trials have compared a strategy of thrombolysis (in hospitals without PCI capability) versus transfer to a PCI centre and have demonstrated a significant reduction in the combined end-point of death, reinfarction and stroke (although with a non-significant reduction in mortality) with transfer. The strategy of transfer for primary PCI is appropriate if the intervention can be performed within 90 minutes of presentation and this is now optimal therapy.

Coronary artery bypass surgery

Cardiac surgery is usually reserved for the complications of myocardial infarction, such as ventricular septal defect or mitral regurgitation.

Complications of myocardial infarction

Heart failure

Cardiac failure post STEMI is a poor prognostic feature that necessitates medical and invasive therapy to reduce the death rate. The Killip classification is used to assess patients with heart failure post MI:

- Killip I – no crackles and no third heart sound
- Killip II – crackles in <50% of the lung fields or a third heart sound
- Killip III – crackles in >50% of the lung fields
- Killip IV – cardiogenic shock.

Mild heart failure may respond to intravenous furosemide 40–80 mg i.v., with GTN administration if the blood pressure is satisfactory. Oxygen is required, with regular oxygen monitoring. ACE inhibitors can be given in <24–48 hours if the blood pressure is satisfactory. Patients with severe heart failure may require Swan–Ganz catheterization to determine the pulmonary wedge pressure. Intravenous inotropes such as dopamine or dobutamine are used in patients with severe heart failure. If the patient is in cardiogenic shock, then revascularization ± intra-aortic balloon pump insertion may be required.

Myocardial rupture and aneurysmal dilatation

Rupture of the free wall of the left ventricle is usually an early, catastrophic and fatal event. The patient will have a haemodynamic collapse, then an electromechanical cardiac arrest. A subacute rupture may allow for pericardiocentesis followed by the surgical repair of the rupture. Aneurysmal dilatation of the infarcted myocardium (Figs 13.17 and 13.76) is a late complication that may require surgical repair.

Ventricular septal defect (VSD)

A VSD may occur in 1–2.0% of patients with STEMI, and may be associated with delayed or failed fibrinolysis. However, mortality is very high with a 12-month unoperative mortality of 92%. An intra-aortic balloon pump (IABP) and coronary angiography may allow for patient optimization prior to surgery.

Mitral regurgitation

Severe mitral regurgitation can occur early in the course of STEMI. Three mechanisms may be responsible for the mitral regurgitation, and a transoesophageal echocardiogram (TOE) may be necessary to confirm the aetiology:

- severe left ventricular dysfunction and dilatation, causing annular dilatation of the valve and subsequent regurgitation
- myocardial infarction of the inferior wall, producing dysfunction of the papillary muscle that may respond to coronary intervention
- myocardial infarction of the papillary muscles, producing sudden severe pulmonary oedema and cardiogenic shock (IABP, coronary angiography and early surgery may improve patient survival).

Cardiac arrhythmias

Ventricular tachycardia and ventricular fibrillation are common in STEMI, particularly with reperfusion. Cardiac arrest requires defibrillation. Ventricular tachycardia should be treated with intravenous beta-blockers (metoprolol 5 mg, esmolol 50–200 μg/kg/min), lidocaine 50–100 mg, or amiodarone 900–1200 mg per 24 hours. If the patient is hypotensive, synchronized cardioversion may be performed. Ensure that the serum potassium is above 4.5 mmol/L. Refractory ventricular tachycardia or fibrillation may respond to magnesium 8 mmol/L over 15 minutes i.v.

Atrial fibrillation occurs frequently and treatment with beta-blockers and digoxin may be required. Cardioversion is possible but relapse is frequent.

Bradyarrhythmias can be treated initially with i.v. atropine 0.5 mg repeated up to six times in 4 hours. Temporary transcutaneous or transvenous pacemaker insertion may be required in patients with symptomatic heart block.

Conduction disturbances

These are common following MI. AV block may occur during acute MI, especially of the inferior wall (the right coronary artery usually supplies the SA and AV nodes). Heart block, when associated with haemodynamic compromise, may need treatment with atropine or a temporary pacemaker. Such blocks may last for only a few minutes, but frequently continue for several days. Permanent pacing may need to be considered if heart block persists for over 2 weeks.

Post-MI pericarditis and Dressler's syndrome

See section below entitled 'Pericardial disease' (p. 794).

Post-MI lifestyle modification

After recovery from an acute myocardial infarction patients should be encouraged to participate in a cardiac rehabilitation programme that provides education and information appropriate to the patients' requirements. An exercise programme forms part of the rehabilitation.

- Patients should be encouraged to eat a Mediterranean-style diet and to consume >7 g of omega 3 fatty acids/week from oily fish or >1 g daily of omega-3-acid ethyl esters
- Patients should maintain alcohol consumption within safe limits (≤21 units/week for men or ≤14 units for women) and to avoid binge drinking.
- Patients should be physically active for 20–30 minutes/day.
- Patients should stop smoking.
- Overweight and obese patients should be offered advice and support to achieve and maintain a healthy weight.
- Patients with hypertension should be treated to <140/90 or <130/80 if chronic kidney disease or diabetes.
- Patients with diabetes should be treated to maintain HbA1c <7%.

Post-MI drug therapy and assessment

Extensive clinical trial evidence has been gathered in post-myocardial infarction patients, demonstrating that a range of pharmaceuticals are advantageous in reducing mortality over the following years. Therefore, post MI most patients should be taking most of the following medications:

- Aspirin 75–100 mg/day.
- A beta-blocker to maintain heart rate <60 b.p.m., e.g. metoprolol 50 mg twice daily.
- ACE inhibitors, e.g. ramipril 2.5 mg twice daily, titrated to maximum tolerated or target dose (if intolerant of ACE inhibitors use ARB, e.g. valsartan 20 mg twice daily titrated to maximum tolerated or target dose)
- Statins, e.g. simvastatin 20–80 mg/day.
- Clopidogrel 75 mg/day for 9–12 months should be added in moderate–high risk patients with non-ST elevation acute coronary syndrome (NST-ACS).
- Aldosterone antagonist, e.g. eplerenone 25 mg/day, should be given in patients post MI with clinical evidence of heart failure and reduced ejection fraction (renal function and potassium levels should be monitored).

If primary angioplasty has not been performed, then it is necessary to identify residual ischaemia and viability, to determine the need for coronary angiography. Uncomplicated patients with no angina during the hospital stay should have a low-level exercise test prior to discharge followed by a formal ETT 6 weeks later. A positive test usually suggests diagnostic/therapeutic coronary angiography/stenting. Alternatively, nuclear scintigraphy or dobutamine stress echocardiography can be used at 5 days to determine the amount of viable myocardium and the extent of myocardial ischaemia. Echocardiography should be performed to guide therapy and to determine baseline ejection fraction. In a patient with an ejection fraction < 30%, ventricular tachycardia on a Holter monitor may warrant an ICD.

SUDDEN CARDIAC DEATH

(see also Table 13.7)

Sudden cardiac death is generally defined as death due to cardiac causes which occurs within 6 hours of the onset of

symptoms. The causes of sudden cardiac death tend to mirror, in risk factors and prevalence, the predominant cardiac causes of death in a given population. In developed countries, the majority (80%) are estimated to be due to coronary artery disease, a further 10–15% to cardiomyopathies and 5% to valvular heart disease. Post-mortem studies have revealed that coronary atheroma is present in 80–90% of cases. Forty per cent of all deaths due to coronary atherosclerosis occur suddenly in this way, although up to 50% of patients dying suddenly because of coronary atheroma have no preceding history of coronary disease. The majority of cases of sudden death due to atheroma appear to be due to fatal ventricular arrhythmia, sometimes triggered by acute myocardial ischaemia. Other less common causes of sudden cardiac death are listed in Table 13.33. Patients presenting with a cardiac arrest require immediate cardiopulmonary resuscitation as outlined in Figure 13.36. In those patients who survive a cardiac arrest, an implantable cardioverter–defibrillator is often required, to prevent further cardiac arrest. Antiarrhythmic drugs such as amiodarone may be used as an alternative to an implantable cardioverter–defibrillator but are less effective.

VALVULAR HEART DISEASE

MITRAL STENOSIS

Almost all mitral stenosis is due to rheumatic heart disease.

At least 50% of sufferers have a history of rheumatic fever or chorea. The single most common valve lesion due to rheumatic fever is pure mitral stenosis (50%) (Table 13.34). The mitral valve is affected in over 90% of those with rheumatic valvular heart disease. Rheumatic mitral stenosis is much more common in women. The pathological process results after some years in valve thickening, cusp fusion, calcium deposition, a narrowed (stenotic) valve orifice and progressive immobility of the valve cusps.

Other causes include:

- Lutembacher's syndrome, which is the combination of acquired mitral stenosis and an atrial septal defect
- a rare form of congenital mitral stenosis
- in the elderly, a syndrome similar to mitral stenosis, which develops because of calcification and fibrosis of the valve, valve ring and subvalvular apparatus (chordae tendineae)
- carcinoid tumours metastasizing to the lung, or primary bronchial carcinoid.

Pathophysiology

When the normal valve orifice area of 5 cm^2 is reduced to approximately 1 cm^2, severe mitral stenosis is present. In order that sufficient cardiac output will be maintained, the left atrial pressure increases and left atrial hypertrophy and dilatation occur. Consequently, pulmonary venous, pulmonary arterial and right heart pressures also increase. The increase in pulmonary capillary pressure is followed by the development of pulmonary oedema. This is partially prevented by alveolar and capillary thickening and pulmonary arterial vasoconstriction (reactive pulmonary hypertension). Pulmonary hypertension leads to right ventricular hypertrophy, dilatation and failure. Right ventricular dilatation results in tricuspid regurgitation. Mitral stenosis is frequently associated with complications (Table 13.35).

Symptoms

Usually there are no symptoms until the valve orifice is moderately stenosed (i.e. has an area of 2 cm^2). In Europe this does not usually occur until several decades after the first attack of rheumatic fever, but children of 10–20 years of age in the Middle or Far East may have severe calcific mitral stenosis.

Because of pulmonary venous hypertension and recurrent bronchitis, progressively *severe dyspnoea* develops. A cough productive of blood-tinged, frothy sputum is quite common, and occasionally frank haemoptysis may occur. The development of pulmonary hypertension eventually leads to *right heart failure* and its symptoms of weakness, fatigue and abdominal or lower limb swelling.

The large left atrium favours *atrial fibrillation*, giving rise to symptoms such as palpitations. Atrial fibrillation may result in *systemic emboli*, most commonly to the cerebral vessels resulting in neurological sequelae, but mesenteric, renal and peripheral emboli are also seen. Clinical pulmonary embolism as a result of mitral stenosis associated with atrial fibrillation is less commonly seen, but it is likely that subclinical pulmonary emboli occur.

Signs (see Clinical memo in Fig. 13.77)

Face

Severe mitral stenosis with pulmonary hypertension is associated with the so-called mitral facies or malar flush. This is a bilateral, cyanotic or dusky pink discoloration over the upper cheeks that is due to arteriovenous anastomoses and vascular stasis.

Pulse

Mitral stenosis may be associated with a small-volume pulse which is usually regular early on in the disease process when most patients are in sinus rhythm. However, as the severity of the disease progresses, many patients develop atrial fibrillation resulting in an irregularly irregular pulse. The development of atrial fibrillation in these patients often causes a dramatic clinical deterioration.

Jugular veins

If right heart failure develops, there is obvious distension of the jugular veins. If pulmonary hypertension or tricuspid stenosis is present, the *a* wave will be prominent provided that atrial fibrillation has not supervened.

Palpation

There is a tapping impulse felt parasternally on the left side. This is the result of a palpable first heart sound combined with left ventricular backward displacement produced by an enlarging right ventricle. A sustained parasternal impulse due to right ventricular hypertrophy may also be felt.

Auscultation

Auscultation (Fig. 13.77) reveals a loud first heart sound if the mitral valve is pliable, but it will not occur in calcific mitral stenosis. As the valve suddenly opens with the force of the increased left atrial pressure, an 'opening snap' will be heard. This is followed by a low-pitched 'rumbling' mid-diastolic murmur best heard with the bell of the stethoscope held lightly at the apex with the patient lying on the left side. If the patient is in sinus rhythm, the murmur becomes louder at the end of diastole as a result of atrial contraction (pre-systolic accentuation).

The severity of mitral stenosis is judged clinically on the basis of several criteria:

- The presence of pulmonary hypertension implies that mitral stenosis is severe. Pulmonary hypertension is recognized by a right ventricular heave, a loud pulmonary component of the second heart sound, eventually with signs of right-sided heart failure, such as oedema and hepatomegaly. Pulmonary hypertension results in pulmonary valvular regurgitation that causes an early diastolic murmur in the pulmonary area known as a Graham Steell murmur.
- The closeness of the opening snap to the second heart sound is proportional to the severity of mitral stenosis.
- The length of the mid-diastolic murmur is proportional to the severity.
- As the valve cusps become immobile, the loud first heart sound softens and the opening snap disappears. When pulmonary hypertension occurs, the pulmonary component of the second sound is increased in

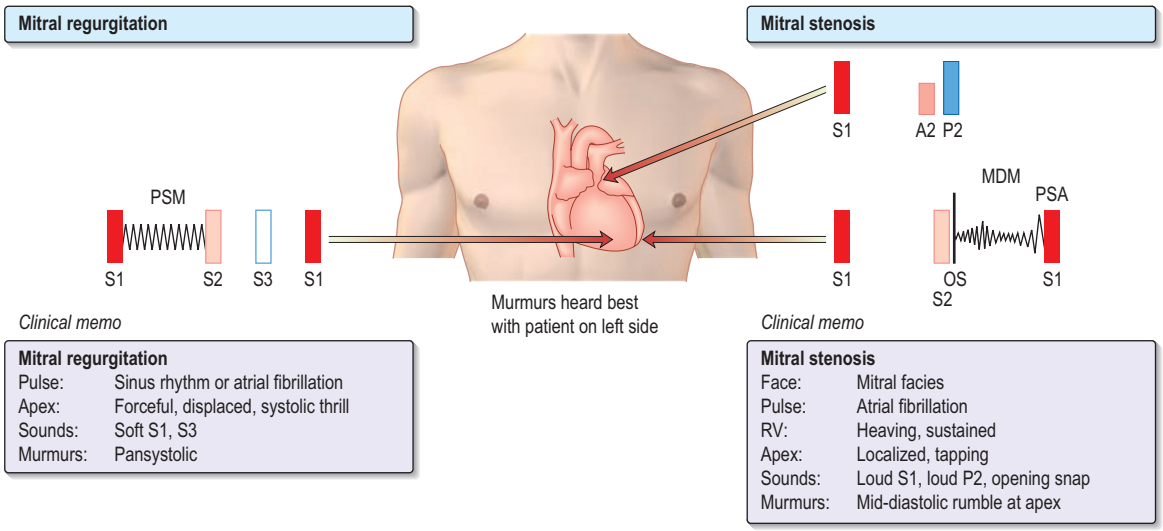

Fig. 13.77 Features associated with mitral regurgitation and mitral stenosis. A2, aortic component of the second heart sound; MDM, mid-diastolic murmur; OS, opening snap; P2, pulmonary component of the second heart sound; PSA, presystolic accentuation; PSM, pansystolic murmur; S1, first heart sound; S2, second heart sound; S3, third heart sound.

intensity and the mitral diastolic murmur may become quieter because of the reduction of cardiac output.

Investigations

Chest X-ray

The chest X-ray usually shows a generally small heart with an enlarged left atrium (Fig. 13.14, p. 693). Pulmonary venous hypertension is usually also present. Late in the course of the disease a calcified mitral valve may be seen on a penetrated or lateral view. The signs of pulmonary oedema or pulmonary hypertension may also be apparent when the disease is severe.

Electrocardiogram

In sinus rhythm the ECG shows a bifid P wave owing to delayed left atrial activation (Fig. 13.78). However, atrial fibrillation is frequently present. As the disease progresses, the ECG features of right ventricular hypertrophy (right axis deviation and perhaps tall R waves in lead V1) may develop (Fig. 13.79).

Imaging

Echocardiogram (Fig. 13.28)

Two-dimensional echocardiography allows assessment of the mitral valve apparatus and calculation of mitral valve area, thus providing a useful guide in determining whether balloon valvotomy or valve replacement is the treatment of choice in patients symptomatic on medical therapy. Two-dimensional echocardiography also determines left atrial and right ventricular size and function. Continuous wave (CW) Doppler may also be used to measure mitral valve area and provides an estimate of pulmonary artery pressure through measurement of the degree of tricuspid regurgitation. In most cases, echocardiography alone is sufficient to judge the severity of mitral stenosis such that decisions regarding surgery can be made.

Transoesophageal echocardiography *(TOE)* is performed to detect the presence of left atrial thrombus (p. 702).

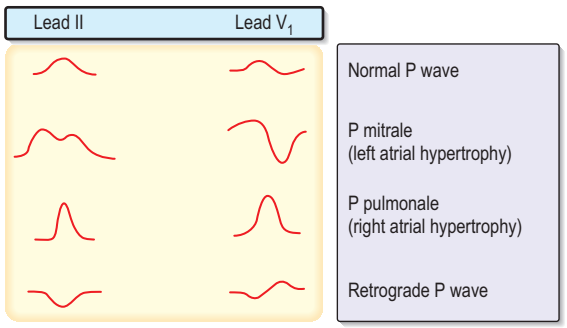

Fig. 13.78 **A bifid P wave as seen on the ECG in mitral stenosis (P mitrale).** Also shown for comparison are other P wave abnormalities.

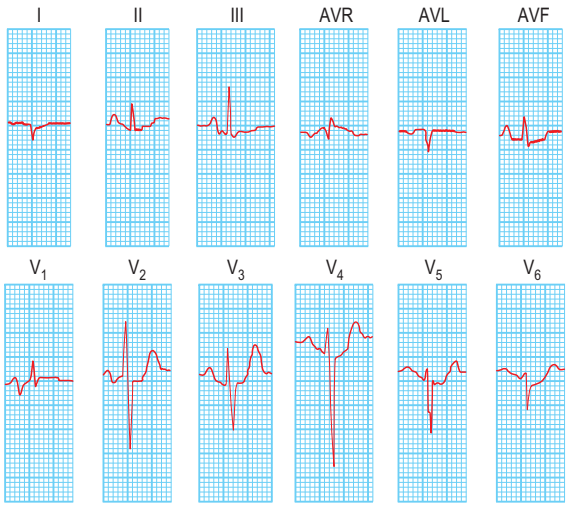

Fig. 13.79 **Severe mitral stenosis** shown by a 12-lead ECG. Note the right axis deviation (frontal plane axis = + 120°), the left atrial conduction abnormality (large terminal negative component of the P wave in V_1) and the right ventricular hypertrophy (R wave in V_1 and right axis deviation).

Cardiac magnetic resonance (CMR; see p. 707)

This accurately shows mitral valve anatomy.

Cardiac catheterization is now seldom required and is only used if coexisting cardiac problems (e.g. mitral regurgitation or coronary artery disease) are suspected. The typical findings in mitral stenosis are a diastolic pressure that is higher in the left atrium than in the left ventricle. This gradient of pressure is usually proportional to the degree of the stenosis.

Treatment

Mild mitral stenosis may need no treatment other than prompt therapy of attacks of bronchitis. Infective endocarditis in pure mitral stenosis is uncommon. Early symptoms of mitral stenosis such as mild dyspnoea can usually be treated with low doses of diuretics. The onset of atrial fibrillation requires treatment with digoxin and anticoagulation to prevent atrial thrombus and systemic embolization. If pulmonary hypertension develops or the symptoms of pulmonary congestion persist despite therapy, surgical relief of the mitral stenosis is advised. There are four operative measures.

Trans-septal balloon valvotomy

A catheter is introduced into the right atrium via the femoral vein. The interatrial septum is then punctured and the catheter advanced into the left atrium and across the mitral valve. A balloon is passed over the catheter to lie across the valve, and then inflated briefly to split the valve commissures. The procedure is performed under local anaesthesia in the cardiac catheter laboratory. As with other valvotomy techniques, significant regurgitation may result, necessitating valve replacement (see below). This procedure is ideal for patients with pliable valves in whom there is little involvement of the subvalvular apparatus and in whom there is minimal mitral regurgitation. The procedure cannot be performed when there is heavy calcification or more than mild mitral regurgitation. The presence of thrombus in the left atrium is a contraindication to balloon valvotomy; therefore, transoesophageal echocardiography must be performed prior to this technique in order that left atrial thrombus can be excluded.

Closed valvotomy

This operation is advised for patients with mobile, non-calcified and non-regurgitant mitral valves. The fused cusps are forced apart by a dilator introduced through the apex of

the left ventricle and guided into position by the surgeon's finger inserted via the left atrial appendage. Cardiopulmonary bypass is not needed for this operation. Closed valvotomy may produce a good result for 10 years or more. The valve cusps often re-fuse and eventually another operation may be necessary.

Open valvotomy

This operation is often preferred to closed valvotomy. The cusps are carefully dissected apart under direct vision. Cardiopulmonary bypass is required. Open dissection reduces the likelihood of causing traumatic mitral regurgitation.

Mitral valve replacement

Replacement of the mitral valve is necessary if:

- mitral regurgitation is also present
- there is a badly diseased or badly calcified stenotic valve that cannot be reopened without producing significant regurgitation
- there is moderate or severe mitral stenosis and thrombus in the left atrium despite anticoagulation.

Artificial valves (see p. 769) may work successfully for more than 20 years. Anticoagulants are generally necessary to prevent the formation of thrombus, which might obstruct the valve or embolize.

MITRAL REGURGITATION

There are many causes of mitral valve regurgitation but rheumatic heart disease (50%) and a prolapsing mitral valve are the most common. Other causes include:

- aortic valve disease
- acute rheumatic fever
- myocarditis
- dilated cardiomyopathy
- hypertensive heart disease
- ischaemic heart disease
- infective endocarditis – mitral regurgitation may result from destruction of the mitral valve leaflets
- hypertrophic cardiomyopathy – left ventricular contraction is disorganized
- rheumatic autoimmune disease – systemic lupus erythematosus (SLE)
- collagen abnormalities – Marfan's syndrome and Ehlers–Danlos syndrome
- degeneration of the valve cusps or mitral annular calcification
- rupture of the chordae tendineae (due to myocardial infarction, infective endocarditis or trauma) – results in acute and very severe mitral regurgitation
- drugs, e.g. centrally acting appetite suppressants, e.g. fenfluramine; dopamine agonists, e.g. cabergoline.

Pathophysiology

Regurgitation into the left atrium produces left atrial dilatation but little increase in left atrial pressure if the regurgitation is long-standing, as the regurgitant flow is accommodated by the large left atrium. With acute mitral regurgitation the normal compliance of the left atrium does not allow much dilatation and the left atrial pressure rises. Thus, in acute mitral regurgitation the left atrial '*v*' wave is greatly increased and pulmonary venous pressure rises to produce pulmonary oedema. Since a proportion of the stroke volume is regurgitated, the stroke volume increases to maintain the forward cardiac output and the left ventricle therefore enlarges.

Symptoms

Mitral regurgitation can be present for many years and the cardiac dimensions greatly increased before any symptoms occur. The increased stroke volume is sensed as a 'palpitation'. *Dyspnoea and orthopnoea* develop owing to pulmonary venous hypertension occurring as a direct result of the mitral regurgitation and secondarily to left ventricular failure. *Fatigue and lethargy* develop because of the reduced cardiac output. In the late stages of the disease the *symptoms of right heart failure* also occur and eventually lead to congestive cardiac failure. *Cardiac cachexia* may develop. Thromboembolism is less common than in mitral stenosis, but *subacute infective endocarditis* is much more common.

Signs (see Clinical memo in Fig. 13.77)

The physical signs of uncomplicated mitral regurgitation are:

- laterally displaced (forceful) diffuse apex beat and a systolic thrill (if severe)
- soft first heart sound, owing to the incomplete apposition of the valve cusps and their partial closure by the time ventricular systole begins
- pansystolic murmur, owing to the occurrence of regurgitation throughout the whole of systole, being loudest at the apex but radiating widely over the precordium and into the axilla
- prominent third heart sound, owing to the sudden rush of blood back into the dilated left ventricle in early diastole (sometimes a short mid-diastolic flow murmur may follow the third heart sound).

The signs related to atrial fibrillation, pulmonary hypertension, and left and right heart failure develop later in the disease. The onset of atrial fibrillation has a much less dramatic effect on symptoms than in mitral stenosis.

Investigations

Chest X-ray

The chest X-ray may show left atrial and left ventricular enlargement. There is an increase in the CTR, and valve calcification is seen.

Electrocardiogram

The ECG shows the features of left atrial delay (bifid P waves) and left ventricular hypertrophy (Fig. 13.80) as manifested by tall R waves in the left lateral leads (e.g. leads I and V_6) and deep S waves in the right-sided precordial leads, (e.g. leads V_1 and V_2). (Note that SV_1 plus RV_5 or $RV_6 > 35$ mm indicates left ventricular hypertrophy.) Left ventricular hypertrophy occurs in about 50% of patients with mitral regurgitation. Atrial fibrillation may be present.

Echocardiogram

The echocardiogram shows a dilated left atrium and left ventricle. There may be specific features of chordal or papillary muscle rupture. CW Doppler can determine the velocity of the regurgitant jet.

The echocardiogram is not as definitive in mitral regurgitation as in mitral stenosis. However, useful information

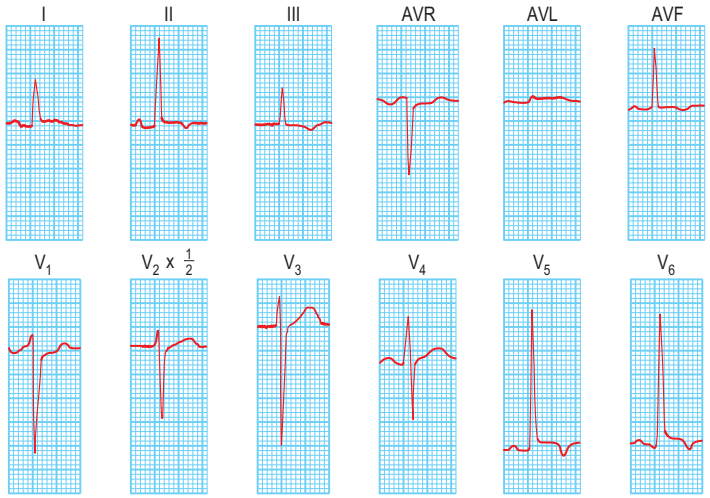

Fig. 13.80 **Left ventricular hypertrophy** shown in a 12-lead ECG. Note the size of the S wave seen in V_1 (21 mm); S in V_1 + R in V_6 = >35 mm.

regarding the severity of the condition can be obtained indirectly by observing the dynamics of ventricular function. Transoesophageal echocardiography (TOE) helps to identify structural valve abnormalities before surgery. Intraoperative TOE can also aid assessment of the efficacy of valve repair.

Cardiac catheterization

This demonstrates a prominent left atrial systolic pressure wave, and when contrast is injected into the left ventricle it is seen regurgitating into an enlarged left atrium during systole. CMR has largely replaced catheterization.

Treatment

Mild mitral regurgitation in the absence of symptoms can be managed conservatively by following the patient with serial echocardiograms. Prophylaxis against endocarditis is discussed in Chapter 4 (see p. 93). Any evidence of progressive cardiac enlargement generally warrants early surgical intervention by either mitral valve repair or replacement. The advantages of surgical intervention are diminished in more advanced disease. In patients who are not considered appropriate for surgical intervention, or in whom surgery will be considered at a later date, management usually involves treatment with ACE inhibitors, diuretics and possibly anticoagulants. Sudden torrential mitral regurgitation, as seen with chordal or papillary muscle rupture or infective endocarditis, necessitates emergency mitral valve replacement.

Prolapsing (billowing) mitral valve

This is also known as Barlow's syndrome or floppy mitral valve. It is due to excessively large mitral valve leaflets, an enlarged mitral annulus, abnormally long chordae or disordered papillary muscle contraction. Histology may demonstrate myxomatous degeneration of the mitral valve leaflets. It is more commonly seen in young women than in men or older women and it has a familial incidence. Its cause is unknown but it is associated with Marfan's syndrome, thyrotoxicosis, rheumatic or ischaemic heart disease. It also occurs in association with atrial septal defect and as part of hypertrophic cardiomyopathy. Mild mitral valve prolapse is so common that it should be regarded as a normal variant.

Pathophysiology

During ventricular systole, a mitral valve leaflet (most commonly the posterior leaflet) prolapses into the left atrium. This may result in abnormal ventricular contraction, papillary muscle strain and some mitral regurgitation. Usually the syndrome is not haemodynamically serious. Thromboembolism occurs.

Symptoms

Atypical chest pain is the most common symptom. Usually the pain is left submammary and stabbing in quality. Sometimes it is substernal, aching and severe. Rarely, it is similar to typical angina pectoris. *Palpitations* may be experienced because of the abnormal ventricular contraction or because of the atrial and ventricular arrhythmias that are commonly associated with mitral valve prolapse. Sudden cardiac death due to fatal ventricular arrhythmias is a very rare but recognized complication.

Signs

The most common sign is a mid-systolic click, which is produced by the sudden prolapse of the valve and the tensing of the chordae tendineae that occurs during systole. This may be followed by a late systolic murmur owing to some regurgitation. With more regurgitation, the murmur becomes pansystolic mitral regurgitation.

Investigations

The diagnosis is confirmed on two-dimensional echocardiography, which typically shows posterior movement of one or both mitral valve cusps into the left atrium during systole.

Treatment

Usually, beta-blockade is effective for the treatment of the atypical chest pain and palpitations. Sometimes more specific antiarrhythmic drug treatment is necessary. When a prolapsing mitral valve is associated with significant mitral regurgitation and atrial fibrillation, anticoagulation is advised to prevent thromboembolism. Mitral valve prolapse associated with severe mitral regurgitation has a risk of sudden cardiac death. Mitral valve repair is indicated in all such cases. Very occasionally, mitral valve replacement rather

than repair may be necessary for severe regurgitation when there is severe prolapse of both leaflets. Prophylaxis against endocarditis is discussed in Chapter 4 (see p. 93).

AORTIC STENOSIS

Congenital aortic valve stenosis develops progressively because of turbulent blood flow through a congenitally abnormal (usually bicuspid) aortic valve. Most congenitally abnormal aortic valves occur in men and will calcify later in life.

Rheumatic fever results in progressive fusion, thickening and calcification of a previously normal three-cusped aortic valve. In rheumatic heart disease the aortic valve is affected in about 40% of cases and there is usually associated mitral valve disease.

Calcific valvular disease is the commonest cause of aortic stenosis and mainly occurs in the elderly. This is an inflammatory process involving macrophages and T lymphocytes with initially thickening of the subendothelium with adjacent fibrosis. The lesions contain lipoproteins which calcify, increasing leaflet stiffness and reducing systolic opening.

Valvular aortic stenosis should be distinguished from other causes of obstruction to left ventricular emptying (Fig. 13.81), which include:

- supravalvular obstruction – a congenital fibrous diaphragm above the aortic valve often associated with mental retardation and hypercalcaemia (William's syndrome)
- hypertrophic cardiomyopathy – septal muscle hypertrophy obstructing left ventricular outflow
- subvalvular aortic stenosis – a congenital condition in which a fibrous ridge or diaphragm is situated immediately below the aortic valve.

Pathophysiology

Obstructed left ventricular emptying leads to increased left ventricular pressure and compensatory left ventricular hypertrophy. In turn, this results in relative ischaemia of the left ventricular myocardium, and consequent angina, arrhythmias and left ventricular failure. The obstruction to left ventricular emptying is relatively more severe on exercise. Normally, exercise causes a many-fold increase in cardiac output, but when there is severe narrowing of the aortic valve orifice the cardiac output can hardly increase. Thus, the blood pressure falls, coronary ischaemia worsens, the myocardium fails and cardiac arrhythmias develop. Left ventricular systolic function is typically preserved in patients with aortic stenosis (cf. aortic regurgitation).

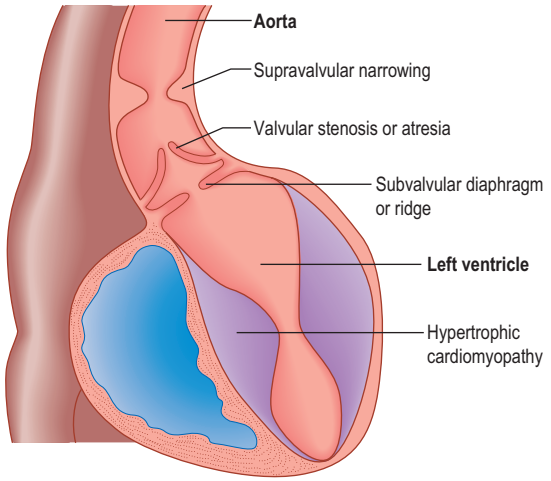
Symptoms

There are usually no symptoms until aortic stenosis is moderately severe (when the aortic orifice is reduced to one-third of its normal size). At this stage, *exercise-induced syncope*, *angina* and *dyspnoea* develop. When symptoms occur, the prognosis is poor – on average, death occurs within 2–3 years if there has been no surgical intervention.

Signs (see Clinical memo in Fig. 13.82)

Pulse

The carotid pulse is of small volume and is slow-rising or plateau in nature (see p. 690).



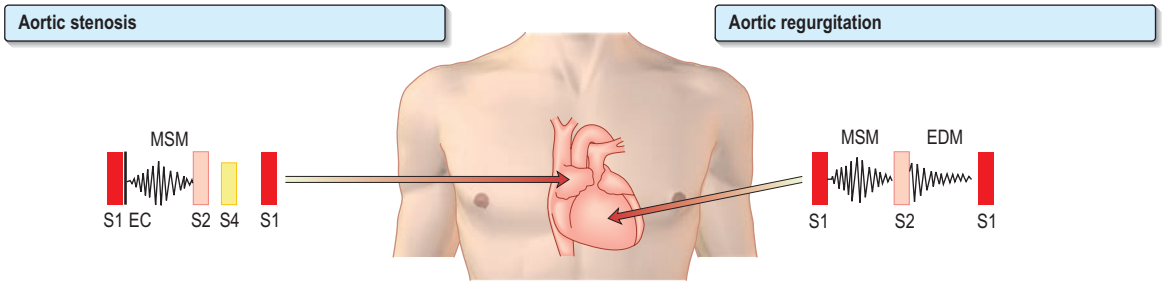


Fig. 13.81 Several forms of left ventricular outflow tract obstruction.

Clinical memo

Aortic stenosis

Pulse:	Sinus rhythm, low volume, slow rising
Aortic area:	Systolic thrill
Apex:	Not displaced, sustained
Sounds:	Ejection click, soft A2, S4
Murmurs:	Systolic, low pitched, ejection, radiating to carotids

Murmurs heard best with patient leaning forwards and breath held in expiration

Clinical memo

Aortic regurgitation

Pulse:	Sinus rhythm, large volume, collapsing
Blood pressure:	Wide pulse pressure
Apex:	Displaced, diffuse, forceful
Murmurs:	(1) High pitched, early diastolic at LSE (2) Ejection systolic at base and into neck (high flow) (3) Mid-diastolic rumble at apex (Austin-Flint) (not shown)

Fig. 13.82 Features of aortic stenosis and aortic regurgitation. EC, ejection click; EDM, early diastolic murmur; MSM, mid-systolic murmur; S1, first heart sound.

Precordial palpation

The apex beat is not usually displaced because hypertrophy (as opposed to dilatation) does not produce noticeable cardiomegaly. However, the pulsation is sustained and obvious. A double impulse is sometimes felt because the fourth heart sound or atrial contraction ('kick') may be palpable. A systolic thrill may be felt in the aortic area.

Auscultation

The most obvious auscultatory finding in aortic stenosis is an ejection systolic murmur that is usually 'diamond-shaped' (crescendo–decrescendo). The murmur is usually longer when the disease is more severe, as a longer ejection time is needed. The murmur is usually rough in quality and best heard in the aortic area. It radiates into the carotid arteries and also the precordium. The intensity of the murmur is not a good guide to the severity of the condition because it is lessened by a reduced cardiac output. In severe cases, the murmur may be inaudible.

Other findings include:

- systolic ejection click, unless the valve has become immobile and calcified
- soft or inaudible aortic second heart sound when the aortic valve becomes immobile
- reversed splitting of the second heart sound (splitting on expiration) (see p. 692)
- prominent fourth heart sound, which is caused by atrial contraction, is heard unless coexisting mitral stenosis prevents this.

Investigations

Chest X-ray

The chest X-ray usually reveals a relatively small heart with a prominent, dilated, ascending aorta. This occurs because turbulent blood flow above the stenosed aortic valve produces so-called 'post-stenotic dilatation'. The aortic valve may be calcified. The CTR increases when heart failure occurs.

Electrocardiogram

The ECG shows left ventricular hypertrophy and left atrial delay. A left ventricular 'strain' pattern due to 'pressure overload' (depressed ST segments and T wave inversion in leads orientated towards the left ventricle, i.e. leads I, AVL, V_5 and V_6) is common when the disease is severe. Usually, sinus rhythm is present, but ventricular arrhythmias may be recorded.

Echocardiogram

The echocardiogram readily demonstrates the thickened, calcified and immobile aortic valve cusps. Left ventricular hypertrophy may also be seen. The gradient across the valve can be estimated by CW Doppler, provided the left ventricular function is reasonable (Fig. 13.27, p. 702).

Cardiac catheterization

Cardiac catheterization can be used to document the systolic pressure difference (gradient) between the aorta and the left ventricle (Fig. 13.83) and assess left ventricular function. This is rarely necessary since all of this information can be gained non-invasively with echocardiography and CMR. Coronary angiography is necessary before recommending surgery.

Treatment

In patients with aortic stenosis, symptoms are a good index of severity and all symptomatic patients should have *aortic valve replacement.* Asymptomatic patients should be under regular review for assessment of symptoms and echocardiography. Antibiotic prophylaxis against infective endocarditis is discussed in Chapter 4 (see p. 93).

Provided that the valve is not severely deformed or heavily calcified, critical aortic stenosis in childhood or adolescence can be treated by valvotomy (performed under direct vision by the surgeon or by balloon dilatation using X-ray visualization). This produces temporary relief from the obstruction. Aortic valve replacement will usually be needed a few years later. Balloon dilatation (valvuloplasty) has been tried in adults, especially in the elderly, as an alternative to surgery. Generally results are poor and such treatment is reserved for patients unfit for surgery or as a 'bridge' to surgery (as systolic function will often improve).

Percutaneous valve replacement

A novel treatment for patients unsuitable for surgical aortic valve replacement is transcatheter implantation with a balloon expandable stent valve. In a recent study valve implantation was successful (86%) with a procedural mortality of 2% and 30-day mortality of 12%. Further larger and randomized studies with long-term follow-up are required.

AORTIC REGURGITATION

The most common causes of aortic regurgitation are rheumatic fever and infective endocarditis complicating a previ-

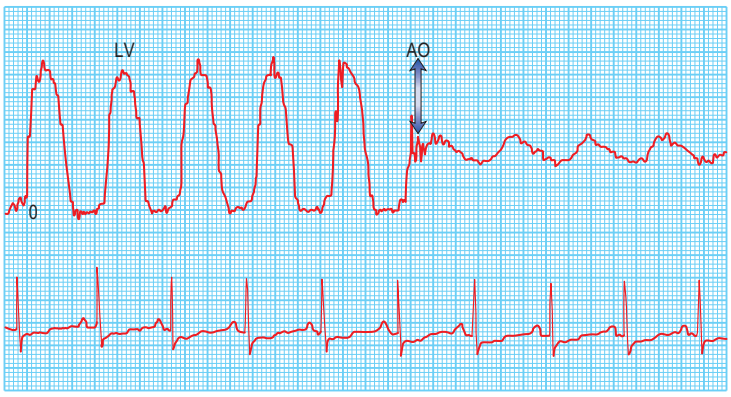

Fig. 13.83 **ECG and pressure trace as a cardiac catheter is withdrawn** from the left ventricle (LV) to the aorta (AO). Note that the peak systolic pressure changes from 250 to 130 mmHg (arrow). The 120 mmHg peak-to-peak systolic gradient indicates severe aortic valvular stenosis.

Failure of prosthetic valve	Bicuspid aortic valve
	Aortic endocarditis
	Marfan's syndrome
	Osteogenesis imperfecta

ously damaged valve. This can be a congenitally abnormal valve (e.g. a bicuspid valve) or one damaged by rheumatic fever. There are numerous other causes and associations (Table 13.36). The majority of patients with aortic regurgitation are men (75%), but rheumatic aortic regurgitation occurs more commonly in women.

Pathophysiology

Aortic regurgitation is reflux of blood from the aorta through the aortic valve into the left ventricle during diastole. If net cardiac output is to be maintained, the total volume of blood pumped into the aorta must increase, and consequently the left ventricular size must enlarge. Because of the aortic run-off during diastole, diastolic blood pressure falls and coronary perfusion is decreased. In addition, the larger left ventricular size is mechanically less efficient so that the demand for oxygen is greater and cardiac ischaemia develops.

Symptoms

In aortic regurgitation, significant symptoms occur late and do not develop until *left ventricular failure* occurs. As with mitral regurgitation, a common symptom is '*pounding of the heart*' because of the increased left ventricular size and its vigorous pulsation. *Angina pectoris* is a frequent complaint. Varying grades of *dyspnoea* occur depending on the extent of left ventricular dilatation and dysfunction. *Arrhythmias* are relatively uncommon.

Signs (see Clinical memo in Fig. 13.82)

The signs of aortic regurgitation are many and are due to the hyperdynamic circulation, reflux of blood into the left ventricle and the increased left ventricular size.

The pulse is bounding or collapsing (see p. 690). The following signs, which are rare, also indicate a hyperdynamic circulation:

- Quincke's sign – capillary pulsation in the nail beds
- De Musset's sign – head nodding with each heart beat
- Duroziez's sign – a to-and-fro murmur heard when the femoral artery is auscultated with pressure applied distally (if found, it is a sign of severe aortic regurgitation)
- pistol shot femorals – a sharp bang heard on auscultation over the femoral arteries in time with each heart beat.

The apex beat is displaced laterally and downwards and is forceful in quality. On auscultation, there is a high-pitched early diastolic murmur best heard at the left sternal edge in the fourth intercostal space with the patient leaning forward and the breath held in expiration.

Because of the volume overload there is commonly an ejection systolic flow murmur. The regurgitant jet can impinge on the anterior mitral valve cusp, causing a mid-diastolic murmur (Austin Flint).

Investigations

Chest X-ray

The chest X-ray features are those of left ventricular enlargement and possibly of dilatation of the ascending aorta. The ascending aortic wall may be calcified in syphilis, and the aortic valve may be calcified if valvular disease is responsible for the regurgitation.

Electrocardiogram

The ECG appearances are those of left ventricular hypertrophy due to 'volume overload' – tall R waves and deeply inverted T waves in the left-sided chest leads, and deep S waves in the right-sided leads. Normally, sinus rhythm is present.

Echocardiogram

The echocardiogram demonstrates vigorous cardiac contraction and a dilated left ventricle. The aortic root may also be enlarged. Diastolic fluttering of the mitral leaflets or septum occurs in severe aortic regurgitation (producing the Austin Flint murmur). The regurgitant jet can be detected by CW Doppler.

Cardiac catheterization

During cardiac catheterization, injection of contrast medium into the aorta (aortography) will outline aortic valvular abnormalities and allow assessment of the degree of regurgitation.

Treatment

The underlying cause of aortic regurgitation (e.g. syphilitic aortitis or infective endocarditis) may require specific treatment. The treatment of aortic regurgitation usually requires aortic valve replacement but the timing of surgery is critical.

Because symptoms do not develop until the myocardium fails and because the myocardium does not recover fully after surgery, operation is performed before significant symptoms occur. The timing of the operation is best determined according to haemodynamic, echocardiographic or angiographic criteria.

Both mechanical prostheses and tissue valves are used. Tissue valves are preferred in the elderly and when anticoagulants must be avoided, but are contraindicated in children and young adults because of the rapid calcification and degeneration of the valves.

Antibiotic prophylaxis against infective endocarditis (see p. 93) is sometimes necessary if a prosthetic valve replacement has been performed.

TRICUSPID STENOSIS

This uncommon valve lesion, which is seen much more often in women than in men, is usually due to rheumatic heart

disease and is frequently associated with mitral and/or aortic valve disease. Tricuspid stenosis is also seen in the carcinoid syndrome.

Pathophysiology

Tricuspid valve stenosis results in a reduced cardiac output, which is restored towards normal when the right atrial pressure increases. The resulting systemic venous congestion produces hepatomegaly, ascites and dependent oedema.

Symptoms

Usually, patients with tricuspid stenosis complain of symptoms due to associated left-sided rheumatic valve lesions. The *abdominal pain* (due to hepatomegaly) and swelling (due to ascites), and *peripheral oedema* that occur are relatively severe when compared with the degree of *dyspnoea*.

Signs

If the patient remains in sinus rhythm, which is unusual, there is a prominent jugular venous *a* wave. This pre-systolic pulsation may also be felt over the liver. There is usually a rumbling mid-diastolic murmur, which is heard best at the lower left sternal edge and is louder on inspiration. It may be missed because of the murmur of coexisting mitral stenosis. A tricuspid opening snap may occasionally be heard.

Hepatomegaly, abdominal ascites and dependent oedema may be present.

Investigations

Chest X-ray

On the chest X-ray there may be a prominent right atrial bulge.

Electrocardiogram

The enlarged right atrium may be manifested on the ECG by peaked, tall P waves (>3 mm) in lead II.

Echocardiogram

The echocardiogram may show a thickened and immobile tricuspid valve, but this is not so clearly seen as an abnormal mitral valve.

Cardiac catheterization

This demonstrates a diastolic pressure gradient between the right atrium and the right ventricle. Contrast injection will demonstrate a large right atrium.

Treatment

Medical management consists of diuretic therapy and salt restriction. Tricuspid valvotomy is occasionally possible, but tricuspid valve replacement is often necessary. Other valves usually also need replacement because tricuspid valve stenosis is rarely an isolated lesion.

TRICUSPID REGURGITATION

Functional tricuspid regurgitation may occur whenever the right ventricle dilates, e.g. in cor pulmonale, myocardial infarction or pulmonary hypertension.

Organic tricuspid regurgitation may occur with rheumatic heart disease, infective endocarditis, carcinoid syndrome, Ebstein's anomaly (a congenitally malpositioned tricuspid valve) and other congenital abnormalities of the atrioventricular valves.

Symptoms and signs

The valvular regurgitation gives rise to high right atrial and systemic venous pressure. Patients may complain of the symptoms of *right heart failure* (see p. 736).

Physical signs include a large jugular venous '*cv*' wave and a palpable liver that pulsates in systole. Usually a right ventricular impulse may be felt at the left sternal edge, and there is a blowing pansystolic murmur, best heard on inspiration at the lower left sternal edge. Atrial fibrillation is common.

Treatment

Functional tricuspid regurgitation usually disappears with medical management. Severe organic tricuspid regurgitation may require operative repair of the tricuspid valve (annuloplasty or plication). Very occasionally, tricuspid valve replacement may be necessary. In drug addicts with infective endocarditis of the tricuspid valve, surgical removal of the valve is recommended to eradicate the infection. This is usually well tolerated in the short term. The insertion of a prosthetic valve for this condition is considered on page 769.

PULMONARY STENOSIS

This is usually a congenital lesion, but it may rarely result from rheumatic fever or from the carcinoid syndrome. Congenital pulmonary stenosis may be associated with an intact ventricular septum or with a ventricular septal defect (Fallot's tetralogy).

Pulmonary stenosis may be valvular, subvalvular or supravalvular. Multiple congenital pulmonary arterial stenoses are usually due to infection with rubella during pregnancy.

Symptoms and signs

The obstruction to right ventricular emptying results in right ventricular hypertrophy which in turn leads to right atrial hypertrophy. Severe *pulmonary obstruction* may be incompatible with life, but lesser degrees of obstruction give rise to *fatigue*, *syncope* and the symptoms of *right heart failure*. Mild pulmonary stenosis may be asymptomatic.

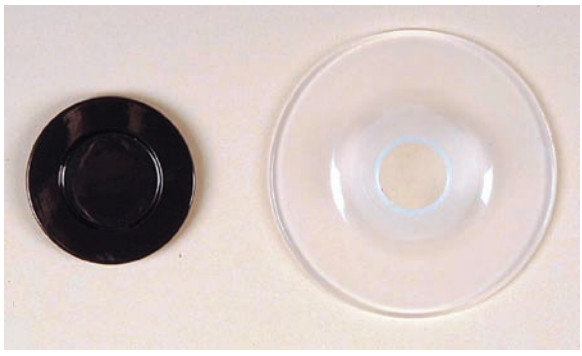
The physical signs are characterized by a harsh midsystolic ejection murmur, best heard on inspiration, to the left of the sternum in the second intercostal space. This murmur is often associated with a thrill. The pulmonary closure sound is usually delayed and soft. There may be a pulmonary ejection sound if the obstruction is valvular. A right ventricular fourth sound and a prominent jugular venous *a* wave are present when the stenosis is moderately severe. A right ventricular heave (sustained impulse) may be felt.

Investigations

Chest X-ray

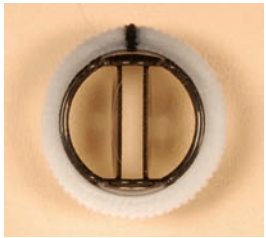
The chest X-ray usually shows a prominent pulmonary artery owing to post-stenotic dilatation.

Electrocardiogram
The ECG demonstrates both right atrial and right ventricular hypertrophy, although it may sometimes be normal even in severe pulmonary stenosis.



Echocardiogram
Doppler is the investigation of choice.

Cardiac catheterization
The passage of a catheter through the right heart allows the level and degree of the stenosis to be established by measuring the systolic pressure gradient.



Treatment
Treatment of severe pulmonary stenosis requires pulmonary valvotomy (balloon valvotomy or direct surgery).

PULMONARY REGURGITATION
This is the most common acquired lesion of the pulmonary valve. It results from dilatation of the pulmonary valve ring, which occurs with pulmonary hypertension. It is characterized by a decrescendo diastolic murmur, beginning with the pulmonary component of the second sound, that is difficult to distinguish from the murmur of aortic regurgitation. Pulmonary regurgitation usually causes no symptoms and treatment is rarely necessary.

PROSTHETIC VALVES
There is no ideal replacement for our own normally functioning, native heart valves. There are two options for valve prostheses: mechanical or tissue (bioprosthetic) (Fig. 13.84).

(a)

(b)

(c)

Fig. 13.84 Prosthetic valves. **(a)** Bjork–Shiley mechanical prosthetic valve. **(b)** St Jude double tilting disc. **(c)** Aortic valve tissue prosthesis (aortic view).

The valves consist of two basic components: an opening to allow blood to flow through and an occluding mechanism to regulate the flow. Mechanical prostheses rely on artificial concluders: a ball and cage (Starr–Edwards), tilting disc (Bjork–Shiley) or double tilting disc (St Jude). Tissue prostheses are derived from human (homograft), or from porcine or bovine (xenograft) origin. A valve replacement from within the same patient (i.e. pulmonary to aortic valve position) is termed an autograft.

Mechanical versus tissue valves
Mechanical valves, being artificial structures, are more durable than their tissue counterparts, which tend to degenerate after 10 years. However, artificial structures are more thrombogenic. Mechanical valves require formal anticoagulation for the lifetime of the prosthesis. Tissue valves only require anticoagulation for a limited postoperative period whilst the suture lines endothelialize; it can then be discontinued unless another risk factor for thromboembolism (e.g. atrial fibrillation) persists. The potential lifetime of the prosthetic valve and the patient's tolerance of long-term anticoagulation can inform the choice of valve to be implanted. On auscultation, tissue valve heart sounds are comparable to those of a native valve. Mechanical valve heart sounds are generally louder and both opening and closing sounds can be heard.

Complications
All prostheses carry a risk of infection. Prosthetic valve endocarditis is associated with significant morbidity and mortality; prevention is the cornerstone of management. Patient education about antibiotic prophylaxis is vital and this should be re-inforced at clinic visits. Any procedure which results in a breach of the body's innate defences (i.e. dental treatment, catheter insertion) increases the risk of exposing the prosthesis to a bacteraemia. This must be borne in mind when managing a patient with a prosthetic heart valve and steps taken to minimize the risk involved. The prosthetic valve occluding mechanism can be interrupted by vegetations, but also by thrombosis and calcification, resulting in either stenosis or regurgitation. The prosthesis can become detached from the valve ring resulting in a *para-prosthetic leak*. Evidence of structural failure can be detected by simple auscultation, with echocardiography as the initial investigation of choice. Transthoracic echocardiography is non-invasive, but scattering of echoes by mechanical valves makes their assessment difficult. Transoesophageal echocardiography provides alternative views and higher image resolution, making it the investigation of choice when prosthetic valve endocarditis is suspected.

INFECTIVE ENDOCARDITIS
Infective endocarditis is an endovascular infection of cardiovascular structures, including cardiac valves, atrial and ventricular endocardium, large intrathoracic vessels and intracardiac foreign bodies, e.g. prosthetic valves, pacemaker leads and surgical conduits. The annual incidence in

the UK is 6–7 per 100 000, but it is more common in developing countries. Without treatment the mortality approaches 100% and even with treatment there is a significant morbidity and mortality.

Aetiology

Endocarditis is usually the consequence of two factors: the presence of organisms in the bloodstream and abnormal cardiac endothelium facilitating their adherence and growth.

Bacteraemia may occur due to patient-specific reasons (poor dental hygiene, intravenous drug use, soft tissue infections) or be associated with diagnostic or therapeutic procedures (dental treatment, intravascular cannulae, cardiac surgery, or permanent pacemakers). Although bacteraemia may occur there is no good evidence that it leads to infective endocarditis (p. 773).

Damaged endocardium promotes platelet and fibrin deposition which allows organisms to adhere and grow, leading to an infected vegetation. Valvular lesions may create non-laminar flow, and jet lesions from septal defects or a patent ductus arteriosus result in abnormal vascular endothelium. Aortic and mitral valves are most commonly involved in infective endocarditis apart from intravenous drug users in whom right sided lesions are more common.

Organisms

Common organisms and the sources of infection are shown in Figure 13.85.

Rare causes

These include the HACEK group of organisms which tend towards a more insidious course (see Box 13.1).

Culture negative endocarditis

This accounts for 5–10% of endocarditis cases. The usual cause is prior antibiotic therapy (good history taking is vital) but some cases are due to a variety of fastidious organisms that fail to grow in normal blood cultures. These include *Coxiella burnetti* (the cause of Q fever), *Chlamydia* species, *Bartonella* species (organisms that cause trench fever and cat scratch disease) and *Legionella*.

Table 13.37 Clinical features of infective endocarditis

	Approximate %

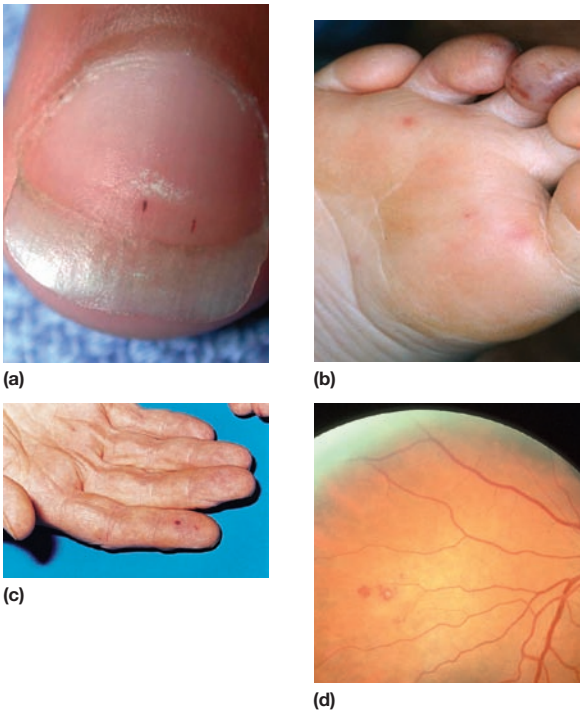
Haematuria	70

Clinical presentation (Table 13.37)

The clinical presentation of infective endocarditis is dependent on the organism and the presence of predisposing cardiac conditions. Infective endocarditis may occur as an acute, fulminating infection but also occurs as a chronic or subacute illness with low-grade fever and non-specific

symptoms. A high index of clinical suspicion is required to identify patients with infective endocarditis and certain criteria should alert the physician.



High clinical suspicion:

- new valve lesion/(regurgitant) murmur
- embolic event(s) of unknown origin
- sepsis of unknown origin
- haematuria, glomerulonephritis and suspected renal infarction
- 'fever' plus:
  - prosthetic material inside the heart
  - other high predisposition for infective endocarditis, e.g. i.v. drug abuse
  - newly developed ventricular arrhythmias or conduction disturbances
  - first manifestation of congestive cardiac failure
  - positive blood cultures (with typical organism)
  - cutaneous (Osler, Janeway) or ophthalmic (Roth) manifestations (Fig. 13.86)
  - peripheral abscesses (renal, splenic, spine) of unknown origin
  - predisposition and recent diagnostic / therapeutic interventions known to result in significant bacteraemia.

Low clinical suspicion. Fever plus none of the above.

Diagnostic criteria

The criteria for the clinical diagnosis of endocarditis have been established – the modified Duke criteria (Box 13.1).

(a) **(b)** **(c)** **(d)**

Fig. 13.86 **Infective endocarditis. (a)** Splinter haemorrhages. **(b)** Janeway lesions. **(c)** Osler's nodes. **(d)** Roth spots. Investigations

Investigations are required to confirm the diagnosis of infective endocarditis; to identify the organism to ensure appropriate therapy; and to monitor the patient's response to therapy.

Box 13.1 Modified Duke criteria for endocarditis*

After Raoult D, Abbara S, Jassal DS, Kradin RL. Case records of the Massachusetts General Hospital. Case 5-2007. A 53-year-old man with a prosthetic aortic valve and recent onset of fatigue, dyspnea, weight loss, and sweats. *New England Journal of Medicine* 2007; **356**: 715. Copyright © 2007 Massachusetts Medical Society. All rights reserved.

Major criteria

- A positive blood culture for infective endocarditis, as defined by the recovery of a typical microorganism from two separate blood cultures in the absence of a primary focus (viridans streptococci, *Abiotrophia* species and *Granulicatella* species; *Streptococcus bovis*, HACEK group†, or community-acquired *Staphylococcus aureus* or enterococcus species), or
- A persistently positive blood cultures, defined as the recovery of a microorganism consistent with endocarditis from either blood samples obtained more than 12 hours apart or all three or a majority of four or more separate blood samples, with the first and last obtained at least 1 hour apart, or
- A positive serological test for Q fever, with an immunofluorescence assay showing phase 1 IgG antibodies at a titre >1:800, or
- Echocardiographic evidence of endocardial involvement:
  - an oscillating intracardiac mass on the valve or supporting structures, in the path or regurgitant jets, or on implanted material in the absence of an alternative anatomical explanation; or
  - an abscess; or
  - new partial dehiscence of prosthetic valve; or
- New valvular regurgitation.

Minor criteria

- Predisposition: predisposing heart condition or intravenous drug use.
- Fever: temperature ≥38°C (100.4°F).
- Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial haemorrhage, conjunctival haemorrhages, Janeway's lesion.
- Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor.
- Microbiological evidence: a positive blood culture but not meeting a major criterion as noted above, or serological evidence of an active infection with an organism that can cause infective endocarditis.‡
- Echocardiogram: findings consistent with infective endocarditis but not meeting a major criterion as noted above.

*The diagnosis of infective endocarditis is definite when: (a) a microorganism is demonstrated by culture of a specimen from a vegetation, an embolism or an intracardiac abscess; (b) active endocarditis is confirmed by histological examination of the vegetation or intracardiac abscess; (c) two major clinical criteria, one major and three minor criteria, or five minor criteria are met.

†HACEK denotes *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens* and *Kingella kingae*.

‡Excluded from this criterion is a single positive blood culture for coagulase-negative staphylococci or other organisms that do not cause endocarditis. Serological tests for organisms that cause endocarditis include tests for *Brucella*, *Coxiella burnetii*, *Chlamydia*, *Legionella* and *Bartonella* species.

Microbiology

- **Blood cultures** are the *key diagnostic investigation* in infective endocarditis. At least three sets of samples (i.e. six bottles) should be taken from different venepuncture sites. Do not use indwelling catheter lines. Liaise with the microbiology department. The yield of any test is increased by the amount of information given about the subject.
- **Serological tests** can be sent when the diagnosis is suspected and the blood cultures are negative. They aid diagnosis in cases where the organisms will not grow in standard blood cultures (i.e. *Coxiella, Bartonella, Legionella* and *Chlamydia*).

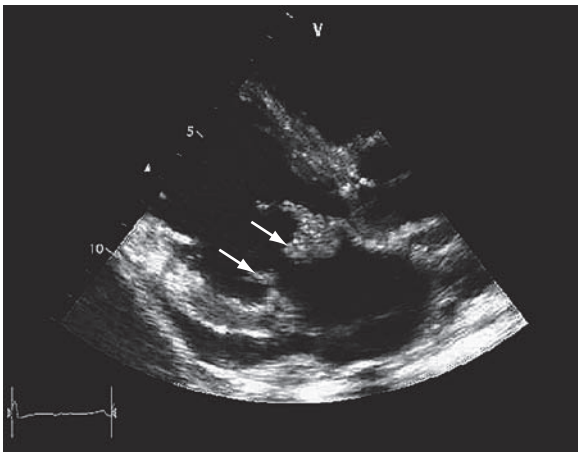
Other laboratory tests

- **Full blood count**. A mild normochromic normocytic anaemia and polymorphonuclear leucocytosis are common. Thrombocytopenia or thrombocytosis can occur.
- **Urea and electrolytes**. Renal dysfunction is common in sepsis.
- **Liver biochemistry**. Serum alkaline phosphatase may be increased.
- **Inflammatory markers**. C-reactive protein (CRP) and erythrocyte sedimentation rate are increased in any infection. CRP may be useful in monitoring response to therapy (and any relapse).
- **Urine**. Proteinuria and haematuria occur frequently.
- **Polymerase chain reaction (PCR)** may be useful in culture-negative infective endocarditis.

Electrocardiogram

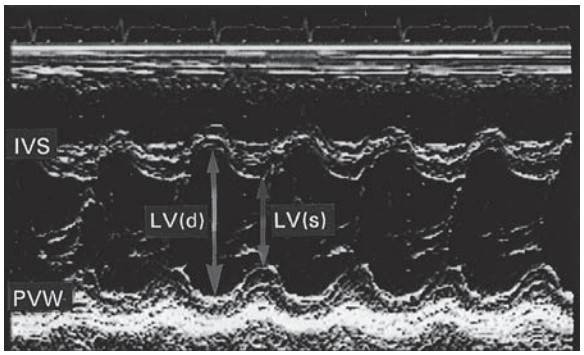
This may show evidence of myocardial infarction (emboli) or conduction defects. New atrioventricular block is suggestive of abscess formation. Patients with suspected infective endocarditis therefore should have an ECG on presentation and repeated regularly during their admission depending on their clinical course.

Chest X-ray



This may show evidence of heart failure or, in right-sided endocarditis, multiple pulmonary emboli and/oral abscesses. The combination of sepsis and pulmonary infiltrates on chest X-ray should alert the clinician to the possibility of right-sided endocarditis.

Echocardiography



Transthoracic echocardiography (TTE) is rapid, non-invasive and has high specificity for visualizing vegetations (Fig. 13.87), although sensitivity is 60–75%. It is also useful in documenting valvular dysfunction and other local complications, such as aortic root abscesses.

Transoesophageal echocardiography (TOE) has a higher sensitivity (>90%) and specificity for abscess formation because of the close physical proximity of the transducer to the aortic root. TOE also enhances the visualization of prosthetic valves and is recommended for all cases of suspected prosthetic valve endocarditis.

Echocardiography is an extremely useful tool if used appropriately. A negative echocardiogram does not exclude a diagnosis of endocarditis. It is not an appropriate screening test for patients with just a fever or an isolated positive blood culture, where there is a low pre-test probability of endocarditis.

(b)

Fig. 13.87 **Infective endocarditis. (a) Two-dimensional echocardiogram (long-axis view) showing vegetations** (arrows) attached to both the anterior and posterior leaflets of the mitral valve in a patient with infective endocarditis. **(b) M-mode echocardiogram of the left ventricle** demonstrating hyperdynamic contraction associated with volume overloading from severe mitral regurgitation in a patient with endocarditis. IVS, interventricular septum; LV(d) and LV(s), diastolic and systolic left ventricular dimensions; PVW, posterior ventricular wall.

Treatment

The location of the infection means that prolonged courses of antibiotics are usually required in the treatment of infective endocarditis. The combination of antibiotics may be synergistic in eradicating microbial infection and minimizing resistance. Blood cultures should be taken prior to empirical antibiotic therapy (but this should not delay therapy in unstable patients. Antibiotic treatment should continue for 4–6 weeks. Typical therapeutic regimens are shown in Table 13.38 but specific therapy should be sought from the local microbiology department according to the organism identified and current sensitivities. Serum levels of gentamicin and vancomycin need to be monitored to ensure adequate therapy and prevent toxicity. In patients with penicillin allergy one of the glycopeptide antibiotics, vancomycin or teicoplanin, can be used. Penicillins, however, are fundamental to the therapy of bacterial endocarditis; allergies therefore seriously compromise the choice of antibiotics. It is essential to confirm the nature of a patient's allergy to ensure that the appropriate treatment is not withheld needlessly. Anaphy-

Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis: diagnosis, antimicrobial therapy, and management of complications: a statement for healthcare professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, and the Councils on Clinical Cardiology, Stroke, and Cardiovascular Surgery and Anesthesia, American Heart Association: endorsed by the Infectious Diseases Society of America. *Circulation* 2005; **111**: e394–434.

Table 13.38 Antibiotics in endocarditis (adapted from British Society for Antimicrobial Chemotherapy (BSAC) guidelines)

Clinical situation	Suggested antibiotic regimen to start (all given i.v.)
Clinical endocarditis, culture results awaited, no suspicion of staphylococci	Penicillin 1.2 g 4-hourly, gentamicin 80 mg 12-hourly
Suspected staphylococcal endocarditis (IVDU, recent intravascular devices or cardiac surgery, acute infection)	Vancomycin 1 g 12-hourly, gentamicin 80–120 mg 8-hourly
Streptococcal endocarditis (penicillin sensitive)	Penicillin 1.2 g 4-hourly, gentamicin 80 mg 12-hourly
Enterococcal endocarditis (no high-level gentamicin resistance)	Ampicillin/amoxicillin 2 g 4-hourly, gentamicin 80 mg 12-hourly
Staphylococcal endocarditis*	Vancomycin 1 g 12-hourly, OR Flucloxacillin 2 g 4-hourly, OR Benzylpenicillin 1.2 g 4-hourly, PLUS gentamicin 80–120 mg 8-hourly

Note:
1. Monitor vancomycin and gentamicin levels, and adjust if necessary.
2. Choice of antibiotic for staphylococci depends on sensitivities.
3. Optimum choice of therapy needs close liaison with Microbiology/Infectious Diseases.
All antibiotics given i.v.
IVDA, intravenous drug abuse.
*NB: MRSA can affect valves.

laxis would be much more influential in antibiotic choice than a simple gastrointestinal disturbance.

Persistent fever

Most patients with infective endocarditis should respond within 48 hours of initiation of appropriate antibiotic therapy. This is evidenced by a resolution of fever, reduction in serum markers of infection and relief of systemic symptoms of infection. Failure of this to occur needs to be taken very seriously. The following should be considered:

- perivalvular extension of infection and possible abscess formation
- drug reaction (the fever should promptly resolve after drug withdrawal)
- nosocomial infection (i.e. venous access site, urinary tract infection)
- pulmonary embolism (secondary right-sided endocarditis or prolonged hospitalization).

In such cases, samples for culture should be taken from all possible sites and evidence sought for the above causes. Changing antibiotic dosage or regimen should be avoided unless there are positive cultures or a drug reaction is suspected. Emergence of bacterial resistance is uncommon. Close liaison with microbiology is recommended and a cardiothoracic surgical opinion should be sought.

Surgery

Decisions about surgical intervention in patients with infective endocarditis should be made after joint consultation between the cardiologist and cardiothoracic surgeon, taking into account patient-specific (age, non-cardiac morbidities, presence of prosthetic material or cardiac failure) and infective endocarditis features (infective organism, vegetation size, presence of perivalvular infection, systemic embolization).

Prevention (p. 93)

The value of antibiotic prophylactic therapy and the optimal regimen have never been established in randomized controlled trials and hence their widespread use has been questioned. The recent NICE guidelines (Table 4.9) suggest no prophylaxis unless there is an infection at the site of gastrointestinal or genitourinary tract procedures in patients at risk of endocarditis; the adverse effects of antibiotics outweigh the risks.

CONGENITAL HEART DISEASE

A congenital cardiac malformation occurs in about 1% of live births. There is an overall male predominance, although some individual lesions (e.g. atrial septal defect and persistent ductus arteriosus) occur more commonly in females. As a result of improved medical and surgical management, more children with congenital cardiac disease are surviving into adolescence and adulthood. Thus there is a need for an increased awareness amongst general physicians and cardiologists of the problems posed by these individuals.

Aetiology

The aetiology of congenital cardiac disease is often unknown, but recognized associations include:

- maternal prenatal rubella infection (persistent ductus arteriosus, and pulmonary valvular and arterial stenosis)
- maternal alcohol abuse (septal defects)
- maternal drug treatment and radiation
- genetic abnormalities (e.g. the familial form of atrial septal defect and congenital heart block)
- chromosomal abnormalities (e.g. septal defects and mitral and tricuspid valve defects are associated with Down's syndrome (trisomy 21) or coarctation of the aorta in Turner's syndrome (45, XO)).

Classification (see Table 13.39)

Symptoms and signs

Congenital heart disease should be recognized as early as possible, as the response is usually better the earlier treatment is initiated. Some symptoms, signs and clinical problems are common in congenital heart disease:

- *Central cyanosis* occurs because of right-to-left shunting of blood or because of complete mixing of systemic and pulmonary blood flow. In the latter case, e.g. Fallot's tetralogy, the abnormality is described as cyanotic congenital heart disease.
- *Pulmonary hypertension* results from large left-to-right shunts. The persistently raised pulmonary flow leads to

Table 13.39 Classification of congenital heart disease

Acyanotic	Cyanotic
With shunts	**With shunts**
Atrial septal defect	Fallot's tetralogy
Ventricular septal defect	Transposition of the great vessels
Patent ductus arteriosus	Severe Ebstein's anomaly
Partial anomalous venous drainage	
	Without shunts
Without shunts	Severe pulmonary stenosis
Coarctation of the aorta	Tricuspid atresia
Congenital aortic stenosis	Pulmonary atresia
	Hypoplastic left heart

Table 13.40 Common congenital lesions

	Percentage of congenital lesions	Occurrence in first-degree relatives (%)
Ventricular septal defect	39	4
Atrial septal defect	10	2
Persistent ductus arteriosus	10	4
Pulmonary stenosis	7	
Coarctation of the aorta	7	2
Aortic stenosis	6	4
Fallot's tetralogy	6	4
Others	15	

the development of increased pulmonary artery vascular resistance and consequent pulmonary hypertension. This is known as the Eisenmenger's reaction (or the Eisenmenger's complex when due specifically to a ventricular septal defect). The development of pulmonary hypertension significantly worsens the prognosis.

- *Clubbing of the fingers* occurs in congenital cardiac conditions associated with prolonged cyanosis.
- *Paradoxical embolism* of thrombus from the systemic veins to the systemic arterial system may occur when a communication exists between the right and left heart. There is therefore an increased risk of cerebrovascular accidents and also abscesses (as with endocarditis).
- *Polycythaemia* can develop secondary to chronic hypoxaemia, leading to a hyperviscosity syndrome and an increased thrombotic risk, e.g. strokes.
- *Growth retardation* is common in children with cyanotic heart disease.
- *Syncope* is common when severe right or left ventricular outflow tract obstruction is present. Exertional syncope, associated with deepening central cyanosis, may occur in Fallot's tetralogy. Exercise increases resistance to pulmonary blood flow but reduces systemic vascular resistance. Thus, the right-to-left shunt increases and cerebral oxygenation falls.
- *Squatting* is the posture adopted by children with Fallot's tetralogy. It results in obstruction of venous return of desaturated blood and an increase in the peripheral systemic vascular resistance. This leads to a reduced right-to-left shunt and improved cerebral oxygenation.

Presentation

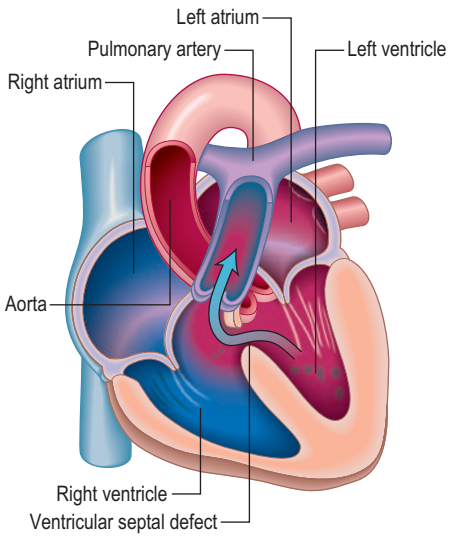
Adolescents and adults with congenital heart disease present with specific common problems related to the long-standing structural nature of these conditions and any surgical treatment:

- endocarditis (particularly in association with otherwise innocuous lesions such as small VSDs or bicuspid aortic valve that can give up to 10% lifetime risk)
- progression of valvular lesions (calcification and stenosis of congenitally deformed valves, e.g. bicuspid aortic valve)
- atrial and ventricular arrhythmias (often quite resistant to treatment)
- sudden cardiac death
- right heart failure (especially when surgical palliation results in the right ventricle providing the systemic supply)
- end-stage heart failure (rarely managed by heart or heart–lung transplantation).

Genetic counselling

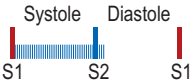
These conditions necessitate active follow-up of adult patients. Pregnancy is normally safe except if pulmonary hypertension or vascular disease is present, when the prognosis for both mother and fetus is poor.

Table 13.40 lists the most common congenital lesions and their occurrence in first-degree relatives.



Genetic factors should be considered in all patients presenting with congenital heart disease. For example, parents with a child suffering from Fallot's tetralogy stand a 4% chance of conceiving another child with the disease, and so fetal ultrasound screening of the mother during pregnancy is essential. Parents with congenital heart disease are also more likely to have affected offspring. Fathers have a 2% risk while mothers have a higher risk (around 5%). Individual families can exhibit even higher risks of recurrence.

Ventricular septal defect (VSD)



VSD is the most common congenital cardiac malformation (1 in 500 live births). It occurs as an isolated abnormality or in association with other anomalies. Left ventricular pressure is higher than right ventricular pressure; blood therefore moves from left to right and pulmonary blood flow increases. When pulmonary blood flow is very large, progressive obliteration of the pulmonary vasculature eventually causes the pulmonary arterial pressure to equal the systemic pressure (Eisenmenger's complex). Consequently, the shunt is reduced or reversed (becoming right-to-left) and central cyanosis develops.

Clinical features (Fig. 13.88)

Small VSDs ('maladie de Roger') are asymptomatic and usually close spontaneously, with 90% no longer patent by 10 years of age. Unfortunately there is a future risk of the development of aortic regurgitation or endocarditis even after spontaneous closure. A *moderate VSD* produces fatigue and dyspnoea with cardiac enlargement and a prominent apex beat. There is often a palpable systolic thrill at the lower left

Heart sounds and murmurs

Harsh pansystolic murmur heard at the left sternal edge, accompanied by a systolic thrill ± left parasternal heave. May be signs of pulmonary hypertension

Pathophysiology

- Left-to-right shunt
- When the left ventricle contracts, it ejects some blood into the aorta and some across the ventricular septal defect into the right ventricle and pulmonary artery
- **Small** VSDs ('maladie de Roger'): loud and sometimes long systolic murmur
- **Moderate** VSDs: loud 'tearing' pansystolic murmur
- **Large** VSDs: cause pulmonary hypertension and soft murmur Eisenmenger's complex may result

Fig. 13.88 **Ventricular septal defect:** Pathophysiology and auscultatory findings.

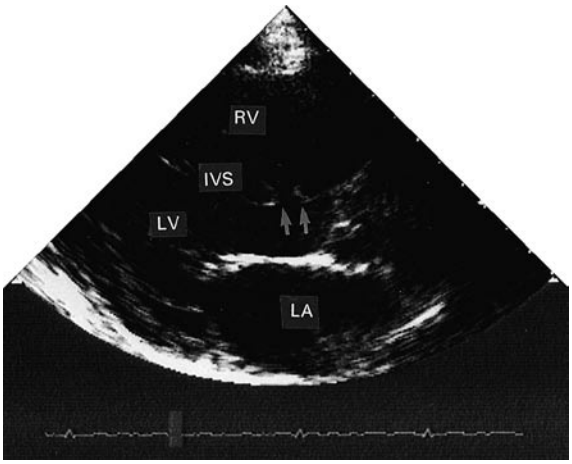


Fig. 13.89 **2-D Echocardiogram (long-axis view) showing a ventricular septal defect** (arrows). Colour Doppler would provide graphic demonstration of the left-to-right shunt. IVS, interventricular septum; LA, left atrium; LV, left ventricle; RV, right ventricle.

sternal edge. A loud 'tearing' pansystolic murmur is heard at the same position. A large VSD eventually causes pulmonary hypertension.

Investigations

A small VSD produces no abnormal X-ray or ECG findings.

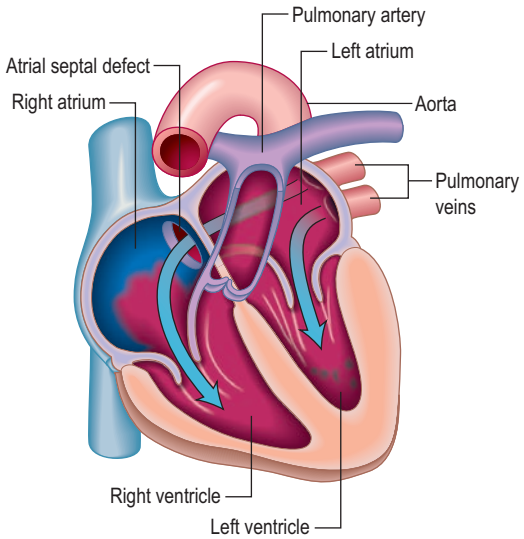
- **Chest X-ray** shows a prominent pulmonary artery owing to increased pulmonary blood flow in larger defects. In Eisenmenger's complex the radiological signs of pulmonary hypertension (i.e. 'pruned' pulmonary arteries) can be seen. Cardiomegaly occurs when a moderate or a large VSD is present. ECG shows features of both left and right ventricular hypertrophy.
- **2-D echocardiography and CW Doppler** (Fig. 13.89) can assess the size and location of the VSD, and its haemodynamic consequences.
- **CMR** is increasingly being used.

Treatment

Moderate and large VSDs should be surgically repaired before the development of severe pulmonary hypertension. Infective endocarditis prophylaxis is discussed on page 93.

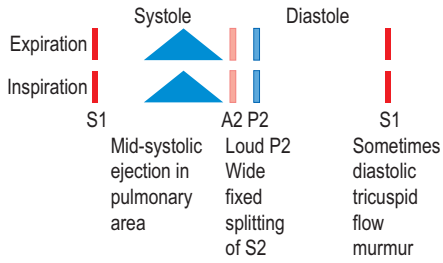
Atrial septal defect (ASD)

Clinical features



This condition is often first diagnosed in adults and represents one-third of all adult congenital heart disease. It is two to three times more common in women than in men. There are two main types of ASD, *ostium secundum* (75%) and *ostium primum* (15%). The common form is the ostium secundum defect, which involves the fossa ovalis in the atrial mid-septum. (This should not be confused with the *patent foramen ovale* (PFO), which is a normal variant and not a true septal defect. PFO is usually asymptomatic but is associated with paradoxical emboli and an increased incidence of embolic stroke.) Communication at the level of the atria allows left-to-right shunting of blood. Because the pulmonary vascular resistance is low and the right ventricle is easily distended (i.e. it is compliant), there is a considerable increase in right heart output. Above the age of 30 years there may be an increase in pulmonary vascular resistance, which gives rise to *pulmonary hypertension*. Atrial arrhythmias, particularly *atrial fibrillation*, are common at this stage.

Most children with ASD are asymptomatic, although they are prone to *pulmonary infection*. Some complain of *dyspnoea* and *weakness*. Palpitations due to atrial arrhythmias are not uncommon. Right heart failure and atrial fibrillation may develop to become the initial presentation in adult life.



The physical signs of ASD reflect the volume overloading of the right ventricle (Fig. 13.90). A right ventricular heave can usually be felt.

Investigations

- **Chest X-ray** reveals a prominent pulmonary artery and pulmonary plethora. There may be noticeable right ventricular enlargement.

Heart sounds and murmurs

Pathophysiology

- Left-to-right shunt through the defect in the interatrial septum
- Dilatation of the pulmonary artery resulting from the shunt
- The murmur is produced by increased flow across pulmonary valve and an increased stroke volume

Fig. 13.90 **Atrial septal defect:** Pathophysiology and auscultatory findings.

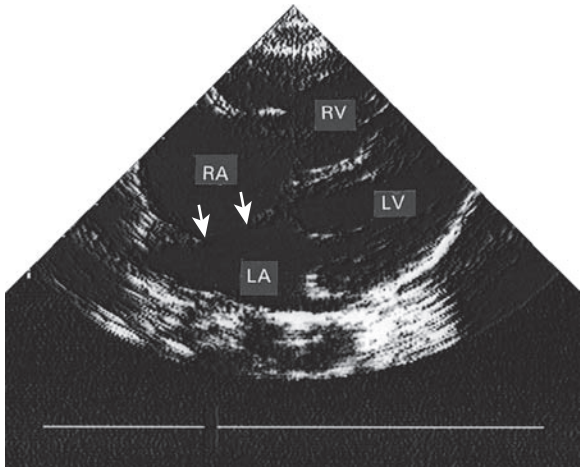


Fig. 13.91 **Ostium secundum atrial septal defect** (arrows) in a young girl, shown by a 2-D echocardiogram subcostal four-chamber view (similar to Fig. 13.89, but rotated clockwise). Colour Doppler can demonstrate the left-to-right shunt. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Fig. 13.92 **Angiographic appearance of a fully deployed ASD closure device.** The device bridges the ASD and wedges against the surfaces of the right and left atrial septa, occluding flow. The metal object in frame is the distal end of a transoesophageal echocardiography probe. Courtesy of Dr D Ward, St George's, University of London.

- **ECG** usually shows some degree of right bundle branch block (because of dilatation of the right ventricle) and right axis deviation. Sometimes the ASD is part of a major developmental abnormality involving the ventricular septum and the mitral and tricuspid valves. In this case there is left axis deviation on the ECG.
- **Echocardiogram** is usually abnormal if a significant defect is present. Indirect evidence includes right ventricular hypertrophy and pulmonary arterial dilatation, and abnormal motion of the interventricular septum. Subcostal views may demonstrate the ASD (Fig. 13.91). Flow disturbance can be assessed by colour Doppler. A 3-D echocardiogram is shown in Fig. 13.25.
- **CMR** can provide additional information.

Treatment

A significant ASD (i.e. a pulmonary flow that is more than 50% increased when compared with systemic flow) should be repaired before the age of 10 years or as soon as possible if first diagnosed in adulthood. There is a dilemma with regard to whether less severe shunts should be closed when diagnosed in adulthood. Anecdotal evidence suggests that the shunt might be progressive and that low-risk closure would be appropriate.

There is a good result from surgery with osteum secundum ASD unless pulmonary hypertension has developed. Angiographic closure is now possible with significantly lower risk using a transcatheter clamshell device (Fig. 13.92).

A PFO discovered in a patient with an otherwise unexplained thrombotic stroke is now closed in this way to prevent paradoxical thromboembolism. In high-risk groups, e.g. deep-sea divers, such closures may be undertaken even though the patients are asymptomatic. Uncorrected ASDs do not require antibiotic prophylaxis for endocarditis. If there is an accompanying valvular lesion, however, prophylaxis may be indicated.

Patent ductus arteriosus (PDA)

The ductus arteriosus connects the pulmonary artery at its bifurcation to the descending aorta immediately distal to the subclavian artery. In fetal life the ductus diverts blood away from the unexpanded, and hence high-resistance, pulmonary circulation into the systemic circulation, where the blood is reoxygenated as it passes through the placenta. At birth, the high oxygen in the lungs and the reduced pulmonary vascular resistance trigger closure of the duct. If the duct is malformed (i.e. it does not contain sufficient elastic tissue), it will not close. This is more common in females and is sometimes associated with maternal rubella. Premature babies are often born with persistent ducts that are anatomically normal but are immature in that they lack the mechanism to close. Other associations include continual prenatal hypoxaemia and high-altitude environments.

Because aortic pressure exceeds pulmonary artery pressure throughout the cardiac cycle, a persistent duct produces continuous aorta-to-pulmonary artery shunting. This leads to an increased pulmonary venous return to the left heart and an increased left ventricular volume load. If the shunt is large, this results in severe left heart failure and pulmonary hypertension. One-third of individuals with an unrepaired ductus die from heart failure, pulmonary hypertension or endocarditis by the age of 40; two-thirds by the age of 60.

Clinical features

There are often no symptoms until later in life when heart failure or infective endocarditis develops.

The characteristic physical sign is a continuous 'machinery' murmur (Fig. 13.93). The peripheral pulse is large in volume ('bounding') because of the increased left heart blood flow and the decompression of the aorta into the pulmonary artery.

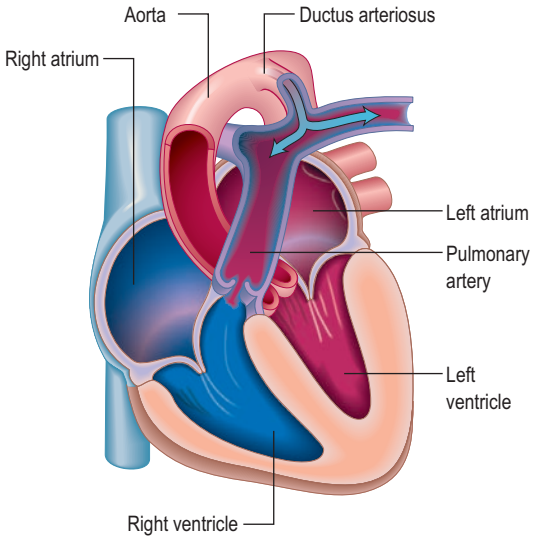
Investigations

The aorta and pulmonary arterial system are usually prominent on X-ray, although a small ductus shows no abnormality. There is both a left atrial abnormality and left ventricular hypertrophy on the ECG. With the development of Eisenmenger's reaction, right ventricular hypertrophy may be seen. The echocardiogram shows a dilated left atrium and left ventricle. Right heart changes are apparent in late disease. CMR can be useful.

Treatment

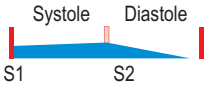
Premature infants with a persistent duct are treated medically with indometacin, which inhibits prostaglandin production and stimulates duct closure. In other cases the duct can be ligated surgically or angiographically with very little risk. Surgery should be performed as soon as possible and not later than the age of 5 years. Closure is inappropriate if pulmonary hypertension is severe.

Coarctation of the aorta



A coarctation of the aorta is a narrowing of the aorta at, or just distal to, the insertion of the ductus arteriosus, i.e. distal to the left subclavian artery (Fig. 13.94). Rarely it can occur proximal to the left subclavian. It occurs twice as commonly in men as in women. It is also associated with Turner's syndrome (p. 1007). In 80% of cases the aortic valve is bicuspid (and potentially stenotic or endocarditic). Other associations include patent ductus arteriosus, ventricular septal defect, mitral stenosis or regurgitation and circle of Willis aneurysms.

Severe narrowing of the aorta encourages the formation of a collateral arterial circulation involving the periscapular and intercostal arteries. Decreased renal perfusion can lead to the development of systemic hypertension that persists even after surgical correction.



Clinical features

Coarctation of the aorta is often asymptomatic for many years. *Headaches* and *nosebleeds* (due to hypertension), and *claudication* and cold legs (due to poor blood flow in the lower limbs) may be present.

Physical examination reveals hypertension in the upper limbs, and weak, delayed (radiofemoral delay) pulses in the legs. If coarcation is present in the aorta, proximal to the left subclavian artery, there will be asynchronious radial pulses

Heart sounds and murmurs

Continuous 'machinery' murmur best heard below the left clavicle in the first interspace or over the first rib.
A thrill can often be felt

Pathophysiology

- Left-to-right shunt
- Some of the blood from the aorta crosses the ductus arteriosus and flows into the pulmonary artery
- Murmur is produced by the turbulent aortic-to-pulmonary artery shunting in both systole and diastole
- Dilatation of the pulmonary artery, left atrium and left ventricle
- As pulmonary hypertension (Eisenmenger's reaction) develops, the murmur becomes quieter, may be confined to systole or may even disappear causing central cyanosis

Fig. 13.93 **Patent ductus arteriosus:** Pathophysiology and auscultatory findings.

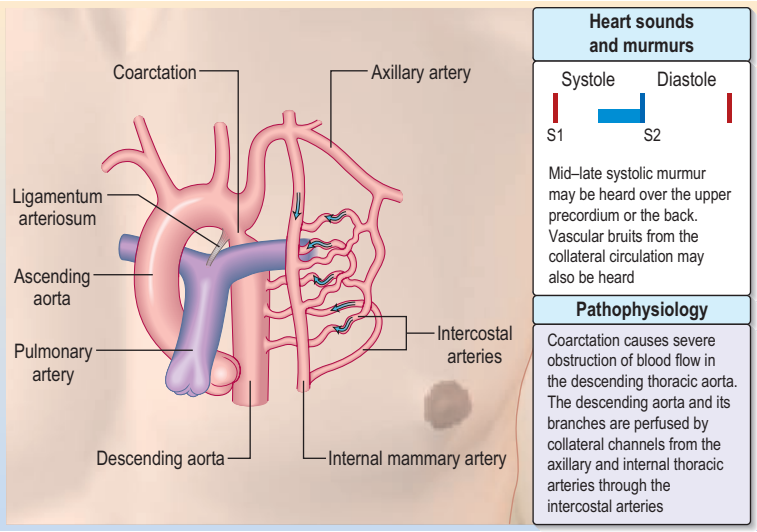


Fig. 13.94 **Coarctation of the aorta:** Pathophysiology and auscultatory findings.

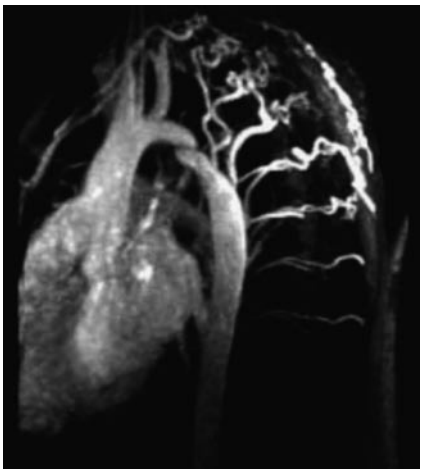

Fig. 13.95 **Cardiac magnetic resonance angiography image of severe aortic coarctation in an adult.**

in right and left arms. Poor peripheral pulses are seen in severe cases.

For heart sounds and murmurs in coarctation of aorta, see Figure 13.94.

Investigations

Chest X-ray may reveal a dilated aorta indented at the site of the coarctation. This is manifested by an aorta (seen in the upper right mediastinum) shaped like a 'figure 3'. In adults, tortuous and dilated collateral intercostal arteries may erode the undersurfaces of the ribs ('rib notching').

ECG demonstrates left ventricular hypertrophy. Echocardiography sometimes shows the coarctation and other associated anomalies. CT and CMR (Fig. 13.95) scanning can accurately demonstrate the coarctation and quantify flow.

Treatment

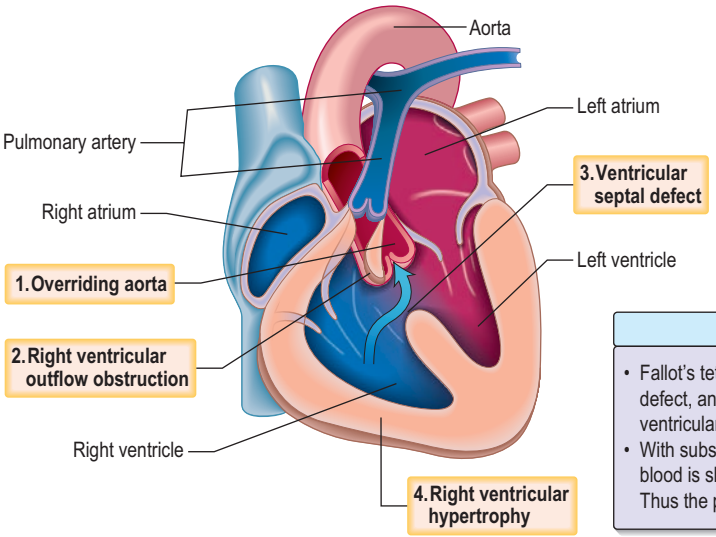
Treatment is usually indicated if the pressure gradient across the coarctation is greater than 30 mmHg. This involves surgical excision of the coarctation and end-to-end anastomosis of the aorta. If the coarctation is extensive, prosthetic vascular grafts may be needed. When surgery is performed in early childhood, hypertension usually resolves completely. However, when the operation is performed on adolescents or adults, the hypertension persists in 70% because of previous renal damage. There is also an increased risk of accelerated atherosclerosis and strokes in these individuals. Balloon dilatation is used in some centres for either primary disease or post-surgical recurrence, although there is a higher incidence of aneurysm formation and post-dilatation recurrence.

Surgical correction in childhood gives a good 25-year survival rate of 83%. If this is delayed until adulthood (20–40 years), the 25-year survival rate drops to 75%. If coarctation is left uncorrected, however, only 25% of patients are alive at 50, while cardiac failure ensues in two-thirds of surviving patients over 40.

Cyanotic congenital heart disease: Fallot's tetralogy

Most children with cyanotic congenital heart disease do not survive the neonatal period. Fallot's is the most common cyanotic anomaly in those who do survive and is commonest amongst adults. Transposition of the great vessels is more common in the neonatal period but is more likely to be fatal. Other cyanotic congenital heart diseases are shown in Table 13.39.

Fallot's tetralogy consists of the four features shown in Figure 13.96.



The level of the right ventricular outflow obstruction may be subvalvular, valvular or supravalvular. The most common obstruction is subvalvular, either alone (50%) or in combination with valvular stenosis (25%).

This combination of lesions leads to a high right ventricular pressure and right-to-left shunting of blood through the VSD. Thus the patient is centrally cyanosed.

Clinical features

Children with this condition may present with *dyspnoea* or *fatigue*, or with hypoxic episodes on exertion (Fallot's spells) – *deep cyanosis* and possible *syncope*. These can even result in seizures, cerebrovascular events or sudden death. *Squatting* is common.

Adults tend not to suffer 'spells' but fatigue easily with dyspnoea on exertion. *Erythrocytosis*, secondary to chronic

Heart sounds and murmurs

Systole Diastole

S1 S2

Systolic ejection murmur often associated with a thrill in the second left interspace close to the sternum. Single second heart sound because the pulmonary component is too soft to be heard

Pathophysiology

- Fallot's tetralogy is characterized by a large ventricular septal defect, an aorta that overrides the left and right ventricles, right ventricular outflow tract obstruction, and right ventricular hypertrophy.
- With substantial obstruction of the right ventricular outflow tract, blood is shunted through the ventricular septal defect from right to left. Thus the patient is centrally cyanosed

Fig. 13.96 **Fallot's tetralogy:** Pathophysiology and auscultatory findings.

hypoxaemia, commonly results in thrombotic strokes. *Endocarditis* is common.

A parasternal sustained heave is evident. Central cyanosis is commonly present from birth, and *finger clubbing* and *polycythaemia* are obvious after about 12 months. Growth is usually retarded.

Investigations

- **Chest X-ray** shows a large right ventricle and a small pulmonary artery (classically described as 'boot-shaped').
- **ECG** reveals right ventricular hypertrophy, and the echocardiogram demonstrates discontinuity between the aorta and the anterior wall of the ventricular septum.
- **CMR** is used (p. 706).
- **Cardiac catheterization** is performed to evaluate the size and degree of the right ventricular outflow obstruction.

Treatment

Complete surgical correction of this combination of lesions is possible even in infancy. As adults, however, these individuals are at increased risk of right ventricular failure and ventricular arrhythmias due to the trauma from past corrective surgery. Less damaging procedures are used presently, the long-term results of which are unknown as yet.

Occasionally a palliative procedure – an anastomosis between a subclavian artery and a pulmonary artery (Blalock shunt) – is performed on very young infants or the premature, in order to increase blood supply to the lungs. Without intervention, 66% survive to 1 year, while only 11% survive to 20 years.

Fallot's spells may need treatment with beta-blockade or, when severe, with diamorphine to relax the right ventricular outflow obstruction. Antibiotic prophylaxis for endocarditis is discussed in Chapter 4 (see p. 93).

Transposition of the great arteries (TGA)

TGA occurs in 2–3/10 000 live births with a male/female ratio of 2:1. In nearly 50% of cases it is associated with a VSD.

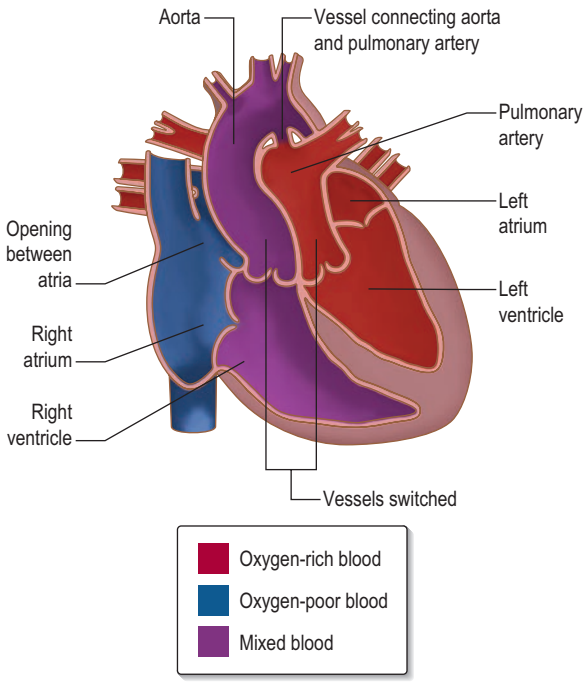


Fig. 13.97 **Transposition of great arteries.** AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

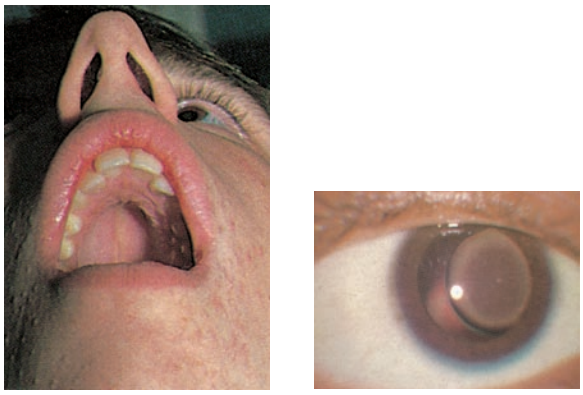
In TGA the right ventricle is connected to the systemic circulation (aorta) and the left ventricle to the pulmonary circulation (pulmonary artery) (Fig. 13.97). The neonate with TGA is cyanosed as the blood circulates in two parallel circuits, i.e. deoxygenated blood from the systemic veins passes to the systemic circulation and oxygenated blood from the pulmonary veins passes back to the lungs.

Clinical features

TGA will present within a few hours of birth as a cyanotic (blue) baby, as maternal/placental oxygenation is removed. Ninety per cent of patients present within a few days. However, in patients with a significant shunt (ASD and VSD or a large PDA) diagnosis may be delayed. Clinical features include dyspnoea, tachycardia and cool clammy skin.

FURTHER READING

Lindsey J, Hillis LD. Clinical update: atrial septal defects in adults. *Lancet* 2007; **369**: 1244–1246.



Investigations

2-D Echocardiography can identify the anatomical connections between the great vessels and the cardiac chambers. It can also detect an associated ASD, VSD or PDA.

Treatment

The initial management in a cyanotic neonate with TGA is an atrial septostomy (Rashkind procedure). Balloon dilatation of the foramen ovale is performed to allow mixing of atrial blood that maintains oxygen saturation of 50–80% prior to more definitive surgery. Prostaglandins (E_1) may be given initially to maintain a PDA.

The arterial switch operation is now performed in the first two weeks of life – the aorta is reconnected to the left ventricle; the pulmonary artery is connected to the right ventricle; the coronary arteries are connected to the aorta and any associated defects are repaired.

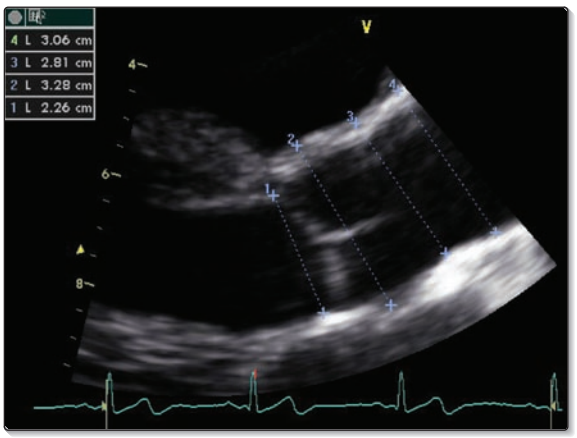
MARFAN'S SYNDROME



Clinical features

Marfan's syndrome (MFS) is one of the most common autosomal dominant inherited disorders of connective tissue, affecting the heart (aortic aneurysm and dissection, mitral valve prolapse), eye (dislocated lenses, retinal detachment) and skeleton (tall, thin body build with long arms, legs and fingers; scoliosis and pectus deformity) (Figs 13.98 and 13.99; Table 13.41).

Table 13.41 **Yearly risk (%) of complications based on aortic size**

	Aortic size (cm)			
	>3.5	>4	>5	>6
Rupture	0.0	0.3	1.7	3.6
Dissection	2.2	1.5	2.5	3.7
Death	5.9	4.6	4.8	10.8
Any of the above	7.2	5.3	6.5	14.1

(c)

	Aortic size			
Yearly risk	> 3.5cm	> 4cm	> 5cm	> 6cm
Rupture	0.0%	0.3%	1.7%	3.6%
Dissection	2.2%	1.5%	2.5%	3.7%
Death	5.9%	4.6%	4.8%	10.8%
Any of the above	7.2%	5.3%	6.5%	14.1%

Fig. 13.99 **Marfan's syndrome. (a)** Photograph of a 63-year-old man. **(b)** 2-D Longitudinal echocardiogram of the aortic root showing measurements of aortic size.

Clinically, two of three major systems must be affected, to avoid overdiagnosing the condition. Diagnosis may be confirmed by studying family linkage to the causative gene, or by demonstrating a mutation in the Marfan's syndrome gene (*MFS1*) for fibrillin (*FBN-1*) on chromosome 15q21.

MFS affects approximately 1 in 5000 population worldwide and 25% of patients are affected as a result of a new mutation. This group includes many of the more severely affected patients, with high cardiovascular risk. Other known associations with early death due to aortic aneurysm and dissection are: family history of early cardiac involvement; family history of dissection with an aortic root diameter of >5 cm; male sex; and extreme physical characteristics, including markedly excessive stature and widespread striae. Histological examination of aortas often shows widespread medial degeneration, described as 'cystic medial necrosis'.

Cardiac investigations

- **Chest X-ray** is often normal but may show signs of aortic aneurysm and unfolding, or of widened mediastinum. Pneumothorax affects 11% and scoliosis is present in 70% of patients.
- **ECG** may be misleadingly normal with an acute dissection. In conjunction with mitral valve prolapse, 40% of patients usually have arrhythmia, with premature ventricular and atrial arrhythmias.
- **Echocardiography** shows mitral valve prolapse, and mitral regurgitation in the majority of patients. High-quality serial echocardiogram measurements of aortic root diameter in the sinuses of Valsalva, at 90° to the direction of flow are the basis for medical and surgical management (Fig. 13.98b).
- **CT or CMR** can detect aortic dilatation and are useful in monitoring.

Management

- **Beta-blocker therapy** slows the rate of dilatation of the aortic root.
- **ACE receptor blockers**. In Marfan's there is upregulation of TNF-β which is specifically inhibited by ACE blockers. A recent small trial has shown no increase in aortic root diameter on this therapy.
- **Lifestyle alterations** are required because of ocular, cardiac or skeletal involvement. Sports that necessitate prolonged exertion at maximum cardiac output, such as cross-country running, are to be avoided. Sedentary occupations are usually best, as patients tend to suffer from easy fatiguability and hypermobile painful joints.
- **Monitoring** with yearly echocardiograms up to aortic root diameter of 4.5 cm, 6-monthly from 4.5 to 5 cm, and then referred directly to a surgeon who is experienced in aortic root replacement in Marfan's syndrome for elective surgery.

Pregnancy is generally well tolerated if no serious cardiac problems are present, but is preferably avoided if the aortic root diameter is over 4 cm, with aortic regurgitation. Echocardiography should be performed every 6–8 weeks throughout pregnancy and during the initial 6 months postpartum. Blood pressure should be regularly monitored and hypertension treated actively. Delivery should be by the least stressful method; ideally a vaginal delivery. Caesarean section should not be routinely performed. However, if the aortic root is over 4.5 cm, delivery at 39 weeks by induction or caesarean section should be considered. Beta-blocker therapy may be safely instituted or continued throughout pregnancy, to help prevent aortic dissection.

Careful medical and surgical management have increased the overall survival rate. On average, 13 years of life is added when surgical survival is compared to that reported in the natural history of MFS.

Genetic counselling

The condition is inherited in an autosomal dominant mode, with each child of one affected parent having a 50:50 chance of inheriting the condition. Males and females are equally often affected. In 25% of all cases, the condition arises as the result of a spontaneous mutation in gene 5 of one of the parents. Fibrillin-1 gene mutations can be identified in 80% of those affected, confirming diagnosis and aiding prognosis. The mutation can also be used to screen at-risk family members, including postnatal or prenatal offspring.

PULMONARY HEART DISEASE

The normal values for mean pulmonary artery pressure (mPAP), mean capillary wedge pressure (mPCWP) and cardiac output (CO) are 12 ± 2 mmHg, 6 ± 2 mmHg and 5 L/min, respectively. The fall in pressure across the lung circulation is known as the transpulmonary gradient and reflects the difference between mPAP and mPCWP. The normal transpulmonary gradient is 6 ± 2 mmHg.

The *pulmonary vascular resistance* (PVR) is calculated by the formula:

$$\frac{\text{mPAP} - \text{mPCWP}}{\text{CO}}$$

It is normally about 1.5 mmHg/L/min (1.5 Wood units). Approximately 60% of the body's endothelial surface is in the lungs and the lungs normally offer a low resistance to blood flow. This is because the media of the precapillary pulmonary arterioles is thin as compared with their more muscular systemic counterparts that have to respond constantly to postural changes under the influence of gravity. The fact that the lung circulation normally offers a low resistance to flow explains the preferential passage of blood through the lungs in specific forms of congenital heart disease, which may eventually lead to remodelling of the lung circulation and pulmonary hypertension.

Pulmonary hypertension

Definition

Pulmonary hypertension is defined as an mPAP of greater than 25 mmHg at rest or of greater than 30 mmHg during exercise. It may present spontaneously with no apparent underlying disease association (and is then known as primary pulmonary hypertension, PPH) or it can occur in association with other disease processes as listed in Table 13.42.

Causes

The most common cause of pulmonary hypertension is chronic obstructive pulmonary disease (COPD). In general, the causes of pulmonary hypertension (Table 13.42) can be subdivided depending on whether their effects on the lung circulation are:

Ask the authors

www.studentconsult.com

Table 13.42 Causes of pulmonary hypertension

Pulmonary vascular disorders
Acute pulmonary thromboembolism (rarely tumour emboli)
Primary pulmonary hypertension
Multiple pulmonary artery stenoses
Pulmonary veno-occlusive disease
Chronic pulmonary thromboembolism
Parasitic infection, e.g. schistosomiasis

Diseases of the lung and parenchyma
COPD
Other chronic lung disorders (see Chapter 14)

Musculoskeletal disorders (causing chronic underventilation)
Kyphoscoliosis
Poliomyelitis
Myasthenia gravis

Disturbance of respiratory control
Obstructive sleep apnoea
Morbid obesity (Pickwickian syndrome)
Cerebrovascular disease

Cardiac disorders
Mitral stenosis
Left ventricular failure
Left atrial myxoma
Congenital heart disease with Eisenmenger's reaction

Miscellaneous
Appetite-suppressant drugs, e.g. dexfenfluramine
Type 1 glycogen storage diseases
Lipid storage diseases, e.g. Gaucher's disease
Rheumatic autoimmune disease, e.g. SLE
Hepatic cirrhosis
Sickle cell disease

- *Precapillary (i.e. in the pulmonary arteries and arterioles).* The most severe elevations in PAP and in PVR occur with these disorders. Examples include PPH, congenital heart disease with Eisenmenger's reaction and multiple pulmonary embolism. In PPH the PCWP is usually normal.
- *Capillary disorders* causing damage to the alveolar capillary mechanisms also cause pulmonary hypertension and these usually fall under the umbrella of parenchymal lung diseases, e.g. COPD and pulmonary fibrosis. Pulmonary arterial hypoxaemia is a potent cause of vasoconstriction and hence of pulmonary hypertension. Any diseases which lead to low pulmonary artery oxygen levels will give rise to pulmonary hypertension.
- *Postcapillary (passive)* processes involve disease in structures distal to the pulmonary capillary bed. They cause pulmonary hypertension through elevated venous pressures. Examples include pulmonary veno-occlusive disease, chronic left ventricular failure and mitral valve disease.

A variety of miscellaneous conditions can also cause pulmonary hypertension, and these include a history of appetite suppressant drug ingestion, and glycogen and lipid storage diseases.

Progressive elevation in PVR ultimately leads to right ventricular dilatation, right ventricular failure and death. When pulmonary hypertension occurs in association with other conditions such as lung disorders or chronic left ventricular failure, the primary underlying cause may have the major influence on mortality and the secondary effects of pulmonary hypertension are additive.

Mechanisms

These depend on the cause and involve hypoxic vasoconstriction, e.g. COPD, decreased surface area of the pulmonary vascular bed, e.g. lung fibrosis, and increased right ventricular volume/pressure, e.g. congenital heart disease.

Following the rise in pulmonary arterial pressure, damage to the pulmonary endothelium leads to excessive release of endothelium-derived vasoconstrictors such as endothelin (ET, see p. 577) which contribute to an increase in PVR. Increased platelet and leucocyte adhesion, elevated serotonin, plasminogen activator inhibitor-1 (PAI-1) and fibrinopeptide A can produce inappropriate intravascular thrombus. ET, angiotensin II and thromboxane A_2 can act as growth factors, giving rise ultimately to vasoconstriction, cell proliferation, fibrosis and smooth muscle hypertrophy. Such vascular remodelling increases the PVR.

The symptoms, signs and investigations of pulmonary hypertension are discussed below.

Management

Since pulmonary hypertension is a condition caused by a heterogeneous group of diseases, treatment is directed at the primary cause, e.g. chest physiotherapy, good nutrition and early antibiotics to treat infection in patients with cystic fibrosis and bronchiectasis.

Surgical or medical therapies to optimize cardiac and respiratory function, supplemental oxygen and anticoagulation are necessary together with newer specific therapies designed at modulating pulmonary vasomotor tone.

Patients who have symptoms resulting in marked limitation of physical activity or those who are symptomatic at rest have a poor median survival (32 and 6 months, respectively). Adverse factors include right ventricular dysfunction and reduced 6-minute walk distance.

Primary pulmonary hypertension

Primary pulmonary hypertension is a condition of unknown cause characterized by clinical, radiological and electrocardiographic evidence of pulmonary hypertension and increased PAP and PVR with normal PCWP. It is estimated that one to two individuals per million per year are diagnosed with PPH compared to five to six individuals per million per year with pulmonary hypertension secondary to rheumatic autoimmune disease. There is an unexplained predominance of females (approximately a 3:1 ratio) with women mainly presenting in the third decade and men in the fourth. Approximately 6–12% of cases are believed to have a familial origin with inheritance in an autosomal dominant fashion.

Some patients with familial PPH have mutations in the gene encoding bone morphogenic protein receptor 2 (*BMPR 2*) on chromosome 2q33. This gene encodes TGF-β, which acts as a growth suppressor and opposes cellular proliferation. Other gene mutations exist.

PPH has also been linked to certain drugs: aminorex fumarate, an amphetamine-like appetite suppressant, talc which is often inhaled with cocaine, fenfluramine and phenteramine in combination (a prescription weight-loss drug).

Plexogenic pulmonary arteriopathy, identical to that seen in PPH, has also been described in patients with rheumatic autoimmune disease (limited cutaneous scleroderma, p. 756). These may have a rapidly progressive and fatal disease associated with pulmonary hypertension.

Patients with *systemic lupus erythematosus* can also develop pulmonary hypertension secondary to vascular remodelling, with identical histopathological features to patients with PPH. Patients with *hepatic cirrhosis* and *Eisenmenger's reaction* also have identical pathology to patients with PPH.

Clinical presentation

Patients with pulmonary hypertension have an insidious onset and indeed often their condition comes to the attention of the physician late in the course of their illness or when symptoms of right ventricular failure develop. Physical examination may reveal findings consistent with pulmonary hypertension and right ventricular overload (Table 13.43). Clinical signs of right ventricular dysfunction may be present.

Chest X-ray may demonstrate enlargement of the pulmonary arteries and the major branches, with marked tapering (pruning) of peripheral arteries. The lung fields are usually lucent and there may be right atrial and right ventricular enlargement. *ECG* may show right ventricular hypertrophy and right atrial enlargement (P pulmonale). *Echocardiography* demonstrates enlarged right ventricular dimensions. *Pulmonary function tests* are usually normal.

The *diagnosis* can be confirmed by CT pulmonary angiography.

The differential diagnoses for PPH are an exclusion of secondary causes as shown in Table 13.42. In particular, mitral stenosis, congenital heart disease with Eisenmenger's reaction, connective tissue disease and sickle cell disease should be excluded.

Treatment

Warfarin and oxygen, followed by oral calcium-channel blockers, is initially used but only helps about 10% of patients. Oral endothelin receptor antagonists (bosentan, sitaxentam), prostanoid analogues (inhaled iloprost, treprostinil, beraprost) or intravenous epoprostenol are also used.

Sildenafil is an orally active phosphodiesterase inhibitor that increases levels of cyclic guanosine monophosphate, resulting in pulmonary arterial vasodilatation and inhibition of smooth muscle cell proliferation. In randomized controlled trials, sildenafil has reduced pulmonary artery pressure and improved exercise capacity, and WHO functional class.

Table 13.43 Clinical signs of pulmonary hypertension

Large '*a*' wave in jugular venous waveform
Right ventricular (parasternal) heave
Pulmonary ejection sound and flow murmur
Loud pulmonary component to second heart sound
Right ventricular fourth heart sound
Right ventricular failure (hepatomegaly, ascites, peripheral oedema)
Prominent '*v*' wave in jugular venous waveform
Right ventricular third heart sound
Tricuspid and pulmonary regurgitation murmurs

Prognosis

Several studies have reported a mean survival of 2–3 years from the time of diagnosis. The cause of death is usually right ventricular failure or sudden death. Increased right atrial pressure above 15 mmHg and cardiac index below 2 L/min/m^2 are haemodynamic predictors of poor prognosis. Heart and lung transplantation is used (p. 741).

Chronic cor pulmonale

Cor pulmonale is enlargement of the right ventricle because of increase in afterload that is due to diseases of the thorax, lung and pulmonary circulation; the presence of right ventricular failure is not necessary for the diagnosis of cor pulmonale.

Pathophysiology

The precise mechanism varies according to the cause of cor pulmonale, but chronic obstructive pulmonary disease (COPD), which is discussed here, is illustrative. Pulmonary vascular resistance is increased because of loss of pulmonary vascular tissue and because of pulmonary vasoconstriction caused by hypoxia and acidosis. The increased pulmonary vascular resistance leads to pulmonary hypertension, which initially occurs only during an acute respiratory infection. Eventually, the pulmonary hypertension becomes persistent and progressively more severe. The pulmonary vascular bed is gradually obliterated by muscular hypertrophy of the arterioles and thrombus formation. Right ventricular function is progressively compromised because of the increased pressure load. Hypoxia further impairs right ventricular function and, as it develops, left ventricular function is also depressed.

Clinical features

Chest pain, exertional dyspnoea, syncope and *fatigue* are common symptoms, and sudden death occurs. Other symptoms are due to the cause of the pulmonary hypertension.

On *physical examination* (see Table 13.43), there is a prominent '*a*' wave in the jugular venous pulse, a right ventricular (parasternal) heave and a loud pulmonary component to the second heart sound. Other findings include a right ventricular fourth heart sound, a systolic pulmonary ejection click, a mid-systolic ejection murmur and an early diastolic murmur due to pulmonary regurgitation (Graham Steell murmur). If tricuspid regurgitation develops, there is a pansystolic murmur and a large jugular '*cv*' venous wave (see p. 691).

Investigations

- **Chest X-ray** may show right ventricular enlargement and right atrial dilatation. The pulmonary artery is usually prominent and the enlarged proximal pulmonary arteries taper rapidly. Peripheral lung fields are oligaemic.
- **ECG** demonstrates right ventricular hypertrophy (right axis deviation, possibly a dominant R wave in lead V_1, and inverted T waves in right precordial leads) and a

right atrial abnormality (tall peaked P waves in lead II) (Fig. 13.100).

- **Echocardiography** will usually demonstrate right ventricular dilatation and/or hypertrophy. It is often possible to measure the peak pulmonary artery pressure indirectly with Doppler echocardiography. The echocardiogram may also reveal the cause of pulmonary hypertension, such as an intracardiac shunt.

Other investigations may also be required to evaluate the cause of pulmonary hypertension and to look for treatable conditions, such as left-to-right shunts, mitral stenosis or left atrial tumours. With direct measurement of pulmonary artery pressure and pulmonary wedge pressure, *cardiac catheterization* is necessary in some patients with severe pulmonary hypertension of unknown cause. *Pulmonary angiography* may be indicated if multiple pulmonary emboli are suspected, but it is dangerous.

If no other cause is found, then a diagnosis of primary pulmonary hypertension is made (see p. 782).

Treatment

Treatment is determined by the condition underlying pulmonary hypertension. Diuretic treatment is used for right ventricular failure, but care should be taken to avoid excessive fluid depletion as this will result in reduced output from the impaired right ventricle. Hypoxia is avoided by the use of oxygen therapy when safe and necessary. In those with COPD and some others, long-term oxygen therapy improves symptoms and prognosis (p. 839). In contrast to their enormous value in those with left ventricular impairment, angiotensin-converting enzyme inhibitors are seldom useful and may make matters worse.

Pulmonary embolism

Thrombus, usually formed in the systemic veins or rarely in the right heart (<10% of cases), may dislodge and embolize into the pulmonary arterial system. Post-mortem studies indicate that this is a very common condition (microemboli are found in up to 60% of autopsies) but it is not usually diagnosed this frequently in life. Ten per cent of clinical pulmonary emboli are fatal.

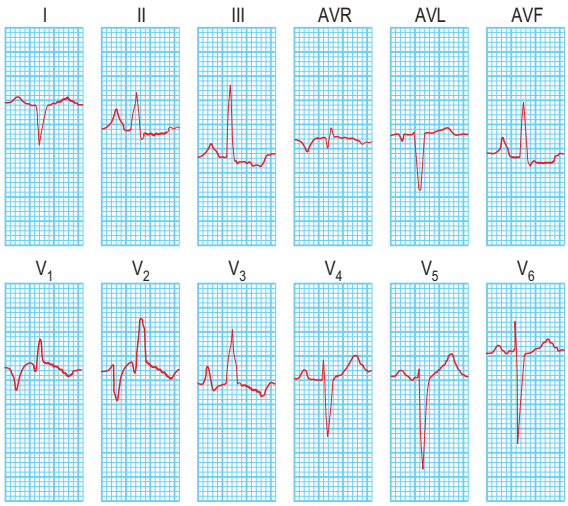

Fig. 13.100 **Pulmonary hypertension shown by a 12-lead ECG.** There is right axis deviation (+ 120°), right ventricular hypertrophy (dominant secondary R wave [R′] in V_1) and a combination of left and right atrial conduction abnormalities.

Most clots which cause clinically relevant pulmonary emboli actually come from the pelvic and abdominal veins, but femoral deep venous thrombosis, and even occasionally axillary thrombosis, can be the origin of the clot. Clot forms as a result of a combination of sluggish blood flow, local injury or compression of the vein and a hypercoagulable state. Emboli can also occur from tumour, fat (long bone fractures), amniotic fluid and foreign material during i.v. drug abuse. Risk factors are shown in Table 8.27 and discussed on page 442.

After pulmonary embolism, lung tissue is ventilated but not perfused – producing an intrapulmonary dead space and resulting in impaired gas exchange. After some hours the non-perfused lung no longer produces surfactant. Alveolar collapse occurs and exacerbates hypoxaemia. The primary haemodynamic consequence of pulmonary embolism is a reduction in the cross-sectional area of the pulmonary arterial bed which results in an elevation of pulmonary arterial pressure and a reduction in cardiac output. The zone of lung that is no longer perfused by the pulmonary artery may infarct, but often does not do so because oxygen continues to be supplied by the bronchial circulation and the airways.

Clinical features

Sudden onset of *unexplained dyspnoea* is the most common, and often the only symptom of pulmonary embolism. *Pleuritic chest pain* and *haemoptysis* are present only when infarction has occurred. Many pulmonary emboli occur silently, but there are three typical clinical presentations. A clinical deep venous thrombosis is not commonly observed, although detailed investigation of the lower limb and pelvic veins will reveal thrombosis in more than half of the cases.

Small/medium pulmonary embolism

In this situation an embolus has impacted in a terminal pulmonary vessel. Symptoms are pleuritic chest pain and breathlessness. Haemoptysis occurs in 30%, often 3 or more days after the initial event. On examination, the patient may be tachypnoeic with a localized pleural rub and often coarse crackles over the area involved. An exudative pleural effusion (occasionally blood-stained) can develop. The patient may have a fever, and cardiovascular examination is normal.

Massive pulmonary embolism

This is a much rarer condition where sudden collapse occurs because of an acute obstruction of the right ventricular outflow tract. The patient has severe central chest pain (cardiac ischaemia due to lack of coronary blood flow) and becomes shocked, pale and sweaty. Syncope may result if the cardiac output is transiently but dramatically reduced, and death may occur. On examination, the patient is tachypnoeic, has a tachycardia with hypotension and peripheral shutdown. The jugular venous pressure (JVP) is raised with a prominent '*a*' wave. There is a right ventricular heave, a gallop rhythm and a widely split second heart sound. There are usually no abnormal chest signs.

Multiple recurrent pulmonary emboli

This leads to increased breathlessness, often over weeks or months. It is accompanied by weakness, syncope on exertion and occasionally angina. The physical signs are due to the pulmonary hypertension that has developed from multi-

ple occlusions of the pulmonary vasculature. On examination, there are signs of right ventricular overload with a right ventricular heave and loud pulmonary second sound.

Diagnosis

The symptoms and signs of small and medium-sized pulmonary emboli are often subtle and non-specific, so the diagnosis is often delayed or even completely missed. Pulmonary embolism should be considered if patients present with symptoms of unexplained cough, chest pain, haemoptysis, new-onset atrial fibrillation (or other tachycardia), or signs of pulmonary hypertension if no other cause can be found.

The Revised Geneva Score (Table 13.44) gives the clinical probability of a pulmonary embolus.

Investigations

Small/medium pulmonary emboli

- **Chest X-ray** is often normal, but linear atelectasis or blunting of a costophrenic angle (due to a small effusion) is not uncommon. These features develop only after some time. A raised hemidiaphragm is present in some patients. More rarely, a wedge-shaped pulmonary infarct, the abrupt cut-off of a pulmonary artery or a translucency of an underperfused distal zone is seen. Previous infarcts may be seen as opaque linear scars.
- **ECG** is usually normal, except for sinus tachycardia, but sometimes atrial fibrillation or another tachyarrhythmia occurs. There may be evidence of right ventricular strain.
- **Blood tests**. Pulmonary infarction results in a polymorphonuclear leucocytosis, an elevated ESR and increased lactate dehydrogenase levels in the serum. Immediately prior to commencing anticoagulants a thrombophilia screen should be checked.

Table 13.44 **Revised Geneva score for the clinical prediction of a pulmonary embolism.** After Righini M, Le Gal G, Aujesky D, et al. *Lancet* 2008; **371**: 1343–1352, with permission from Elsevier

	Score
Risk factors	
Age >65 years	+1
Previous deep venous thrombosis or pulmonary embolism	+3
Surgery or fracture within 1 month	+2
Active malignancy	+2
Symptoms	
Unilateral leg pain	+3
Haemoptysis	+2
Clinical signs	
Heart rate (b.p.m.):	
75–94	+3
≥95	+5
Pain on leg deep vein palpation and unilateral oedema	+4
Clinical probability	
Low	0–3
Intermediate	4–10
High	≥11

- **Plasma D-dimer** (see p. 441) – if this is undetectable, it excludes a diagnosis of pulmonary embolism.
- **Radionuclide ventilation/perfusion scanning ($\dot{V}/\dot{Q}$ scan)** is a good and widely available diagnostic investigation. Pulmonary ^{99m}Tc scintigraphy demonstrates underperfused areas (Fig. 13.101) which, if not accompanied by a ventilation defect on a ventilation scintigram performed after inhalation of radioactive xenon gas (see p. 824), is highly suggestive of a pulmonary embolus. There are limitations to the test, however. For example, a matched defect may arise with a pulmonary embolus which causes an infarct, or from emphysematous bullae. This test is therefore conventionally reported as a probability (low, medium or high) of pulmonary embolus and should be interpreted in the context of the history, examination and other investigations.
- **Ultrasound scanning** can be performed for the detection of clots in pelvic or iliofemoral veins (see p. 810).
- **CT scans**. Contrast-enhanced multidetector CT angiograms (CTA) (Fig. 13.102), have a sensitivity of 83% and specificity of 96%, with a positive predictive value of 92%. These values will increase with the use of 64-multislice scanners.
- **MR imaging** gives similar results and is used if CT angiography is contraindicated.

Massive pulmonary emboli

- **Chest X-ray** may show pulmonary oligaemia, sometimes with dilatation of the pulmonary artery in the hila. Often there are no changes.
- **ECG** shows right atrial dilatation with tall peaked P waves in lead II. Right ventricular strain and dilatation give rise to right axis deviation, some degree of right bundle branch block, and T wave inversion in the right precordial leads (Fig. 13.103). The 'classic' ECG pattern with an S wave in lead I, and a Q wave and inverted T waves in lead III (S1, Q3, T3), is rare.

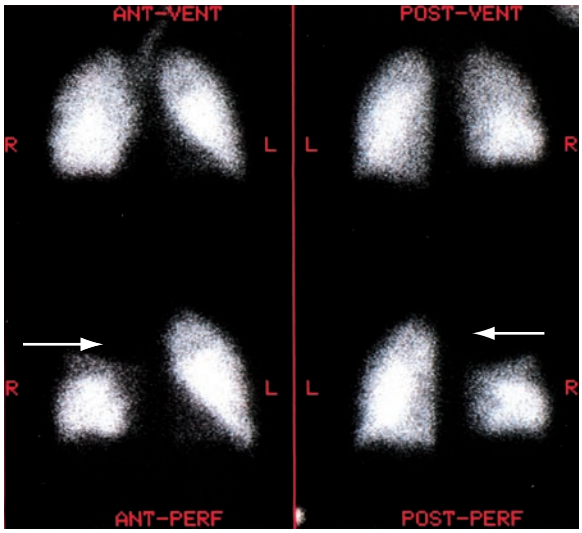

Fig. 13.101 **Ventilation (top) and perfusion (bottom) lung scans** which demonstrate absence of perfusion in the right upper lobe, i.e. probably pulmonary embolism (arrows).

- **Blood gases** show arterial hypoxaemia with a low arterial CO_2 level, i.e. type I respiratory failure pattern.
- **Echocardiography** shows a vigorously contracting left ventricle, and occasionally a dilated right ventricle and a clot in the right ventricular outflow tract.
- **Pulmonary angiography** has now been replaced by CT and MR angiography.

Multiple recurrent pulmonary emboli

- **Chest X-ray** may be normal. Enlarged pulmonary arterioles with oligaemic lung fields indicate advanced disease.
- **ECG** can be normal or show signs of pulmonary hypertension (Fig. 13.100).
- **Leg imaging** with ultrasound and venography may show thrombi.
- $\dot{V}/\dot{Q}$ scan may show evidence of pulmonary infarcts.
- **Multidetector CT scans** can detect small emboli.

Further tests looking for exercise-induced hypoxaemia and catheter studies to estimate pulmonary artery pressures are sometimes required.

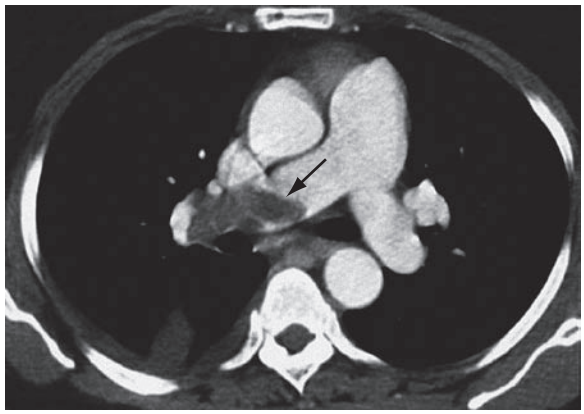

Fig. 13.102 **CT pulmonary angiographic image** at level of the main right and left pulmonary arteries showing a large thrombus (arrow) in the right pulmonary artery.

Righini M, Le Gal G, Aujesky G, et al. Diagnosis of pulmonary embolism by multidetector CT alone or combined with venous ultrasonography of the leg: a randomized non-inferiority trial. *Lancet* 2008; **371**: 1343–1352.

Tapson VF. Acute pulmonary embolism. *New England Journal of Medicine* 2008; **358**: 1037–1052.

Treatment

Acute management

- All patients should receive high-flow oxygen (60–100%) unless they have significant chronic lung disease. Patients with pulmonary infarcts require bed rest and analgesia.
- In severe cases, intravenous fluids and even inotropic agents to improve the pumping of the right heart are sometimes required, and very ill patients will require care on the intensive therapy unit (see p. 904).
- *Fibrinolytic therapy* such as streptokinase (250 000 units by i.v. infusion over 30 minutes, followed by streptokinase 100 000 units i.v. hourly for up to 12–72 hours according to manufacturer's instructions) has been shown in controlled trials to clear pulmonary emboli more rapidly and to confer a survival benefit in massive PE. It should be used more often.
- *Surgical embolectomy* is rarely necessary, but there may be no alternative when the haemodynamic circumstances are very severe.

Prevention of further emboli

A comparison of low-molecular-weight heparin (LMWH) with unfractionated heparin has shown no difference. As LMWHs simplify treatment (see p. 444) they are used exclusively if available, although they are more expensive. Oral anticoagulants are usually begun immediately and the heparin is tapered off as the oral anticoagulant becomes effective. Oral anticoagulants are continued for 6 weeks to 6 months, depending on the likelihood of recurrence of venous thrombosis or embolism. In some situations, such as after recurrent embolism, lifelong treatment is indicated.

Occasionally, physical methods are required to prevent further emboli. This is usually because recurrent emboli occur despite adequate anticoagulation, but it is also indicated in high-risk patients in whom anticoagulation is absolutely contraindicated. The most common method by which pulmonary embolism is treated in this situation is by insertion of a filter in the inferior vena cava via the femoral vein to above the level of the renal veins.

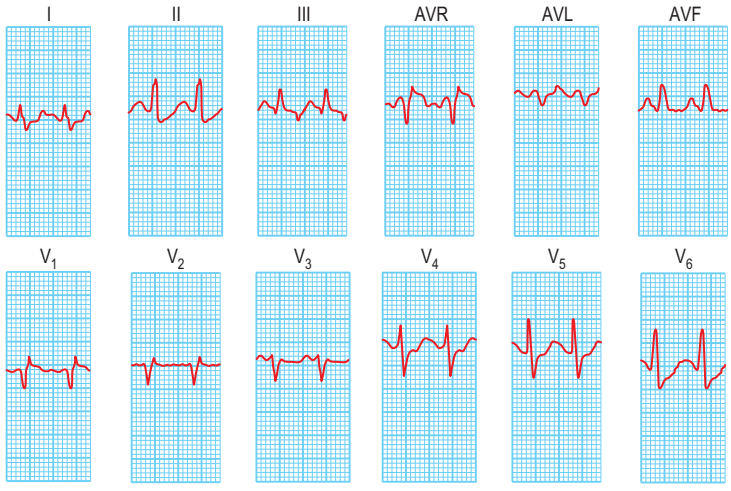

Fig. 13.103 **Acute pulmonary embolism shown by a 12-lead ECG.** There is an S wave in lead I, a Q wave in lead III and an inverted T wave in lead III (the S1, Q3, T3 pattern). There is sinus tachycardia (160 b.p.m.) and an incomplete right bundle branch block pattern (an R wave in AVR and V_1 and an S wave in V_6).

MYOCARDIAL AND ENDOCARDIAL DISEASE

ATRIAL MYXOMA

This is the most common primary cardiac tumour. It occurs at all ages and shows no sex preference. Although most myxomas are sporadic, some are familial or are part of a multiple system syndrome. Histologically they are benign. The majority of myxomas are solitary, usually develop in the left atrium and are polypoid, gelatinous structures attached by a pedicle to the atrial septum. The tumour may obstruct the mitral valve or may be a site of thrombi that then embolize. It is also associated with constitutional symptoms: the patient may present with dyspnoea, syncope or a mild fever. The physical signs are a loud first heart sound, a tumour 'plop' (a loud third heart sound produced as the pedunculated tumour comes to an abrupt halt), a mid-diastolic murmur and signs due to embolization. A raised ESR is usually present.

The diagnosis is easily made by echocardiography because the tumour is demonstrated as a dense space-occupying lesion (Fig. 13.104). Surgical removal usually results in a complete cure.

Myxomas may also occur in the right atrium or in the ventricles. Other primary cardiac tumours include rhabdomyomas and sarcomas.

MYOCARDIAL DISEASE

Myocardial disease that is not due to ischaemic, valvular or hypertensive heart disease, or a known infiltrative, metabolic/toxic or neuromuscular disorder may be caused by:

- an acute or chronic inflammatory pathology (myocarditis)
- idiopathic myocardial disease (cardiomyopathy).

Myocarditis

Acute inflammation of the myocardium has many causes (Table 13.45). Establishment of a definitive aetiology with isolation of viruses or bacteria is difficult in routine clinical practice.

In western societies, the commonest causes of infective myocarditis are Coxsackie or adenoviral infection. Myocarditis in association with HIV infection is seen at post-mortem in up to 20% of cases but causes clinical problems in less than 10% of cases. Chagas' disease, due to *Trypanosoma cruzi*, which is endemic in South America, is one of the commonest causes of myocarditis world-wide. Additionally toxins (including prescribed drugs), physical agents, hypersensitivity reactions and autoimmune conditions may also cause myocardial inflammation.

Pathology

In the acute phase myocarditic hearts are flabby with focal haemorrhages; in chronic cases they are enlarged and hypertrophied. Histologically an inflammatory infiltrate is present – lymphocytes predominating in viral causes; polymorphonuclear cells in bacterial causes; eosinophils in allergic and hypersensitivity causes (Fig. 13.105).

Clinical features

Myocarditis may be an acute or chronic process; its clinical presentations range from an asymptomatic state associated with limited and focal inflammation to *fatigue*, *palpitations*, *chest pain*, *dyspnoea* and *fulminant congestive cardiac*

Table 13.45 Causes of myocarditis

Idiopathic

Infective

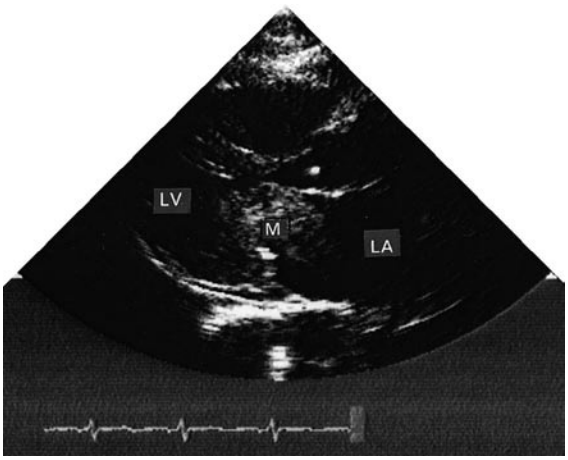
- **Viral:** Coxsackievirus, adenovirus, CMV, echovirus, influenza, polio, hepatitis, HIV
- **Parasitic:** *Trypanosoma cruzi, Toxoplasma gondii* (a cause of myocarditis in the newborn or immunocompromised)
- **Bacterial:** Streptococcus (most commonly rheumatic carditis), diphtheria (toxin-mediated heart block common)
- **Spirochaetal:** Lyme disease (heart block common), leptospirosis
- **Fungal**
- **Rickettsial**

Toxic

- **Drugs:** Causing hypersensitivity reactions, e.g. methyldopa, penicillin, sulphonamides, antituberculous, modafinil
- **Radiation:** May cause myocarditis but pericarditis more common

Autoimmune

An autoimmune form with autoactivated T cells and organ-specific antibodies may occur



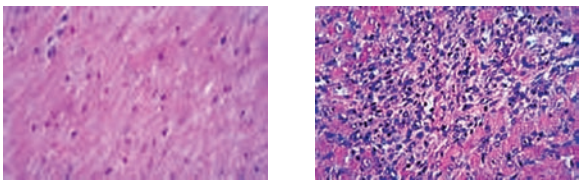


Fig. 13.104 **Atrial myxoma shown by a 2-D echocardiogram** (long-axis view). The myxoma is an echo-dense mass obstructing the mitral valve orifice. It was removed surgically. LV, left ventricle; LA, left atrium; M, mass.

(a) (b)

Fig. 13.105 **Biopsies showing (a) normal myocardium and (b) myocarditis,** with increased interstitial inflammatory cells.

failure due to diffuse myocardial involvement. An episode of viral myocarditis, perhaps unrecognized and forgotten, may be the initial event that eventually culminates in an 'idiopathic' dilated cardiomyopathy. Physical examination includes soft heart sounds, a prominent third sound and often a tachycardia. A pericardial friction rub may be heard.

Investigations

- **Chest X-ray** may show some cardiac enlargement, depending on the stage and virulence of the disease.
- **ECG** demonstrates ST- and T wave abnormalities and arrhythmias. Heart block may be seen with diphtheritic myocarditis, Lyme disease and Chagas' disease (see below).
- **Cardiac enzymes** are elevated.
- **Viral antibody titres** may be increased. However, since enteroviral infection is common in the general population, the diagnosis depends on the demonstration of acutely rising titres.
- **Endomyocardial biopsy** may show acute inflammation but false negatives are common by conventional criteria. Biopsy is of limited value outside specialized units.
- **Viral RNA** can be measured from biopsy material using polymerase chain reaction (PCR). Specific diagnosis requires demonstration of active viral replication within myocardial tissue.

Treatment

The underlying cause must be identified, treated, eliminated or avoided. Bed rest is recommended in the acute phase of the illness and athletic activities should be avoided for 6 months. Heart failure should be treated conventionally with the use of diuretics, ACE inhibitors/AII receptor antagonists, beta-blockers, spironolactone ± digoxin. *Antibiotics* should be administered immediately where appropriate. *NSAIDs* are contraindicated in the acute phase of the illness but may be used in the late phase. The use of *corticosteroids* is controversial and no studies have demonstrated an improvement in left ventricular ejection fraction or survival following their use. The administration of high-dose intravenous *immunoglobulin* on the other hand appears to be associated with a more rapid resolution of the left ventricular dysfunction and improved survival. Novel and effective antiviral, immunosuppressive (e.g. gamma-interferon) and *immunomodulating* (e.g. IL-10) agents may become available in the future to treat viral myocarditis.

Giant cell myocarditis

This is a severe form of myocarditis characterized by the presence of multinucleated giant cells within the myocardium. The cause is unknown but it may be associated with sarcoidosis, thymomas and autoimmune disease. It has a rapidly progressive course and a poor prognosis. Immunosuppression is recommended.

Chagas' disease

Chagas' disease is caused by the protozoan *Trypanosoma cruzi* and is endemic in South America where upwards of 20 million people are infected. Acutely, features of myocarditis are present with fever and congestive heart failure. Chronically, there is progression to a dilated cardiomyopathy with a propensity towards heart block and ventricular arrhythmias. Treatment is discussed on page 158. Amiodarone is helpful for the control of ventricular arrhythmias; heart failure is treated in the usual way (p. 737).

CARDIOMYOPATHY

Cardiomyopathies are a group of diseases of the myocardium that affect the mechanical or electrical function of the heart. They are frequently genetic and may produce inappropriate ventricular hypertrophy or dilatation and can be primarily a cardiac disorder or part of a multi-system disease (Table 13.46). Abnormal myocardial function produces systolic or diastolic heart failure; abnormal electrical conduction results in cardiac arrhythmias and sudden cardiac death.

Hypertrophic cardiomyopathy (HCM)

HCM includes a group of inherited conditions that produce hypertrophy of the myocardium in the absence of an alternate cause (e.g. aortic stenosis or hypertension). It is the most common cause of sudden cardiac death in young people and affects 1 in 500 of the population. The majority of cases are familial autosomal dominant, due to mutations in the genes encoding sarcomeric proteins (Fig. 13.106). The most common causes of HCM are mutations of the β-myosin heavy chain and myosin-binding protein C. Other mutations include troponin T and I, regulatory and essential myosin light chains, titin, α tropomyosin, α actin, α myosin heavy chain and muscle LIM protein (although over 400 mutations have been identified.) There are non-sarcomeric protein mutations in genes that control cardiac metabolism that result in glycogen storage diseases (Danon's, Pompe's and Fabry's disease) that are indistinguishable from HCM.

Clinical features

HCM is characterized by variable myocardial hypertrophy frequently involving the interventricular septum and

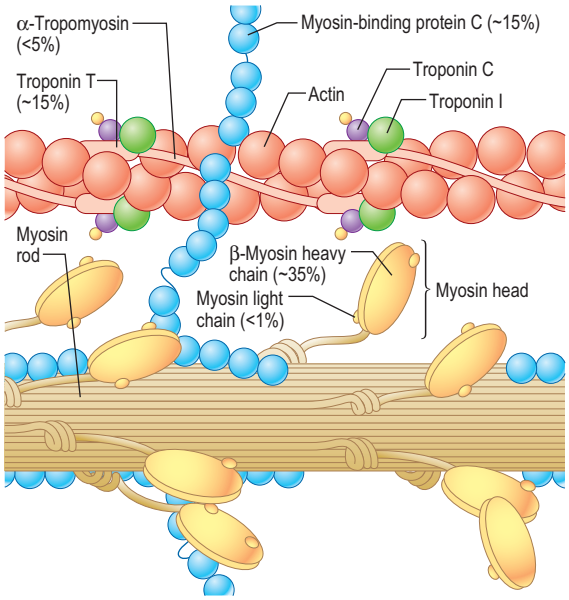

Fig. 13.106 **Sarcomeric proteins implicated in hypertrophic cardiomyopathy.** From Spirito P, Seidman CE, McKenna WJ, Maron BJ. The management of hypertrophic cardiomyopathy. *New England Journal of Medicine* 1997; **336**: 775–785. Copyright © Massachusetts Medical Society, all rights reserved.

Table 13.46 Cardiomyopathies

(a) Primary cardiomyopathies

Genetic	Mixed (genetic/acquired)	Acquired
Hypertrophic cardiomyopathy	Dilated cardiomyopathy	Inflammatory (myocarditis)
Arrhythmogenic right ventricular cardiomyopathy	Restrictive (non-hypertrophic and non-dilated)	Stress produced (Tako-tsubo)
Left ventricular non-compaction		Peripartum
		Tachycardia induced
		Infants of mothers with Type 1 diabetes
Conduction defects (see p. 726)		
Mitochondrial myopathies (see p. 37)		
*Ion channel disorders		
LQTS		
Brugada		
SQTS		
CPVT		
Asian SUNDS		

LQTS, long QT syndrome; SQTS, short QT syndrome; CPVT, catecholaminergic polymorphic ventricular tachycardia; Asian SUNDS, Asian sudden unexpected nocturnal death syndrome.
*Excluded from the European Society of Cardiology classification.

(b) Secondary cardiomyopathies

Infiltrative*	e.g. amyloidosis, Gaucher's disease†, Hurler's disease†, Hunter's disease†
Storage‡	e.g. hereditary haemochromatosis, Fabry's disease†, glycogen storage disease (type II, Pompe)†, Niemann–Pick disease†
Toxicity	e.g. drugs (e.g. cocaine), alcohol, heavy metals (e.g. cobalt), chemical agents
Endomyocardial	e.g. endomyocardial fibrosis, Loeffler's endocarditis
Inflammatory (granulomatous)	e.g. sarcoidosis, post-infective (e.g. Chagas' disease)
Endocrine	e.g. diabetes mellitus†, hyper- or hypo-thyroidism, hyperparathyroidism, phaeochromocytoma, acromegaly
Cardiofacial	e.g. Noonan syndrome†, lentiginosis†
Neuromuscular/neurological	e.g. Friedrich's ataxia†, Duchenne–Becker muscular dystrophy†, myotonic dystrophy†, neurofibromatosis†
Nutritional deficiencies	e.g. beriberi (thiamin), pellagra, scurvy, selenium, carnitine, kwashiorkor
Autoimmune/collagen	e.g. systemic lupus erythematosus, dermatomyositis, systemic sclerosis
Electrolyte imbalance	
Consequences of cancer therapy	e.g. anthracyclines (e.g. doxorubicin), daunorubicin, cyclophosphamide, radiation

*Accumulation of abnormal substances between myocytes (i.e. extracellular).
†Genetic (familial) origin.
‡Accumulation of abnormal substances within myocytes (i.e. intracellular).

disorganization ('disarray') of cardiac myocytes and myofibrils. Twenty-five per cent of patients have dynamic left ventricular outflow tract obstruction due to the combined effects of hypertrophy, systolic anterior motion (SAM) of the anterior mitral valve leaflet and rapid ventricular ejection. The salient clinical and morphological features of the disease vary according to the underlying genetic mutation. For example, marked hypertrophy is common with β myosin heavy chain mutations whereas mutations in troponin T may be associated with mild hypertrophy but a high risk of sudden death. The hypertrophy may not manifest before completion of the adolescent growth spurt, making the diagnosis in children difficult. HCM due to myosin-binding protein may not manifest until the sixth decade of life or later.

Symptoms

- many are asymptomatic and are detected through family screening of an affected individual or following a routine ECG examination
- chest pain, dyspnoea, syncope or pre-syncope (typically with exertion), cardiac arrhythmias and sudden death are seen
- sudden death occurs at any age but the highest rates (up to 6% per annum) occur in adolescents or young adults. Risk factors for sudden death are discussed below
- dyspnoea occurs due to impaired relaxation of the heart muscle or the left ventricular outflow tract obstruction that occurs in some patients. The systolic cavity remains small until the late stages of disease when progressive dilatation may occur. If a patient develops atrial fibrillation there is often a rapid deterioration in clinical status due to the loss of atrial contraction and the tachycardia – resulting in elevated left atrial pressure and acute pulmonary oedema.

Signs

- double apical pulsation (forceful atrial contraction producing a fourth heart sound)

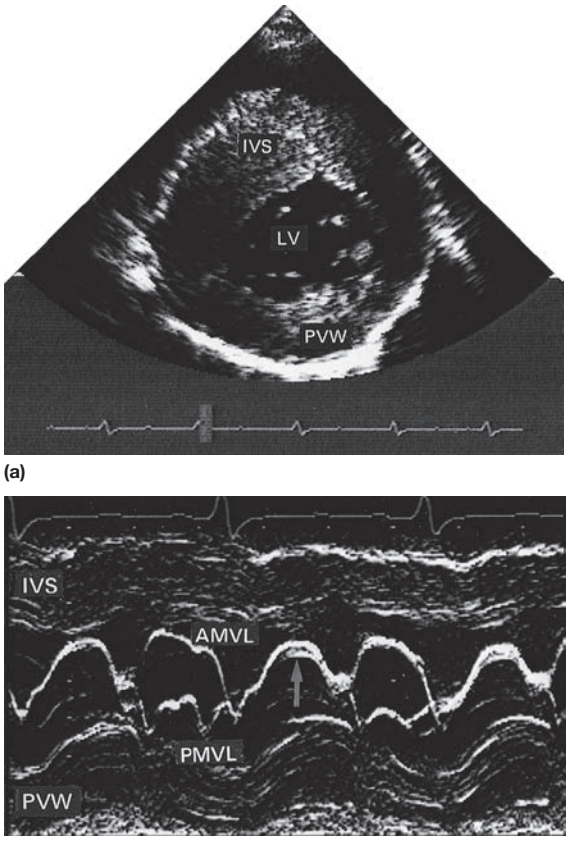

Fig. 13.107 **Hypertrophic cardiomyopathy. (a)** A 2-D echocardiogram (short-axis view). **(b)** M-mode recording. The grossly thickened interventricular septum is shown, resulting in a small left ventricular cavity. This condition is associated with an abnormal anterior motion of the mitral valve during systole (arrow). IVS, interventricular septum; LV, left ventricle; PVW, posterior ventricular wall; AMVL, PMVL, anterior and posterior mitral valve leaflets.

- jerky carotid pulse because of rapid ejection and sudden obstruction to left ventricular outflow during systole
- ejection systolic murmur due to left ventricular outflow obstruction late in systole – it can be increased by manoeuvres that decrease after-load, e.g. standing or Valsalva, and decreased by manoeuvres that increase after-load and venous return, e.g. squatting
- pan-systolic murmur due to mitral regurgitation (secondary to SAM)
- fourth heart sound (if not in AF).

Investigations

- **ECG** abnormalities of HCM include left ventricular hypertrophy (see Fig. 13.80), ST and T wave changes, and abnormal Q waves especially in the infero-lateral leads.
- **Echocardiography** is usually diagnostic and in classical HCM there is asymmetric left ventricular hypertrophy (involving the septum more than the posterior wall), systolic anterior motion of the mitral valve, and a vigorously contracting ventricle (Fig. 13.107). However, any pattern of hypertrophy may be seen, including concentric and apical hypertrophy.
- **Cardiac MR** can detect both the hypertrophy but also abnormal myocardial fibrosis (Fig. 13.108).

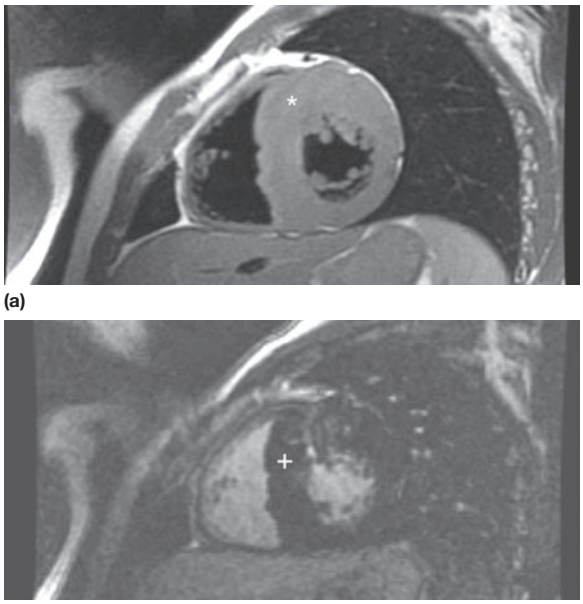

Fig. 13.108 **Cardiac MR in a patient with hypertrophic cardiomyopathy. (a)** Turbo spin-echo demonstrates marked thickening of the basal to mid-anterior wall and septum (*). **(b)** Inversion recovery image post gadolinium demonstrates regional fibrosis with enhancement (+).

- **Genetic analysis**, where available, may confirm the diagnosis and provide prognostic information for the patient and relatives.

Treatment

The management of HCM includes treatment of symptoms and the prevention of sudden cardiac death in the patient and relatives.

Risk factors for sudden death:

- massive left ventricular hypertrophy (>30 mm on echocardiography)
- family history of sudden cardiac death (<50 years old)
- non-sustained ventricular tachycardia on 24-hour Holter monitoring
- prior unexplained syncope
- abnormal blood pressure response on exercise (flat or hypotensive response).

The presence of these cardiac risk factors is associated with an increased risk of sudden death, and patients with two or more should be assessed for implantable cardioverter–defibrillator (ICD). In patients in whom the risk is less, amiodarone is an appropriate alternative.

Chest pain and dyspnoea are treated with beta-blockers and verapamil either alone or in combination. An alternative agent is disopyramide if patients have left ventricular outflow tract obstruction. In some patients with significant left outflow obstruction and symptoms, dual-chamber pacing is necessary. Alcohol (non-surgical) ablation of the septum has been investigated and appears to give good results in reduction of outflow tract obstruction and subsequent improvement in exercise capacity. This procedure carries risks, including the development of complete heart block and myocardial infarction. Occasionally surgical resection of septal myocardium may be indicated. Vasodilators should be avoided because

they may aggravate left ventricular outflow obstruction or cause refractory hypotension.

Arrhythmogenic right ventricular cardiomyopathy (ARVC)

ARVC is an uncommon (1 in 5000 population) inherited condition that predominantly affects the right ventricle with fatty or fibro-fatty replacement of myocytes, leading to segmental or global dilatation (Fig. 13.109). Left ventricular involvement has been reported in up to 75% of cases. The fibro-fatty replacement leads to ventricular arrhythmia and risk of sudden death in its early stages, and right ventricular or biventricular failure in its later stages.

Autosomal dominant ARVC has been mapped to eight chromosomal loci within mutations in four genes – cardiac ryanodine receptor RyR2 (also responsible for familial catecholaminergic polymorphic ventricular tachycardia, CPVT), desmoplakin, plakophillin-2 and mutations altering the regulatory sequences of the transforming growth factor-β gene.

There are two recessive forms – *Naxos disease* (associated with palmoplantar keratoderma and woolly hair) that is due to a mutation in junctional plakoglobin, and *Carvajal syndrome*, due to a mutation in desmoplakin.

Clinical features

Most patients are asymptomatic. Symptomatic ventricular arrhythmias, syncope or sudden death occur. Occasionally presentation is with symptoms and signs of right heart failure, although this is more common in the later stages of the disease. Some patients may be detected through family screening, although frequently the morphological appearances of the right ventricle is normal despite significant cardiac arrhythmias.

Investigations

- **ECG** is usually normal but may demonstrate T wave inversion in the precordial leads related to the right ventricle (V_1–V_3). Small-amplitude potentials occurring at the end of the QRS complex (epsilon waves) may be present (Fig. 13.110) and incomplete or complete RBBB is sometimes seen. Signal averaged ECG may indicate the presence of late potentials, the delayed depolarization of individual muscle cells. Twenty-four-hour Holter monitoring may demonstrate frequent extrasystoles of right ventricular origin or runs of non-sustained ventricular tachycardia.
- **Echocardiography** is frequently normal but with more advanced cases may demonstrate right ventricular dilatation and aneurysm formation, and there may be left ventricular dilatation.
- **Cardiac MR** can more accurately assess the right ventricle and in some cases can demonstrate fibro-fatty infiltration (Fig. 13.111).
- **Genetic testing** may soon be the diagnostic gold standard.

Treatment

Beta-blockers are first-line treatment for patients with non-life-threatening arrhythmias. Amiodarone or sotalol are used for symptomatic arrhythmias but for refractory or life-threatening arrhythmias an ICD is required. Occasionally cardiac transplantation is indicated either for intractable arrhythmia or cardiac failure.

Left ventricular non-compaction (LVNC)

LVNC is a recently recognized condition associated with a sponge-like appearance of the left ventricle. The condition

Fig. 13.109 **Gross pathological specimen demonstrating thinning and fibrofatty replacement of right ventricular free wall.** From Basso C, Thiene G, Corrado D, et al. *Circulation* 1996; **94**: 983–991, with permission.

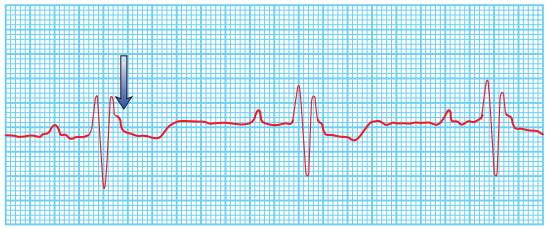

Fig. 13.110 **Electrocardiogram from an adult with arrhythmogenic right ventricular cardiomyopathy (ARVC)** demonstrating RBBB and precordial T wave insertion with epsilon waves visible at the terminal of the QRS complex (arrow).

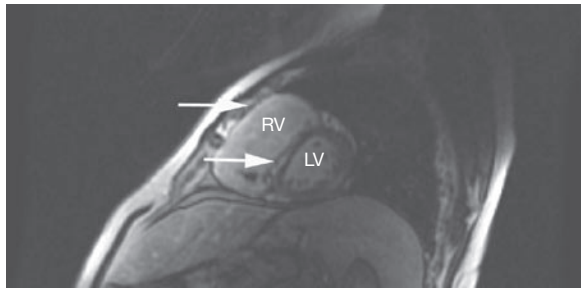

Fig. 13.111 **Arrhythmogenic right ventricular cardiomyopathy (ARVC).** Inversion recovery MR image post gadolinium demonstrates marked hyperenhancement (arrows) in the right ventricular free wall and infero-septum consistent with fibro-fatty replacement in right and left ventricles.

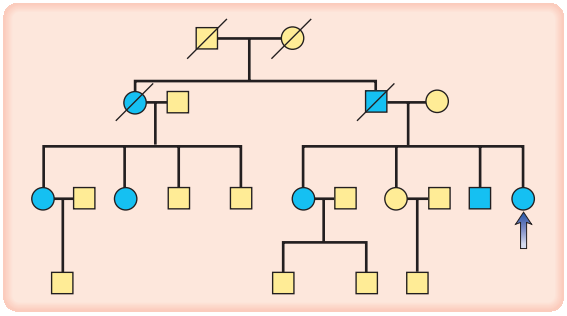

Fig. 13.112 **Pedigree of a family with dilated cardiomyopathy.** Blue symbols are affected family members. The arrow indicates the index case.

predominantly affects the apical portion of the left ventricle with persistent deep sinusoids in communication with the cavity due to arrested embryological differentiation. LVNC may be associated with congenital heart abnormalities. The condition is diagnosed by echocardiography, cardiac MR or left ventricular angiography. The natural history of the condition is unresolved but includes congestive cardiac failure, thromboembolism, cardiac arrhythmias and sudden death. Familial and spontaneous cases have been described.

Conduction system disease

Lenegre disease (p. 719) is a progressive disease of the cardiac conduction system (His–Purkinje system) that causes broad QRS duration, long pauses and bradycardia which presents with syncope. Sick-sinus syndrome is phenotypically similar.

Ion channelopathies

Features of the ion channelopathies are long QT syndrome (LQTS) (p. 727), Brugada syndrome (p. 727), catecholaminergic polymorphic ventricular tachycardia (CPVT), short QT syndrome (SQTS) and idiopathic ventricular fibrillation (VF).

Dilated cardiomyopathy (DCM)

DCM has a prevalence of 1 in 2500 and is characterized by dilatation of the ventricular chambers and systolic dysfunction with preserved wall thickness.

Familial DCM is predominantly autosomal dominant and can be associated with over 20 abnormal loci and genes (Fig. 13.112). Many of these are genes encoding cytoskeletal or associated myocyte proteins (dystrophin in X-linked cardiomyopathy; actin, desmin, troponin T, beta myosin heavy chain, sarcoglycans, vinculin and lamin a/c in autosomal dominant DCM) (Fig. 13.113). Many of these have prominent associated features such as skeletal myopathy or conduction system disease and therefore differ from the majority of cases of DCM.

Sporadic DCM can be caused by multiple conditions (Table 13.46):

- myocarditis – Coxsackie, adenoviruses, erythroviruses, HIV, bacteria, fungae, mycobacteria, parasitic (Chagas' disease)
- toxins – alcohol, chemotherapy, metals (cobalt, lead, mercury, arsenic)
- autoimmune

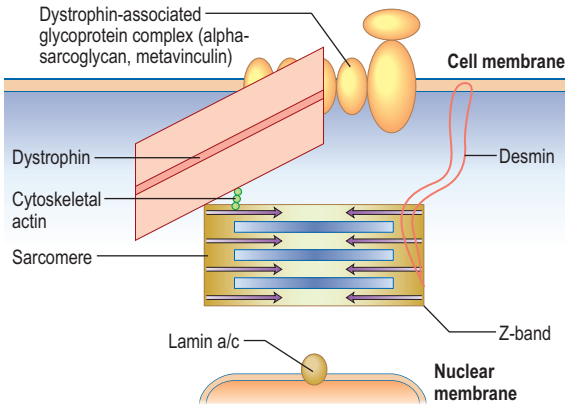

Fig. 13.113 **Schematic representation of myocyte proteins implicated in dilated cardiomyopathy (DCM).** See also Figure 13.4.

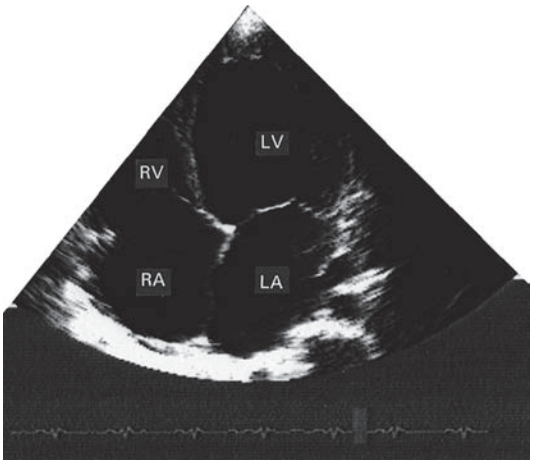
- endocrine
- neuromuscular.

Clinical features

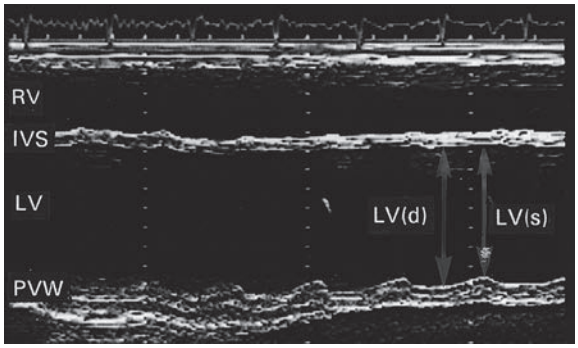
DCM can present with heart failure, cardiac arrhythmias, conduction defects, thromboembolism or sudden death. Increasingly, evaluation of relatives of DCM patients is allowing identification of early asymptomatic disease, prior to the onset of these complications. Clinical evaluation should include a family history and construction of a pedigree where appropriate.

Investigations



- **Chest X-ray** demonstrates generalized cardiac enlargement.
- **ECG** may demonstrate diffuse non-specific ST segment and T wave changes. Sinus tachycardia, conduction abnormalities and arrhythmias (i.e. atrial fibrillation, ventricular premature contractions or ventricular tachycardia) are also seen.
- **Echocardiogram** reveals dilatation of the left and/or right ventricle with poor global contraction function (Fig. 13.114).
- **Cardiac MR** may demonstrate other aetiologies of left ventricular dysfunction (e.g. previous myocardial infarction) or demonstrate abnormal myocardial fibrosis (Fig. 13.115). Cardiac MR is also useful for identifying myocardial thrombus (Fig. 13.116).
- **Coronary angiography** should be performed to exclude coronary artery disease in all individuals at risk (generally patients >40 years or younger if symptoms or risk factors are present).
- **Biopsy** is generally not indicated outside specialist care.

Treatment



Treatment consists of the conventional management of heart failure (see p. 737) with the option of cardiac resynchronization therapy and ICDs in patients with NYHA III/IV grading. Cardiac transplantation is appropriate for certain patients.

Primary restrictive non-hypertrophic cardiomyopathy

This is a rare condition in which there is normal or decreased volume of both ventricles with bi-atrial enlargement, normal

(a)

(b)

Fig. 13.114 **Dilated cardiomyopathy. (a)** 2-D (apical four-chamber view) and **(b)** M-mode echocardiograms. The heart has a 'globular' appearance with all four chambers dilated. The extremely impaired left ventricular function can be appreciated from the M-mode recording. Compare the systolic shortening fraction with that of Figures 13.24 and 13.28. LA, left atrium; RA, right atrium; LV, left ventricle; LV(d) and LV(s), diastolic and systolic left ventricular dimensions; IVS, interventricular septum; PVW, posterior ventricular wall.

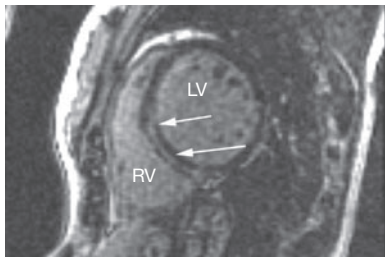


Fig. 13.115 **Dilated cardiomyopathy.** Inversion recovery MR post gadolinium demonstrates septal mid-wall hyperenhancement (arrows) consistent with fibrosis in a patient with dilated cardiomyopathy.

wall thickness, normal cardiac valves and impaired ventricular filling with restrictive physiology but near normal systolic function. The restrictive physiology produces symptoms and signs of heart failure. Conditions associated with this form of cardiomyopathy include amyloidosis (commonest), sarcoidosis, Loeffler's endocarditis and endomyocardial fibrosis; in the latter two conditions there is myocardial and endocardial fibrosis associated with eosinophilia. The idiopathic form of restrictive cardiomyopathy may be familial.
